The same environmental drivers that are stimulating fuel cell development are also causing increased interest in alternatives. For example, in stationary power applications, microturbines are being developed that might compete with fuel cells for distributed power generation. In transportation, there is renewed interest in diesel engines, hybrid propulsion systems, and alternative-fueled vehicles. Advances in solar cells may also eliminate potential markets for fuel cells. Despite the strong, entrenched competition, there are reasons to believe that fuel cell commercialization is inevitable. Perhaps the strongest energy trend is the gradual shift toward renewable hydrogen. For example, wind-generated electricity can be used for electrolyzing water and, despite the extra step, the *potential* advantage of hydrogen over electricity is its easier transmission and storage. As Figure 5 indicates, the process of using fuels with ever-increasing H:C ratio has been developing for over 100 years. Recently, such a shift has been reinforced by environmental arguments. Should hydrogen evolve to be the fuel of the future, there is a compelling case to convert this into end-use electricity using fuel cells.

It must be recognized, however, that hydrogen usage for transportation will always create a trade-off between energy efficiency (fuel economy) and energy density (range), whereas this trade-off is non-existent for other applications.

In summary, fuel cell development is being accelerated both by the wide variety of applications and by the search for cleaner and more efficient utilization of primary energy and, ultimately, renewable energy. Because these forces for change are unlikely to disappear, it is quite likely that fuel cells will emerge as one of the most important and pervasive power sources for the future.

FUEL CELL VEHICLES

ENVIRONMENTAL CONCERNS CONVERGE ON TECHNOLOGY PROGRESS

International concerns about the release of greenhouse gas emissions, deteriorating air quality, and reliance on oil sources in the Middle East oil continue to place pressure on the automobile industry to develop cleaner and more efficient vehicles. In practice there are three main ways this can be achieved: vehicle weight reduction, deployment of more efficient propulsion systems, and cleaner fuels. Fuel cell technology, by virtue of its unique means of operation, is well placed to address the power train limitations of both conventional internal combustion (IC), engines (i.e., nonzero emissions and relatively low efficiency) and batteries (i.e., inadequate range and long “recharging” time).

Many of the world’s major automakers, prompted by both this consumer demand and progress in reducing the inherent cost and size of fuel cells, are now committed to developing and commercializing fuel cell vehicles.

FUEL CELL BASICS

A fuel cell creates electricity directly from a fuel, usually hydrogen. The hydrogen is fed into one side of the fuel cell (the anode) where electrons are stripped off it to produce hydrogen ions (protons). In a vehicle, these electrons energize a motor to turn the wheels, and then they return to the cathode to combine with incoming oxygen from the air to produce oxygen anions. Meanwhile, the protons pass through the electrolyte and link up with the oxygen ions to produce water. The net effect is identical to the combustion of hydrogen in air except that the transfer of electrons has been channeled directly into making electricity, as opposed to heat.

As with batteries, differences in electrolytes create several types of fuel cells. The automobile’s demanding requirements for compactness and fast start-up have led to the Proton Exchange Membrane (PEM) fuel cell being the preferred type. This fuel cell has an electrolyte made of a solid polymer.

CHALLENGES TO FUEL CELL VEHICLE COMMERCIALIZATION

The biggest challenge facing fuel cells is cost. Current fuel cell systems probably cost about ten times as much as the $25/kW target set by the IC engine. Novel materials and manufacturing processes must be developed because mass production alone will not drive fuel cell stack (series of fuel cells combines to generate a useable voltage) costs down to the required level. Inexpensive bipolar plate materials, more effective catalyst utilization, and refined flowfields for efficiently channelling the input gases and exhaust water will contribute to the cost reduction.

It is expected that the fuel cell should be able to compete with an IC engine in terms of size and weight. As an added advantage, many fuel cell components can be configured into a relatively wide array of shapes to take advantage of space onboard the vehicle.

A fuel cell system also needs ancillaries to support the stack, just as an IC engine has many of the same type of ancillary subsystems. Major subsystems are needed for providing adequate humidification and cooling, and for supplying fuel and oxidant (air) with the correct purity and appropriate quantity.

These subsystems profoundly affect the fuel cell system performance. As an example, the inherently slow air (oxygen) electrode reaction must be accelerated using an air compressor, but this creates noise and exacts high power consumption, typically 10 to 15 percent of the fuel cell stack output. Fuel cell *system* efficiency, therefore, drops drastically when the fuel cell is operating at light load (below 10% rated power) even though the *stack* efficiency increases under these conditions. Low-cost, highly efficient air compressors that exploit the hot compressed exhaust gases may have more impact on increasing system efficiency than stack improvements would have.

Although the fuel cell is more efficient than an IC engine, it does produce waste heat at low temperature, and this poses problems from a heat rejection standpoint. Because there are vehicle styling constraints on how large the radiator can be, there is significant research into raising fuel cell stack operating temperatures by up to 10°C. If this can be achieved without degrading the electrolyte's durability, then it may almost halve the temperature differential between waste heat and ambient air in extremely hot conditions, with corresponding reductions in radiator size.

An automobile must also operate reliably in freezing conditions, which means that the humidifying, de-ionized water may need draining from the fuel cell system at key-off and reinjection during start-up. The coolant must also be freeze tolerant. These requirements for immediate power will probably force the vehicle to contain an energy storage component, such as a battery, flywheel, or ultracapacitor. This hybridization should also boost fuel economy because it enables regenerative braking and reduces the time that the fuel cell system spends below 10% rated load (where it is least efficient and where the driven car spends much of its time).

The vehicle also puts constraints on the choice of fuel. A combination of factors, such as the anticipated fuel and vehicle cost, both vehicular and "well-to-wheels" emissions and efficiency, perceived or real safety, and infrastructure will determine the choice of optimum fuel.

FUEL SELECTION AFFECTS PERFORMANCE AND COMMERCIALIZATION

Environmentally benign hydrogen is clearly the ideal fuel for use with fuel cells. The question is whether to store the hydrogen on-board or to generate it on board from liquid fuels that are easier to store and distribute.

The problem is that hydrogen, even at 10,000 psi (or 690 bar), requires five to ten times the volume of today's gasoline tank, depending on the fuel cell vehicle's real world efficiency. Packaging volume is compromised even further because pressurized tanks require thick carbon fiber walls and are, therefore, nonconformable. Moreover, they may cost several thousand dollars more than a conventional gasoline tank.

Although liquifying the hydrogen to 20K (–253°C) does increase energy density, it also creates new problems, such as cryogenic handling and venting (as ambient heat passes through the walls of the insulated vessel and evaporates the liquid). In addition, liquefaction is highly energy intense.

The third method of storing hydrogen is to absorb it into a metal. The only metal hydrides that can currently liberate their absorbed hydrogen at 80°C (allowing exploitation of the waste heat from the PEM fuel cell) are low-temperature ones and these can only store around 2% hydrogen by weight. Since 5 kg (11 lb) of hydrogen may be required to provide 380 miles (610 km) range in an 80 mpg (3 l/100 km) vehicle, the hydride will weigh more than 250 kg (550 lb). This weight not only reduces fuel economy but adds significant cost.

Hydrogen can also be adsorbed onto activated carbons; storage occurs in both gaseous and adsorbed phases. Existing carbon adsorbents outperform compressed gas storage only at relatively low pressures, when most of the gas is stored in the adsorbed phase. At pressures above 3,000 psi (207 bar), which are needed to store significant amounts, the adsorbent tends to be counterproductive since it blocks free space. Carbon adsorbents and metal hydrides introduce several control issues, such as risk of poisoning, and heat management during refueling and discharging.

Improved hydrogen storage is the key to a hydrogen economy. Without adequate storage, hydrogen may remain a niche transportation fuel which in turn, could limit the development of a hydrogen infrastructure. Of course, hydrogen could still play a leading role in *stationary* power generation without the need for dramatic improvements in storage.

Another concern with hydrogen is safety. Reputable organizations with extensive experience in using hydrogen have concluded that hydrogen is often safer than gasoline because it has a tendency to rapidly disperse upwards. However, its invisible flame and wide flammability range cause legitimate concerns. Reversing hydrogen's image requires a combination of public education and real world vehicle demonstrations. Automakers must design safe ways to store hydrogen on board. Despite these storage and safety concerns, hydrogen is considered the most attractive fuel for fuel cell buses because central refueling is possible and there is adequate space for hydrogen storage on the roof, which is also probably the safest location. However, for cars and light-duty trucks used by individuals, there is great interest in generating hydrogen on board the vehicle from fuels that are easier to store and transport.

Natural gas (CH_4) is also bulky to store, but reacting it with steam generates methanol (CH_3OH), an ambient-temperature liquid fuel. Having already been manufactured from natural gas outside the vehicle and containing no C-C bonds, methanol can generate hydrogen relatively easily and efficiently on board the vehicle using the steam produced by the fuel cell ($CH_3OH + H_2O \rightarrow 3H_2 + CO_2$). This hydrogen is then fed into the fuel cell to generate electricity. Unlike alkaline fuel cells used in the Apollo space missions, the carbon dioxide diluent can be fed into the PEM fuel cell without harm. Another attraction of methanol is the potential to ultimately eliminate the complexity of a reformer by using a direct methanol fuel cell where methanol is converted into hydrogen inside the cell. Because of these advantages, methanol is currently the leading candidate to propel mainstream fuel cell vehicles, absent a hydrogen storage breakthrough.

However, there are several issues with widespread methanol usage. Methanol production from natural gas is relatively inefficient (~67%), and this largely offsets the vehicular improvement in efficiency and carbon dioxide reduction (since gasoline can be made with ~85% efficiency from oil). Additionally, the PEM fuel cell demands very pure methanol, which is difficult to deliver using existing oil pipelines and may require a new fuel distribution infrastructure.

Compared with methanol, gasoline is more difficult to reform into hydrogen because it contains C-C (carbon-carbon) bonds. Breaking these down to generate hydrogen requires small amounts of air (called partial oxidation or POX) and this lowers the efficiency and makes heat integration more difficult. Also, gasoline is not a homogenous compound like methanol. Its sulfur poisons the fuel processor and fuel cell stack catalysts, and its aromatics have a tendency to form soot. Finally, gasoline's hydrogen-carbon (H:C) ratio is under two whereas methanol's is four. Gasoline, therefore, it yields less hydrogen and this reduces fuel cell stack output and efficiency. The net effect is that gasoline fuel cell vehicles are likely to be less efficient and more complex than methanol fuel cell vehicles. However, use of gasoline keeps the refueling infrastructure intact, and even gasoline fuel cell vehicles offer potential to be cleaner and more efficient than gasoline engines.

A fuel closely related to gasoline is naphtha, which is also a potential fuel cell fuel. Naphtha is already produced in large quantities at refineries and is a cheaper fuel than gasoline, which must have octane-boosting additives blended into it. Unlike methanol, naphtha can be distributed in the same pipelines as gasoline. From the fuel cell's perspective, it has a higher H:C ratio and lower sulfur and aromatics content than gasoline.

Given the technical challenges facing gasoline reforming, it is possible that gasoline fuel cells may be introduced to vehicles as an Auxiliary Power Unit (APU) feature. A 5 kW APU that provides electricity to power air conditioning and other electrical loads can operate with less demanding transient performance than is necessary for propulsion. Moreover, lower efficiency can be tolerated since it competes with a gasoline engine-alternator combination at idle and not with a gasoline engine directly.

The transition from the IC engine to fuel cells will not alleviate energy supply insecurity. All of these fuel options—hydrogen, methanol, gasoline, and naphtha will be generated most economically from fossil fuels (natural gas or oil) in the near to mid-term. However, fuel cells are still expected to reduce carbon dioxide emissions since propulsion is not dependent on combustion. With respect to local air quality, fuel cell vehicles should significantly reduce pollutants, particularly if they use hydrogen. The only emissions from a hydrogen fuel cell vehicle would be pure water, thus allowing it to qualify as a Zero Emission Vehicle. In addition, fuel cell vehicles should stimulate development of cleaner fuels more quickly than IC engines because they are less tolerant of fuel impurities and benefit more from hydrogen-rich fuels.

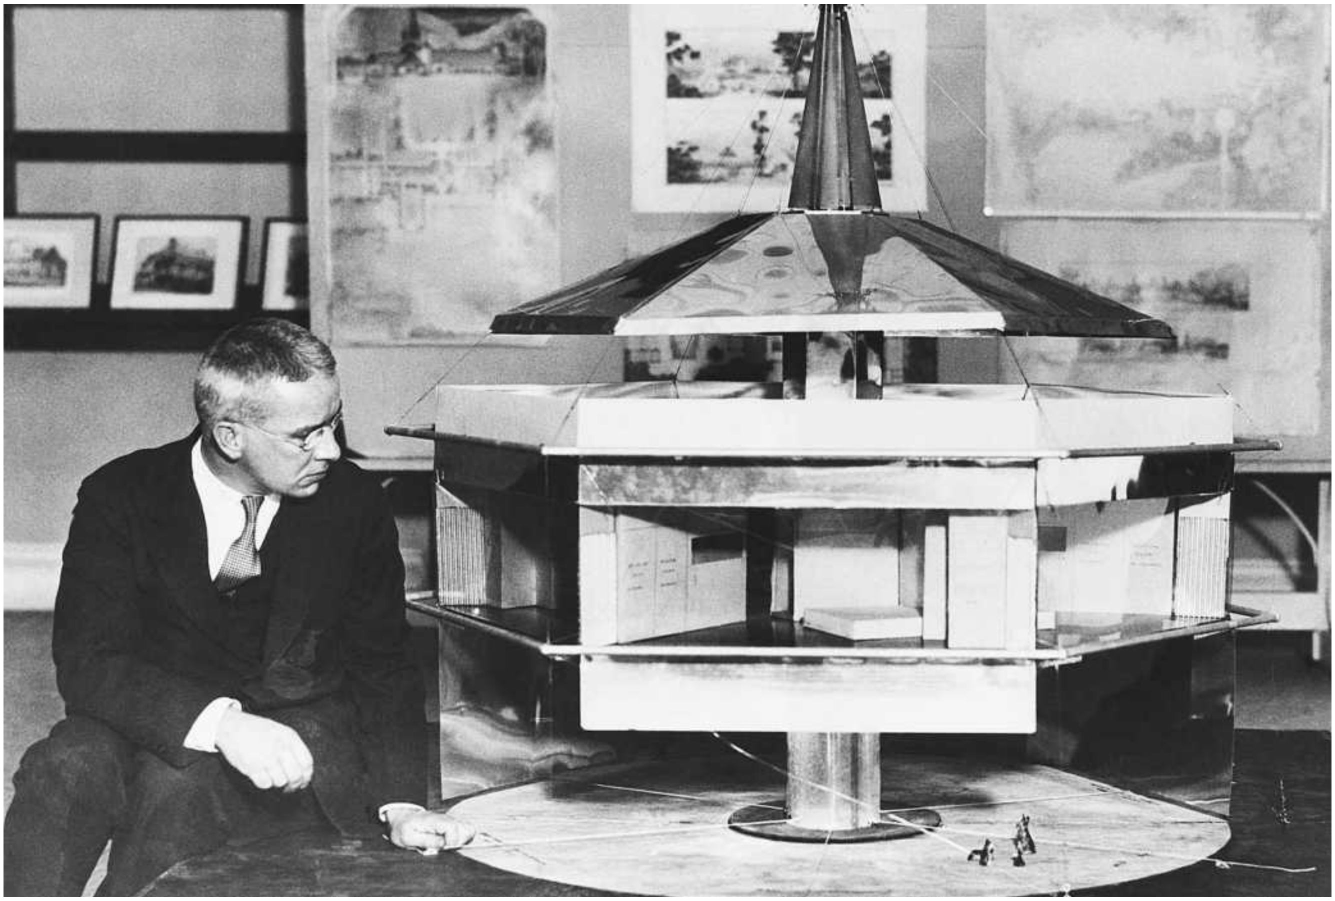
FULLER, R. BUCKMINSTER, JR. (1895–1983)

Richard Buckminster Fuller, Jr., best known as the architect of Houston’s Astrodome and other geodesic structures, enjoyed a long and varied career as a structural engineer and unconventional humanistic thinker. A colorful and gregarious individual, Fuller was first embraced by government officials for his innovative designs and later cherished by the 1960s counterculture. He patented more than twenty new inventions, authored twenty-five books and dozens of articles, lectured globally on energy issues and the wise use of world resources, and dabbled in both art and science. Never one to be modest, Fuller called himself “an engineer, inventor, mathematician, architect, cartographer, philosopher, poet, cosmologist, comprehensive designer and choreographer.” He especially liked the self-description “anticipatory comprehensive design scientist,” because he saw himself as a scientist who anticipated human needs and answered them with technology in the most energy-efficient way.

Fuller’s “more with less” philosophy first gained the attention of Americans in the 1920s with his “Dymaxion” inventions. Fuller employed this term—a combination of “dynamic,” “maximum,” and “ion”—to describe inventions that do the most with the least expenditure of energy. His Dymaxion house was self-sufficient in that it generated its own power, recycled water, and converted wastes into useable energy. It also featured air conditioning and built-in laborsaving utilities including an automatic laundry machine, a dishwasher that cleaned, dried, and reshelved the dishes, and compressed air and vacuum units. The Dymaxion bathroom was a one-piece aluminum unit containing a “fog gun”—an economical showerhead using a mixture of 90 percent air and 10 percent water. Fuller’s Dymaxion car ran on three wheels, had front-wheel drive with rear-wheel steering, and registered a reported forty to fifty miles per gallon in 1933. None of these projects were mass-produced, but his futuristic designs, and later his geodesic buildings, World Game workshops, and startling questions and proposals about natural resources and human survival stimulated imaginations and encouraged others to explore ways to create a more energy-efficient environment.

Born in Milton, Massachusetts, in 1895 to Richard and Caroline Fuller, Bucky, as most knew him, spent his summers at the family retreat, Bear Island, in Penobscot Bay, Maine. As Fuller remembered it, his interest in building better “instruments, tools, or other devices” to increase the “technical advantage of man over environmental circumstance” began there. One of his tasks each day as a young boy was to row a boat four miles round trip to another island for the mail. To expedite this trip, he constructed his “first teleologic design invention,” a “mechanical jelly fish.” Noting the structure of the jellyfish and attending to its movement through the water, Fuller copied nature and produced a boat of greater speed and ease. Observing natural phenomena remained his lifelong source of inspiration which was not surprising, given that Fuller was the grandnephew of transcendentalist Margaret Fuller.

Following his Brahmin family’s tradition, Fuller went to Harvard, but instead of graduating as a lawyer or Unitarian minister as his ancestors had, he was expelled twice for cutting classes, failing grades, and raucous living. He never did gain a bachelor’s degree. Instead, Fuller tutored himself in the arts and



Buckminster Fuller, sitting beside a model of his "Dymaxion" house, seen in the 1930 World's Fair in Chicago. (Corbis Corporation)

sciences, and the Navy and apprenticeships at a cotton mill machinery plant and a meat-packing factory provided him with a practical education. Eventually, Fuller garnered multiple honorary doctorates and awards, including a Presidential Medal of Freedom shortly before his death in 1983.

In 1917, Fuller married Anne Hewlett, the daughter of the respected New York architect James M. Hewlett. A year later their daughter Alexandra was born, only to die a few years later from infantile paralysis. From 1922 to 1926, Fuller and his father-in-law founded and ran the Stockade Building System that produced lightweight construction materials. Fuller failed miserably at the business and, in 1927, stung by the death of his daughter, years of carousing, and financial failure, he considered suicide. Impoverished and living in the gangster region of Chicago with his wife and newborn daughter, Allegra, Fuller walked to the shore of Lake Michigan with the intent of throwing himself in. Instead, he had a revelation: "You do not have the right to eliminate yourself, you do not belong to you. You belong to the universe. . . apply yourself to converting all your experience to the highest advantage of others." At this point, Fuller made it his ambition to design "tools for living," believing that human life would improve if the built environment was transformed.

Fuller approached his mission both philosophically and practically. He explored mathematics in search of "nature's coordinate system" and invented his own "energetic-synergetic geometry" as his expression of the underlying order he saw. He also studied philosophy and physics for understanding of time and motion. But his philosophical musings always had a practical bent. For example, Fuller, taken with Albert Einstein's theories about time and motion, sought to employ physics in his design initiatives.

Fuller devoted his early years to the problem of building energy-efficient and affordable housing, but his projects and ideas were largely confined to a few students in architectural schools, executives of small corporations, and readers of *Shelter* and *Fortune* magazines. His most successful enterprise was the manufacture of Dymaxion Deployment Units for use by the Army in World War II. Fuller tried to convert these military units into civilian housing, but failed to raise production funds.

In 1949, Fuller's luck changed with the construction of his first geodesic dome at Black Mountain College. Motivated by a desire to create an energy-efficient building that covered a large space with a minimal amount of material, Fuller fashioned a sphere-shaped structure out of triangular pyramids. He joined these tetrahedrons together by pulling them tight in tension rather than relying on compression to raise the dome. In doing so, Fuller reconceptualized dome engineering and created a practical, efficient, cost-effective, strong, and easy-to-transport-and-assemble building.

Several hundred thousand geodesics function today worldwide as auditoriums, aviaries, banks, churches, exposition halls, greenhouses, homes, industrial plants, military sheds, planetariums, playground equipment, and sports arenas. Some of these geodesics, including the clear, thin-skinned "Skybreak" and "Garden-of-Eden" structures, were experiments in using renewable energy sources. These transparent spheres, primarily functioning as greenhouses or as experimental biodomes by environmentalists before the much-publicized Biosphere projects, relied on solar power to regulate temperature. Fuller also had more fantastic ideas to reduce energy losses in summer cooling and winter heating: in 1950, for example, he proposed building a dome over Manhattan to regulate the environment.

Fuller's vision was more expansive than creating better shelter systems, however. His scope was global and his ideals utopian. At the same time that he was creating "machines for living," he was surveying Earth's resources, designing maps, and plotting strategies for an equitable distribution of goods and services. In 1927 Fuller started his "Inventory of World Resources, Human Trends and Needs." In the 1930s he began his Dymaxion map projects to gain a global perspective, and by the 1960s, in the heart of the Cold War, Fuller was busy devising ways to ensure the survival of the earth.

For Earth to continue functioning for the maximum gain of people everywhere, Fuller believed that resources must be used wisely and shared equally. He scorned reliance on fossil fuels and encouraged the development of renewable energy sources, including solar, wind, and water power. To convey his ideas, Fuller employed the metaphor of Earth as a spaceship. This spacecraft, he explained in his best-selling book, *Operating Manual for Spaceship Earth*, was finite and in need of careful management. With limited materials on board, "earthians" must work out an equitable and just distribution to keep the spaceship operating smoothly and efficiently.

Intent upon channeling human energy and resources into projects for "livingry," as opposed to "weaponry," Fuller participated in cultural exchanges between the Soviet Union and the United States, worked on United Nations projects, and traveled the world to communicate his vision. He conducted marathon "thinking-aloud" sessions before large audiences, taking on a cult status for some and the role of crackpot for others. He criticized political solutions to world problems and promoted technological design to reallocate wealth, labor, and resources.

The culmination of these thoughts can be found in Fuller's strategic global planning organization, the World Game Institute. Counter to military war games, World Game was both a tool for disseminating information and an exercise to engage others in problem-solving. Through a set of simulated exercises, participants used Fuller's inventory of resources, synergetic geometry, and Dymaxion maps to plot strategies to "make the world work for 100% of humanity in the shortest possible time, through spontaneous cooperation, and without ecological offense or the disadvantage of anyone." Begun in small college classrooms in the 1960s, World Game attracted a dedicated following. In the 1990s, the World Game Organization established itself on the Internet to facilitate innovative thinking about world resources.

Fuller's lifelong engagement in global energy issues and his lasting contributions in engineering design make him a noteworthy study in twentieth century debates on energy supply and use. Fuller believed that world problems of war, poverty, and energy allocation could be eradicated by cooperation between nations and through technological innovation. His optimistic celebration of technology pitted him against individuals such as historian Lewis Mumford who questioned the salutary effects of technology, and placed him at odds with Paul Ehrlich and other environmentalists who believed that Earth's resources could not support the world's growing population. Fuller, a modernist at heart, maintained that the trouble was in distribution, and that continual employment of technology would not destroy but save the planet.

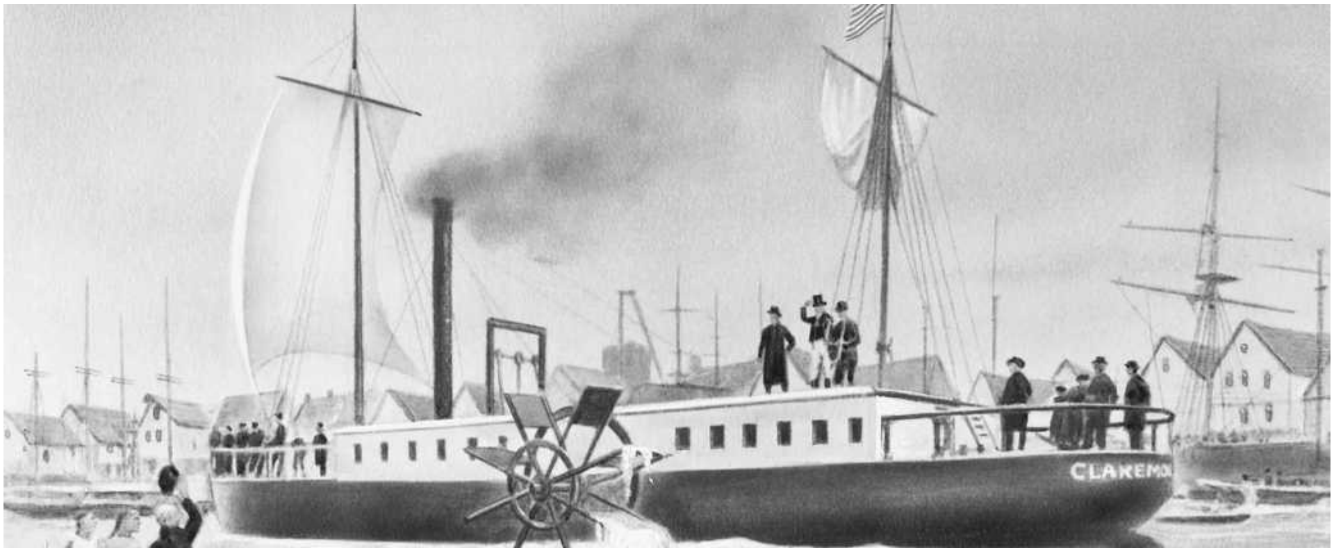
FULTON, ROBERT (1767–1815)

Robert Fulton was unique among inventors of his time, since he was born in America, apprenticed in Europe and returned to his native country to perfect his greatest invention, the steamboat. Fulton was born in 1765 of a respectable family in Little Britain, Pennsylvania, in Lancaster County. Unlike many inventors, he was not motivated by paternal leadership since he grew up fatherless after the age of three. His mother is credited for his soaring interest in the world of painting. Despite, or perhaps because of, the loss of his father, Robert's free time was spent with local mechanics or alone with his drawing pencil. By age seventeen, he was accomplished enough as a landscape and portrait artist that he earned income from it in the city of Philadelphia for four years. He earned enough to build a home for his mother in Washington County before receiving a generous



Robert Fulton's "Clermont." The illustrator mistakenly used the name "Claremont." (Corbis Corporation) offer to take his artistic talents to England in 1786, at age 21, where they were equally well received.

Over the next seven years, he made numerous acquaintances, including two who were instrumental in his transition from artist to civil engineer—the Duke of Bridgewater, famous for work with canals, and Lord Stanhope, who specialized in works of science and mechanical arts. By 1793, Robert was experimenting with inland navigation, an area that remained of interest throughout his life. A year later, he filed a patent in Britain for a double inclined plane, and spent several years in Birmingham, the birthplace of the Industrial Revolution that came about thanks to the powerful engines built by James Watt as early as 1763.

Remarkable for someone so talented in the arts, Fulton was able to use his accomplished drawing skills to express his designs. As a now noted draftsman, he invented numerous pieces of equipment such as tools to saw marble, spin flax, make rope and excavate earth. Sadly, he once lost many of his original manuscripts during a shipping accident.

By the beginning of the nineteenth century, Fulton turned his attention to his obsession with submarines and steamships. He made no secret of his goal for submarines—he intended to build them in order to destroy all ships of war so that appropriate attention could be devoted by society to the fields of education, industry and free speech. In 1801, he managed to stay under water for four hours and twenty minutes in one of his devices, and in 1805 he demonstrated the ability to utilize a torpedo to blow up a well built ship of two hundred tons. Unfortunately for Robert, neither the French nor British government was particularly impressed with the unpredictable success, nor the importance of his innovations; so he packed his bags and returned to America in December of 1806.

By the time Robert Fulton arrived in America, he had been studying steam navigation for thirteen years. Five years earlier, he had met Chancellor Livingston, who was partly successful in building a steam vessel, but yielded to Fulton's skill by allowing him to take out a patent in the latter's name to begin his improvements. By 1807, there was much skepticism and derision expressed along the banks of the East River in New York when Fulton prepared to launch his steamship, "The Clermont," from the ship yard of Charles Brown. A few hours later, there were nothing but loud applause and admiration at the spectacular achievement that had been termed "Fulton's Folly." Finding his own design flaws, Fulton modified the water wheels and soon launched the ship on a stunning three-hundred-mile round-trip run to Albany. The total sailing time was sixty-two hours, a remarkable endurance record for so new an invention. Soon there were regular runs being made on the Hudson River and by rival ships around the country, with many disputes over the patent rights of different vessels in different states. But the industry was clearly set in motion by Fulton's uncanny designs.

By 1812, he added a double-hulled ferryboat to his credits, designing floating docks to receive them. In 1814, the citizens of New York vindicated his years of war vessel experiments by demanding a protective ship in defense of their New York Harbor. In March of that year, the President of the United States, James Madison, was authorized to enlist Fulton to design a steam-powered frigate, with full explosive battery, as a military defense weapon. He also empowered Fulton to complete a design for the defensive submarine Fulton longed to finish. Unfortunately, just three months before the completion of the steam frigate, Fulton fell victim to severe winter exposure on the river, dying on February 24, 1815, in New York City at the age of 50.

The public mourning was said to be equal to that expressed only for those who held public office of considerable acclaim. But by this time, the word 'folly' had long been dropped from his name. Just as George Stephenson followed the inventors of locomotives to gain credit for creating Britain's railways, Robert Fulton was not the inventor of the steam boat. What he *was*, however, was the brilliant creator of such an improved version that it made possible the many advancements of steamships in succeeding years. He took theory out of the experimentation process and designed machinery that opened the door to unlimited practical use from the technology available at the time.

FURNACES AND BOILERS

Furnaces and boilers are devices that burn fuel to space heat homes, offices, and industrial facilities. Natural gas, liquefied petroleum gas, and heating oil are the dominant fuels used for furnaces and boilers. In the United States, furnaces and boilers burning gas and oil take care of over 75 percent of all space heating.

EARLY HISTORY

The first oil burning devices for heating appeared in the oil-rich Caucasus region of Russia as early as 1861. But because of the remoteness of this region, those devices remained in obscurity, out of the flow of marketable goods. An event almost 115 years ago marks the birth of the modern oil burner. On August 11, 1885, the U.S. Patent office granted a patent to David H. Burrell of Little Falls, New York, for a "furnace apparatus for combining and utilizing oleaginous matters." As noted in the June 1985 centennial issue of *Fuel Oil News*, Burrell's invention "...was the forerunner of today's modern oil burner, and is generally accepted as the one that started the oil heat industry."

Gas burners are different from oil burners in that they control the mixing of air and gas and are referred to as *aerated burners*. This type of burner was invented around 1855 by Robert Wilhelm von Bunsen and is often called a *Bunsen burner* or *blue flame burner*. Natural gas is mostly methane and typically found underground in pockets. Liquified petroleum gas (LPG) occurs in "wet" natural gas and crude oil and must be extracted and refined before use.

GAS AND OIL HEAT BASICS

Liquid fuels, including heating oil after it is refined from crude oil, are transported by pipelines, oil tankers, barges, railroads, and highway tanker trucks to local bulk storage facilities, and delivered by tank trucks to the homeowner's tank, which is located either underground or in the basement, garage, or utility room. Figure 1 shows a typical residential oil heating system. These tanks typically store 275 to 500 gallons of fuel that can supply heat for a typical house for a month, and usually several oil tank truck deliveries to the home are needed during the year. LPG is similarly transported under pressure as a liquid by tanker trucks to the homeowner's above-ground tank. LPG may also be delivered in portable tanks typically 100-250 lbs, or as small as the 20-lb. tanks, used for portable gas grills. LPG is heavier than air and should not be stored inside a house for safety reasons.

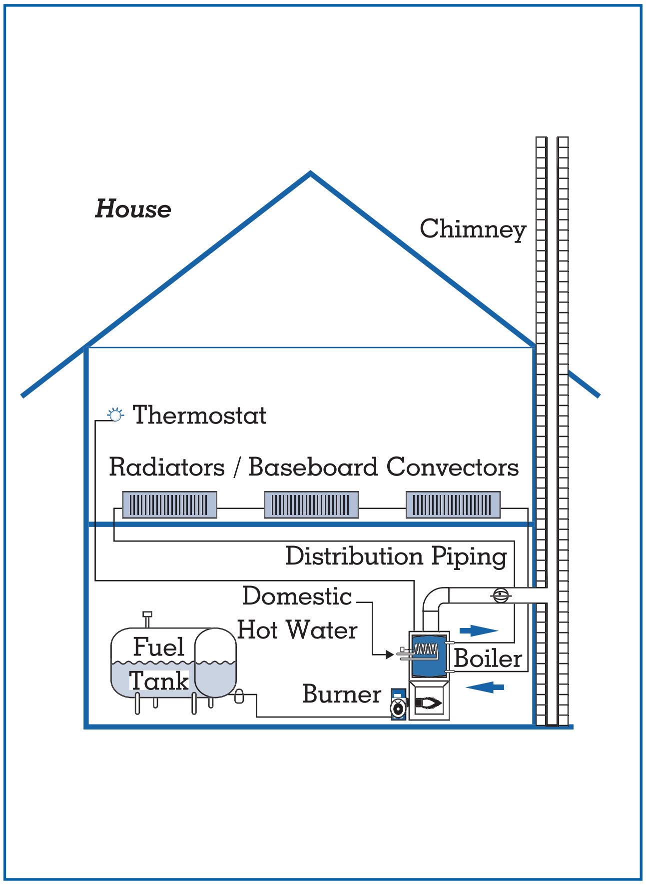

Figure 1.
Oil heating system.

Natural gas is transmitted in pipelines first across the country under high pressure in transcontinental pipe lines to local gas utility companies. The gas utility company reduces the pressure and distributes the gas through underground mains, and again reduces pressure from the street main into the home.

Gas or oil fuel is burned in a furnace or boiler (heat exchanger) to heat air or water, or to make steam that carries the heat absorbed from the combustion process to the rooms in the house, as shown in Figure 2. This is accomplished by circulating the warm air through ducts directly to the rooms, or by circulating hot water or steam through pipes to baseboard hot water convector units or radiators in the room. The boiler loop is completed with warm water returned through pipes to the boiler, or return air through the return register to air ducts back to the furnace to be reheated. In recent years, radiant floor heating systems that also rely on hot water circulation have come back into use. Boilers may also serve the additional function of heating water for showers and baths. A water heating coil immersed within the boiler is often used to heat this water as needed at a fixed rate. Another option is to have the coil immersed in a very well insulated water tank. The tank can provide a large supply of hot water at a very high rate of use. This is accomplished by exchanging heat from boiler water that passes through the inside of the coil to the domestic hot water stored in the tank. This method can provide for more hot water since a full tank of hot water is standing by for use when needed. The boiler operates only when the tank temperature drops below a certain set point. This results in fewer burner start-ups and is a more efficient way to heat water during the non-heating season months, enhancing year-round efficiency.

A recent alternative to the furnace or boiler for space heating is to use the hot water heater to heat the house. A separate air handler is sold along with a pump that pumps hot water from the water heater to the air handler where hot water flows through a finned tube heat exchanger coil. A blower in the air handler pushes air over the hot water coil and then through ducts to the rooms. Water out of the coil returns back to the water heater to be reheated. This way the water heater does double duty: it operates as a combination space heater and water heater. Gas water heaters can be used this way in mild climates and for homes or apartments with smaller heating requirements. Oil-fueled water heaters can also be used this way to handle homes in colder climates because they have higher firing rates and re-heat water faster. The installation cost is much lower for this approach in new construction, but units with high efficiency are not available for the gas water heaters as they are for gas furnaces or boilers.

Furnaces and boilers sold today must by law have annual fuel utilization efficiency of at least 78 to 80 percent. Gas water heaters operating this way as space heaters are equivalent to the efficiency of pre-1992 furnaces and boilers which had space heating efficiencies typically in the mid-60 percent range. However, the combined efficiency for space and water heating together may partly make up for the inefficiency of the water heater alone. There is also a concern regarding the life expectancy of water heaters, typically 5 to 10 years as compared to a boiler that will last anywhere from 20 to 40 years (or longer) depending on its design.

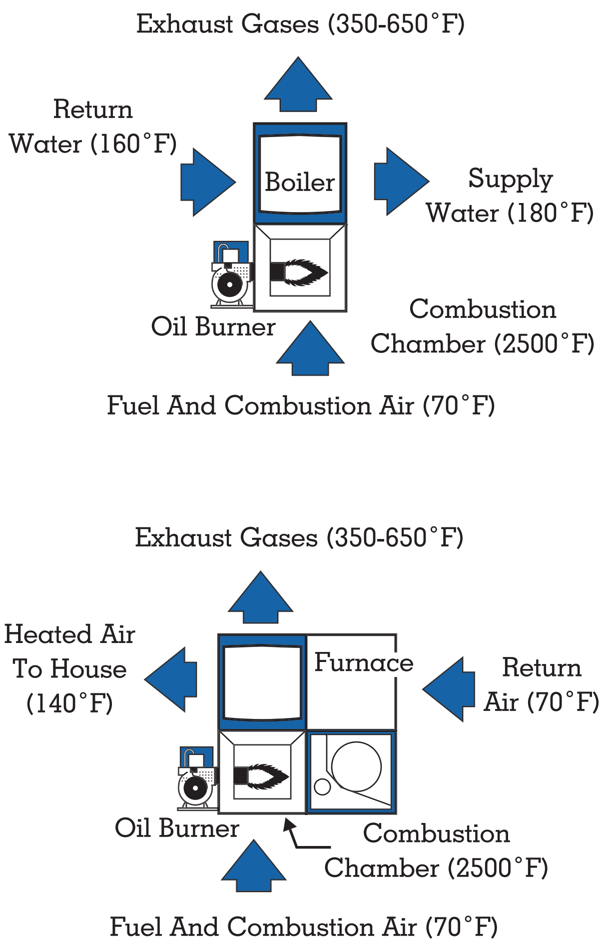

Figure 2.
Typical boiler or furnace operation
NOTE: Temperatures can vary.

Both gas and oil-fired heating systems consist of several subsystems. The oil burner pump draws fuel from the tank; the fuel is atomized and mixed with just the right amount of air for clean combustion; an electric spark provides the ignition of the fuel/air mixture; and the flame produces the heat in a combustion chamber. The heat is then released to the heat exchanger to heat air in the furnace and water in the boiler or to make steam. The process is similar for gas that is supplied under regulated gas pressure into the house piping to the furnace. The sequence of operation for the system starts at the wall thermostat. When the room temperature drops below the set point, a switch closes allowing the gas valve to send gas to the burners. With almost all new gas furnaces today, a spark or glowing hot wire igniter typically lights a gas pilot, or a spark system ignites the oil spray. The presence of the ignition source or pilot is proven, and the gas valve opens, sending gas mixed with air to the burner for ignition. The flame sensing system must be satisfied that the flame ignites or else it will quickly shut the burner off to prevent significant amounts of unburned fuel from accumulating in the heating appliance. The flue pipe connects the unit to a chimney to exhaust the products of combustion from the furnace into the outside ambient environment. A side wall vented flue pipe made of a plastic is used for some high efficiency condensing furnaces. The combustion of natural gas and fuel oils, which are primarily hydrocarbon molecules, results primarily in the formation of water vapor and carbon dioxide. The process also results in very minor amounts of sulfur dioxide (which is proportionate to the sulfur content of fuel oil, typically less than one half of one percent by weight), and trace amounts of other sulfur oxides, nitrogen oxides, and particulate matter (unburned hydrocarbon-based materials) in the range of parts per million to parts per billion or less.

The furnace blower or boiler circulator pump starts up to send heated room air or hot water through the ducts or hot water pipes to the steam radiators, or hot water baseboard units, or individual room air registers located throughout the house. When the thermostat is satisfied that the room temperature has reached the set point, the burner shuts off. In furnaces, the blower continues to run a few seconds until the air temperature drops to about 90° F, then the blower also shuts off. The furnace blower may come on again before the next burner start-up to purge heat out of the furnace, particularly if the fan has a low turn-on set point. The cycle repeats when the room temperature drops below the set point. In boilers, heat may be purged from the boiler by running the circulator for a controlled amount of additional time, delivering either more heat to the living space or hot water to a storage tank. Heat will continue to be supplied to the room from the radiators or hot water baseboard units until they cool down to room temperature.

U.S. HOUSEHOLD ENERGY CONSUMPTION AND EXPENDITURES

There were 10.8 million U.S. households that used fuel oil for space and/or water heating in 1993. The average household using fuel oil typically comsumed 684 gallons a year for space heating. In addition, 3.6 million U.S. homes used kerosene. Together they represented 14.4 million homes or 15 percent of the 96.6 million households in the United States. These households consumed a total of 7.38 billion gallons of heating fuel and 340 million gallons of kerosene.

There were 52.6 million U.S. households that used natural gas for space and/or water heating and/ or use in other appliances (mainly cooking ranges) in 1993. In addition there were 5.6 million U.S. homes that used LPG. Together they represented 58.2 million homes or 60 percent of the 96.6 million households in the United States. These households consumed a total of 4,954 billion cubic feet of natural gas and 3.84 billion gallons of LPG for space and water heating. The average household using natural gas typically uses about 70 million Btu a year for space heating.

Whereas heated homes are mostly located in the colder regions of the United States like the north and northeast, natural gas and LPG are used for heating homes through out the United States in both warmer and colder climates.

EFFICIENCY

Most new gas and oil-fueled furnaces and boilers have similar efficiencies. The range of efficiency has narrowed with the introduction of minimum efficiency standards for new products sold since 1992. New gas and oil heating equipment currently available in the marketplace have Annual Fuel Utilization Efficiency (AFUE) ratings of at least 78 to 80 percent. AFUE is a measure of how efficient a furnace operates on an annual basis and takes into account cycling losses of the furnace or boiler. It does not include the

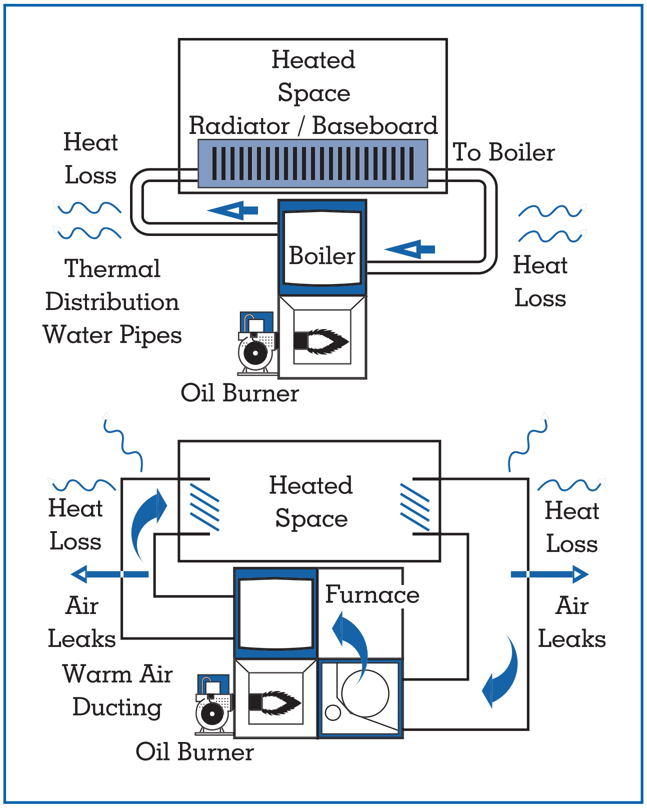

Figure 3.
Heat loss from distribution pipes and air ducts.

distribution losses in the duct system, which can be as much as 30 percent or more, especially when ducts are located in unheated areas such as the attic or unheated crawl space (see Figure 3). The AFUE also does not include the electricity to operate the blowers and any other electrical motors, controls or ignitors. The AFUE for gas furnaces are clustered in two groups: those in the range of 78 to 82 percent AFUE and those in the range of 90 to 96 percent. Few if any gas furnaces are available between these ranges because the upper range is a condensing furnace that requires an additional heat exchanger of a special alloy steel, a condensate pump and drain, and a special flue pipe material.

Because of the price diffferential between low- and high-efficiency condensing furnaces, only 22 percent of gas furnaces sold in the mid-1990's were high-efficiency condensing-type furnaces. Condensate is water that forms as a result of the combustion process. When the hydrogen in the fuel combines with oxygen from the combustion air, it forms water vapor (steam) that is cooled and condensed in a condensing furnace during the heat exchange process. Carbon dioxide in the flue gases makes this water act like soda water and becomes acidic. Fuel oil contains less hydrogen than natural gas and is therefore less likely to condense water vapor in the flue gases when operated in the mid-80 percent range. Therefore oil furnaces with up to 87 percent AFUE are available without condensing. The availability of condensing oil-fueled furnaces is limited since there is little efficiency benefit to be gained from the additional cost of a special alloy heat exchanger.

Some new features of furnaces available today include variable speed blowers, which deliver warm air more slowly and more quietly when less heat is needed, and variable heat output from the burner, which when combined with the variable speed blower allows for more continuous heating than the typical fixed firing rate. Distribution system features can be sophisticated with zoned heating which employs a number of thermostats, a sophisticated central controller, and a series of valves or dampers that direct airflow or water to different parts of the home only when needed in those areas.

The average AFUE of all installed furnaces is 65 to 75 percent, much lower than post-1992 efficiency standards due to the different vintages of furnaces and boilers. Systems that are 40 years old or older are even less efficient (55-65%), but these represent a very small fraction of furnaces operating in the United States today.

The U.S. Department of Energy develops test procedures for efficiency measurements and sets minimum efficiency standards for furnaces, boilers, and water heaters. Information on energy efficiency of buildings and equipment is available from the DOE.

FUTURES

OVERVIEW

A futures contract is an agreement that calls for a seller to deliver to a buyer a specified quantity and quality of an identified commodity, at a fixed time in the future, at a price agreed to when the contract is made. An option on a commodity futures contract gives the buyer of the option the right to convert the option into a futures contract. Energy futures and options contracts are used by energy producers, petroleum refiners, traders, industrial and commercial consumers, and institutional investors across the world to manage their inherent price risk, to speculate on price changes in energy, or to balance their portfolio risk exposure.

With very limited exceptions, futures and options must be executed on the floor of a commodity exchange through persons and firms registered with regulatory authorities. The contracts are traded either by open outcry, where traders physically transact deals face to face in specified trading areas called pits or rings, or electronically via computerized networks. The futures market provides a standardized trading environment such that all users know exactly what they are trading and where their obligations and risks lie. By entering into a standard futures and/or options contract, a certain amount of price assurance can be introduced into a world of uncertainty and price volatility.

Most futures contracts assume that actual delivery of the commodity can take place to fulfill the contract. However, some futures contracts require cash settlement instead of delivery. Futures contracts can be terminated by an offsetting transaction (i.e., an equal and opposite transaction to the one that opened the position) executed at any time prior to the contract's expiration. The vast majority of futures contracts are terminated by offset or a final cash payment rather than by physical delivery.

HISTORICAL PERSPECTIVE

Futures contracts for agricultural commodities have been traded in the United States since the nineteenth century and have been under federal regulation since the 1920s. Starting in the late 1970s, futures trading has expanded rapidly into many new markets, beyond the domain of traditional physical and agricultural commodities such as metals and grains. Futures and options are now offered on many energy commodities such as crude oil, gasoline, heating oil, natural gas, and electricity, as well as on a vast array of other commodities and financial instruments, including foreign currencies, government securities, and stock indices.

TERMS AND CONDITIONS

A typical futures contract might call for the delivery of 1,000 barrels (42,000 U.S. gallons) of unleaded gasoline meeting defined specifications at petroleum product terminals in New York Harbor during the next twelve months at an agreed price in dollars and cents per gallon. All terms and conditions other than the price are standardized. Gasoline is sold through hundreds of wholesale distributors and thousands of retail outlets, and is the largest single volume refined product sold in the United States. It accounts for almost half of national oil consumption. A market that diverse is often subject to intense competition, which in turn breeds price volatility and the need for reliable risk management instruments for energy producers and users.

OPTIONS

There are two types of options — call options and put options. A call option on a futures contract gives the buyer the right, but not the obligation, to purchase the underlying contract at a specified price (the strike or exercise price) during the life of the option. A put option gives the buyer the right to sell the underlying contract at the strike or exercise price before the option expires. The cost of obtaining this right to buy or sell is known as the option's "premium." This is the price that is bid and offered in the exchange pit or via the exchange's computerized trading system. As with futures, exchange-traded option positions can be closed out by offset.

HOW FUTURES AND OPTIONS DIFFER

The major difference between futures and options arises from the different obligations of buyer and seller. A futures contract obligates both buyer and seller to perform the contract, either by an offsetting transaction or by delivery. Both parties to a futures contract derive a profit or loss equal to the difference between the price when the contract was initiated and when it was terminated. In contrast, an option buyer is not obliged to fulfill the option contract. Buying an options contract is similar to buying insurance. The buyer is typically paying a premium to remove risk, while the seller earns the premium and takes on risk. The option buyer's loss is limited to the premium paid, but in order for the buyer to make a profit, the price must increase above (call option) or decrease below (put option) the option's strike price by more than the amount of the premium paid. In turn, the option seller (writer or grantor), in exchange for the premium received, must fulfill the option contract if the buyer so chooses. Thus, the option's exercise takes place if the option has value (is "in the money") before it expires.

FEATURES NEEDED FOR A WELL-FUNCTIONING MARKET

Whatever the item, such as crude oil, underlying the futures or options contract, every market needs certain ingredients to flourish. These include

- Risk-shifting potential—the contract must provide the ability for those with price risk in the underlying item to shift that risk to a market participant willing to accept it. In the energy world, commercial producers, traders, refiners, distributors and consumers need to be able to plan ahead, and frequently enter into commitments to buy or sell energy commodities many months in advance.
- Price volatility—the price of the underlying item must change enough to warrant the need for shifting price risk. Energy prices are subject to significant variance due to factors affecting supply and demand such as level of economic activity, weather, environmental regulations, political turmoil, and war. Market psychology also plays its part.
- Cash market competition—the underlying cash (or physicals) market for the item must be broad enough to allow for healthy competition, which creates a need to manage price risk and decreases the likelihood of market corners, squeezes, or manipulation. The physical market in energy commodities is the largest such market in the world.
- Trading liquidity—active trading is needed so that sizable orders can be executed rapidly and inexpensively. Popular markets such as crude oil, heating oil, and unleaded gasoline have thousands of contracts traded daily.
- Standardized underlying entity—the commodity or other item underlying the futures contract must be standardized and/or capable of being graded so that it is clear what is being bought and sold. Energy commodities are fungible interchangeable goods sold in accordance with strict specifications and grades.

Energy is considered to be a well-functioning market because it satisfies these criteria. The existence of such a market has a significant modifying effect on short-term price volatility, and will temper the impact of any future disruptions such as those that occurred in the pre-futures market 1970s. However, even a well-functioning futures market cannot be expected to eliminate the economic risks of a massive physical supply interruption.

MARKET PARTICIPANTS

Most of the participants in the energy futures and option markets are commercial or institutional energy producers, such as petroleum producers, refiners, and electric utilities; traders; or users, such as industrial and transportation companies. The energy producers and traders, most of whom are called "hedgers," want the value of their products to increase and also want to limit, if possible, any loss in value. Energy users, who are also hedgers, want to protect themselves from cost increases arising from increases in energy prices. Hedgers may use the commodity markets to take a position that will reduce their risk of financial loss due to a change in price. Other participants are "speculators" who hope to profit from changes in the price of the futures or option contract. It is important to note that hedgers typically do not try to make a killing in the market. They use futures to help stabilize their revenues or their costs. Speculators, on the other hand, try to profit by taking a position in the futures market and hoping the market moves in their favor. Hedgers hold offsetting positions in the cash market for the physical commodity but speculators do not.

THE MECHANICS OF TRADING

The mechanics of futures and options trading are straightforward. Typically, customers who wish to trade futures and options contracts do so through a broker. Both, buyers and sellers, deposit funds—traditionally called margin, but more correctly characterized as a performance bond or good-faith deposit—with a brokerage firm. This amount is typically a small percentage—less than 10 percent—of the total value of the item underlying the contract.

The New York Mercantile Exchange (NYMEX) is the largest physical commodity futures exchange in the world. The exchange pioneered the concept of risk management for the energy industry with the launch of heating oil futures in 1978, followed by options and/or futures for sweet and sour crude oil, unleaded gasoline, heating oil, propane, natural gas, and electricity. The NYMEX is owned by its members and is governed by an elected board of directors. Members must be approved by the board and must meet strict business integrity and financial solvency standards.

The federal government has long recognized the unique economic benefit futures trading provides for price discovery and offsetting price risk. In 1974, Congress created the Commodity Futures Trading Commission (CFTC), replacing the previous Commodity Exchange Authority, which had limited jurisdiction over agricultural and livestock commodities. The CFTC was given extensive authority to regulate commodity futures and related trading in the United States. A primary function of the CFTC is to ensure the economic utility of futures markets as hedging and price discovery vehicles.

The London-based International Petroleum Exchange (IPE) is the second largest energy futures exchange in the world, listing futures contracts that represent the pricing benchmarks for two-thirds of the world's crude oil and the majority of middle distillate traded in Europe. IPE natural gas futures may also develop into an international benchmark as the European market develops larger sales volume.

Besides NYMEX and IPE, there are a number of other exchanges offering trading opportunities in energy futures. These include the Singapore International Monetary Exchange (North Sea Brent crude), The Chicago Board of Trade (electricity), Kansas City Board of Trade (western U.S. natural gas), and the Minneapolis Grain Exchange (Twin Cities' electricity). Domestic energy futures trading opportunities have arisen due to deregulation of the electricity and natural gas industries introducing many new competitors prepared to compete on the basis of price.

There has been discussion of the possibility of a futures market in emission credits arising from domestic regulations or international treaties to reduce energy use-related greenhouse gas emissions. These so-called pollution credits would be generated when Country A (or Corporation A) reduces its emissions below a specific goal, thereby earning credits for the extra reductions. At the same time, Country/Corporation B decides that emission controls are too expensive, so it purchases A's emission reduction credits. A declining cap on allowable emissions would reduce the available number of credits over time. The controversial theory is that market forces would thereby reduce emissions. Although there is some U.S. experience with the private sale and barter of such emission credits (a cash or "physicals" market), it remains to be seen if a true exchange-traded futures market in emission credits will arise.

ENERGY AND FUTURES PRICES

In addition to providing some control of price risk, futures and options markets are also very useful mechanisms for price discovery and for gauging market sentiment. There is a world-wide need for accurate, real-time information about the prices established through futures and options trading, that is, a need for price transparency. Exchange prices are simultaneously transmitted around the world via a network of information vendors' terminal services directly to clients, thereby allowing users to follow the market in real time wherever they may be. Energy futures prices are also widely reported in the financial press. These markets thus enable an open, equitable and competitive environment.

G

GASOLINE AND ADDITIVES

Gasoline is the primary product made from petroleum. There are a number of distinct classes or grades of gasoline. Straight-run gasoline is that part of the gasoline pool obtained purely through distillation of crude oil. The major portion of the gasoline used in automotive and aviation is cracked gasoline obtained through the thermal or catalytic cracking of the heavier oil fractions (e.g., gas oil). A wide variety of gasoline types are made by mixing straight-run gasoline, cracked gasoline, reformed and synthesized gasolines, and additives.

Motor fuels account for about one-quarter of all energy use in the United States. The energy content of gasoline varies seasonally. The average energy content of regular gasoline stands at 114,000 Btu/gal in the summer and about 112,500 Btu/gal in the winter. The energy content of conventional gasolines also varies widely from batch to batch and station to station by as much as 3 to 5 percent between the minimum and maximum energy values.

Gasoline can be made from coal as well as petroleum. In the 1930s and 1940s, Germany and other European countries produced significant quantities of gasoline from the high-pressure hydrogenation of coal. But to convert the solid coal into liquid motor fuels is a much more complex and expensive process. It could not compete with the widely available and easily refined petroleum-based motor fuels.

In the United States, all gasoline is produced by private commercial companies. In many cases, they are vertically integrated so that they drill for, find, and transport oil, process the oil into gasoline and other products and then sell the gasoline to a network of retailers who specialize in certain brand name gasolines and gasoline blends. These large refiners may also market these products to other refiners, wholesalers, and selected service stations.

GROWING DEMAND FOR GASOLINE

At the end of the nineteenth century, virtually all of the gasoline produced (around 6 million barrels) was used as a solvent by industry, including chemical and metallurgical plants and dry cleaning establishments, and as kerosene for domestic stoves and space heaters. But by 1919, when the United States produced 87.5 million barrels of gasoline, 85 percent was consumed by the internal combustion engine (in automobiles, trucks, tractors, and motorboats).

Between 1899 and 1919, as demand for gasoline grew, the price increased more than 135 percent, from 10.8 cents/gal to 25.4 cents/gal. From 1929 to 1941, gasoline use by passenger cars increased from 256.7 million barrels to 291.5 million barrels. Consumption of aviation fuel went from only 753,000 barrels in 1929 to over 6.4 million barrels at the start of World War II. By 1941, gasoline accounted for over one-half of petroleum products with 90 percent of gasoline output used as fuel for automotive and aircraft engines.

Between 1948 and 1975, per capita consumption of gasoline in the United States increased from about 150 gal/yr to a little less than 500 gal/yr. A growing trend after the war was the increasing use of jet fuel for aircraft and the decline in use of aviation gasoline. After 1945, oil production increased in other parts of the world, especially the Middle East and Latin America. By the 1970s, the Middle East became a dominant oil producing region. The cartel formed by the major Middle Eastern oil producing countries, known as OPEC, became a major force in setting oil prices internationally through the control of oil production.

Since the mid-1970s, the rate of growth of per capita gasoline consumption has slowed. An important factor in causing this moderation in demand was the trend to improve automobile fuel economy that was initiated by worldwide fuel shortages. Fuel economy hovered around 14.1 mpg between 1955 and 1975; it rose sharply over the next 15 years, reaching around 28.2 mpg in 1990.

An aging population and continued improvements in engine technology and fuel economy may slow U.S. gasoline demand in the early part of the twenty-first century from the 2 percent annual growth rate of the 1990s.

KNOCKING AND OCTANE RATING

The process of knocking has been studied extensively by chemists and mechanical engineers. Knocking is rapid and premature burning (i.e., preignition) of the fuel vapors in the cylinders of the engine while the pistons are still in the compression mode. Research on knocking was carried out prior to World War I, but it was only with the increase in the size and power of automotive engines after 1920 that significant attempts were made to deal with the problem on a commercial basis.

Knocking, which has a distinctive metallic “ping,” results in loss of power and efficiencies and over time causes damage to the engine. Knocking is a great energy waster because it forces the automobile to consume greater quantities of gasoline per mile than do engines that are functioning properly. The problem of engine knocking was an important factor in the U.S. push for a gasoline rating system. Around the time of World War I, there was no single standard specification or measure of gasoline performance. Many states developed their own specifications, often conflicting with those promulgated by the automotive and petroleum industries and the federal government. Even the various branches of government had their own specifications. The specifications might be based on the boiling point of the gasoline fraction, miles allowed per gallon of fuel, or the chemical composition of the gasoline.

The octane numbering system was developed in the late 1920s and was closely linked to the federal government’s program of measurement standards, designed jointly by the Department of the Army and the National Bureau of Standards.

The octane number of a fuel is a measure of the tendency of the fuel to knock. The octane scale has a minimum and maximum based on the performance of reference fuels. In the laboratory, these are burned under specific and preset conditions. One reference fuel is normal heptane. This is a very poor fuel and is given an octane rating of zero. On the opposite end of the scale is iso-octane (2,2,4 trimethyl pentane). Iso-octane is a superior fuel and is given a rating of 100.

The octane rating of fuels is derived by simple laboratory procedures. The fuel being tested is burned to determine and measure its degree of “knocking.” Then the two reference fuels are blended together until a reference gasoline is formed that knocks to the same degree as the tested fuel. The proportion of iso-octane present in the reference fuel is then the octane number of the tested gasoline. Some compounds, like methanol and toluene, perform better than iso-octane and, by extrapolation, their octane numbers are over 100. A higher octane number is important from a very practical consideration: it gives better engine performance in the form of more miles per gallon of gasoline.

From the 1920s to the 1940s, catalytic cracking processes were developed that not only increased processing efficiencies, but progressively raised the octane number of gasoline. In 1913, prior to the devising of the octane scale, the commercialization of the Burton Process, a noncontinuous thermal technology, produced gasoline with an estimated octane number of between 50 and 60. Continuous thermal cracking, first operated in the early 1920s, produced gasoline with an octane number of close to 75. With the first catalytic process in the form of the Houdry technology (1938), cracked gasoline reached the unprecedented octane level in the high 80s. Fluid catalytic cracking, the culmination of the cracking art that came on line in 1943, pushed the quality of gasoline to an octane level of 95.

While octane rating provided an objective and verifiable measure of performance across all grades of gasoline, it did not immediately lead to unified standards. It was not until the 1930s, when both the octane rating and new types of octane-boosting additives entered the industry, that automotive fuel began to center around two major types of gasoline—regular and premium—each operating within its own octane range. Over the next 60 years, octane rating of gasoline increased due to improved refining practices and the use of additives. In the 1970s and 1980s, the use of additives became increasingly tied to environmental concerns (i.e., clean air), as well as higher octane ratings. Gasoline has come a long way since the Model T, and it is important to note that, in terms of constant dollars, it is cheaper today than it was in 1920.

Table 1 shows the major gasoline additives that were introduced from the 1920s through the 1980s. The increase in octane number of gasoline with use of these additives is shown.

Additive	*Octane Number*
Tetraethyl lead (TEL)	100
Methanol	107
Ethanol	108
Methyl-t-butyl ether (MTBE)	116
Ethyl-t-butyl ether (ETBE)	118

Table 1.
Octane Numbers of Common Gas Additives

TETRAETHYLEAD: THE FIRST GASOLINE ADDITIVE

One source of knocking was related to the vehicle engine. All else being equal, an automobile engine with a higher compression ratio, advanced spark schedule, or inefficient combustion is more likely to experience knocking. Within the United States, research into knocking has focused on the chemical aspects of gasoline, which is a complex hydrocarbon mixture of paraffins, naphthenes, and aromatics.

Chemical additives first entered the industry in the first decade of the century. These additives served a number of uses. For example, they lessened the capacity of gasoline to vaporize out of the gas tank or to polymerize (i.e., produce gummy residues) in the engine. In the early 1920s, the most important application for these substances was to eliminate knocking. Tetraethylead (TEL) was the first major gasoline additive to be commercialized for this purpose.

Charles F. Kettering, the inventor of the self starter, the Delco battery, and other major components of modern automotive engineering, started to work on the problem in 1916 at his Dayton Engineering Laboratories Company (DELCO). Kettering was induced into this research not by the problems faced by the automobile but by gasoline-powered electric lighting systems for farms. These systems employed generators utilizing internal combustion engines. These engines, which burned kerosene and not gasoline, knocked badly. Kettering and his team addressed this nonautomotive concern as a profitable research project and one of potentially great benefit to the agricultural sector.

Kettering hired Thomas Midgley Jr., a mechanical engineer from Cornell, to work with him on the project. Studying the combustion process in more detail, Kettering and Midgley determined that low volatility in the fuel caused knocking to occur. This conclusion led them to search for metallic and chemical agents to blend with the gasoline to increase volatility and reduce knocking.

A promising line of research led Midgley to the halogen group of chemicals and specifically iodine and its compounds. General Motors purchased DELCO Labs in 1919 and the search for an antiknock agent came under GM management, with Kettering and Midgley remaining on board to continue the work, but with the focus now on automotive application.

Using iodine as their starting point, they experimented with a series of compounds including the anilines and a series of metals near the bottom of the periodic table. Lead turned out to be the most effective of the additives tested. But lead alone caused a number of problems, including the accumulation of its oxide in engine components, and particularly the cylinders, valves, and spark plugs.

Experiments continued to find an appropriate form of lead that could at the same time prevent the formation of oxide deposits. Ethylene was found to combine with lead to form tetraethyllead (TEL), a stable compound that satisfied this requirement.

Kettering and Midgley were the first to identify it as a prime antiknock agent, though the compound had been known since 1852. They estimated that only a very small amount of TEL—a few parts per thousand—would result in a 25 percent increase in horsepower as well as fuel efficiency.

The next stage of development was to design a production process to link the ethyl group to lead. GM attempted to make TEL from ethyl iodide. They built an experimental plant, but the process proved too expensive to commercialize.

An alternative source of the ethyl component was ethyl bromide, a less expensive material. It was at this point that GM called upon DuPont to take over process development. DuPont was the largest U.S. chemical company at the time. It had extensive experience in the scale-up of complex chemical operations, including explosives and high-pressure synthesis. The manufacturing process was undertaken by DuPont's premier department, the Organic Chemical section. GM contracted with DuPont to build a 1,300 pound per day plant. The first commercial quantities of TEL were sold in February 1923 in the form of ethyl premium gasoline.

In 1923, GM set up a special chemical division, the GM Chemical Co., to market the new additive. However, GM became dissatisfied with DuPont's progress at the plant. In order to augment its TEL supply, and to push DuPont into accelerating its pace of production, GM called upon the Standard Oil Company of New Jersey (later Esso/Exxon) to set up its own process independently of DuPont. In fact, Jersey Standard had obtained the rights to an ethyl chloride route to TEL. This turned out to be a far cheaper process than the bromide technology. By the mid-1920s, both DuPont and Jersey were producing TEL.

GM brought Jersey in as a partner in the TEL process through the formation of the Ethyl Corporation, each party receiving a 50 percent share in the new company. All operations related to the production, licensing, and selling of TEL from both DuPont and Jersey were centralized in this company.

Soon after production began, TEL was held responsible for a high incidence of illness and deaths among production workers at both the DuPont and Jersey Standard plants. The substance penetrated the skin to cause lead poisoning. Starting in late 1924, there were forty-five cases of lead poisoning and four fatalities at Jersey Standard's Bayway production plant. Additional deaths occurred at the DuPont Plant and at the Dayton Laboratory. This forced the suspension of the sale of TEL in 1925 and the first half of 1926.

These incidents compelled the U.S. Surgeon General to investigate the health effects of TEL. The industry itself moved rapidly to deal with the crisis by instituting a series of safety measures. Now, ethyl fluid was blended at distribution centers and not at service stations (it had been done on the spot and increased the chances of lead poisoning to service station attendants). Also, ethyl gasoline was dyed red to distinguish it from regular grade gasoline. DuPont and Jersey placed tighter controls over the production process. The federal government placed its own set of restrictions on TEL. It set the maximum limit of 3 cc of TEL per gallon of gasoline. By 1926, TEL was once again being sold commercially.

Ironically, this episode proved beneficial to DuPont. DuPont became the dominant source of TEL after the mid-1920s because they perfected the chloride process and were far more experienced than Jersey Standard in producing and handling toxic substances.

The Ethyl Corp. and DuPont held the TEL patent, and controlled the TEL monopoly. The company held the sole right to the only known material that could eliminate automotive knocking. And it used its influence in the gasoline market to manipulate prices. Over the next few years, the company wielded its monopoly power to maintain a 3–5 cent differential between its "ethyl" gasoline and the regular, unleaded gasoline sold by the rest of the industry.

Throughout the 1930s TEL proved itself a profitable product for DuPont, which remained virtually the only TEL producer into the post–World War II period. With no advantage to be gained in further collaboration, DuPont severed its ties with Ethyl Corp. in 1948 and continued to manufacture TEL independently.

COMPETING AGAINST TEL: ALTERNATIVE ANTIKNOCK TECHNOLOGY

As the automotive industry continued to introduce higher compression engines during the 1920s and 1930s, refiners increasingly relied on TEL to meet gasoline quality. By 1929, fifty refiners in the United States had contracted with the Ethyl Corp. to incorporate TEL in their high test gasoline.

TEL was not the only way to increase octane number. Those few companies who did not wish to do business with Jersey Standard, sought other means to produce a viable premium gasoline. TEL represented the most serious threat to the traditional gasoline product. It was cheap, very effective, and only 0.1 percent of TEL was required to increase the octane number 10 to 15 points. In contrast, between 50 to 100 times this concentration was required of alternative octane enhancers to achieve the same effect.

Benzol and other alcohol-based additives improved octane number, up to a point. Experiments using alcohol (ethanol, methanol) as a replacement for gasoline began as early as 1906. In 1915, Henry Ford announced a plan to extract alcohol from grain to power his new Fordson tractor, an idea that never achieved commercial success.

The shortage of petroleum after World War I induced an intense search for a gasoline substitute in the form of alcohol. The trade press felt alcohol would definitely replace gasoline as a fuel at some point. The advantages of alcohol cited in the technical press included greater power and elimination of knocking.

The push to use alcohol as a fuel surfaced at various times coinciding with real or perceived gasoline shortages and often directed by the farm lobby during periods of low grain prices. The great discoveries of oil in the Mid-Continental fields in the1920s reduced the incentive for the use of alcohol as a fuel. But in the 1930s the severe agricultural crisis brought back interest in alcohol. Alcohol distillers, farmers, and Midwest legislators unsuccessfully attempted to regulate the blending into gasoline of between 5–25 percent ethanol. It took the oil supply disruptions of the 1970s for farm state legislators to pass legislation to highly subsidize ethanol. The subsidies, which remain in effect today, are the reason ethanol continues to play a notable role as a fuel additive.

As experiments at Sun Oil Co. in the early 1930s indicated, there were serious disadvantages associated with alcohol. While alcohol did in fact appear to increase the octane number, it left large amounts of deposits in the engine. Alcohol also vaporized out of the gas tank and engine at rapid rates. And the combustion temperature of the alcohol group is lower than for hydrocarbons because it is already partially oxidized.

The most effective competitive approach for the more independent refiners was in developing new types of cracking technologies. Companies like Sun Oil, one of the few companies who remained independent of Jersey and Ethyl, continued to expand the limits of thermal cracking, notably by employing higher pressures and temperatures. Sun's gasoline reached octane levels close to those achieved by gasolines spiked with TEL (i.e., between 73 and 75). Sun Oil continued to compete with additives purely through advanced cracking technology, a path that would lead by the late 1930s to the first catalytic cracking process (i.e., the Houdry Process). But by this time, more advanced refining processes were coming on line and competing with the Houdry Process. By the early 1940s, Jersey Standard developed fluidized bed catalytic cracking technology. Fluidized cracking proved superior to Houdry's fixed bed process with respect to both production economies and the quality of the product (i.e., octane rating of the gasoline). Fluidized cracking quickly displaced Houdry's catalytic cracking technology as the process of choice.

Competition did not center on quality alone. Price and packaging were called into play as weapons against the onslaught of TEL. For example, as a marketing tool, Sun Oil dyed its gasoline blue to more easily identify it as a high premium fuel (customers actually saw the gasoline being pumped in a large clear glass reservoir on top of the gas pump). Sun then competed aggressively on price. Whereas TEL-using refiners sold two grades of gasoline, regular and premium, Sun marketed only its premium "blue Sunoco" at regular grade prices. Sun could do this because it was not burdened, as TEL was, with such additional costs as blending and distribution expenses that cut into profit margins.

By the late 1920s and into the 1940s, with the use of either TEL, other additives, or advanced cracking technology, a number of premium grade gasolines appeared on the market. In addition to Sun's premium, there was Gulf's "NoNox," Sinclair's premium "H.C.'s" gasoline, and Roxana Petroleum's "Super-Shell." The use of TEL has plummeted since the government's mandate in 1975 to install catalytic converters for reducing the carbon monoxide and unburned hydrocarbons in automotive exhaust gases. This is because lead poisons the noble metal (chiefly platinum) catalysts used. In addition the lead bearing particulates in the emissions from engines burning leaded fuel are toxic in their own rights.

POSTWAR DEVELOPMENTS: GASOLINE AND THE ENVIRONMENT

Additives and the blending process became an increasingly important part of gasoline manufacture after World War II. Refiners had to balance such factors as customer specifications, regulatory requirements, and probable storage (i.e., nonuse) time. The industry became more precise in how, when, and how many of components should be added to gasolines. The large, modern refinery increasingly incorporated complex computer programs to help plan and effect blending requirements. Critical factors that had to be factored into these calculations included seasonal adjustments, current and anticipated demand, regulatory levels, and supply schedules of the various components.

Since the 1950s, an increasing portion of a refiner's R&D has gone into new and improved additives. Beyond their role as antiknock agents, additives and blending agents have taken on an ever broadening range of functions to improve the performance of fuels in automotive and aircraft engines.

Sulfur and Gasoline

In recent years, there has been a greater understanding of the role of automotive emissions as environmental pollutants. Sulfur dioxide, nitrogen oxides, and carbon monoxide degrade the earth's atmosphere and are health hazards. Carbon dioxide adds to the atmospheric buildup of greenhouse gases and in turn accelerates the process of global warming.

Sulfur is a particular problem as an environmental hazard. It occurs naturally in various concentrations in petroleum, and it is difficult and costly to remove all of it. Distillation and cracking removes some, but small amounts survive the distillation and cracking processes and enter into the gasoline. The average level of sulfur in gasoline has not changed much since 1970, remaining at 300 parts per million (ppm) with a range between 30 and 1,000 ppm.

High levels of sulfur not only form dangerous oxides, but they also tend to poison the catalyst in the catalytic converter. As it flows over the catalyst in the exhaust system, the sulfur decreases conversion efficiency and limits the catalyst's oxygen storage capacity. With the converter working at less than maximum efficiency, the exhaust entering the atmosphere contains increased concentrations, not only of the sulfur oxides but also, of hydrocarbons, nitrogen oxides, carbon monoxides, toxic metals, and particulate matter.

In the 1990s, the EPA began controlling sulfur through its reformulated gasoline program. It developed regulations in 1999 that would sharply reduce the sulfur content in gasoline from 300 ppm to a maximum of 80 ppm.

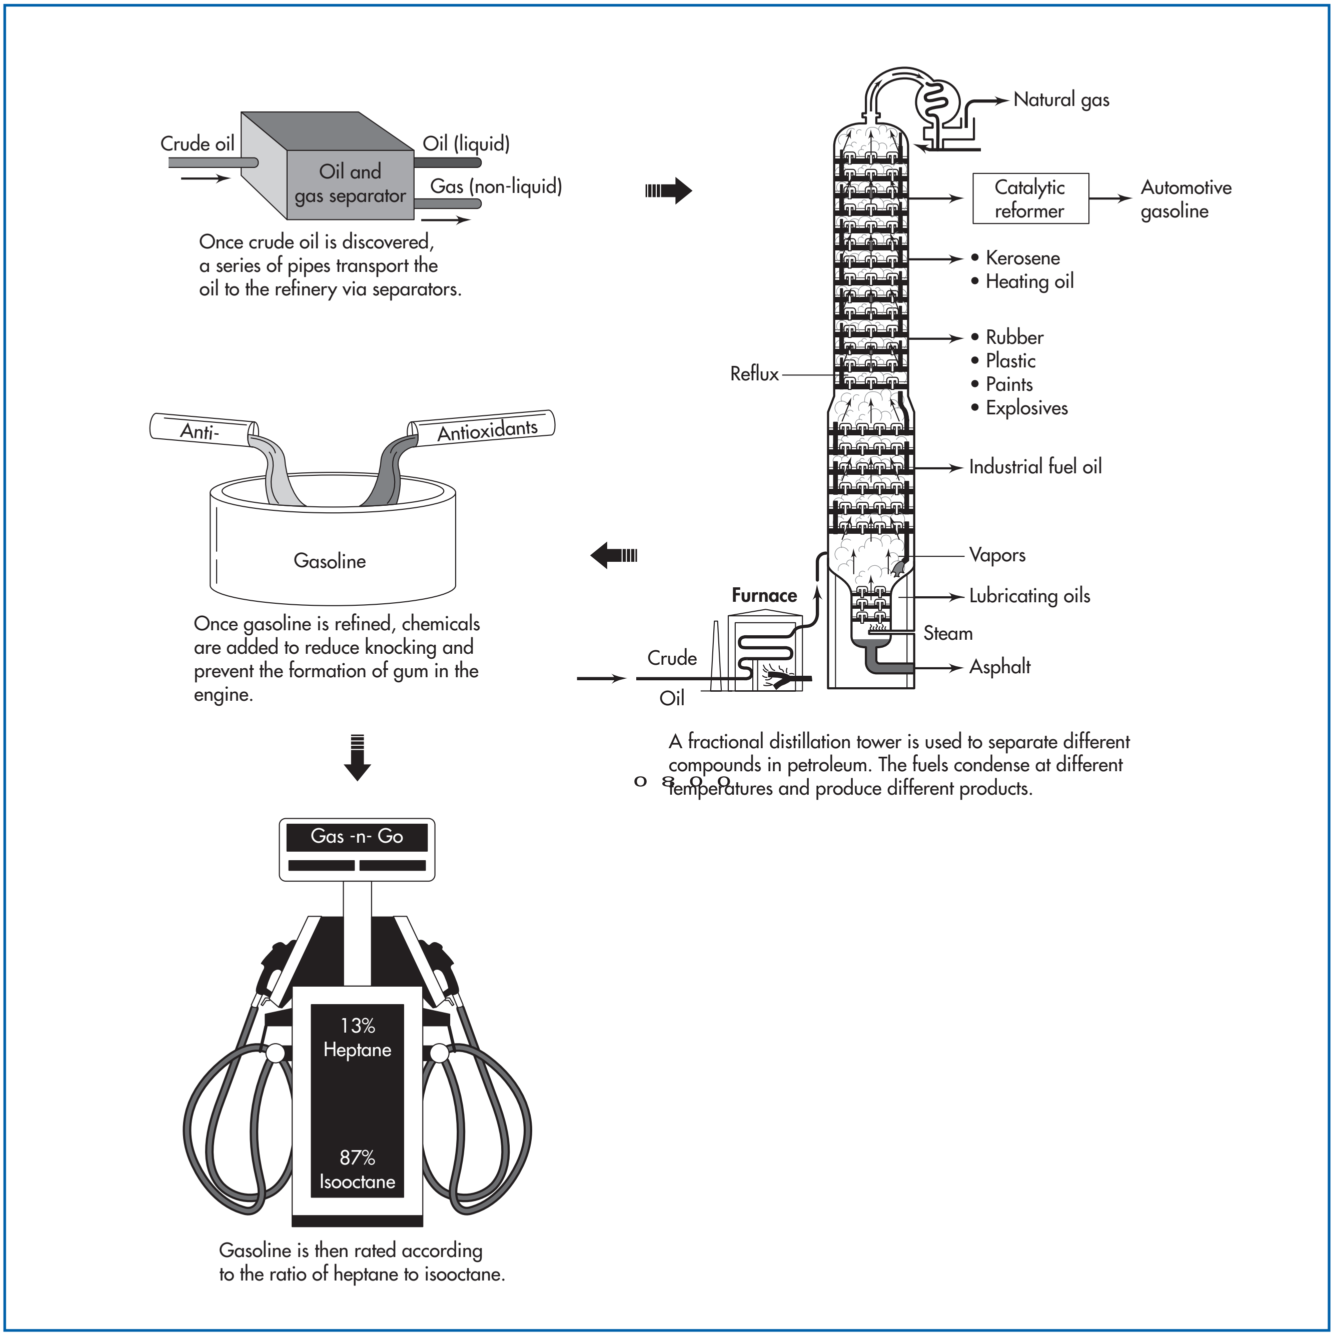
The new regulations, scheduled to go into effect in 2004, are compelling certain refiners to purchase low-sulfur content ("sweet") crude oil. This is the strategy being pursued by Japanese refiners. However, the Japanese are not major oil producers but import oil from other producing countries. U.S. refiners, in contrast, consume oil from a wide range of ("sour") petroleum sources that have a high-sulfur content, including Venezuela, California, and parts of the Gulf Region. U.S. companies own and operate oil producing infrastructures (i.e., derricks, pipelines), within the United States and overseas. They are committed to working these oil fields, even if producing high-sulfur oil. U.S. refineries thus need to continue dealing with high-sulfur crude oil. Imported crude from the Middle East, while historically low in sulfur, is also becoming increasingly less sweet.

Petroleum refiners will have to reduce sulfur content at the refineries. This will require the costly retooling of some of their plant operations in order to achieve a suitable fuel mix. Removing additional amounts of sulfur at the refinery will entail installation of separate catalyst-based process such as hydrosulfurization. Another possible approach is the removal of sulfur in liquid oil or gasoline by the use of both organic and inorganic scavenger agents added to the oil or gasoline to seek out, combine with, and precipitate out sulfur and its compounds.

Reformulated Gasoline and MTBE

Prior to the Clean Air Act of 1990, environmental regulations were aimed at reducing emissions as they left the exhaust system. The catalytic converter has been the primary means of attacking air pollution in this way. After 1990, regulations for the first time undertook to alter the composition of the fuel itself. Reformulated gasoline applies to gasoline that is sold in the nine metropolitan areas designated by the EPA with the highest level of ozone pollution. About 48 million people reside in areas where ozone concentrations exceed federal standards.

Reformulation refers to the transformation of gasoline to make it cleaner with respect to emissions. Beginning in 1995, specifications for reformulated gasoline included a 2 percent minimum oxygen content and a maximum content of various organic and inorganic pollutants. In addition, heavy metal additives in gasoline are prohibited. A disadvantage of



Once crude oil is discovered, a series of pipes transport the oil to the refinery via separators.

A fractional distillation tower is used to separate different compounds in petroleum. The fuels condense at different temperatures and produce different products.

Once gasoline is refined, chemicals are added to reduce knocking and prevent the formation of gum in the engine.

Gasoline is then rated according to the ratio of heptane to isooctane.

The gasoline-making process. (Gale Group)

reformulated gasoline is that it contains 1 to 3 percent less energy per gallon than traditional gasoline.

Many reformulated gasolines use oxygenated compounds as additives. Clean Air regulations specify the need for oxygenated fuel in 39 metropolitan areas with high carbon monoxide concentrations. The regulations for oxygenated fuel are seasonal: during the winter season, gasoline must contain a minimum of 27 percent oxygen. The oxygen helps engines to burn the fuel more completely which, in turn, reduces monoxide emissions. The major additive to supply the additional oxygen to reformulate gasoline to satisfy these requirements is the methanol derivative, methyl tertiary butyl ether (MTBE).

Currently, this additive is used in over 30 percent of U.S. gasoline.

MTBE was first used as a fuel additive in the 1940s and was a popular additive in Europe in the 1970s and 1980s. In the late 1970s, MTBE began replacing lead in this country to enhance octane number. In the late 1980s, California led the way in the United States for its use as an oxygenate for cleaner burning fuel. The consumption of MTBE in the United States increased rapidly between 1990 and 1995 with the passage of the Clean Air Act and, a few years later the implementation of the federal reformulated gasoline program. Currently, MTBE is produced at 50 U.S. plants located in 14 states. About 3.3 billion gallons of MTBE, requiring 1.3 billion gallons of methanol feedstock, are blended annually into reformulated gasoline.

In the late 1990s, MTBE came under serious attack on grounds of both efficacy and safety. A report by the National Research Council (1999) stated that the addition of oxygen additives in gasoline, including MTBE and ethanol, are far less important in controlling pollution than emission control equipment and technical improvement to vehicle engines and exhaust systems.

Moreover, MTBE has been found in groundwater, lakes and reservoirs used for drinking water, and it has been linked to possible serious disease. The probable occurrence of cancerous tumors in laboratory rats injected with MTBE alerted federal agencies as to its possible health hazards. In 1999, the EPA reversed itself, recommending the phasing out of MTBE as an additive to gasoline.

During the first half of 2000, MBTE production in the Unites States averaged 215,000 barrels per day. In the same six-month period, the average production offuel ethanol was 106,000 barrels per day. In light of the EPA's 1999 recommendation, ethanol will most likely replace MTBE as an effective oxygenate additive. In addition to its use as an oxygenate, ethanol enhances octane ratings and dilutes contaminants found in regular gasoline.

New and Emerging Gasoline Additives

The development and blending of additives is undertaken for the most part by the petroleum refining industry. Additives are essential to the economic well-being of the industry because they tend to boost sales for gasoline and diesel fuel. In most cases, additives do not differ in price by more than three to four cents a gallon. The recently developed additives do not necessarily sacrifice fuel efficiency for higher octane numbers. They are multifunctional. In addition to boosting octane ratings they may also clean the engine, which, in turn, leads to greater fuel efficiency.

Beyond their role in enhancing octane numbers and reducing emissions, the group of more recent fuel additives performs a growing range of functions: antioxidants extend the storage life of gasoline by increasing its chemical stability; corrosion inhibitors prevent damage to tanks, pipes, and vessels by hindering the growth of deposits in the engine and dissolving existing deposits; demulsifiers or surface active compounds prevent the formation of emulsions and the dirt and rust entrained in them that can foul the engine and its components.

Beginning in the 1970s, gasoline additives increasingly took on the role of antipollutant agent in the face of government attempts to reduce automotive emissions into the atmosphere. Despite the advances made in cracking and reforming technologies and in the development and blending of additives (not to mention enhancements in the engine itself), the use of automotive gasoline has increased the level of air pollution. This is so because modern distillates, blends of straight run and cracked or chemically transformed product, tend to have a higher aromatic content. The result is longer ignition delays and an incomplete combustion process that fouls the engine and its components and increases particulate and oxide emissions.

Continued implementation of clean air legislation, especially within the United States, is expected to accelerate the consumption of fuel additives. In 1999, the EPA proposed wide-ranging standards that would effectively reformulate all gasoline sold in the United States and significantly reduce tailpipe emissions from trucks and sports utility vehicles. These regulations require potentially expensive sulfur-reducing initiatives from both the oil industry and the automakers. For refiners, it will require significant redesign and retooling of plant equipment and processes will be required in order to achieve suitable changes in the fuel mix because the U.S. oil industry is committed to continue development of its sour petroleum reserves. The DOE expects that the more complex processing methods will add six cents to the cost of a gallon of gasoline between 1999 and 2020.

In the United States alone, the demand for fuel additives is expected to reach over 51 billion pounds by 2002. Oxygenates are anticipated to dominate the market, both within the United States and internationally. Nonpremium gasoline and diesel fuel represent the fastest growing markets for fuel additives.

A recently marketed fuel additive is MMT (methylcyclopentadienylmanganese tricarbonyl). MMT was first developed by the Ethyl Corporation in 1957 as an octane enhancing agent and has experienced a growth in demand in the 1990s. MMT was Ethyl Corporation's first major new antiknock compound since TEL.

However, in 1997, the EPA blocked the manufacture of MMT. The Agency took this action for two reasons. It determined that MMT had the potential for being hazardous to humans, and in particular to children. The EPA is especially concerned about the toxic effects of the manganese contained in MMT. Also, the EPA discovered that MMT was likely interfering with the performance of the catalytic converters in automobiles and in turn causing an increase in exhaust emissions in the air. In 1998, the EPA decision was overturned by a federal appeals court in Washington. The court's decision allows the Ethyl Corp. to test MMT while it is selling the additive. The decision set no deadline for the completion of tests. In addition to its use in the United States, MMT is consumed as an additive in unleaded gasoline in Canada.

In addition to MTBE and MMT, other kinds of additives are being developed. Some of these are derivatives of alcohol. Variations of MTBE are also being used, especially the ether-derived ETBE (ethyl-t-butyl ether).

A new generation of additives specifically designed for aircraft gasoline are also being developed. These additives address such problems as carbon buildup, burned and warped valves, excessive cylinder head temperatures, stuck valves and piston rings, clogged injectors, rough idle, and detonation. Aviation fuel additives often act as detergents (to remove deposits), octane enhancers, and moisture eliminators.

Competition from Alternative Fuels

Most alternative fuel vehicles on the road today were originally designed for gasoline, but converted for use with an alternative fuel. Because the petroleum industry has successfully responded to the competitive threats of alternative fuels by developing reformulated gasolines that burn much cleaner, the conversions are typically performed more for economic reasons (when the alternative fuel is less expensive, which has occurred with propane) rather than environmental reasons. It is likely that technical advances will continue to permit petroleum refiners to meet the increasingly more stringent environmental regulations imposed on gasoline with only minor increases in the retail price. And since petroleum reserves will be abundant at least through 2020, gasoline promises to dominate automotive transportation for the foreseeable future.

However, fuel cell vehicles, which are designed to generate their power from hydrogen, pose a major long-term threat to the preeminence of gasoline. Automakers believe the best solution is to extract hydrogen from a liquid source because hydrogen has a low energy density and is expensive to transport and store. All the major automakers are developing fuel cell vehicles powered by hydrogen extracted from methanol because reforming gasoline into hydrogen requires additional reaction steps, and a higher operating temperature for the reformer. Both requirements are likely to make the gasoline reformer larger and more expensive than the methanol reformer. Moreover, the sulfur content of gasoline is another major reason that automakers are leery of developing gasoline reformers for fuel cell vehicles. Quantities as low as a few parts per million can be a poison to the fuel cell stack. There are no gasoline reformer fuel cell vehicles in operation, so an acceptable level of sulfur has not been determined. If it is determined that an ultralow-sulfur gasoline blend can be developed specifically for fuel cell vehicles, it would be a far less expensive solution than developing the fuel production, delivery and storage infrastructure that would be needed for methanol-powered fuel cell vehicles.

GASOLINE ENGINES

The gasoline engine is a device to convert the chemical energy stored in gasoline into mechanical energy to do work—to mow a lawn; chainsaw a tree; propel a car, boat, or airplane; or to perform myriad other tasks. The energy in the gasoline is transformed into heat within the engine through combustion, so the gasoline engine is an internal combustion engine. Because combustion is normally initiated by an electric spark, the gasoline engine is also frequently known as a spark-ignition engine.

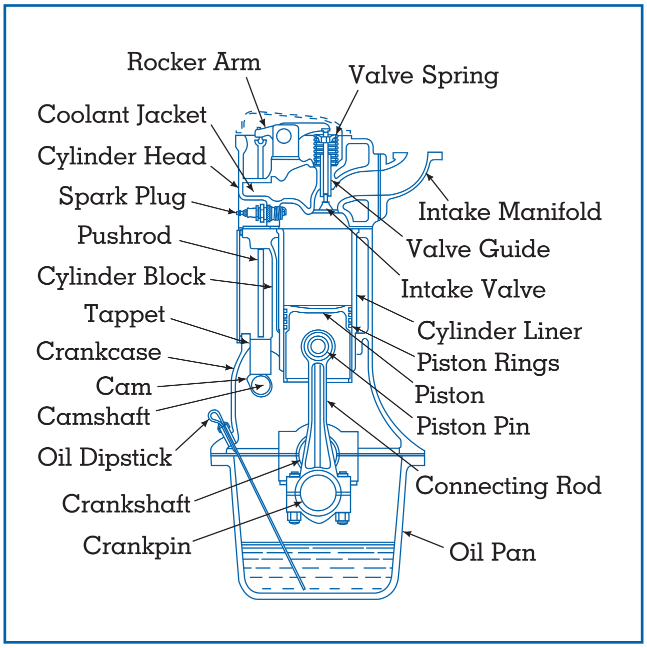

Figure 1.
Cross section through gasoline engine using push-rod valve actuation.

A number of different kinematic mechanisms have been used to extract mechanical work from the heated products of combustion. The preferred option is the slider-crank mechanism, which is incorporated into the gasoline-engine cross section of figure 1. In the slider-crank mechanism, the piston reciprocates up and down within a cylinder, alternately doing work on and extracting work from the gas enclosed by the piston, cylinder walls, and cylinder head. A poppet-type intake valve in the cylinder head opens during part of the engine cycle to admit a fresh charge of air and fuel. A spark plug ignites the mixture at the appropriate time in the cycle. A poppet-type exhaust valve (hidden behind the intake valve in Figure 1) opens later in the cycle to allow the burned products of combustion to escape the cylinder.

The reciprocating motion of the piston is transformed into rotary motion on the crankshaft by two of the links in the slider-crank mechanism—the connecting rod and the crank (hidden from view in this cross section). The connecting rod joins the piston pin to the crank pin. The crank connects the crank

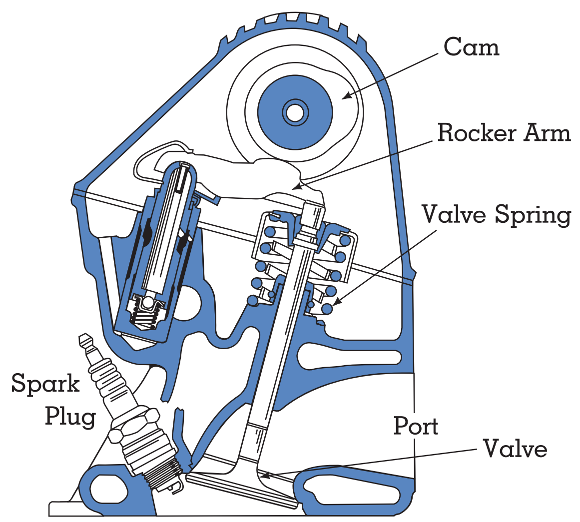

Figure 2.
Overhead-cam valve actuation.

pin to the crankshaft. The crank and the crank pin are usually integral parts of the crankshaft.

In Figure 1, the intake and exhaust valves are actuated by a camshaft chain, or a gear-driven from the crankshaft at half engine speed. The camshaft, operating through a tappet and push rod, tilts one end of a pivoted rocker arm at the appropriate time during the cycle. The opposite end of the rocker arm, working against the force of a valve spring, opens and closes a poppet valve. Each intake and exhaust valve has its own such mechanism.

This arrangement of valves defines a push-rod engine. In the alternative approach of Figure 2, the camshaft is moved to a position above the cylinder head, eliminating the push rod. This configuration defines an overhead-cam engine. The overhead camshaft is driven from the crankshaft by either a belt or a chain.

Other essential elements of a gasoline engine are also evident in Figure 1. The oil pan, fastened to the bottom of the crankcase, contains a reservoir of oil that splashes up during engine operation to lubricate the interface between the cylinder wall and the piston and piston rings. These rings seal the gas within the space above the piston. The dipstick used to verify an adequate oil supply is evident. Liquid in the coolant jacket seen in the cylinder head and surrounding the cylinder wall maintains the engine parts exposed to combustion gases at an acceptable temperature.

HISTORICAL BACKGROUND

The first practical internal-combustion engine is attributed to the Frenchman Jean Lenoir in 1860. His single-cylinder engine completed its cycle in but two strokes of the piston. On the first stroke, the piston drew a fresh charge of air and a gaseous fuel into the cylinder. Near midstroke, the intake valve closed, a spark ignited the trapped charge, the ensuing combustion quickly raised cylinder pressure, and the remainder of the piston stroke involved expansion of the combustion products against the piston to produce useful output work for transmission to the crankshaft. On the return stroke of the piston, the combustion products were expelled from the cylinder through an exhaust valve.

Four-Stroke Piston Engine

In France in 1862, Beau de Rochas outlined the principles of the four-stroke engine so common today. However, he never transformed those principles into hardware. Among the improvements proposed by de Rochas was compression of the charge prior to combustion. In contrast, the charge in the Lenoir engine was essentially at atmospheric pressure when combustion was initiated.

The operating principles of the four-stroke cycle are illustrated in Figure 3. In Figure 3a the descending piston draws a fresh charge into the cylinder through the open intake valve during the intake stroke. In Figure 3b, the intake valve has been closed, and the ascending piston compresses the trapped charge. As the piston approaches top dead center (TDC) on this compression stroke, the spark plug ignites the mixture. This initiates a flame front that sweeps across the chamber above the piston. Combustion is normally completed during the expansion stroke (see Figure 3c) well before the piston reaches bottom dead center (BDC). Before BDC is reached, the exhaust valve begins to open, releasing pressurized combustion products from the cylinder.

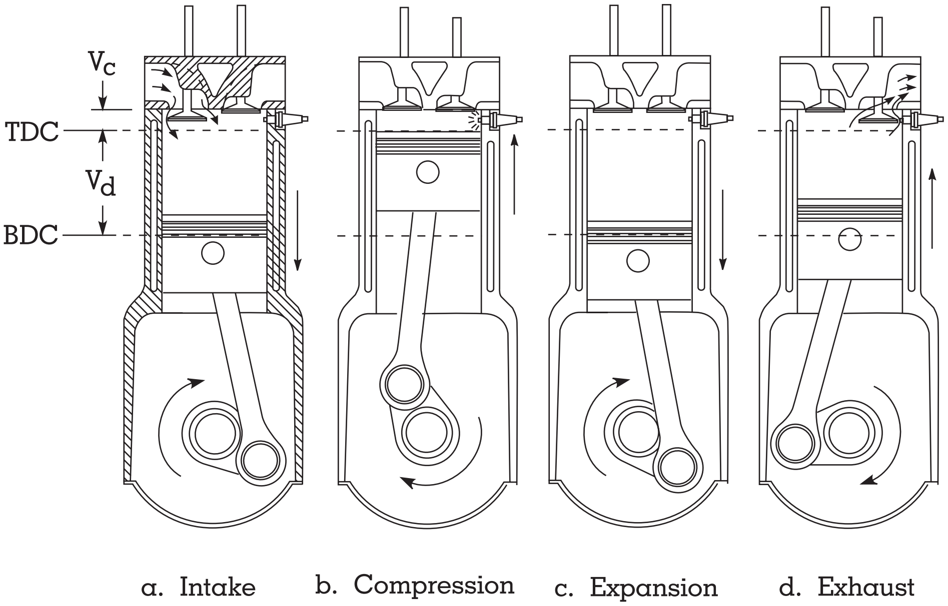

Figure 3.
Four-stroke cycle. TDC and BDC = top dead center and bottom dead center positions of the piston, respectively. V_d = displacement. V_c = clearance volume. Compression ratio = $(V_d + V_c)/V_c$.

During the exhaust stroke (see Figure 3d) the ascending piston expels most of the remaining products through the open exhaust valve, in preparation for a repetition of the cycle.

In 1876 in Germany, Nikolaus Otto built the first four-stroke engine, even though he was apparently unaware of the proposals of de Rochas. An idealized version of the cycle on which his 1876 engine operated is represented on coordinates of cylinder pressure versus volume in Figure 4. From 1 to 2, the piston expends work in compressing the fresh charge as it moves from BDC to TDC. At 2, combustion releases chemical energy stored in the fuel, raising cylinder pressure to 3. From 3 to 4, the products expand as the piston returns to BDC, producing useful work in the process. From 4 to 5, the burned gas is expelled from the cylinder as pressure drops to its initial value. These four events comprise what has come to be known in engineering thermodynamics as the Otto cycle.

The horizontal line at the bottom of the pressure-volume diagram of Figure 4 traces the other two strokes of the four-stroke cycle. On the exhaust stroke, from 5 to 6, the rising piston expels most of the remaining combustion products from the cylinder. On the intake stroke, from 6 to 7 (= 1), the descending piston inducts a fresh charge for repetition of the cycle. The net thermodynamic work developed in this cycle is proportional to the area enclosed by the pressure-volume diagram. In the ideal case, both the exhaust and intake strokes occur at atmospheric pressure, so they have no effect on the net output work. That justifies their exclusion from the thermodynamic representation of the ideal Otto

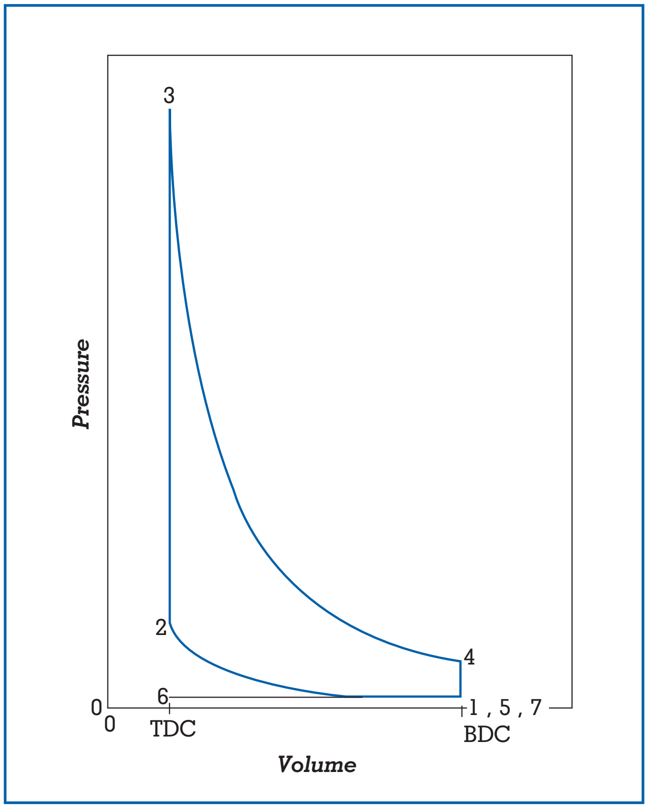

Figure 4.
Pressure-volume diagram for ideal Otto cycle (1-2-3-4-5), with exhaust and intake of four-stroke cycle (5-6-7) added .

cycle. The pressure-volume diagram for an actual operating engine deviates somewhat from this idealization because of such factors as noninstantaneous combustion, heat loss from the cylinder, and pressure loss across the valves during intake and exhaust.

Two-Stroke Piston Engine

Toward the end of the nineteenth century, successful two-stroke engines operating on the Otto cycle were developed by Dugald Clerk, James Robson, Karl Benz, and James Day. In this engine, the intake, combustion, expansion, and exhaust events all occur with but two piston strokes, or one crankshaft revolution. In principle this should double the output of a four-stroke engine of equal piston displacement. However, instead of the intake and exhaust events taking place during sequential strokes of the piston, they occur concurrently while the piston is near BDC. This impairs the ability of the engine to induct and retain as much of the fresh charge as in an equivalent four-stroke engine, with its separate intake and exhaust strokes. Thus the power delivered per unit of piston displacement is somewhat less than twice that of a comparable four-stroke engine, but still translates into a size and weight advantage for the two-stroke engine.

To deliver a fresh charge to the cylinder in the absence of an intake stroke, the two-stroke engine requires that the incoming charge be pressurized slightly. This is often accomplished by using the underside of the piston as a compressor, as illustrated in Figure 5. In Figure 5a, the piston is rising to compress the charge trapped in the cylinder. This creates a subatmospheric pressure in the crankcase, opening a spring-loaded inlet valve to admit a fresh charge. In Figure 5b, the mixture has been ignited and burned as the piston descends on the expansion stroke to extract work from the products. Later during the piston downstroke, Figure 5c, the top of the piston uncovers exhaust ports in the cylinder wall, allowing combustion products to escape. During descent of the piston, Figures 5b and c, the air inlet valve has been closed by its spring, and the underside of the piston is compressing the charge in the crankcase. In Figure 5d, the piston is just past BDC. Intake ports in the cylinder wall have been uncovered, and the piston, which has just completed its descent, has transferred the fresh charge from the crankcase into the cylinder through a transfer passage.

Note in Figure 5 that with the piston near BDC, both intake and exhaust ports are open concurrently. This provides a pathway whereby some of the incoming charge can “short-circuit” the cycle and exit with the exhaust gas. If the engine uses an upstream carburetor to mix fuel into the air before the charge enters the crankcase, then a fraction of the fuel leaves with the exhaust gas. That penalizes fuel economy and increases exhaust emissions. This escape path for unburned fuel can be eliminated by injecting fuel directly into the cylinder after both ports are closed, but at the cost of increased complexity.

If the crankcase compression illustrated in Figure 5 is used, the reservoir of lubricating oil normally contained in the crankcase of a four-stroke engine (see Figure 1) must be eliminated. Cylinder lubrication is then usually accomplished by mixing a small quantity of oil into the fuel. This increases oil consumption. An alternative allowing use of the

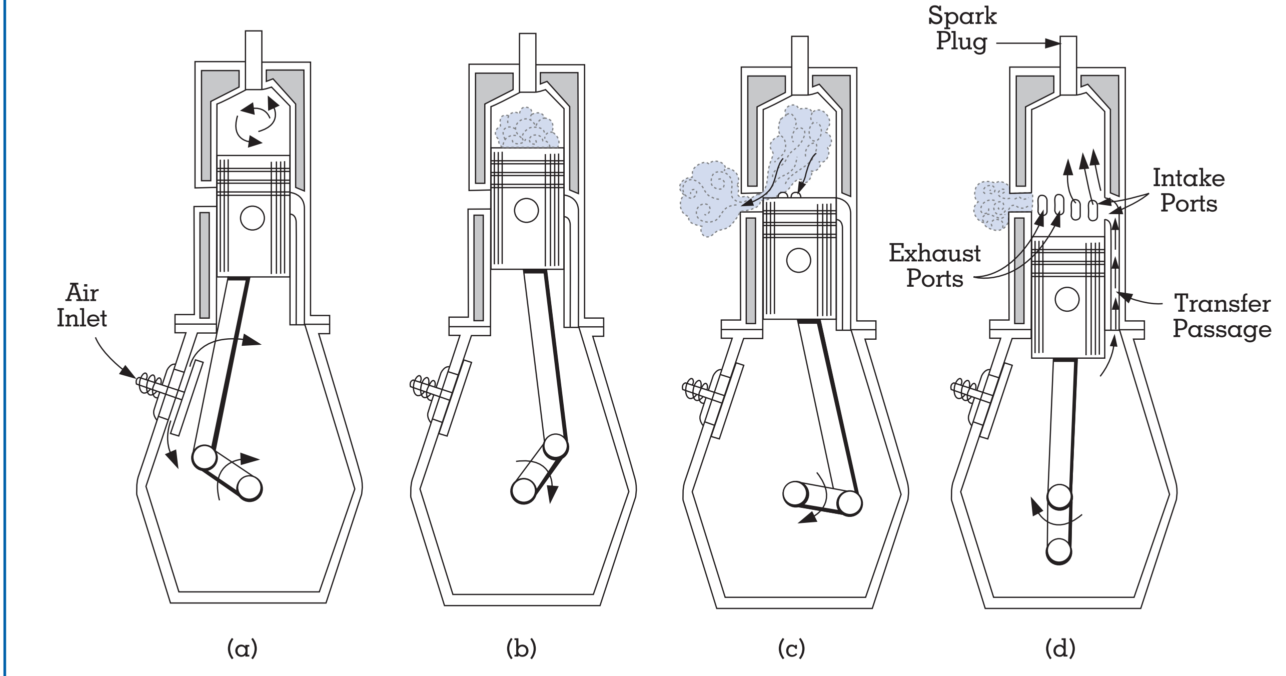

Figure 5.
Two-stroke cycle with crankcase compression.

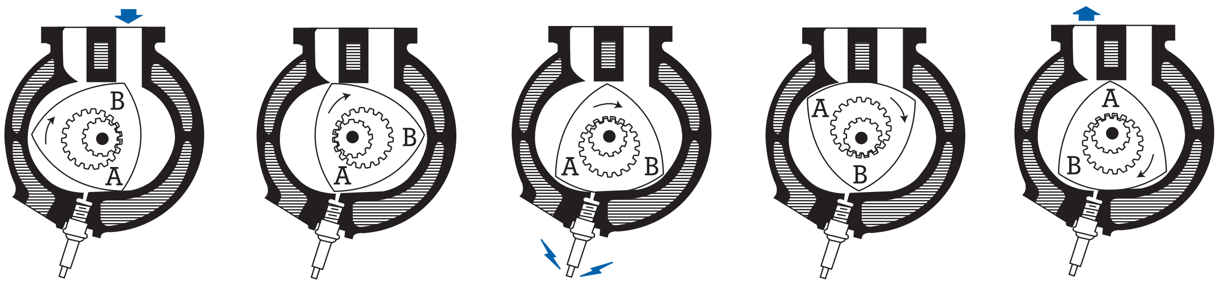
crankcase as an oil reservoir is to eliminate the transfer passage and add an engine-driven blower to provide the pressurized fresh charge directly through the intake ports. Again this increases engine complexity.

Rotary Engine

The four-stroke and two-stroke engines described above both use the slider-crank mechanism to transform piston work into crankshaft torque, but other intermittent-combustion engines have been conceived that use different kinematic arrangements to achieve this end. The only one that has realized significant commercial success is the rotary engine first demonstrated successfully in Germany by Felix Wankel in 1957.

Illustrated in Figure 6, this engine incorporates a flat three-sided rotor captured between parallel end walls. The rotor orbits and rotates around the central shaft axis, and within a stationary housing that is specially shaped so that the three apexes of the rotor always remain in close proximity to the inner wall of the housing. Linear apex seals separate three chambers, each enclosed by a rotor flank, the stationary housing, and the two end walls. The chambers are further sealed by rotor side seals that rub against the end walls. As the rotor orbits and rotates, the volume of each chamber periodically increases and decreases, just as the cylinder volume above a piston of the slider-crank mechanism changes throughout the engine cycle. A crankshaft-mounted eccentric transmits the output work from the rotor to the engine output shaft.

The engine cycle can be understood by following the flank AB in Figure 6. In Figure 6a, the fresh charge is entering the chamber through a peripheral inlet port. As the rotor rotates clockwise, in Figure 6b the volume of the chamber is decreasing to compress the charge. In Figure 6c, the chamber volume is near its minimum and the spark plug has ignited the mix-



a. Intake b. Compression c. Ignition d. Expansion e. Exhaust

Figure 6.
Wankel rotary combustion engine.

ture. In Figure 6d, the burned products are expanding. In Figure 6e, apex A has uncovered the peripheral exhaust port to release the expanded products. Thus each chamber mimics the four-stroke cycle of the slider-crank mechanism.

Given the three flanks of the rotor, there are three power pulses per rotor revolution. The output shaft rotates at three times rotor speed. Thus there is one power pulse for each revolution of the output shaft, just as in a two-stroke piston engine. This, combined with the absence of connecting rods and the ability of the engine to run smoothly at high speeds, contributes to the compactness of the Wankel rotary engine. However, the segments of the housing exposed to the heat of the combustion and exhaust processes are never cooled by the incoming charge, as in the reciprocating piston engine. The high surface-to-volume ratio of the long, thin combustion chamber promotes high heat loss. The chambers have proved difficult to seal. Such factors penalize the fuel economy of the Wankel engine relative to its slider-crank counterpart, which is one of the factors that has impaired its broader acceptance.

MULTICYLINDER ENGINES

Otto's single-cylinder engine of 1876 had a nominal cylinder bore of half a foot and a piston stroke of a foot. Operating at 180 rpm, it developed about 3 horsepower from its 6-liter displacement. Today a 6-liter automotive engine would likely have eight cylinders and deliver more than a hundred times as much power.

The most common arrangements for multicylinder engines are illustrated in Figure 7. Configurations employing four cylinders in line (I-4), and vee arrangements of either six (V-6) or eight (V-8) cylinders, currently dominate the automotive field. However, I-3, I-5, I-6, V-10, V-12, and six-cylinder horizontally opposed (H-6) arrangements are used as well.

Also represented in Figure 7 is the radial arrangement of cylinders common in large aircraft engines before the advent of jet propulsion. Five, seven, or nine cylinders were arranged in a bank around the crankshaft. Larger engines used two banks, one behind the other. One of the last, most powerful radial aircraft engines employed twenty-eight cylinders in four banks of seven cylinders each. These radial aircraft engines were air-cooled.

Individual-cylinder piston displacement in contemporary gasoline engines generally ranges from 0.15 to 0.85 liter, with the bore/stroke ratio varying between 0.8 and 1.3. Mean piston speed, which is twice the product of stroke and crankshaft rotational speed, generally falls between 8 and 15 meters/per second. Thus engines with larger cylinders are designed for slower rotational speeds. Choosing the number of cylinders

Radial

Figure 7.
Some multicylinder engine arrangements.

and their physical arrangement in engine design are often influenced significantly by such issues as the dimensions of the engine compartment or the bore-centerline spacing built into existing tooling.

ENGINE EFFICIENCY

It is common practice to measure the effectiveness of the engine as an energy conversion device in terms of the fraction of the fuel energy consumed that is actually delivered as useful output work. This fraction is customarily termed "thermal efficiency." In vehicular use, fuel economy (e.g., miles/per gallon) is directly proportional to thermal efficiency, although vehicle fuel economy also depends on such parameters as vehicle weight, aerodynamic drag, rolling resistance, and the energy content of a gallon of fuel.

The efficiency of the 1860 Lenoir engine was no more than 5 percent. An efficiency of 14 percent was claimed for Otto's original four-stroke engine of 1876. The best efficiency of modern automobile engines burning gasoline is in the 30 to 35 percent range. Small engines are generally somewhat less efficient than large ones. As discussed above, the simplicity of the crankcase-scavenged two-stroke engine, commonly employed in such low-power engines as those used in gardening equipment, carries an additional efficiency penalty. At the other extreme, large, slow-speed marine engines have demonstrated efficiencies in the 50 percent range, but these are compression-ignition engines operated on diesel fuel rather than gasoline.

The best efficiency attainable from a gasoline engine of specified power rating depends heavily on four parameters: compression ratio, air/fuel ratio, spark timing, and the fraction of the mechanical energy developed in the cylinder or cylinders devoted to overcoming parasitic losses. The compression ratio is the ratio of cylinder volume at BDC to volume at TDC. The air/fuel ratio is simply the mass of air inducted by the cylinders divided by the mass of fuel added to it. The spark timing is the number of degrees of crankshaft rotation before TDC at which the ignition spark is discharged. Parasitic losses include (1) engine friction, (2) the energy consumed by such essential components as the oil pump, fuel pump, coolant pump, generator used for charging the battery, and radiator cooling fan, and (3) the pumping loss associated with drawing the fresh charge into the cylinder during intake and expelling the combustion products from the cylinder during the exhaust.

Compression Ratio

Raising the compression ratio generally increases the thermal efficiency of the gasoline engine, as can be demonstrated by thermodynamic analysis of the engine cycle. The simplest such analysis is of the air-standard Otto cycle (see Figure 3, path 1-2-3-4-5). This technique assumes that the cylinder is filled with air behaving as a perfect gas (i.e., with constant specific heat), that from 2 to 3 heat is added to the air from an external source (no internal combustion), that from 4 to 5 heat is rejected from the air to the surroundings (no exhaust process), and that during compression (1 to 2) and expansion (3 to 4) the air exchanges no heat with its surroundings. This constitutes a thermodynamic cycle because the composition, pressure, and temperature of the cylinder contents are the same at the end of the cycle, point 5, as at the beginning, point 1. The thermodynamic efficiency (η) of this air-standard Otto cycle is given by $\eta=1\text{-}R^a$ where R = compression ratio and $\alpha = -0.4$.

A thermodynamically closer approximation to the actual engine is provided by fuel-air cycle analysis. In it the cylinder contents during compression are assumed to consist of air, fuel, and residual burned gas from the previous cycle. The specific heat of the cylinder gas is varied with temperature and composition. Constant-volume combustion is assumed, with the products in chemical equilibrium. At the end of the expansion stroke and during the exhaust stroke, the combustion products are allowed to escape from the cylinder, being replaced by a fresh charge during the intake stroke. No exchange of heat between the cylinder gas and its surroundings is considered.

In contrast to the air-standard cycle, the fuel-air cycle is a cycle in the mechanical sense only. It is not a true thermodynamic cycle because neither the composition nor the temperature of the cylinder contents returns to its initial state at point 1. This, of course, is also true of a real internal-combustion engine. With the more realistic assumptions of the fuel-air cycle, exponent $\alpha \equiv 0.28$ in $\eta=1\text{-}R^a$ for the normal range of air-fuel ratios used with a gasoline engine. This relationship defines an upper limit for efficiency of an otto-cycle engine burning premixed air and gasoline.

According to $\eta=1\text{-}R^a$, the efficiency of the ideal Otto cycle increases indefinitely with increasing compression ratio. Actual engine experiments, which inherently include the real effects of incomplete combustion, heat loss, and finite combustion time neglected in fuel-air cycle analysis, indicate an efficiency that is less than that given by $\eta=1\text{-}R^a$ when $\alpha = 0.28$. Furthermore, measured experimental efficiency reached a maximum at a compression ratio of about 17 in large-displacement automotive cylinders but at a somewhat lower compression ratio in smaller cylinders.

Otto's engine of 1876 had a compression ratio of 2.5. By the beginning of the twentieth century, the efficiency advantage of higher compression ratios was recognized, but liquid-fueled engines built with higher compression ratios often experienced an unexplained, intolerable, explosive combustion noise. Over a couple of decades, researchers came to realize that the noise was caused by autoignition in the unburned mixture ahead of the normal flame front as it advanced from the spark plug. This autoignition is caused by the increase in pressure and temperature within the cylinder once normal combustion has been initiated. The phenomenon can be likened to the compression ignition of fuel in the diesel engine. Experience taught that a fuel such as kerosene was more prone to this "combustion knock" than more volatile petroleum products, such as gasoline.

Thomas Midgley, working with a group of researchers under Charles F. Kettering, discovered a fuel-additive, tetraethyl lead that enhanced the knock resistance of existing fuels. By the time this additive entered commercial use in 1923, the average compression ratio of new U.S. cars had advanced to 4.3.

An octane rating scale was devised for fuels to quantify their knock resistance. Further research led to cataloguing the antiknock qualities of the myriad individual hydrocarbon species found in gasoline.

Fuel refiners learned how to rearrange the atoms in fuel molecules to enhance the octane number of the fuel available at gasoline stations. Studying the combustion process led to combustion-chamber designs with lower octane requirements. All of these activities fostered a nearly continuous increase in the average compression ratio of the new U.S. car, as follows: 4.3 in 1923; 5.1 in 1930; 6.3 in 1940; 7.0 in 1950; 9.0 in 1960; 9.8 in 1970; and 8.6 in 1980. The drop from 1970 to 1980 resulted from the imposition of increasingly severe exhaust emission standards in the United States, which included the need to design engines to run on unleaded gasoline. This was necessitated by the introduction of the catalytic converter to the exhaust system. The catalyst is poisoned by lead in the fuel.

Since 1980, further improvements in engine design have allowed the average compression ratio to creep back up to the range of 9 to 10, despite the absence of tetraethyl lead. Barring an unanticipated increase in the octane number of commercial gasoline, a further major increase in the average compression ratio of the contemporary gasoline engine is unlikely. A variable compression ratio engine that would retain the currently acceptable ratio at high engine loads but increase it at light load, where combustion knock is less likely, is a concept that has long existed but has yet to be implemented commercially on a significant scale.

Air-Fuel Ratio

The second important parameter affecting efficiency is air/fuel ratio. For every hydrocarbon fuel, there is an air/fuel ratio that, in principle, causes all the hydrogen in the fuel to burn to water vapor and all the carbon in the fuel to burn to carbon dioxide. This chemically correct proportion is called the stoichiometric ratio.

If the engine is fed a mixture containing more fuel than the stoichiometric amount, the mixture is said to be rich, and carbon monoxide (CO) and hydrogen are added to the combustion products. Because these two gases are fuels themselves, their presence in the exhaust signifies incomplete combustion and wasted energy.

If the engine is fed a mixture containing more air than the stoichiometric amount, the mixture is said to be lean, and unconsumed oxygen appears in the combustion products. This signifies that the full power-producing potential of the air inducted by the engine has not been utilized.

Among the lesser constituents of engine exhaust are unburned hydrocarbons (HC) and oxides of nitrogen (NOx). Exhaust HC concentration increases rapidly as the mixture is enriched from stoichiometric. Exhaust NOx concentration peaks at a mixture ratio slightly leaner than stoichiometric and falls off as the mixture is made either richer or leaner. These two exhaust-gas constituents react in the atmosphere in the presence of sunlight to form ozone, a major ingredient of photochemical smog. Consequently their mass emissions, along with that of CO, are regulated for environmental reasons.

For conventional gasoline, the stoichiometric ratio is approximately 14.7. Its precise value varies slightly with the composition of the gasoline. Maximum power is achieved with a slightly rich air/fuel ratio—say, 12.5. Maximum efficiency is achieved with a slightly lean mixture—say, 16—although this best-economy mixture ratio is somewhat dependent on combustion quality.

For most of the nineteenth century, the fuel and air were mixed upstream of the engine in a carburetor. In the automobile, the carburetor contains an inlet throttle valve linked to the accelerator pedal. The throttle valve is fully opened when the accelerator pedal is depressed to the floorboard, but barely open when the pedal is released so that the engine runs at its idle condition. The intent of the carburetor is to supply the engine with its highest air-fuel ratio during midspeed cruise conditions. As the throttle approaches its wide-open position, the mixture is enriched to maximize engine power. The mixture prepared by the carburetor is also temporarily enriched when the throttle is opened suddenly, as during a sharp vehicle acceleration, because the resultant fuel-flow increase lags behind the increase in airflow. As engine idle is approached, the mixture is enriched to compensate for poor combustion quality at the low-speed, low-pressure idle condition. For cold starting, the carburetor includes a choke valve that enriches the mixture so that enough of the fuel is vaporized near the spark plug to ensure ignition.

In early days, the mixture supplied to the engine was often quite rich in order to ensure smooth engine operation. This, of course, wasted fuel energy through incomplete combustion. Fleet surveys in early years showed marked improvement in the percentage of fuel that was wasted: 15.5% in 1927, 7.5%

in 1933, and only 1.5% by 1940. (The vehicles were operated at 40 miles per hour, with gasoline having a stoichiometric air-fuel ratio of 15).

Following World War II, engine improvements included further leaning of the mixture, especially toward the leaner-than-stoichiometric best-economy ratio during cruise. Then in the early 1980s, U.S. emission standards became so stringent that the catalytic converter, which had been added in about 1975 to oxidize HC and CO in the exhaust, also had to reduce NOx. This has led to the widely used three-way catalyst that controls all three emissions, but only if the air/fuel ratio is kept in a narrow range about the stoichiometric ratio.

Such tight mixture control is beyond the capability of the traditional carburetor. Consequently, after sorting through a number of alternatives, industry has settled on closed-loop-controlled port-fuel injection. Typically, an electronically controlled fuel injector is mounted in the intake port to each cylinder. A sensor in the air intake system tells an on-board computer what the airflow rate is, and the computer tells the fuel injectors how much fuel to inject for a stoichiometric ratio. An oxygen sensor checks the oxygen content in the exhaust stream and tells the computer to make a correction if the air/fuel ratio has drifted outside the desired range. This closed-loop control avoids unnecessary use of an inefficient rich mixture during vehicle cruise.

An old concept for increasing thermal efficiency at part load that is the subject of renewed interest is the use of a much leaner average mixture ratio at part load. To burn such an overall-lean mixture in the time made available by the contemporary gasoline engine, this concept calls for stratifying the fresh charge. Thus a combustible richer-than-average cloud of air and fuel is segregated near the spark plug and surrounded by fuel-free air. Although gains in part-load efficiency have been demonstrated with this concept, emissions control issues must be resolved before this concept is suitable for automotive use.

Ignition Timing

The third important parameter affecting engine efficiency is ignition timing. For each engine operating speed and throttle position, there is a spark timing giving best efficiency. In the early days of the automobile, timing was adjusted manually by the driver, so fuel economy was somewhat dependent on driver skill.

Eventually, automatic control of spark advance evolved. The conventional controller included two essential elements. Mechanically, spring-restrained rotating flyweights responding to centrifugal force advanced the spark as engine speed increased. Pneumatically, a diaphragm that sensed the increasing vacuum in the intake manifold as the intake throttle was closed added additional spark advance as the resulting reduction in cylinder pressure slowed flame speed.

With the advent of electronic engine controls, the on-board computer now manages ignition timing. It offers greater versatility in timing control, being able to integrate signals from sensors monitoring engine speed, airflow rate, throttle position, intake-manifold pressure, engine temperature, and ambient pressure.

Combustion knock can still be experienced in the engine near full throttle if the octane rating of the fuel is too low for the compression ratio, or vice versa. When ignition timing was controlled manually, the driver could retard the spark when knock was heard. In the era of mechanical/pneumatic control, the built-in timing schedule typically included slight retard from best-economy spark advance near full throttle to allow use of a slightly higher compression ratio for greater engine efficiency at part load. With the advent of electronic control, many engines are now equipped with knock sensors that detect incipient knock and maximize efficiency by retarding the spark just enough to avoid it. This technology has contributed to the modest increase in average compression ratio in automobiles since the 1980s.

Parasitic Losses

When parasitic losses are measured as a fraction of the power developed in the cylinder or cylinders, that fraction can be improved in two ways. Either the parasitic losses themselves can be reduced, or the power developed in the cylinder or cyinders can be increased. Over the years, both paths have been pursued.

Energy lost to mechanical friction has been decreased significantly through a large number of small, incremental improvements. In the typical modern engine, about half of the friction occurs between the cylinder wall and the piston/piston ring assembly. The sidewall contact surfaces of the piston have been specially shaped to minimize engine friction. Piston ring tension has been reduced, commensurate with adequate sealing of the combustion chamber. Oil viscosity has been chosen, and oil composition altered, to reduce friction. Analysis of the effects of operating pressure and temperature on engine dimensional changes has led to improved conformity between piston and cylinder during engine operation. Bearing dimensions and clearance have been selected to decrease friction. Reciprocating elements of the slider-crank mechanism have been lightened to decrease inertia loads on the bearings. In the valvetrain, sliding contact between adjacent members has often been replaced with rolling contact. Valves have been lightened, and valve-spring tension reduced.

Improved aerodynamic design of intake and exhaust ports has contributed to lower pumping losses. Paying greater attention to pressure drop in the catalytic converter also has helped. When recirculating exhaust gas into the intake system at part load to decrease NOx production, a common practice since 1973, the throttle has to be opened further to produce the same power at a given speed. This reduces intake pumping loss at a given part-load power.

Power requirements for oil, coolant, and fuel pumps are generally minor. Coolant-system power requirement increased when the thermo-siphon cooling system of early automobiles was superseded by an engine-driven coolant pump as engine power rating increased. Avoiding the use of unnecessarily high oil pressure has been beneficial. On the other hand, the higher pressure used in fuel injectors, compared to the fuel-pressure requirement of the carburetor, has not. In passenger cars, perhaps the largest reduction in auxiliary-power consumption has come by changing from an engine-driven cooling fan, running continuously, to an electrically driven fan that is inoperative as long as the radiator provides adequate cooling from ram air flowing through it as a result of vehicle forward motion.

The power that can be produced in each cylinder depends on the amount of air it can induct. Recent interest in replacing the traditional single-intake valve per cylinder with two smaller ones, and in a few cases even three, has increased total intake-valve area, and hence engine airflow at a given speed. At the same time, engine speed capability has been increased. These changes have raised the air capacity of the engine, resulting in increased power delivery for a given displacement. If the engine displacement is then decreased to hold maximum power constant, the parasitic losses are smaller for the same output power capability. This can be translated into improved vehicle fuel economy.

GEOGRAPHY AND ENERGY USE

Geography looks for patterns in the distribution of diverse phenomena, and it tries to explain their variation by examining a wide range of underlying environmental and socioeconomic factors. Many fundamental realities of modern civilization cannot be fully appreciated without the basic understanding of the geography of energy use. There is a very high degree of inequality in the use of energy resources throughout the word: this is true for aggregate use of energy, for every individual fuel or renewable energy flow, as well as for the consumption of electricity. These consumption disparities are inevitably accompanied by large differences in energy self-sufficiency and trade.

A country's dependence on energy imports, its size and climate, its stage of economic development, and the average quality of life of its inhabitants are the key variables determining the patterns of fuel and electricity consumption among the world's 180 countries. Large countries also have distinct regional patterns of energy consumption, but the progressing homogenization of energy use has been reducing some of these differences. For example, in the United States sports utility vehicles are now favored by both urban and rural drivers, and, unlike a few decades ago, utilities in both southern and northern states have summer peak loads due to air conditioning.

ENERGY SELF-SUFFICIENCY AND IMPORTS

Energy self-sufficiency is not just a matter of possessing substantial domestic resources; it is also determined by the overall rate of consumption. The United States, following the sharp decline of Russian's output, is now the world's second largest producer of crude oil (after Saudi Arabia); it is also the world's largest importer of crude oil, buying more than 50 percent of it in order to satisfy its high demand for transportation energy. The only affluent economies self-sufficient in fossil fuels are Canada (due to its relatively small population and vast mineral resources), and the United Kingdom and Norway (thanks to the North Sea oil and gas fields).

Russia is the most notable case of a middle-income country with large surpluses of energy. Its huge oil and gas exports are now surpassed only by Saudi Arabia, the largest OPEC oil producer. OPEC produces about 40 percent of the world's crude oil output and it supplies about 45 percent of all traded petroleum. In total, almost 60 percent of the world's crude oil extraction is exported from about forty-five hydrocarbon-producing countries—but the six largest exporters (Saudi Arabia, Iran, Russia, Norway, Kuwait, and the United Arab Emirates) sell just over 50 percent of the traded total. In contrast, more than 130 countries import crude oil and refined oil products; besides the United States, the largest buyers are Japan, Germany, France, and Italy.

About 20 percent of the world's natural gas production was exported during the late 1990s, three-quarters of it through pipelines, and the rest by LNG tankers. The former Soviet Union, Canada, the Netherlands, and Norway are the largest pipeline exporters, while Indonesia, Algeria, and Malaysia dominate the LNG trade. The largest importers of piped gas are the United States, Germany, Italy, and France; Japan and South Korea buy most of the LNG.

In comparison to hydrocarbons, coal trade is rather limited, with only about a tenth of annual extraction of hard coals and lignites exported, mainly from Australia, United States, South Africa, and Canada. Because of their lack of domestic resources and large iron and steel industries, Japan and South Korea are the two biggest buyers of steam and metallurgical coal. Although the development of high-voltage networks has led to rising exports of electricity, less than 4 percent of the global generation is traded internationally; France (mainly due to its large nuclear capacity), Canada, Russia, and Switzerland are the largest exporters. This trade will rise as the markets for electricity grow, and electricity transmission and distribution improves. Only 33 of the 180 countries are net energy exporters, and about 70 countries do not export any commercial energy. Self-sufficiency in energy supply was a major goal of many nations following the first "Energy Crisis" in 1973, but the collapse of OPEC's high crude oil prices in 1985 and the subsequent stabilization of the world's oil supply have greatly lessened these concerns during the 1990s.

AGGREGATE ENERGY USE AND ITS COMPOSITION

During the late 1990s annual consumption rates of commercial energy ranged from less than 25 kgoe (or

	Energy	*Consumption*			
Source	***1950***	***1973***	***1985***	***1990***	***1998***
Solid fuels	1040	1700	2170	2330	2220
Liquid fuels	460	2450	2520	2790	3010
Natural gas	170	1100	1460	1720	2020
Primary Electricity	30	130	300	360	440
Total	1700	5380	6450	7200	7650

Table 1.
Global Energy Consumption
Note: All fuel conversions according to the UN rates; all primary electricity expressed in terms of its thermal equivalent.

less than 1 GJ) per capita in the poorest countries of sub-Saharan Africa to nearly 8 toe (or more than 300 GJ) per capita in the United States and Canada. The global mean was close to 1.5 toe (or 60 GJ) per capita—but the sharply bimodal distribution of the world's energy use reflecting the rich-poor divide meant that only a few countries (including Argentina and Portugal) were close to this level. Affluent countries outside North America averaged close to 3.5 toe per capita, while the mean for low-income economies was just 0.6 toe, close to the Chinese average. This huge gap in aggregate energy consumption has been narrowing slowly. In 1950 industrialized countries consumed about 93 percent of the world's commercial primary energy. Subsequent economic development in Asia and Latin America reduced this share, but by 1998 industrialized countries containing just one fifth of global population still consumed about 70 percent of all primary energy.

The United States alone, with less than 5 percent of the world population, claims about 25 percent of the world in total commercial energy use. Among the world's affluent countries only Canada has a similarly high per capita use of fossil fuels and primary electricity (about 8 t of crude oil equivalent per year). In spite of its huge fuel and electricity production, the United States imports more than a fifth of its total energy use, including more than half of its crude oil consumption. Almost two fifths of all commercial energy is used by industry, a quarter in transportation, a fifth by households, and a bit over one sixth goes into the commercial sector.

In contrast, during the late 1990s the poorest quarter of humanity—made up of about fifteen sub-Saharan African countries, Nepal, Bangladesh, Indochina, and most of rural India—consumed a mere 2.5 percent of all commercial energy. The poorest people in the poorest countries, including mostly subsistence peasants but also millions of destitute people in large cities, do not directly consume any commercial fuels or electricity at all!

All of the world's major economies, as well as scores of smaller, low-income nations, rely mainly on hydrocarbons. Crude oil now supplies two-fifths of the world's primary energy (Table 1). There are distinct consumption patterns in the shares of light and heavy oil products: the United States burns more than 40 percent of all its liquid fuels as gasoline, Japan just a fifth; and the residual fuel oil accounts for nearly a third of Japanese use, but for less than 3 percent of the U.S. total. Small countries of the Persian Gulf have the highest per capita oil consumption (more than 5 t a year in the United Arab Emirates and in Qatar); the U.S. rate is more than 2.5 t a year; European means are around 1 t; China's mean is about 120 kg, and sub-Saharan Africa is well below 100 kg per capita.

Natural gas supplies nearly a quarter of the world's primary commercial energy, with regional shares ranging from one half in the former Soviet Union to less than 10 percent in the Asia Pacific. The United States and Russia are by far the largest consumers, followed by the United Kingdom, Germany, Canada, Ukraine, and Japan; leaving the small Persian Gulf emirates aside, Canada, the Netherlands, the United States, Russia, and Saudi Arabia have the highest per capita consumption. Coal still provides 30 percent of the world's primary commercial energy, but outside China and India—where it is still used widely for heating, cooking, and in transportation, and where it supplies, respectively, about three quarters and two

Table 2.
Global Electricity Production

thirds of commercial energy consumption—it has only two major markets: electricity generation and production of metallurgical coke.

When converted at its heat value (1 kWh = 3.6 MJ) primary electricity supplied about 6 percent of global commercial energy consumption during the late 1990s. Hydro and nuclear generation account for about 97 percent of all primary electricity, wind, geothermal, and solar—in that order—for the rest (Table 2). Canada, the United States, Russia, and China are the largest producers of hydroelectricity; the United States, Japan, and France lead in nuclear generation; and the United States, Mexico, and the Philippines are the world's largest producers of geothermal electricity.

ENERGY CONSUMPTION AND ECONOMIC DEVELOPMENT

On the global level the national per capita rates of energy consumption (Table 3) correlate highly ($r \geq 0.9$) with per capita gross domestic product (GDP): the line of the best fit runs diagonally from Nepal (in the lower left corner of a scattergram) to the United States (in the upper right corner). This commonly used presentation has two serious shortcomings: the exclusion of biomass fuels and the use of exchange rates in calculating national GDPs in dollars. Omission of biomass energies substantially underrates actual fuel use in low-income countries where wood and crop residues still supply large shares of total energy demand (more than 90% in the poorest regions of sub-Saharan Africa; about a fifth in China), and official exchange rates almost invariably undervalue the GDP of low-income countries.

Inclusion of biomass energies and comparison of GDPs in terms of purchasing power parities (PPP) weaken the overall energy-economy correlation, and disaggregated analyses for more homogeneous regions show that energy-GDP correlations are masking very large differences at all levels of the economic spectrum. Absence of any strong energy-GDP correlation is perhaps most obvious in Europe: while France and Germany have very similar PPP-adjusted GDPs, Germany's per capita energy use is much higher; similar, or even larger, differences can be seen when comparing Switzerland and Denmark or Austria and Finland.

Another revealing look at the energy-economy link is to compare national energy/GDP intensities (i.e., how many joules are used, on the average, to produce a unit of GDP) expressed in constant monies. These rates follow a nearly universal pattern of historical changes, rising during the early stages of economic development and eventually commencing gradual declines as economies mature and become more efficient in their use of energy. This shared trend still leaves the economies at very different energy-intensity levels. The U.S. energy intensity fell by more than a third since the mid-1970s—but this

Table 3.
Per Capita Consumption of Commercial Energy

impressive decline has still left the country far behind Japan and the most affluent European countries. China cut its energy intensity by half since the early 1980s—but it still lags behind Japan.

Weak energy-GDP correlations for comparatively homogeneous groups of countries and substantial differences in energy intensities of similarly affluent economies have a number of causes. A country's size plays an obvious role: there are higher energy burdens in integrating larger, and often sparsely inhabited, territories by road and rail, and in affluent countries the need to span long distances promotes air travel and freight, the most energy-intensive form of transportation. Not surprisingly, Canadians fly two to three times more frequently than most Europeans do. Even within countries, there are wide consumption disparities. In the United States, gasoline and diesel fuel consumption by private cars is highest in Wyoming where an average car travels nearly 60 percent more miles annually than the national mean; Montana and Idaho are the other two thinly populated states with considerably longer average car travel.

Climate is another obvious determinant of a country's energy use. For example, Canada averages annually about 4,600 heating degree days compared to Japan's 1,800, and this large difference is reflected in a much higher level of household and institutional fuel consumption. But climate's effects are either partially negated or highly potentiated by different lifestyles and by prevailing affluence. The Japanese and British not only tolerate much lower indoor temperatures (below 15°C) than Americans and Canadians (typically above 20°C), but they also commonly heat only some rooms in the house or, in the case of Japan, merely parts of some rooms (using *kotatsu* foot warmers).

Larger, overheated and often poorly insulated American houses mean that the U.S., with the national annual mean of 2,600 heating degree days, uses relatively more fuel and electricity for heating than does Germany with its mean of 3,200 heating degree days. Space heating takes half of U.S. residential consumption, water heating (with about 20%) comes second, ahead of air conditioning. Widespread adoption of air conditioning erased most of the previously large differences in residential energy consumption between the U.S. snowbelt and the sunbelt: now Minnesota and Texas, or Nevada and Montana have nearly identical per capita averages of household energy use. The most notable outliers are Hawaii (40% below the national mean: no heating, limited air conditioning) and Maine (almost 30% above the mean due to heating).

Composition of the primary energy consumption makes a great deal of difference. Because coal combustion is inherently less efficient due to the presence of combustible ash than the burning of hydrocarbons, the economies that are more dependent on coal (China, United States) are handicapped in comparison with nations relying much more on liquid fuels, natural gas, and primary electricity (Japan, France). So are the energy exporting countries: energy self-sufficiency (be it in Russia or Saudi Arabia) is not conducive to efficient conversions, but high dependence on highly taxed imports (as in Japan or Italy) promotes frugality.

Differences in industrial structure are also important: Canada is the world's leading producer of energy-intensive aluminum—but Japan does not smelt the metal at all. And as the only remaining superpower, the United States still invests heavily in energy-intensive production of weapons and in the maintenance of military capacity. Annual energy consumption of all branches of the U.S. military averaged about 25 million t of oil equivalent during the 1990s (more than half of it as jet fuel): that is more than the total primary commercial consumption of nearly two-thirds of the world's countries! In contrast, the size of Japan's military forces is restricted by the country's constitution.

But no single factor is more responsible for variations in energy intensity among high-income countries than the level of private, and increasingly discretionary (as opposed to essential), energy use. During the late 1990s, the Japanese used only about 0.4 toe in their generally cramped and poorly heated apartments and houses, but U.S. residential consumption was about 1 toe. Ubiquitous air-conditioning, overheating of oversized houses, and heating of large volumes of water explain the difference. Refrigerator and washing machine ownership is nearly universal throughout the rich world, but the appliances are smaller outside of North America where clothes dryers, dishwashers, and freezers are also much rarer.

There are even greater disparities in energy used for transportation: North American commuters commonly consume three times as much gasoline per year as do their European counterparts who rely much more on energy-efficient trains; and Americans and

Canadians also take many more short-haul flights, the most energy-intensive form of transportation, in order to visit families and friends or to go for vacation. They also consume much more fuel during frequent pastime driving and in a still growing range of energy-intensive recreation machines (SUVs, RVs, ATVs, boats, snowmobiles, seadoos).

In total, cars and light trucks consume nearly three-fifths of all fuel used by U.S. transportation. In spite of a more than 50 percent increase in average fuel efficiency since 1973, the U.S. cars still consume between 25 to 55 percent more fuel per unit distance than the average in European countries (11.6 l per 100 kilometers compared to 9.1 l in Germany, and 7.4 l in Denmark in 1995). All forms of residential consumption and private transportation thus claim more than 2 toe per capita in the United States, compared to less than 1 toe in Europe and about 0.75 toe in Japan.

ENERGY USE AND THE QUALITY OF LIFE

But does the higher use of energy correlate closely with the higher quality of life? The answer is both yes and no. There are obvious links between per capita energy use and the physical quality of life characterized above all by adequate health care, nutrition, and housing. Life expectancy at birth and infant mortality are perhaps the two most revealing indicators of the physical quality of life. The first variable subsumes decades of nutritional, health-care and environmental effects and the second one finesses these factors for the most vulnerable age group. During the 1990s average national life expectancies above 70 years required generally annual per capita use of 40 to 50 GJ of primary energy—as did the infant mortality rate below 40 (per thousand newborn).

Increased commercial energy use beyond this range brought first rapidly diminishing improvements of the two variables and soon a levelling-off with hardly any additional gains. Best national achievements—combined male and female life expectancies of 75 years and infant mortalities below ten—can be sustained with energy use of 70 GJ per year, or roughly half of the current European mean, and less than a quarter of the North American average. Annual commercial energy consumption around 70 GJ per capita is also needed in order to provide ample opportunities for postsecondary schooling—and it appears to be the desirable minimum for any society striving to combine a decent physical quality of life with adequate opportunities for intellectual advancement.

On the other hand, many social and mental components of the quality of life—including such critical but intangible matters as political and religious freedoms, or satisfying pastimes—do not depend on high energy use. Reading, listening to music, hiking, sports, gardening and craft hobbies require only modest amounts of energy embodied in books, recordings, and appropriate equipment or tools—and they are surely no less rewarding than high-energy pastimes requiring combustion of liquid fuels.

It is salutary to recall that the free press and the ideas of fundamental personal freedoms and democratic institutions were introduced and codified by our ancestors at times when their energy use was a mere fraction of ours. As a result, contemporary suppression or cultivation of these freedoms has little to do with overall energy consumption: they thrive in energy-rich United States as they do in energy-poor India, and they are repressed in energy-rich Saudi Arabia as they are in energy-scarce North Korea. Public opinion polls also make it clear that higher energy use does not necessarily enhance feelings of personal and economic security, optimism about the future, and general satisfaction with national or family affairs.

The combination of abundant food energy supplies and of the widespread ownership of exertion-saving appliances has been a major contributor to an epidemic of obesity (being at least a 35% over ideal body weight) in North America. National health and nutrition surveys in the United States how that during the 1990s every third adult was obese, and an astonishing three-quarters of all adults had body weights higher than the values associated with the lowest mortality for their height.

GEOTHERMAL ENERGY

Geothermal energy is heat energy that originates within Earth itself. The temperature at the core of our planet is 4,200°C (7,592°F), and heat flows outward to the cooler surface, where it can produce dramatic displays such as volcanoes, geysers, and hot springs, or be used to heat buildings, generate electricity, or perform other useful functions. This outward flow of heat is continually being maintained from within by the decay of radioactive elements such as uranium, thorium, and radium, which occur naturally in Earth. Because of its origin in radioactivity, geothermal energy can actually be thought of as being a form of natural nuclear energy.

The U.S. Department of Energy has estimated that the total usable geothermal energy resource in Earth's crust to a depth of 10 kilometers is about 100 million exajoules, which is 300,000 times the world's annual energy consumption. Unfortunately, only a tiny fraction of this energy is extractable at a price that is competitive in today's energy market.

In most areas of the world, geothermal energy is very diffuse—the average rate of geothermal heat transfer to Earth's surface is only about 0.06 watt per square meter. This is very small compared to, say, the solar radiation absorbed at the surface, which provides a global average of 110 watts per square meter. Geothermal energy can be readily exploited in regions where the rate of heat transfer to the surface is much higher than average, usually in seismic zones at continental-plate boundaries where plates are colliding or drifting apart. For example, the heat flux at the Wairakei thermal field in New Zealand is approximately 30 watts per square meter.

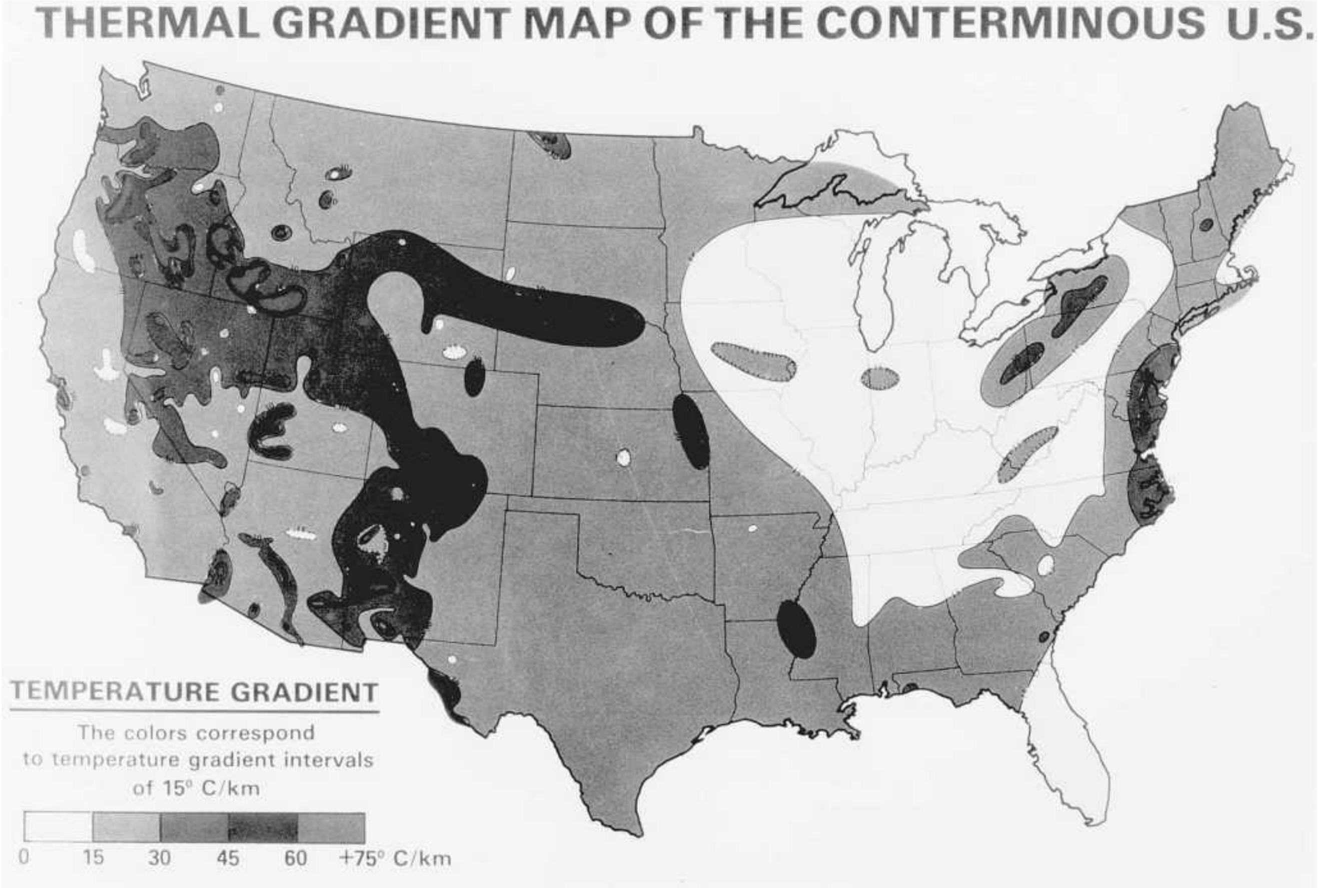
A related aspect of geothermal energy is the thermal gradient, which is the increase of temperature with depth below Earth's surface. The average thermal gradient is about 30°C (54°F) per kilometer, but it can be much higher at specific locations—for instance, in Iceland, where the increase is greater than 100°C (180°F) per kilometer in places.

TYPES OF GEOTHERMAL SOURCES

Geothermal sources are categorized into various types: hydrothermal reservoirs, geopressurized zones, hot dry rock, normal geothermal gradient, and magma.

Hydrothermal Reservoirs

Groundwater can seep down along faults in Earth's crust and become heated through contact with hot rocks below. Sometimes this hot water accumulates in an interconnected system of fractures and becomes a hydrothermal reservoir. The water might remain underground or might rise by convection through fractures to the surface, producing geysers and hot springs.



Map indicating regions of high thermal gradient where HDR geothermal techniques may be applied. (U.S. Department of Energy)

Geothermal power plant located in a lava field in Blue Lagoon, Iceland. (Corbis-Bettmann)

Hydrothermal reservoirs are the only geothermal sources that have been used for commercial energy production. Because of the high pressure deep below Earth's surface, the water in these sources can become heated well above the usual boiling temperature of 100°C (212°F). As the superheated water makes its way to the surface, either by convection or because a geothermal well has been drilled, some or all of the water will vaporize to become steam because of the lower pressures encountered. The most desirable geothermal sources have very high temperatures—above 300°C (572°F)—and all of the water vaporizes to produce dry steam (containing no liquid water), which can be used directly in steam-electric turbines.

Wet steam reservoirs are much more common than the simple dry type. Again, the field is full of very hot water, under such high pressure that it cannot boil. When a lower-pressure escape route is provided by drilling, some of the water suddenly evaporates (flashes) to steam, and it is a steam-water mixture that reaches the surface. The steam can be used to drive a turbine. The hot water also can be used to drive a second turbine in a binary cycle, described in the section "Electricity Generation" in this article.

Many geothermal reservoirs contain hot water at a temperature too low for electricity generation. However, the water can be used to heat buildings such as homes, greenhouses, and fish hatcheries. This heating can be either direct or through the use of heat pumps.

Geopressurized Zones

Geopressurized zones are regions where water from an ancient ocean or lake is trapped in place by impermeable layers of rock. The water is heated to temperatures between 100°C (212°F) and 200°C (392°C) by the normal flow of heat from Earth's core, and because of the overlying rock, the water is held under very high pressure as well. Thus energy is contained in the water because of both the temperature and the pressure, and can be used to generate electricity. Many geopressurized zones also contain additional energy in the form of methane from the decay of organic material that once lived in the water. The U.S. Geological Survey has estimated that about one third of the energy from geopressurized zones in the United States is available as methane.

Hot Dry Rock

In many regions of the world, hot rocks lie near Earth's surface, but there is little surrounding water. Attempts have been made to fracture such rocks and then pump water into them to extract the thermal energy, but the technical difficulties in fracturing the rocks have proven to be much more troublesome than anticipated, and there has been a problem with water losses. Consequently, progress in extracting energy from hot, dry rocks has been slow. However, experiments are ongoing in the United States, Japan, and Europe because the amount of energy available from hot, dry rocks is much greater than that from hydrothermal resources. The U.S. Department of Energy estimates that the total energy available from high-quality hot, dry rock areas is about 6,000 times the annual U.S. energy use.

Normal Geothermal Gradient

In principle the normal geothermal gradient produces a useful temperature difference anywhere on the globe. If a hole is drilled to a depth of 6 kilometers (which is feasible), a temperature difference of about 180°C (324°F) is available, but no technology has been developed to take advantage of this resource. At this depth, water is unlikely, and the problems of extracting the energy are similar to the difficulties encountered with hot, dry rocks near the surface.

Magma

Magma is subterranean molten rock, and although the potential thermal resource represented by magma pools and volcanoes is extremely large, it also presents an immense technological challenge. The high temperatures produce obvious problems with melting and deformation of equipment. The most promising candidates for heat extraction from magma are young volcanic calderas (less than a few million years old) that have magma relatively close to the surface. There have been some preliminary test wells drilled at the Long Valley caldera, located about 400 kilometers north of Los Angeles. The hope is that heat can be extracted in this area by drilling a well down to the magma level and pumping water into the well to solidify the magma at the bottom of the well. Then more water could be pumped into the well, become heated by contact with the solidified magma, and then returned to the surface to generate steam for electricity production.

ELECTRICITY GENERATION

There are two general ways by which geothermal energy can be utilized: generation of electricity, and space heating. Production of electricity from a geothermal source was pioneered in an experimental program at the Larderello thermal field in Italy in 1904, and a 205-kilowatt generator began operation at this site in 1913. By 1998 the world's geothermal electrical generating capacity was about 8,240 megawatts, which represents only a small portion of the total electricity capacity of 2 million megawatts from all sources. However, the geothermal capacity has been growing steadily, and the 1998 amount represents a 40 percent increase above the 1990 value of 5,870 megawatts. The amount of electrical energy generated geothermally worldwide in 1998 was about 44 terawatt-hours, or 0.16 exajoule, representing approximately 0.4 percent of global electricity generation.

The United States is the world leader in geothermal electricity production, with about 2850 megawatts of capacity. As shown in Table 1, nine other countries each had more than 100 megawatts of electrical capacity in 1998, with this group being led by the Philippines, producing 1,850 megawatts of geothermal electrical power.

The world's most developed geothermal source is at the Geysers plant in California's Mayacamas Mountains, about ninety miles north of San Francisco. Electricity has been generated at this site since 1960, and as of 1999 the total installed generating capacity there was 1,224 megawatts. It has been demonstrated at the Geysers and at other geothermal electric plants that electricity from geothermal resources can be cost-competitive with other sources.

To produce electricity from a geothermal resource, wells are drilled into the reservoir, and as the hot, high-pressure water travels to Earth's surface, some of it vaporizes into steam as the pressure decreases. The hotter the original source, the greater the amount of dry steam produced. For dry-steam sources, the technology is basically the same as for electric plants that use the burning of fossil fuels to produce steam, except that the temperature and pressure of the geothermal steam are much lower. Dry-steam fields are being used in the United States, Italy, and Japan. In the Geysers geothermal area in California, the steam temperature is about 200°C (392°F) and the pressure about 700 kilopascals (7 atmospheres). Because geothermal steam is cooler than fossil-fuel steam, the efficiency of conversion of thermal energy to electricity is less than at a fossil-fuel plant; at the Geysers it is only 15 to 20 percent, compared to 40 percent for fossil fuels. The generating units are also smaller, ranging in size from 55 to 110 megawatts at the Geysers.

For geothermal reservoirs that are at lower temperatures, and hence produce less dry steam, working plants usually employ multiple-vaporization systems. The first vaporization (“flash”) is conducted under some pressure, and the remaining pressurized hot water from the ground, along with the hot residual water from the turbine, can be flashed again to lower pressure, providing steam for a second turbine. Flashed power production is used in many countries, including the United States, the Philippines, Mexico, Italy, Japan, and New Zealand.

If the temperature of the original hot water is too low for effective flashing, the water can still be used to generate electricity in what is referred to as binary cycle (or organic cycle) electricity generation. The hot water is pumped to the surface under pressure to prevent evaporation, which would decrease the temperature, and its heat is transferred to an organic fluid such as isobutane, isopentane, Freon, or hexane, all of which have a boiling temperature lower than that of water. The fluid is vaporized by the heat from the water and acts as the working fluid in a turbine. It has been estimated that geothermal reservoirs with temperatures suitable for binary cycle generation are about fifty times as abundant as sources that provide pure dry steam.

Some geothermal power plants use a combination of flash and binary cycles to increase the efficiency of electricity production. An initial flash creates steam that drives a turbine; then the binary cycle is run, using either the hot water remaining after the initial flash or the hot exhaust from the turbine.

Geopressurized zones, discussed earlier, also are areas where electricity could be generated geothermally, not only from the hot water but also from the associated methane. Three geopressurized well sites in the United States have been developed experimentally for electricity production, but the cost of the electricity generated is considerably higher than that from conventional energy sources.

Countries with fewer than 10 megawatts of capacity are not listed.

DIRECT GEOTHERMAL ENERGY USE

Geothermal sources at too low a temperature for electricity generation can be utilized for space heating, bathing, and other uses. Hot fluid from the reservoir is piped to the end-site location through insulated pipes to minimize loss of heat energy. Pumps are installed either in the geothermal well itself (if the temperature is low enough) or at the surface to drive the fluid through the piping system. To operate, these pumps require energy, usually supplied by electricity. The hot fluid can be used itself to provide the heating, or it can be pass through a heat exchanger where another working fluid is heated.

Direct geothermal energy is used for space heating of homes, greenhouses, livestock barns, and fish-farm ponds. As well, it is employed as a heat source in some industrial processes, such as paper production in New Zealand and drying diatomite in Iceland. Since the industrial applications usually require high-

Types of Geothermal Direct Use Worldwide and in the Top Four Countries, 1995 (in %)

er temperatures than, say, space heating, it is advantageous to cascade the geothermal fluid, using it first at high temperature in industry and then afterward at lower temperature for another use.

Another way by which heat from the ground can be utilized is through the use of heat pumps. Pipes containing a fluid are buried in the ground, and heat can be extracted from the ground in the winter to heat a building, and dissipated in the ground in the summer to provide air conditioning. Essentially a heat pump acts like a refrigerator, extracting thermal energy from one area and moving it to another area. In the winter, the ground is cooled and the building is heated, and in the summer the heat pump runs in reverse, to cool the building and heat the ground.

An extensive summary of the various direct uses of geothermal energy has been compiled. Worldwide the most common use is for space heating (33%), followed by bathing, swimming, and therapeutic use of baths (19%). Table 2 shows the worldwide percentages for other uses, as well as percentages for the top four direct-use countries. As seen in this table, the specific uses of geothermal energy vary greatly from country to country.

The geothermal direct-use power capacity worldwide in 1997 was close to 10,000 megawatts, with China and the United States leading the way with 1910 megawatts each. Iceland and Japan also had more than 1,000 megawatts each, as shown in Table 3, and more than thirty countries in total were using geothermal heat. Total geothermal direct-use energy in 1997 was about 37 terawatt-hours, or 0.13 exajoule.

One of the countries that makes extensive use of direct geothermal heat is Iceland. This might seem surprising for a country with “ice” as part of its name, but Iceland lies in a region of continental-plate activity. Virtually all the homes and other buildings in Iceland are heated geothermally, and there is also a small geothermal electric plant. In Iceland’s capital city, Reykjavik, geothermally heated water has been used for space heating since 1930, and the cost of this heating is less than half the cost if oil were used.

Other important examples of geothermal heating are in France, both near Paris and in the Southwest. During oil-exploration drilling in the 1950s, hot water was discovered in the Paris region, but exploitation did not begin until the 1970s as a result of rapidly increasing oil prices. In France, the equivalent of 200,000 homes are being provided with space heating and water heating from geothermal sources. One interesting feature of the French geothermal sources is that they do not occur in regions of elevated thermal gradient.

ENVIRONMENTAL EFFECTS OF GEOTHERMAL ENERGY

The most important potential environmental impacts of geothermal energy are water and air pollution. At the largest geothermal plants, thousands of tons of hot water and/or steam are extracted per hour, and these fluids contain a variety of dissolved pollutants. The hot geothermal water dissolves salts from surrounding rocks, and this salt produces severe corrosion and scale deposits in equipment. To prevent contamination of surface water, the geothermal brine must either be returned to its source or discarded carefully in another area. In addition to salts, the geothermal waters sometimes contain high concentrations of toxic elements such as arsenic, boron, lead,

Located in Sonoma and Lake Counties in Calif., the geysers complex produces over 900,000 kW of electricity using steam from geothermal wells 7,000 to 10,000 feet below the surface. (U.S. Department of Energy)

and mercury. The 180-megawatt Wairakei geothermal electrical plant in New Zealand dumps arsenic and mercury into a neighbouring river at a rate four times as high as the rate from natural sources nearby.

Geothermal water often contains dissolved gases as well as salts and toxic elements. One of the gases that is often found in association with geothermal water and steam is hydrogen sulfide, which has an unpleasant odor—like rotten eggs—and is toxic in high concentrations. At the Geysers plant in California, attempts have been made to capture the hydrogen sulfide chemically, but this job has proven to be surprisingly difficult; a working hydrogen sulfide extractor is now in place, but it was expensive to develop and install, and its useful life under demanding operating conditions is questionable. Geothermal brines also are a source of the greenhouse gas carbon dioxide, which contributes to global warming. However, a typical geothermal electrical plant produces only about 5 percent of the carbon dioxide emitted by a fossil-fuel-fired plant generating the same amount of electricity. Many modern geothermal plants can capture the carbon dioxide (as well as the hydrogen sulfide) and reinject it into the geothermal source along with the used geothermal fluids. At these facilities, the carbon dioxide that escapes into the atmosphere is less than 0.1 percent of the emissions from a coal- or oil-fired plant of the same capacity.

Another potential problem, particularly if geothermal water is not returned to its source, is land subsidence. For example, there has been significant subsidence at the Wanaker field in New Zealand. Finally, an annoying difficulty with geothermal heat has been the noise produced by escaping steam and water. The shriek of the high-pressure fluids is intolerable, and is usually dissipated in towers in which the fluids are forced to swirl around and lose their kinetic energy to friction. However, the towers provide only partial relief, and the plants are still noisy.

GEOTHERMAL ENERGY—RENEWABLE OR NOT?

Most people tend to think of geothermal energy as being renewable, but in fact one of the major problems in choosing a geothermal energy site lies in estimating how long the energy can usefully be extracted. If heat is withdrawn from a geothermal source too rapidly for natural replenishment, then the temperature and pressure can drop so low that the source becomes unproductive. The Geysers plants have not been working at full capacity because the useful steam would be depleted too quickly. Since it is expensive to drill geothermal wells and construct power plants, a source should produce energy for at least thirty years to be an economically sound venture, and it is not an easy task to estimate the working lifetime beforehand.

THE FUTURE OF GEOTHERMAL ENERGY

The main advantage of geothermal energy is that it can be exploited easily and inexpensively in regions where it is abundantly available in hydrothermal reservoirs, whether it is used for electricity production or for direct-use heat. Geothermally produced electricity from dry-steam sources is very cheap, second only to hydroelectric power in cost. Electricity from liquid-dominated hydrothermal sources is cost-competitive with other types of electrical generation at only a few sites. It is unlikely that other types of geothermal sources, such as hot, dry rock and the normal geothermal gradient, will soon become economical. Hence, geothermal energy will provide only a small fraction of the world's energy in the foreseeable future.

An important feature of geothermal energy is that it has to be used locally, because steam or hot water cannot be piped great distances without excessive energy loss. Even if electricity is generated, losses also are incurred in its transmission over long distances. As a result, geothermal energy use has geographical limitations.

The future development of geothermal energy resources will depend on a number of factors, such as cost relative to other energy sources, environmental concerns, and government funding for energy replacements for fossil fuels. An important concern that many members of the public have about future developments is centered around whether resources such as hot springs and geysers should be exploited at all. Many of these sources—such as those in Yellowstone National Park in Wyoming—are unique natural phenomena that many people feel are important to protect for future generations.

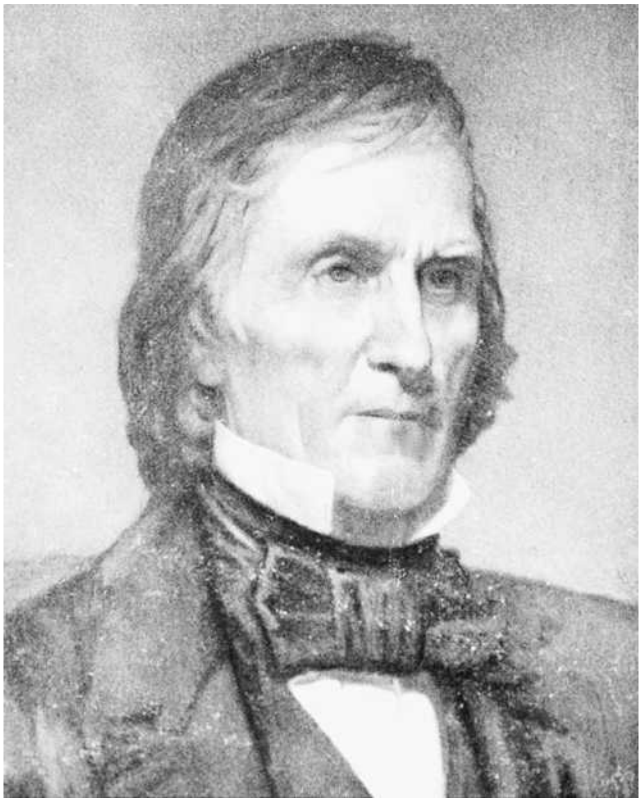
GIBBS, JOSIAH WILLARD (1839–1903)

Gibbs came from an academic family in New Haven, Connecticut. His father was a noted philologist, a graduate of Yale and professor of sacred literature there from 1826 until his death in 1861. The younger Gibbs grew up in New Haven and graduated from Yale College, having won a number of prizes in both Latin and mathematics. He continued at Yale as a student of engineering in the new graduate school and, in 1863, received one of the first Ph.D. degrees granted in the United States. After serving as a tutor in Yale College for three years, giving elementary instruction in Latin and physics, Gibbs left New Haven for further study in Europe. He spent a year each at the universities of Paris, Berlin, and Heidelberg, attending lectures in mathematics and physics and reading widely in both fields. He was never a student of any of the luminaries whose lectures he attended (the list includes Liouville and Kronecker in mathematics, and Kirchhoff and Helmholtz in physics) but these European studies, rather than his earlier engineering education, provided the foundation for his subsequent scientific work. A qualification was a life-long fondness for geometrical reasoning, evident in Gibbs's scientific writings, but first developed in his dissertation.

Gibbs returned to New Haven in 1869. He never again left America and seldom left New Haven except for annual summer holidays in northern New England and a very occasional journey to lecture or attend a meeting. Gibbs never married and lived all his life in the house in which he had grown up, less than a block from the college buildings. In 1871, two years before he published his first scientific paper, Gibbs was appointed professor of mathematical physics at Yale. He held that position without salary



Josiah Willard Gibbs. (Library of Congress)

for nine years, living on inherited income. It was during this time that he wrote the memoirs on thermodynamics that, in most estimates, constitute his greatest contribution to science. Gibbs declined the offer of a paid appointment at Bowdoin College in 1873, but he was tempted to leave Yale in 1880 when he was invited to join the faculty of the newly-founded Johns Hopkins University in Baltimore. Only then did Yale provide Gibbs a salary, as tangible evidence of the high regard his colleagues had for him and of his importance to the University. Gibbs remained at Yale and continued to teach there until his death, after a brief illness, in 1903.

Gibbs worked on electromagnetism during the 1880s, concentrating on optics and particularly on James Clerk Maxwell's electromagnetic theory of light, and on statistical mechanics from at least the mid-1880s until his death. The latter research resulted in his seminal *Elementary Principles in Statistical Mechanics*, published in 1902. However, it seems more appropriate in this place to briefly describe Gibbs's memoirs on thermodynamics.

In his first work on thermodynamics in 1873, Gibbs immediately combined the differential forms of the first and second laws of thermodynamics for the reversible processes of a system to obtain a single "fundamental equation":

$$\mathrm{d}U = T\mathrm{d}S - p\mathrm{d}V,$$

an expression containing only the state variables of the system in which U, T, S, p and V are the internal energy, temperature, entropy, pressure, and volume, respectively. Noteworthy here is the assumption, which Gibbs made at the outset but which was not common at the time, that entropy is an essential thermodynamic concept. At the same time, the importance of energy was also emphasized. As Gibbs wrote at the beginning of his great memoir, "On the Equilibrium of Heterogeneous Substances," whose first installment appeared in 1876: "The comprehension of the laws which govern any material system is greatly facilitated by considering the energy and entropy of the system in the various states of which it is capable." The reason, as he then went on to explain, is that these properties allow one to understand the interactions of a system with its surroundings and its conditions of equilibrium.

As was usual with him, Gibbs sought to resolve the problem in general terms before proceeding to applications. Again beginning with the differential forms of the first two laws (which, in effect, define the state functions U and S), but this time for any process, whether reversible or irreversible, he combined the two expressions to yield the general condition of equilibrium for any virtual change:

$$\delta U - T\delta S - \delta W > 0$$

where W is the external work. If a system is isolated, so that $\delta W = 0$, this condition becomes:

$$(\delta U)_S \geq 0 \text{ or } (\delta S)_U \leq 0$$

for constant S and U, respectively. The second inequality, which Gibbs showed to be equivalent to the first, immediately indicates that thermodynamic equilibrium is a natural generalization of mechanical equilibrium, both being characterized by minimum energy under appropriate conditions.

The first and probably most significant application of this approach was to the problem of chemical equilibrium. In a heterogeneous system composed of several homogeneous phases, the basic equilibrium condition leads to the requirement that temperature, pressure, and the chemical potential (a new concept introduced by Gibbs) of each independent chemical component have the same values throughout the system. From these general conditions, Gibbs derived the phase rule:

$$\delta = n+2-r,$$

that cornerstone of physical chemistry, which specifies the number of independent variations δ in a system of r different coexistent phases having n independent chemical components.

Among many other valuable results in his memoir on heterogeneous equilibrium is a formulation of the Gibbs free energy, also called the Gibbs function, which is defined by the equation

$$G = H-TS,$$

where H is the enthalpy, that is, the sum of the internal energy of a body orsystem and the product of itspressure and volume. It is useful for specifying the conditions of chemical equilibrium at constant temperature and pressure, when G is a minimum. More generally, Gibbs's memoir greatly extended the domain covered by thermodynamics, including chemical, electric, surface, electromagnetic, and electrochemical phenomena into one integrated system.

Gibbs's thermodynamic writings were not as widely read—much less appreciated—as they deserved to be in the decade following their appearance. One reason is that they were published in the obscure *Transactions of the Connecticut Academy of Sciences.* Gibbs sent offprints of his memoirs to many scientists, but only Maxwell seems to have recognized their importance. That changed after Wilhelm Ostwald published a German translation in 1892. In the meantime, continental scientists such as Helmholtz and Planck independently developed Gibbs's methods and results, unaware of his prior work.

Another reason for lack of interest is the severity of Gibbs's style. Austere and logically demanding, it was a challenge even for mathematicians as distinguished as Poincaré. The same severity extended to Gibbs's lectures, which his few students found clear and well-organized, but not easy to understand, owing to their great generality and meticulous precision.

A third reason is that Gibbs made no effort to promote or popularize his results. He seems to have been a solitary, self-contained, and self-sufficient thinker, confident in his ability, who worked at his own unhurried pace, neither needing nor wanting feedback from others. An attitude of detachment from the work of his students plus his own solitary habit of work is undoubtedly responsible for the fact that Gibbs founded no "school" or group of students to develop his ideas and exploit his discoveries.

GLOBAL WARMING

See: Climatic Effects

GOVERNMENT AGENCIES

Energy is the economic lifeblood of all economies. It is an essential gear for the economies of the developed world, and of ever growing importance to developing nations. It is of concern to the largest of nations as well as the smallest. And it is as great a concern of local governments as national ones.

Government action or inaction at all levels in energy policy has varied tremendously. Prior to 1930, involvement in energy issues at all levels of government was minimal in the United States because of relatively moderate demand for energy consuming technology, and an abundant and relatively cheap supply of fossil fuels. The government's approach to energy changed with the Depression and the New Deal. The United States began to subsidize energy by building hydroelectric stations (the Tennessee Valley Authority), supporting rural electrification, and subsidizing of nuclear research. Much of the developing world, as well as the Soviet Union, began subsidizing energy early in the twentieth century as a means to buy votes and strengthen political support. Because of World War II, the strategic role of energy to economic growth and national security became much more apparent. Almost all governments began to take a more active role in energy markets as world energy consumption accelerated, as spending was boosted on all aspects of the energy puzzle—exploration, production, distribution, consumption, and the energy statistics to track all of the above.

Traditionally, the developed world has paid the greatest attention to petroleum (reserves, resources, security, price), and devoted the most resources to nuclear energy research (both fission and fusion), a source that proponents in the 1950s believed would someday turn out to be "too cheap to meter." Planning, funding, and development of renewables and other energy resources has fluctuated much more wildly through the years, usually inversely to the real and perceived availability of oil. During and following an oil crisis, where there is great supply uncertainty and prices skyrocket, planning, funding and development grow, and correspondingly decrease when oil supplies are more secure and stable.

WORLD AGENCIES

The pooling of resources to meet shared objectives have been the factor most responsible for the establishment and growth of international agencies concerned with energy issues. The three most important issues bringing about cooperation have been the need to coordinate production, the pooling of resources for research and development of energy technology, and the coordinating of activities to secure supply.

Organization of Petroleum Exporting Countries (OPEC)

The OPEC cartel was founded by Iraq, Iran, Saudia Arabia, Kuwait, and Venezuela in September 1960 as a way to coordinate petroleum production and pricing among member countries. It was not until the 1970s that the cartel tried to become an effective monopoly.

As of 2000, membership has expanded to thirteen, accounting for over 60 percent of all production. The reserves controlled by Member Countries were much higher in the 1970s, and consequently so was the cartel's monopoly power in controlling prices. But because of exploration discoveries, advances in technology (enhanced recovery of existing wells, improved offshore equipment), and the lack of cooperation from non-OPEC producers, the power of the cartel to control oil production and prices has steadily diminished. During the 1970s, an announcement of an OPEC meeting would be the major news story of the day, but by the 1990s, low oil prices and a secure supply caused the media to only superficially cover OPEC meetings. As most economists predicted, the ability of the cartel to control the price of petroleum did not last long. There will always be an incentive for member states—especially the smaller producers—to "cheat" on their quotas, and the free market will always react swiftly to higher prices by pumping up other sources of oil production and securing other energy resources.

As OPEC's share of the world oil supply market continued to fall in the 1990s, they began taking steps to better coordinate production with non-OPEC producers such as Mexico and other members of the Independent Petroleum Exporting Countries (IPEC). By exchanging information, and undertaking joint studies of issues of common interest, the hope was to stabilize prices and improve the economic outlook for all oil producers. This collaboration between OPEC and major non-OPEC producers helped raise oil prices to over $27 a barrel in 1999 from a low of less than $13 in 1998.

International Energy Agency (IEA)

In response to the Arab embargo, and the attempt of OPEC to dictate the supply and price of petroleum, the Organization for Economic Cooperation and Development (OECD) established the International Energy Agency (IEA) in November 1974. IEA membership included all of Western Europe, Canada, the

United States, Australia, New Zealand, and Japan. Besides compiling useful consumption and production statistics, its mandate was for cooperation and coordination of activities to secure an oil supply in times of supply disruption. IEA's first action to insulate member countries from the effects of supply disruptions was the Emergency Sharing System (ESS). This system was to be put into effect only in cases of serious disruptions, an actual or anticipated loss of 7 percent of expected supply. The System consisted of three parts: a building up of supplies, a reduction of consumption during periods of short supply, and a complex sharing system that would attempt to distribute the loss equitably. During the 1979–1981 oil supply disruption, the system was never really tested because the loss of supplies never reached a level to trigger the ESS. Nevertheless, because of the economic hardship felt by many nations during the 1979–1981 disruption, in 1984 the Coordinated Emergency Response Measures (CERM) was adopted. The CERM were intended as a means to reach rapid agreement on oil stockpile drawdown and demand restraint during oil supply disruptions of less than 7 percent. Because of ESS and CERM, and the agreement of other OPEC Member States to boost production, the supply disruption caused by the Iraqi occupation of Kuwait, and the subsequent United Nations embargo of all oil exports from Iraq and Kuwait, did not have such a large effect.

Twenty-five years after its establishment, the focus of the IEA has changed and expanded significantly. Whereas in 1974, the IEA looked at coal and nuclear energy as the two most promising alternatives to oil, the call for more environmentally acceptable energy sources has pushed to the forefront the development of renewable energy, other nonfossil fuel resources, and the more clean and efficient use of fossil fuels. To avoid duplication of effort and better research and development results, the IEA coordinates cooperation among members to more efficiently use resources, equipment, and research personnel.

United Nations (UN)

The United Nations officially came into existence at the end of World War II on October 24, 1945 to help stabilize international relations and better secure peace. Through the years, the UN has greatly expanded its mission to include other issues such as development and protecting the environment. Because energy is such a key piece of the development puzzle, in 1947 the UN established a statistics division that began tracking energy consumption and production throughout the world in 1992.

The divisions established to take an active role in energy and development issues were the United Nations Development Program (UNDP) and the Commission on Sustainable Development in 1993. Funded by voluntary contributions from member states, with funding directed toward countries with annual per-capita GNP of $750 or less, UNDP focuses on preventing unsustainable production and consumption patterns, and ways of curbing pollution and slowing the rate of resource degradation—economic growth with environmental protection and conservation. The burden of environmental protection is far greater for poorer nations because it diverts resources away from more pressing problems such as poverty, low levels of social development, inadequate energy infrastructure, and a lack of capital for infrastructure. Despite emissions of industrial countries dropping from 1980 to 2000, many emissions, most notably toxic substances, greenhouse gases, and waste volumes are continuing to increase in the developing world.

Global warming is another energy-related problem that the UN has attempted to address through its Intergovernmental Panel of Climate Change (IPCC). The IPCC was very successful in negotiating an agreement to solve the problem of chlorofluorocarbons (January 1987 Montreal Protocol on Substances That Deplete the Ozone Layer), yet the task of getting member countries to agree on carbon emission reductions to combat the perceived threat of global warming has proven to be a much more daunting task. The science is more uncertain, there are no easy solutions (the combustion that provides the majority of the world's energy needs always entails carbon emissions), and to achieve the cuts that climate modelers feel would be necessary to fully address the problem will require a complete restructuring of current civilization. Nevertheless, based on the work of the IPCC, the United Nations Framework Convention on Climate Change adopted the Kyoto Protocol on December 11, 1997, as a first step in the process. The Kyoto Protocol calls for most of the developed nations to reduce carbon emissions by 10 percent of 1990 levels by the year 2010. Most nations ratified the treaty despite no reduction commitments from the developing nations. The poorer nations strongly objected to universal emission reductions. They countered that energy drives development, and the exploitation of cheap and abundant energy, often at the expense of the poorer nations, is how the richer nations achieved their higher standard of living. Burdensome environmental regulations of energy would severely retard development; thus, the poorer nations feel it is only equitable that the richer nations, who created the majority of carbon emissions in the last 150 years, first make the effort to curtail emissions.

The Kyoto negotiations show the tremendous friction energy issues can cause between the richest and poorest countries in the world. Addressing future energy-related conflicts—whether it be wars over oil fields or disputes over carbon emission quotas—will remain a major role of the UN.

The International Atomic Energy Agency (IAEA)

To address the technology, waste, safety and security issues concerning nuclear energy, the UN established the International Atomic Energy Agency (IAEA) in 1957, a few years after U.S. President Dwight D. Eisenhower's famous "Atoms for Peace" speech before the United Nations General Assembly.

As the political, economic, and technological realities of the world evolved, so did IAEA. The scope of products, services, and programs of the IAEA has expanded well beyond its original function as the world's central intergovernmental forum for scientific and technical nuclear cooperation, and the watchdog for civilian nuclear power programs. In the 1990s, the IAEA helped countries carry out comparative cost effective assessments of how to expand electric power generation capacity such as the potential roles of renewable energy, and the different options and costs for reducing atmospheric and greenhouse gas emissions. They also conduct research and provide outreach through the Agency's laboratories. The IAEA tries to go beyond technology transfer and energy capacity building to help provide solutions to problems of sustainable human development.

International Institute for Applied Systems Analysis

Founded in 1972 by the United States, the Soviet Union, and ten other countries, the International Institute for Applied Systems Analysis is a research organization located in Laxenburg, Austria that conducts scientific studies in many energy-related areas of global consequences such as transboundary air pollution, sustainable forest resources, climate change, and environmentally compatable energy strategies.

World Bank

Established in 1946, with a subscribed capital fund of $7.67 million, the primary mission of the World Bank is to combat poverty by securing low cost funding for sustainable development. The largest shareholder is the U.S., followed by the United Kingdom, Japan, Germany, and France.

Although the World Bank provides loans for a variety of purposes, energy-related infrastructure receives over 7 percent, which primarily goes toward electric power infrastructure (hydroelectric, fossil fuel, nuclear) but also oil and natural gas exploration, production and distribution. Other energy-related areas making up a considerable share of the World Bank's loan portfolio are the transportation and agricultural sector. Loans to improve the energy and logistic efficiency of the transportation sector account for 11 percent of funding, followed by 10 percent going toward agriculture to provide assistance in expanding the amount of food energy produced.

By 1999 the World Bank loan portfolio for the energy and mining sectors had grown to $4.1 billion. Its strategy for energy development is to reform and restructure markets to attract private investment to build energy infrastructure, and expand energy access to the rural and low-income populations, and promote an environmentally responsible energy supply and use. One priority is to get more of the 2 billion plus poor people access to modern energy for cooking and lighting. Without modern energy, the world's poor rely on wood, crop residues, and other biofuels that result in environmentally damaging deforestation. Deforestation is of interest to all nations because it is not only a habitat destroyer, but also contributes to the increasing concentrations of carbon dioxide, a gas long suspected of creating global warming.

The World Bank grants financing for fossil fuel electricity generation, yet finances only facilities that have advanced emission control equipment. And although the World Bank has never financed a nuclear power plant, a zero carbon emitter, it is very active in evaluating hydropower projects, helping to establish the World Commission on Large Dams.

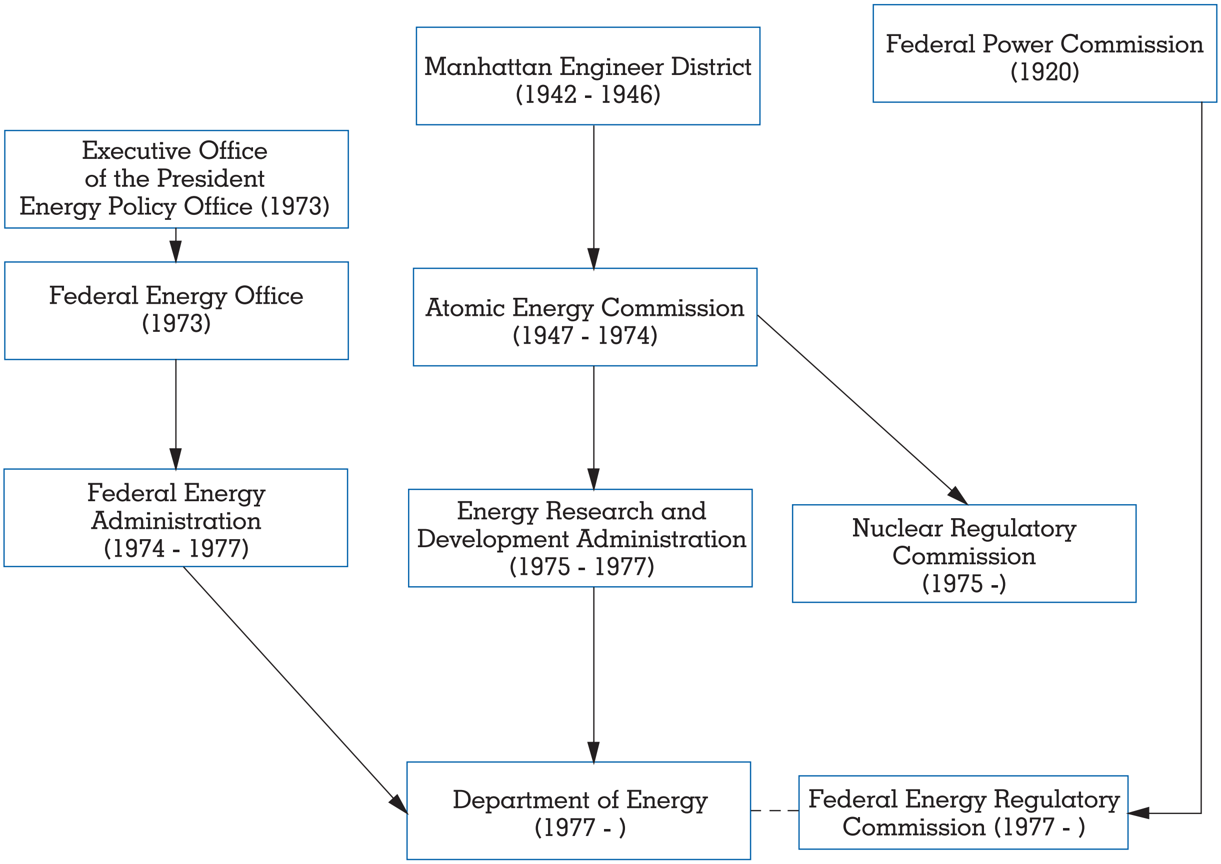

Figure 1.
Precursors and agencies related to the U.S. Department of Energy.

The World Bank also looks for energy efficiency improvement opportunities by pushing for the elimination of fossil fuel subsidies (estimated at over $200 billion a year in the developing world), improving demand-side efficiency, and making the energy supply system more cost conscious.

UNITED STATES AGENCIES

The focus of U.S. energy policy is with the Department of Energy, but because energy issues touch almost every sector of the economy, the Department of Commerce, the Department of Transportation, Department of Agriculture, Department of Defense, and the Environmental Protection Agency also devote a considerable amount of resources toward energy issues.

The Department of Energy (DOE)

The Department of Energy was established on June 3, 1977, unifying offices, laboratories, and staffs from other federal agencies (see Figure 1). Besides replacing and taking on all the responsibilities of the Federal Energy Administration, the Energy Research and Development Administration, and the Atomic Energy Commission, limited functions were transferred from the Departments of Agriculture, Commerce, Housing and Urban Development, and Transportation. The newly formed agency had around 20,000 employees and a budget of $10.4 billion.

Prior to the energy crisis of 1973, the federal government took a limited role in formulating a national energy policy. Markets operated freely, long-range planning was left up to the private sector, and oversight controlled by state, local, and regional authorities. Americans felt comfortable with private industry controlling production, distribution, marketing, and pricing. But in the case of natural monopolies, such as in the interstate transportation of natural gas and electricity, it was generally acknowledged that the Federal Power Commission (established in 1920) was necessary to ensure fair prices.

The regulatory agency that the DOE established for oversight of natural monopolies was the Federal Energy Regulatory Commission (FERC). The five-member commission was set up to control the regulation and licensing of hydroelectric power facilities, the regulation of the transmission and sale of electric power, the transportation and sale of natural gas, and the operation of natural gas and oil pipelines.

After the Oil Embargo, the Economic Regulatory Administration within DOE administered oil pricing, energy import programs, the importing and exporting of natural gas, programs to curtail natural gas consumption, and to supervise the conversion of electric power production from natural gas and oil to coal. These command and control programs continued through the Carter Administration, but ended early in the Reagan Administration, a strong free market advocate.

To provide long-term energy trends to the Department, President, Congress and the public, the DOE set up a statistics division called the Energy Information Administration. The federal government had been gathering and publishing energy statistics since 1949, but under the centralized control of the Energy Information Administration, the scope of data gathering expanded and continued to expand through the 1990s to encompass related areas of interest like carbon emissions.

During the Carter Administration, funding increased to pay for the greater focus on conserving energy, greater oil production including increasing the production of oil, natural gas and synthetic fuel from coal and shale oil reserves, and speeding the development and implementation of solar power. The Carter Administration took a very activist approach to energy policy, and believed that the United States could be getting 20 percent of its energy from the sun or other renewable energy sources by the year 2000. Toward this end, the Carter Administration pushed through Congress very generous subsidies for residential and commercial solar and wind installations.

The Reagan Administration (1981–1989) came in with a completely different vision of the federal role in the energy field. Reagan wanted to abolish the DOE, but with that being politically impossible, he set about restructuring it, letting private industry and the free marketplace set energy priorities. By ending government regulations and price controls, which were detrimental to domestic oil and natural gas production, he felt a free marketplace would prevent or limit the impact of future energy crises. And although Reagan reduced and eliminated subsidies for energy conservation and energy technologies like solar—preferring private capital to demonstrate commercial viability of technology—he continued to support long-term energy research and development, such as fusion, that private industry felt too risky to undertake. Despite these cutbacks, the DOE budget grew during the Reagan era mainly because of the emphasis on defense-related spending and the Strategic Defense Initiative designed to stop incoming nuclear warhead missiles.

The Bush Administration (1989–1993) had a similar free marketplace philosophy as Reagan, but faced the daunting task of having to start directing billions toward cleaning up after forty years of neglect at the contaminated weapons complex, particularly the federal facilities at Savannah River South Carolina, Hanford Washington, and Rocky Flats Colorado. The cleanup plan was fourfold: characterize and prioritize all waste cleanups at departmental sites, confine and correct immediate problems, establish long-term cleanup plans, and mandate compliance with all applicable laws. By the end of the Bush Administration, environmental management of defense-related nuclear waste consumed nearly a third of the budget, which reflected the dauntingly difficult and expensive nature of the cleanup.

Perhaps the most noteworthy energy-related accomplishment of the Bush Administration was the handling of the Persian Gulf Crisis of 1970 and the January 15, 1991 Operation Desert Storm—a military action that many categorized as an energy war. Because Iraqi and Kuwaiti production constituted around 4.3 million barrels per day, or 9 percent of the world total, the role of the DOE during the crisis was to reassure the public and press about oil issues, improve energy coordination with other countries primarily through the IEA, and promote energy conservation and increase energy production. Rapidly rising spot market prices for crude oil as well as gasoline prices did occur, but because of these efforts, along with the short duration of the crisis, the impact on world economies was minimized.

The Clinton Administration (1993–2000) that followed was far more inclined to embrace environmental activism than Reagan or Bush, and far more likely to propose command and control solutions to energy and environmental problems. However, the Clinton Administration also realized the need to allow markets to work, to do otherwise would result in some of the disastrous consequences of intervention policies used in the 1970s.

To pay for boosted spending for conservation grants, energy research and development, and spending on defense waste management, the Administration dramatically cut defense research and development. Many energy policy decisions of the Administration were directly linked to the quality and health of the environment. And unlike the Reagan and Bush Administrations that remained skeptical of global warming, the Clinton Administration made action on the global warming threat a priority. On the first Earth Day of the Administration, Clinton promised to stabilize greenhouse gas emissions at 1990 levels by the year 2000, an extremely ambitious goal. The method proposed was the Btu tax, a 25.7 cents per million Btus tax (4 %) on all forms of energy except solar, geothermal, and wind, and an additional 34.2 cents per million Btus tax for gasoline (4 cents a gallon) and other refined petroleum products. Although projected to reduce emissions by 25 million metric tons, the proposal was rejected by Congress primarily because it was widely viewed as a tax increase to finance increased social program spending. In December 1997, the Clinton Administration signed the Kyoto Protocol calling for dramatic carbon emission reductions, but never sent it to the Senate for ratification because of certain defeat. Almost all Senators felt there should be future carbon emission targets for the developing world, and the inequity of the cuts would give an unfair competitive advantage to the developing economies of the world, such as China, that did not agree to emission reductions.

By the end of the Clinton Administration in 2000, the budget for the agency had nearly doubled, and the number of employees exceeded 170,000, a figure that includes all those employed at DOE's national laboratories, cleanup sites, and other facilities. Despite organizational reshuffling and shifts in funding, much of the DOE mission—energy security, developing new energy sources, and collecting statistics about energy production and consumption—remains the same. The 1997 Budget allocated 38 percent toward nuclear security, followed by nuclear cleanup at 36 percent, basic science 15 percent, and energy subsidies 11 percent. Many critics feel the $6 billion spent annually for nuclear cleanup of DOE facilities is extremely wasteful. Instead of trying to return these sites to pristine conditions, critic feel DOE should renegotiate the cleanup plan with the EPA, and state and local authorities so that the emphasis can be shifted toward containment and neutralization of waste.

As the DOE moves into the twenty-first century, the Department faces significant challenges in defining a mission to warrant its generous funding. As long as fossil fuel supplies remain cheap and abundant, and the public remains skeptical of global warming, there will remain a desire to cut funding.

The Environmental Protection Agency (EPA)

To consolidate the environmental protection activities of the federal government, the Environmental Protection Agency was formed on December 2, 1970 from three federal Departments, three Administrations, three Bureaus, and several other offices. The mission of EPA was to collect data on pollution, conduct research on the adverse effects of pollution, and through grants and technical assistance, develop methods for controlling it.

Much of the EPA's regulatory activity centers around the energy business, and in many ways, its actions have a greater impact on altering production and consumption patterns in the energy sector than the DOE's actions. Oil drilling, production, transportation (pipelines and tankers), and refining are all heavily regulated segments of the energy sector. Refining, in particular, is subjected to periodic EPA audits for hazardous waste by-products and airborne emissions released during the refining process. The stringency of EPA refinery regulations, and the uncertainty about future regulations, partly explains why the industry has not built any new major refineries in the United States since the mid-1970s.

Power plant and auto emissions are two other energy areas touched by EPA regulations. These are regulated through the Clean Air Act of 1970, and the amendments in 1977 and 1990 that set guidelines for acceptable emission levels. The Clean Air Act has been widely praised for improving air quality, significantly lowering emissions of sulfur dioxide, nitrous oxide, and other particulate matter. However, most economists feel that the benefits from the EPA administered safety investments (including nonenergy aspects) are far less cost effective than the safety investments of other regulatory agencies (see Table 1).

Regulatory Agency	*Median Cost/ Life-Year Saved*
Federal Aviation Administration	$23,000
Consumer Product Safety Commission	$68,000
National Highway Traffic Safety Administration	$78,000
Occupational Safety and Health Administration	$88,000
Environmental Protection Agency	$7,629,000

Table 1.
Median Value of Cost/Life-Year Saved For Five Regulatory Agencies
SOURCE: Tengs, 1995

The 1990 amendments, which gave the Agency broad new power to revise Clean Air standards if EPA felt the results of studies warranted changes, has been particularly troublesome for the energy sector. Much of the EPA's air standard actions taken during the 1990s came under intense criticism for not being warranted by science. In particular, the EPA severely toughened new Clean Air particulate matter standards for power plant emissions in 1996, claiming it would save 15,000 lives a year, and reduce hospital admissions and respiratory illness. This was followed, in 1999, by a new lower sulfur content gasoline standard for refiners (effective in 2004) that will add 2 to 6 cents to the price of a gallon of gasoline. The EPA claims an additional 2,400 deaths will be prevented every year from this new standard. It was impossible to dispute the merits of either new standard because the EPA prevented public review of the data upon which these regulations are based (the "Pope" study) as required by the Freedom of Information Act (taxpayer-funded scientific data used to support federal regulations must be made available). Without access to the data, there can be no confirmation that the new standards will save any lives.

On the nuclear energy front, the EPA was instrumental in the late 1980s for bringing DOE nuclear facilities into compliance with the Nuclear Waste Policy Act of 1982 and 1987 (high-level radioactive wastes), the Low-Level Radioactive Waste Policy Act of 1980 and 1985, the Uranium Mill Tailings Radiation Control Act of 1978, and the Superfund statute. The most egregious sites needing cleanup are the nuclear weapons production sites located at Savannah River South Carolina, Rocky Flats Colorado, and Hanford Washington, that are all going to take decades to cleanup and cost billions of dollars. The EPA action at these DOE sites was touted as a sign that the federal government can police itself, and that the environmental laws that apply in the private sector apply equally to the public sector.

To combat the dangers of global warming by reducing carbon emissions, the Clinton Administration formed the Climate Protection Division (CPD), formerly the Atmospheric Pollution Prevention Division. This Division has been directed to find nonregulatory ways to reduce greenhouse gases through energy-efficiency improvements in all sectors of the economy. In collaboration with DOE, the EPA established the Energy Star Labeling Program as a way to develop voluntary energy-efficiency specifications for products such as office equipment, heating and cooling equipment, residential appliances, and computers. This Program allows manufacturers to prominently place an Energy Star label on qualifying products. The hope is for consumers to learn to recognize the label as the symbol for energy-efficiency, and become accustomed to buying only energy efficient products with the Energy Star label.

The Department of Commerce (DOC)

The commercial and industrial sectors account for more than fifty percent of all energy consumption in the United States. The Department of Commerce (DOC), whose mission is to improve the overall competitiveness of the commercial and industrial sector, is very concerned with reducing consumption through conservation and energy efficiency, and in improving the competitiveness of the energy businesses on the production issues.

On the energy use side, the DOC helps promote the DOE and the EPA energy efficiency programs (Energy Star) for the industrial and commercial sectors of the economy. To aid the energy businesses on the production side, the International Trade Administration and the Office of Energy, Infrastructure and Machinery assist all the energy fuel industries in improving their market competiveness and ability to participate in international trade. One of the more aggressive actions of the Department under the Clinton Administration was to sponsor trade missions to promote the export of U.S. electric power production technology.

Another major function of the DOC is the management of energy-related research through the National Institute of Standards and Technologies Laboratories in Gaithersburg, Maryland and Boulder, Colorado and the research laboratories of the National Oceanic and Atmospheric Administration.

The National Institute of Standards and Technology (NIST), formerly the National Bureau of Standards (NBS), was established by Congress in 1901. Its mission is to assist industry in the development of technology needed to improve product quality, to modernize manufacturing processes, to ensureproduct reliability, and to facilitate rapid commercialization of products based on new scientific discoveries. For example, it provides measurements that support the nations' standards for lighting and electric power usage. In 1988, NIST added three major new programs to its measurement andstandards laboratories: The Advanced Technology Program (ATP) which in partnership with industry accelerates innovative, enabling technologies with strong potential to deliver large payoff for the nation; the Manufacturing Extension Partnership (MEP), a network of local centers offering technical and business assistance to smaller manufacturers; and the Malcomb Baldridge National Quality Award that recognizes business performance excellence. Programs the ATP is funding in the energy arena include the development of rapid thermal processing to produce low-cost solar cells with Solarex (a business unit of Amoco/Enron Solar), and ultrathin silicon ribbon for high-efficiency solar cells with Evergreen Solar, Inc.

The Office of Oceanic and Atmospheric Research (OAR) is the division of NOAA that conducts and directs oceanic and atmospheric research. Since carbon dioxide is a greenhouse gas and fossil fuels are the leading generator of carbon dioxide, the work of the twelve Environmental Research Laboratories and eleven Joint Institutes of OAR to describe, monitor, and assess climate trends are of great interest to all parties interested in the affect of energy use on climate change.

The Department of the Interior

The Department of the Interior is the home of the Bureau of Land Management, the Minerals Management Service, the Office of Surface Mining Reclamation and Enforcement, and the U.S Geological Survey (USGS).

The Bureau of Land Management is responsible for the leasing of land for coal, oil, and natural gas exploration and production, and the Minerals Management Service does likewise for offshore leasing. Both divisions rely on resource evaluation information provided by the USGS in negotiating leases. The main responsibilities are the inspection and enforcement of leases, and the collection of royalty payments and other revenues due the Federal Government from the leasing and extraction of energy resources. Besides providing the statistics for the other Department of the Interior divisions, the USGS compiles databases and geologic maps of energy reserves and resources.

The mining industry has taken great steps in limiting environmental problems in developing energy resources, yet much of the mining industry prior to the 1980s abandoned sites leaving huge environmental problems. The Office of Surface Mining Reclamation and Enforcement was established to formulate policy and working plans for the Abandoned Mine Land reclamation programs. This was necessary because the Department cannot sue many of the offending mining companies for cleanup costs because most no longer exist.

The Department of Agriculture (USDA)

Energy issues are a major, yet indirect, focus of the Department of Agriculture (USDA). Energy is involved in every step of agriculture: it takes energy to produce the inputs of nitrogen, phosphate, seeds and pest/weed control, energy to run the machinery to plant, maintain, harvest and process crops, and energy to transport crops by truck, train, barge and container ships. And the even the end result, food itself, is essentially energy. Food is as essential to humans as gasoline is to the automobile.

The USDA has an inherent conflict of interest: promote eating more dairy products and meats to relieve agriculture surpluses, while promote good eating with the ubiquitous USDA Food Pyramid. Out of a budget of over $65 billion in 2000, about two-thirds of the USDA budget goes toward nutritional programs and social programs for the poor, such as food stamps, to ensure that all Americans can afford an ample supply of food energy. For the middle and upper class of society, food prices are artificially low because of the subsidies to producers. An overabundance of food, that is more affordable to more of the population than ever before, has turned the United States into an equal opportunity obesity society. Over 20 percent of the population is obese (over 50 percent overweight), and obesity can be found in large percentages at all income levels. This is unlike most of the world where obesity is far less prevalent and mostly found among the affluent.

Another function of the USDA is the promotion of biofuels like ethanol as an important market for the nation's farm products. Ethanol is an alcohol fuel produced from corn and is blended with gasoline to enhance octane and reduce automobile emissions of pollutants. From 1980 through 2000, ethanol producers have received a subsidy of nearly $10 billion. To prop up the price of corn and help the ethanol industry, in 1986 the USDA Office of Energy started to give away free corn for all ethanol producers, which was extended to even the very largest and most profitable ethanol producers like Archer Daniels Midland Corporation. These huge subsidies are very controversial. Proponents claim ethanol as a fuel provides an additional market for corn farmers, and also claim the fuel is better for the environment and helps reduce imports of foreign oil. Critics counter that the energy content of ethanol is one-third that of gasoline. Moreover, the DOE and Congressional Research Service found it was not better for the environment, and would retail at a price much higher than gasoline if not for the heavy subsidies. And because it takes considerable energy to convert corn to ethanol, there can be a net loss in energy in producing ethanol (a gallon of ethanol contains around 76,000 British Thermal Units (Btus) of energy and estimates of the energy to produce that gallon range from around 60,000 to 90,000 Btus).

Another biofuel of importance is wood. The Forest Service, which is part of USDA, administers national forest lands for the sale of wood for wood fuel. Besides determining the quantity of wood fuel to bring to market by collecting and analyzing statistics on woody biomass supply and use, the Forest Service sponsors forest biomass energy-related research in conjunction with federal and state agencies, as well as universities.

The Department of Transportation (DOT)

Because every means of transportation requires energy for propulsion, how energy is used in transportation is something that is carefully tracked by the Office of Transportation Policy Development within the Department of Transportation (DOT). The transportation sector felt the greatest impact from the oil supply disruptions in the 1970s because it was, and continues to be, the sector most dependent on oil. It is also the sector with the least flexibility to switch fuels. (see also Consumption)

National Aeronautic and Space Administration (NASA)

The National Aeronautic and Space Administration is involved in every aspect of atmospheric and space science. Because of the special energy requirements of spacecraft and satellites, NASA has been the proving grounds for many emerging energy technologies such as fuel cells and photovoltaics. In the area of transportation, the Jet Propulsion Laboratory in Pasadena California is a leading center for bettering jet and rocket engines and developing new technologies such as ion propulsion. NASA is also responsible for building, launching, and collecting the data from satellites trying to detect global warming.

The Department of Defense (DOD)

The DOD consumes more energy than most nations of the world, and four times more energy than all the other federal agencies combined. The DOD took an interest in energy long before there was an energy crisis. Energy in the form of petroleum is what fuels military technology, and almost every military strategy involves, directly or indirectly, energy. The DOD is not only interested in the logistics of petroleum planning (through the Defense Fuel Supply Center), but also in developing an array of nontraditional energy technologies, everything from better nuclear propulsion for ships and submarines to solar photovoltaic applications and battery technologies to power mobile communication technologies.

Nuclear Regulatory Commission

The Nuclear Regulatory Commission (NRC) is an independent federal agency that licenses and decommissions commercial nuclear power plants and other nuclear facilities. NRC inspections and investigations are designed to assure compliance with the Agency's regulations, most notably the construction and operation of facilities, the management of high-level and low-level nuclear wastes, radiation control in mining, and the packaging of radioactive wastes for transportation.

STATE AND LOCAL AGENCIES

Almost every state in the nation has an energy policy and planning agency charged with ensuring a reliable and affordable energy supply. Duties of these agencies include forecasting future energy needs, siting and licensing power plants, promoting energy efficiency, and planning for energy emergencies. Instead of leaving all energy decisions entirely up to the free market, many states actively promote changes in production and consumption. Faced with some of the worst air quality problems, the California Energy Commission is one of the most active state agencies in implementing demand side management and market transformation strategies.

In an effort to coordinate policy, exchange information, and to convey to the federal government the specific energy priorities and concerns of the states, the state agencies formed the National Association of State Energy Officials (NASEO) in 1986. To better ensure that appropriate policy was being implemented, NASEO set up the Association of Energy Research and Technology Transfer Institute to track the successes and failures of different programs.

Because the federal government has taken a more hands-off approach toward energy since the 1970s, this trend of state and local governments becoming more active in making energy and environmental decisions about electricity production and transportation issues is likely to continue, especially for the more populace areas of the country like California and the Northeast.

GOVERNMENT AND THE ENERGY MARKETPLACE

Government intervention in energy markets involves either government ownership of industry resources or, more commonly, planning and regulation of privately held resources. The proper role of government planning and regulation has been a hotly debated issue among economists and politicians for many years. Through the twentieth century, governments of the United States and of most of the rest of the developed world have become increasingly larger and more involved in taking action that affect the outcomes of how energy is produced, transported, and consumed. Some believe government intervention in markets is the best solution; others believe government intervention should be avoided. Given the extensive number of energy markets and the extensive use of government intervention in those markets, it is not surprising that the record is mixed. Markets have proved to be reasonably efficient, yet also can be harsh; government action has provided important protections, yet also has made some good situations bad and bad situations worse.

THE VIRTUES OF THE MARKETPLACE

Markets decide what energy resources shall be produced, how they shall be produced, and who will receive the benefits of the production processes. With millions of different activity options, and millions of individuals making individual and collective decisions, it is an overwhelmingly complex process. At the same time, it is usually very efficient because self-interested market players communicate through the price system. A self-interested rational individual will make decisions based on true preferences, and follow those preferences in a way that will provide the greatest satisfaction. Choices will be made under certain constraints that apply to all consumers: income, energy prices, and the ability to switch fuels or fuel providers.

Economic theory holds that individuals will make decisions based on what is in their best interests. Government intervention distorts these capital investment decisions; it alters constraints by favoring or giving preferences or incentives to one choice or type of behavior over another. Government intervention tends to subtly manipulate supply and demand of energy, which usually increases costs to users, reduces supply, and leads to higher prices. Political revolt to government intervention is rare since the consumer often is unable to separate the interventionist component of price (the price premium attributable to regulation and taxation) from what the price would be in the free market.

REASONS FOR GOVERNMENT INTERVENTION

Government intervention is justified as a way to correct the shortcomings of the marketplace. Proponents of intervention do not necessarily believe that markets in general do not work, but rather that there are dynamics going on in certain markets that require intervention to cause them to work in a more socially desirable manner. First, intervention is justified in the energy arena because of problems arising from the laws regarding the ownership and exchange of property rights and the purchase and sale of energy rights. Property rights are far more troublesome in the oil and gas production business than most other businesses for two reasons: the commodity of value sits below the surface, and the commodity is a liquid or a gas not a solid, which means it can migrate many miles. Since energy resources know no boundaries (oil and gas deposits often straddle the property of several owners) a system is needed to assign energy rights.

Second, intervention is justified because social costs may exceed private costs as well as private benefits. For example, when an individual chooses to take a personal automobile to work instead of mass transit, the individual driver receives the short-term benefits (privacy, comfort, speed, and convenience) while the negative social costs (greater air pollution, highway construction, traffic jams, and resource depletion) are shared by all. Intervention usually is an attempt to lower the social costs. However, the problem is that social costs may be easily identifiable in theory, but much more difficult to accurately quantify in practice.

A third function of intervention is the oversight of energy utility monopolies for electricity and natural gas. Utilities have been considered natural monopolies because it was generally cost effective to have a sole generator, transmitter or distributor of electricity or natural gas for a local area due to the large infrastructure required and economies of scale. Without competitors, government historically felt a duty to protect customers from unfair price gouging. But new technology is challenging the concept of natural monopoly in the utilities, and has resulted in the deregulation of energy generation, transmission and distribution in the 1990s. Government's role is shifting to establishing the rules, guidelines, and procedures that attempt to be equitable to all parties (industry and customers) and minimize the social costs to society by ensuring these markets are also socially desirable.

Finally, government intervention is often called for to establish standards by essentially reducing informational market barriers. This is important because the rational individual can only make a decision in his best interest when the information is at hand to make that decision.

TYPES OF GOVERNMENT INTERVENTION

Governments intervene in all energy markets—exploration, production, distribution, and consumption—and carry out intervention in many different ways. While some impacts of intervention are intended, other impacts occur indirectly as an unintended consequence. Examples of a direct impact are the price-lowering effect of subsidies for the biofuel ethanol, and the increased desirability of conservation resulting from a tax on energy use. Examples of unintended indirect impacts are the encouragement of single passenger driving over mass transit resulting from the provision of free parking, or a dramatic increase in the price of coal-generated electricity resulting from clean air regulations to reduce air pollution.

Taxes

Governments levy taxes to raise revenue and to discourage consumption of what is taxed. The primary purpose of United States federal and state gasoline taxes is to raise revenue for transportation infrastructure, particularly highway construction. In Europe and Japan, where gasoline taxes are many times greater (gasoline retails for over twice as much as in the United States), the purpose is also to discourage consumption. However, when taxes are implemented, rarely are drops in transportation energy consumption immediate. Even very steep increases in gasoline taxes usually take time to result in a reduction in consumption. People who drive fifty miles to work still need to get to work by driving in the short term. Only over the long term can people decide whether to move closer to work, change jobs, rearrange schedules to use mass transit or to carpool, purchase a more fuel efficient car, or accept higher energy costs by maintaining the same lifestyle.

Unlike the gasoline tax that only impacts the transportation sector, carbon taxes affect all sectors of the economy. Implemented by some European countries and proposed in the United States by the Clinton Administration in 1993, the carbon tax makes consumption of fossil fuels more expensive for the energy user. The goals of a carbon tax are to reduce the consumption of energy and to make non-carbon emitting sources like wind and hydroelectric more cost-competitive with fossil fuels.

Subsidies

Subsidies are transfer payments from governments to business interests and individuals. Governments have been involved in the subsidizing of energy since the early part of the twentieth century. For democratic governments, subsidies have been often used as a means to buy votes, and for authoritarian governments, as an important means of placating the masses. Price supports for ethanol, tax credits for renewable energy, depletion allowances for oil and gas production, and grants for energy conservation measures for low income families fit the narrow definition of energy subsidies. But if subsidies are considered in a broader context, trade barriers, regulations, and U.S. military spending to ensure the flow of oil from the Persian Gulf can be considered subsidies as well.

Regulation

Regulations are rules set by governments to protect consumers and to control or direct conduct in the marketplace. Production, transportation, consumption, and prices have all been affected by energy regulations.

Allocation control regulations affecting oil prices were issued in the 1970s in response to what was perceived as a number of market inefficiencies. The primary motivation was fairness to low-income individuals and families, yet price controls ended up exacerbating the inefficiencies—worsening the problem it was supposed to solve. Since prices convey critical information to buyers and sellers of energy, government intervention that tries to alter the message can distort market signals so that everyone ultimately ends up less satisfied. Price controls send the wrong signal by artificially stimulating consumption (more demand at a lower price) and reducing the quantity supplied (producers are willing to produce less at the lower price).

The most-well known energy regulations are probably the ones covering the production, transmission, and distribution of electricity and natural gas. To avoid the inefficiency of having multiple electric cables or gas lines run down each street and into every home, in the past governments awarded the right to serve an area to one firm—a "natural monopoly." Unlike most countries, where the government owns and operates electric and gas monopolies, in the United States most of the power industry remains privately-owned and the government regulates it by setting prices, the amount that can be earned, and the quality of service provided. Although Congress develops legislation that authorizes regulation, identifying and enforcing of the rules for specific cases are carried out by the Federal Energy Regulatory Commission and state public service commissions.

Criticism of the way public utility monopolies have been regulated usually centers around the built-in biases that may be favorable to the utility and the customer but are also socially undesirable. Electric utility regulation was structured so that companies earned more by building more facilities, selling more power, encouraging consumption, and discouraging conservation. In the late 1970s and early 1980s, states instituted demand-side management programs that attempted to shift the incentive away from consumption to conservation.

In the late 1970s, public policies began to focus on opening up power generation markets so that non-utility generators and independent power producers could have access to transmission systems and electricity markets. By the early 1990s, much more aggressive public policies were being considered and adopted. These public policies envisioned giving customers in all customer classes the opportunity to select their electricity suppliers. It was recognized that allowing customer choice would require not only providing open access to transmission systems but also the total "unbundling" of power production from power delivery and customer service functions to prevent discriminatory transactions and self dealing.

While unbundling was seen as a necessary step for deregulation, utility companies pointed out that unbundling could create "stranded assets." The creation of stranded assets could be devastating to those utility companies that had made investments in nuclear power plants and other assets that would be uneconomic or unable to compete in open markets. To address the stranded assets issue, government intervention sought to create transition plans elevating rates above market values and allowing the recovery of stranded costs. In the longer term, it is likely that many electric power marketers will be buying power from many different electricity producers, and then turning around and selling the power to industry, business and the residential customers.

"Cross subsidies" have traditionally been used in establishing rates. Industrial customers pay a higher rate for their electricity than residential customers and, in effect, subsidize the power supply for residential customers. In a different context, "cross subsidies" can be created to select power generation technologies based on their environmental impact. There is political pressure from the environmental interest groups to include ratepayer cross-subsidies so that the less desirable power generation technologies (e.g., coal-fired steam turbines) subsidize the more desirable power generation technologies (e.g., wind turbines). This is being considered as part of the deregulation process. Pollution costs fall largely on third parties. In the case of fossil fuel electric power plants, only a small fraction of air pollution costs are borne by the beneficiaries of the power production. Proponents view cross subsidies as an effective way to raise the cost of fossil fuel energy production, lower the cost of renewable energy, and support energy efficiency and conservation programs. Programs like "Plant a tree whenever you build a new fossil fuel power plant" are, in effect, cross subsidy programs because they balance environmental objectives with economic objectives in power generation planning.

Compared to regulation, cross subsidies are a more market-based approach for discouraging air pollution emissions from energy production. Economists generally agree that economic approaches to pollution control (taxes, subsidies, pollution allowances, and trading programs) have been far more efficient and equitable solutions than "command and control" approaches to regulations that have mandated specific emission levels and specific technology.

Since there is an environmental impact with almost all energy production, environmental regulations and policy are indirectly having a greater impact on the energy industry than direct energy policy. Clean air regulations continue to make it more expensive to burn fossil fuels, especially coal; clean water regulations present expensive challenges for the transportation (oil tankers) and storage (underground fuel tanks) of petroleum products; carbon dioxide reduction policies to prevent global warming favor the growth of renewable energy over fossil fuels.

Safety is another major regulatory area. The Occupational Safety and Health Administration (OSHA) enforces many worker safety regulations covering the operation of refineries and electric power plants, and the Nuclear Regulatory Commission oversees the regulations ensuring the safety of nuclear power plants. There are also numerous safety regulations covering the operations of oil and natural gas pipelines and oil tankers. These protective programs have unquestionably provided major social benefits. However, critics contend that these programs have gone too far, have been too expensive, and have placed too much emphasis on government as the interpreter of safety.

When regulation fails to achieve the intended objective, the question arises of whether it was a failure solely of administration or of theory too. If advocates of regulation can prove failure to be largely administrative, it is easier to make the case for new regulations under improved administration.

Information

There have been considerable efforts made at moral persuasion aimed at the social conscience to convince those involved in high consumption behavior to behave more responsibly. During the 1970s, the United States government embarked on a campaign to persuade the public to conserve energy by, among other things, driving 55 mph, keeping car tires inflated, and turning down thermostats in buildings to 65 degrees. In the 1980s, energy use appliance labels were mandated so that rational consumers could compare the efficiency of models and purchase the more energy efficient models. (This was followed by Energy Star Labeling, a joint action of the EPA and DOE in the 1990s that recognizes products such as computers or windows that meet a given energy efficiency standard. Early in the twenty-first century, an emerging target of moral persuasion is the sports utility vehicles (SUV). Compared to the average automobile, the average SUV consumes about 30 percent more fuel per mile and generates more air pollutants and far greater carbon dioxide emissions. The message is that it is unpatriotic to purchase these energy-guzzling, high-emission vehicles. The combination of moral persuasion and the reclassification of SUVs as automobiles (to meet the tougher emission and Corporate Average Fuel Economy standard for automobiles) could be an effective means of curtailing SUV purchases.

Moral persuasion has been most effective in times of short-term emergencies, like the energy shortages of the 1970s, but is far less effective in the long-term and for problems not universally viewed as problems. The benefits of such efforts are the speed, the inexpensiveness of the approach, and the implicit threat behind the effort: stop the undesirable activity by choice or society will take direct measures to curtail it.

Research and development

Europe, Russia, Japan, and the United States have spent billions for energy research and development since the 1970s. The United States alone spent over $60 billion from 1978 to 1996. Nations liberally spend on energy research to try to expand supply options, to develop indigenous resources for national security reasons, and to speed invention and innovation that will benefit society. When the energy research and development budget was significantly boosted in the mid-1970s, the hope was that nuclear fusion, solar energy and other renewable energy sources could develop into the primary energy sources of the next century. But because there have been no major breakthroughs, and fossil fuels have remained relatively inexpensive, renewables' share of energy production has actually fallen. Fossil fuels research and development have shown better results: cleaner transportation fuels and vehicles, more efficient natural gas turbines, and the clean coal program, which raised efficiency and reduced the harmful emissions from coal burning power plants. Largely because of the disappointing overall results of federal spending on energy research and development—the poor track record of picking winners, the inequitable funding based more on politics than scientific merit, and the draining of research and development capital away from the private sector—the amount of money spent on energy R&D has been falling throughout the 1980s and 1990s as a percent of total U.S. research and development. It is uncertain whether this trend will continue. Many energy experts still advocate government spending because industrial goals are usually short-term and do not necessarily reflect national goals such as energy security and environmental quality.

THE NEXT ENERGY CRISIS

Historically government intervention has been primarily crisis-driven. During the Energy Crisis of the 1970s, it was easy for government leaders to gather popular support for government policies that subsidized alternative energy sources (boosting supply) and promised to lower the price of energy. Yet once the crisis passed, gathering support for new initiatives became much more difficult. That is largely why there have been only minor new energy initiatives since the end of the Carter Administration in 1980.

Freer and more diverse world energy markets make another major energy crisis less likely. If one does occur, it is likely to again trigger strong cries for government action. But because of the valuable economic lessons learned from government actions in the 1970s, any crisis-related intervention should achieve better results; the ineffective and harmful mistakes of the past are unlikely to be repeated. Moreover, because the total value of crude oil to the economy is much smaller, any oil supply disruption is unlikely to be as severe for the American economy as the oil price hikes of 1973 and 1979. The economy can more easily substitute coal and natural gas for petroleum, and the very energy-dependent industries like aluminum, steel and petrochemicals have grown more slowly and make up a smaller share of the economy than high growth industries like pharmaceuticals, computer technology and the service economy.

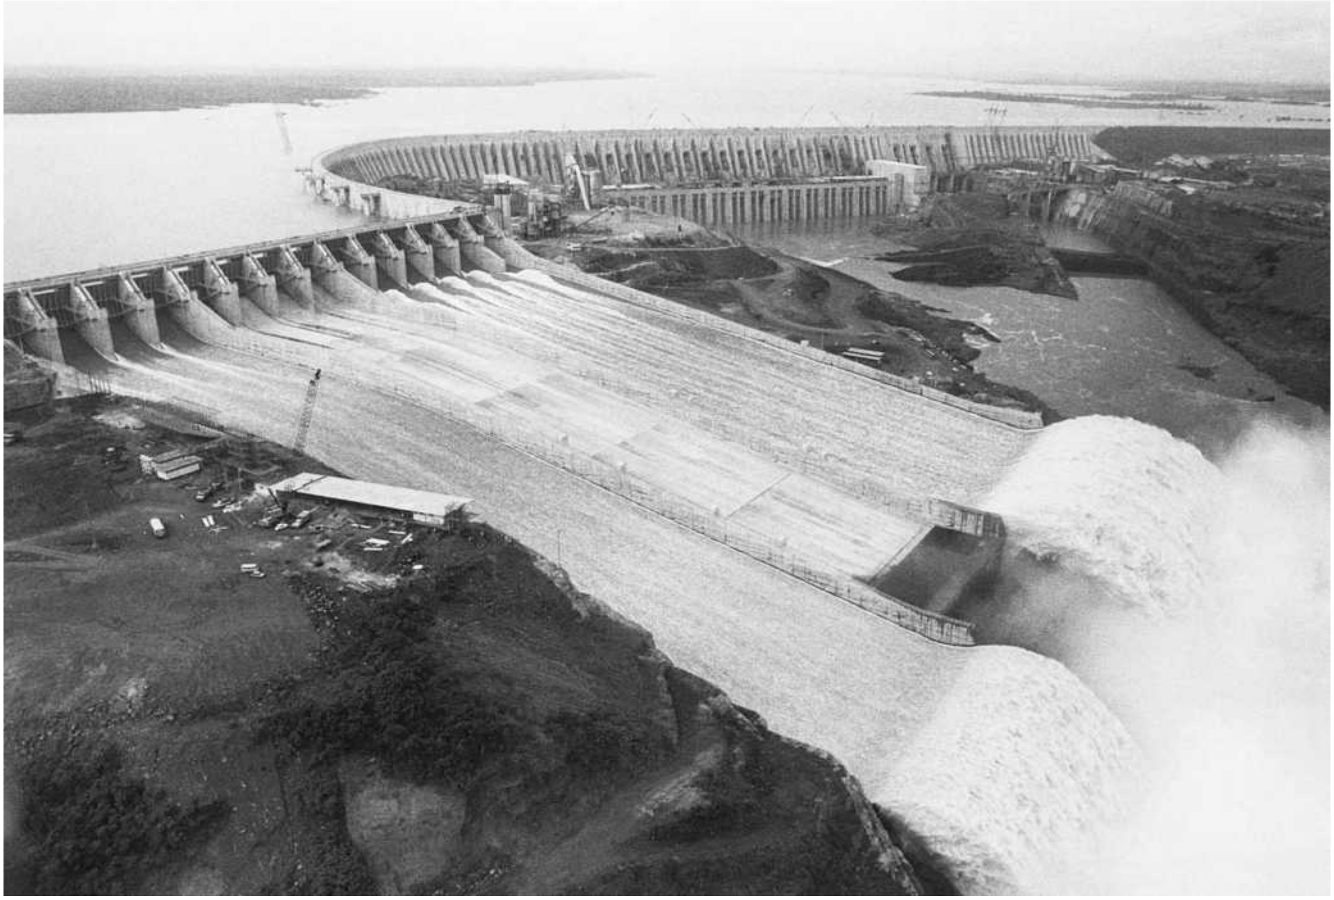
GRAVITATIONAL ENERGY

Earth's moon is held in orbit by an attractive gravitational force between Earth and the moon. Tides on Earth are due mainly to the gravitational pull of the moon on Earth. Any two masses whether or not Earth and the moon, experience a mutual gravitational force that tends to pull them together. A mass in a position to be pulled to another position by a gravitational force has gravitational potential energy. Anything—water, a book, a parachutist, a molecule in the atmosphere, etc.—has gravitational energy if it is in a position to move closer to the center of Earth. Ordinarily, something has to do work to get the object to the elevated position. A book on the floor of a room has no gravitational energy if it cannot move lower than the floor. But if you lift the book, and place it on top of a table, it has gravitational energy because it is in a position to fall to the floor. The act of lifting the book and doing work produces the gravitational energy of the book. Water atop a dam has gravitational potential energy, but the water did not get into its position at the top of a dam without some agent doing work. The mechanism elevating the water could be a mechanical pump or the natural processes of water evaporating, rising in the atmosphere, condensing to liquid, and falling as rain. Ocean water pulled into a natural basin by the gravitational pulls of the moon and the sun has gravitational potential energy that we refer to as tidal energy.

Electric energy produced by a hydroelectric power plant is derived from gravitational energy. The process starts with gravitational forces pulling the water to the bottom of the dam, where the gravitational energy is converted to kinetic energy (energy due to matter in motion). When the moving water impinges on the blades of a turbine, some of the kinetic energy is converted to rotational energy, causing the turbine to rotate. The turbine is coupled to an electric generator, where the rotational energy of the turbine is converted to electric energy. The electric generator is connected to transmission lines that deliver the electric energy to consumers.

Electricity supplied to consumers is produced primarily by massive generators driven by steam turbines. The system is most efficient and most economical when the generators produce electricity at a constant rate. However, the problem is that demand varies widely by time of day. At night, when consumer demand is low, it would be seem that a utility could keep their most efficient generators running and store electric energy for times when needed. Unfortunately, there is no practical way of storing the quantities of electric energy produced by a large generator. It is possible, however, to convert the electric energy to some other form and store it. Then when electricity is neededm the secondary form of energy is converted back again to electricity. One way of doing this is to keep efficient generators running at night, when the demand is low, and use them to operate electrically driven pumps that store the water as gravitational energy in an elevated reservoir.



The Paraná River meets the Itaipu Dam in Foz Do Iguacu, Brazil. (Corbis Corporation)

When consumer demand picks up during the day, the water is allowed to flow to a lower level to a hydroelectric unit, where the gravitational energy is converted to electric energy. A system like this is called a *pumped-storage facility*. The electric energy recovered in the hydroelectric unit is always less than the electric energy used to store the water as gravitational energy. However, the former is economical because electricity produced at night is relatively cheap. There are a number of these systems throughout the world, the most prominent in the United States being the Robert Moses Plant, near the base of Niagara Falls.

GREEN ENERGY

Green pricing for electricity allows consumers to voluntarily pay a premium for more expensive energy sources that are considered better for the environment. The initiative presumes that the buying public believes: (1) the existing corpus of environmental regulation has not fully corrected the negative effects of producing electricity from hydrocarbons (oil, natural gas, orimulsion, and coal); (2) nuclear power is not environmentally friendly despite the absence of air emissions; and (3) certain renewable technologies are relatively benign for the environment.

OPEN-ACCESS RESTRUCTURING: DRIVER OF GREEN PRICING

Electricity typically has been purchased from a single franchised monopolist or municipality. The physical commodity (electrons) and the transmission service were bundled together into one price. The power could be generated (in terms of market share in the United States in 1998) from coal (56%), nuclear (20%), natural gas (11%), hydro (8%), oil (3%), biomass (1.5%), geothermal (0.2%), wind (0.1%), and solar (0.02%). Recently, wholesale and some retail markets have been unbundled, allowing competitors to sell electrons with the monopoly utility or municipality providing the transmission service. Open-access restructuring gives customers choices and creates a commodity market in which the lowest-cost electricity wins market share at the expense of higher-cost alternatives.

The prospect and reality of open-access restructuring is responsible for the current interest in green pricing. Monopoly suppliers became interested in green pricing as a marketing strategy to retain their customer base given the prospect of open-access competition from new commodity suppliers. Independent suppliers operating in open-access states embraced green pricing as an important form of product differentiation. At the same time, environmentalist interest groups campaigned for consumers to use their newfound buying power to absorb a price premium to support those energies perceived to have lower social costs than private costs due to their environmental advantages.

GREEN POWER SUBSIDIES

Electricity generated from biomass, geothermal, solar, and wind facilities (non hydro renewables) have been subsidized by government policies since the 1970s with research and development grants, accelerated depreciation, tax credits, ratepayer cross-subsidies, and must-buy provisions. On an energy production basis, these subsidies have been substantially greater than for conventional generating sources. Without government subsidies today, natural gas technologies would easily dominate the new capacity market in the United States due to their combined economic and environmental characteristics relative to other generation technologies, both conventional and nonconventional.

CHALLENGES FOR GREEN PRICING

The ability of consumers to voluntarily pay a premium to purchase environmentally preferred electric generation would seem to be a happy middle ground between free-market energy proponents and “clean energy” advocates. Yet, on closer inspection there are numerous issues that concern a maturing green-pricing market.

Government Codependence.

Green pricing is not stand-alone philanthropy, but a voluntary addition to mandated subsidies from the entire ratepayer and taxpayer class for the same renewables. Since "green" energy is often intermittent (the sun does not always shine nor the wind always blow), conventional energy with round-the-clock reliability sets the foundation for green pricing. Yet, conventional supply is not compensated for providing the reliability for intermittent "green" energy. Green pricing attempts to get uneconomic renewables "over the top," given upstream subsidies that alone might not be enough to make the renewables economic in a competitive market.

In a free market, the absence of these subsidies might make the green pricing premium prohibitive for consumers. In California, for example, a 1.5-cent per kilowatt hour (kWh) subsidy for green-pricing customers has led to over 100,000 customers for "green" power. There are serious questions about what will happen when the subsidy is reduced or expires. This subsidy is over and above other favors that have led to the construction of high-cost renewable capacity in the last decade—subsidies that may or may not continue in the future.

The codependency of green pricing on government favor is apparent in another way. Green pricing is a short-term consumer commitment, yet needed capacity is capital-intensive and long-lived, requires long lead times, and generates power that may be too expensive to profitably sell in the spot market. To secure financing for such projects, mandates and financial subsidies are required unless qualifying "green" capacity already exists (which predominately has been the case to date). Noneconomic projects built on the strength of short-term green-pricing commitments could become stranded or abandoned assets if the month-to-month consumer premiums cease. This is a reason why ten states as of 1999 have guaranteed a minimum percentage of new capacity to be renewables-based in their electricity restructuring programs. A federal Renewable Portfolio Standard is being sought as well to mandate (nonhydro) renewable quotas nationally.

Subjective Qualifications.

Green pricing assumes that an objective environmental standard exists for consumers to compare competing energies where, in fact, very complicated and subjective tradeoffs exist. A list of issues can be constructed.

Should the programs apply to existing generation, new generation, or both? Applying green pricing to existing projects is a windfall for owners since it is over and above the sustainable support the market originally provided. Many environmentalists have been critical of green pricing programs that utilize existing capacity since no incremental environmental benefits are secured in return for the premium that customers pay. "Greener" for some customers automatically makes the remainder "browner."

Should hydropower be part of the green portfolio since it is renewable and does not emit air pollution, albeit conventional? A green energy primer from the Renewable Energy Policy Project segments hydro into "cleaner" and "polluting" based on river system impacts. Some green pricing programs include projects below 30 megawatts, while other programs do not allow hydro at all.

Should wind projects, like hydro, be bifurcated into "low" and "high" impact categories depending on avian impacts and other nonair emission considerations? Prominent environmental groups have raised concerns over certain bird-sensitive wind sites without generating opposition from other environmental groups pushing windpower as a strategy to reduce air emissions.

Should biomass be included as a "green" energy, given that it has direct air emissions and may not be renewable in its most common application—waste burning?

Should geothermal be included as a "green" energy, given that projects deplete over time and release toxics in many, if not most, applications?

Is nuclear "green" since it produces no air emissions—and in this sense is the cleanest of all energy sources in the aggregate—or should waste disposal and the hazards of plant failure be controlling?

Should "green" energies be blended with "nongreen" sources for genres of green pricing, and if so, in what amounts?

Should power generation from natural gas be included as a "green" energy since it is the cleanest of the hydrocarbons and may compare favorably with some major renewable options in as many as five environmental categories: front-end (embedded) air emissions, wildlife disturbance, land usage, noise, and visual blight? The Renewable Energy Policy

Project delineates between "cleaner" new gas technologies and "polluting" old natural gas technologies—and reserves a third "cleanest" category for energy efficiency/conservation, solar, wind, and geothermal (but not hydro or biomass).

Should "clean" coal plants meeting more stringent new source review standards be differentiated from older plants "grandfathered" to lesser requirements in an energy-environmental matrix? Restated, should operational distinctions used for other renewable sources and natural gas also be made for coal plants for the purpose of environmentally based price differentiation?

Should carbon dioxide (CO_2) emissions from hydrocarbons be rewarded or penalized in green-pricing programs? CO_2 fertilization plays a positive role in plant growth and agricultural productivity. Agricultural economists and scientists have calculated net benefits to a moderately warmer, wetter, and CO_2-enriched world. Other analysis has concluded that unregulated CO_2 emissions, potentially elevating global temperatures enough to destabilize the climate, should be penalized.

Can solar technologies be part of green-pricing programs since they are two or three times more expensive than other renewable options?

Who decides? The above issues point toward a potentially intricate color-coded system differentiating energy not only according to its general type, but also according to operational, site-specific attributes. The categorizations would also have to be revised for new scientific data and pollution-control developments. Can green-pricing programs accommodate this complexity and subjectivity short of resorting to government intervention to define what is "green?"

The leading green-pricing arbiter in the early U.S. experience is the nonprofit Center for Resource Solutions. Their Green-e Certification Seal sets an "objective" standard for green energy under the following criteria:

- Fifty percent or more of the volumetric offering must be from newly constructed, but not mandated, renewable capacity from wind, solar, biomass, geothermal, ocean, or small hydro.
- The remaining 50 percent or less of supply must have an average emission rate below the system average for fossil-fuel-emitted sulfur dioxide, nitrogen oxide, and carbon dioxide.
- No new nuclear supply can be added to the generation mix of a blended product.

State regulators across the country have approved the Green-e labeling program, although marketers do not have to receive the seal to operate. Of greater concern for free green choice is an interest by the Federal Trade Commission and the National Association of Attorneys General to set green power guidelines.

Tracking and Labeling Issues

How should "green" electrons be documented for premium-paying consumers? The industry has proposed that green electrons be certified upon generation, creating a paper record that can be traded and ultimately balanced downstream between sales and purchases. Certain environmentalist interest groups have proposed instead that each "green" electron be physically tracked in the transaction chain so that the final consumer gets actual "green" electrons. Industry groups have resisted this proposal, believing any tracking attempt would reduce flexibility and increase transaction costs when a paper system would result in the same impetus for "green" supply. Physics dictates that electrons flow freely; supplies by necessity are commingled and balanced as they move downstream. In other words, the person buying "green" electrons will not necessarily receive those electrons.

As part of green pricing, environmentalists have proposed a labeling system in which all batches of electricity enter the system with specific information about their generation mix and air-emission characteristics. Industry has proposed that labeling just be made for a positive assertion of green power rather than a blanket reporting of mix and emissions—again for cost and flexibility reasons.

OTHER CONCERNS

The environmental community has raised concerns that green pricing could be construed by lawmakers and the public as a substitute for taxpayer and ratepayer subsidies. A major consumer group has complained that green pricing is only for the affluent, and nonparticipants get to "free ride" on the more environmentally conscious users. Independent power marketers have worried about utility green-pricing programs increasing barriers to entry when the market opens to competition.

CONCLUSION

Green pricing, although nominally a free-market support program for consumer environmental preferences, is closely intertwined with government intervention in energy markets and prone to special interest politics. To pass a free market test, regulators and providers would have to establish open, standalone green-pricing programs that do not contain upstream subsidies or require downstream quotas on market participants. In such a world, voluntary labeling standards and common law protections against fraudulent misrepresentation can ensure the integrity of the program.

Green pricing in a true market would have to respect the heterogeneity and fluidity of consumer preferences. Consumer opinion about what is "green" can be expected to evolve and mature, particularly if environmental programs reduce or remove the perceived negative externalities of less expensive energy, relative economics substantially change between energies, or new information becomes available about environmental characteristics of competing energy choices.

HEAT AND HEATING

MAINTAINING CONSTANT TEMPERATURE

The purpose of a heating system is to maintain a constant temperature. To do this, all heating systems—whether it is for heating a small room or a domed stadium—must compensate for heat losses with heat gains. Even though the human body continually loses heat through conduction with the surrounding air and evaporation of water from the surface of the skin, the temperature of the human body is remarkably constant. For every joule of heat flowing from the body, there is one joule produced by mechanisms that convert energy from food. If heat loss quickens (e.g., while one is swimming), the heat regulators in the body convert more energy from food to compensate.

It is the same with a room in a building. Heat is lost through many tiny openings to the outside and through conduction through walls and windows. A heating system makes up this loss keeping the temperature constant. The greater the temperature difference between the inside and outside of a building, the greater is the heat loss. This is why the heating system must provide more heat when you want to maintain a higher temperature as well as when the outside temperature is extremely cold.

FORCED-AIR HEATING SYSTEM

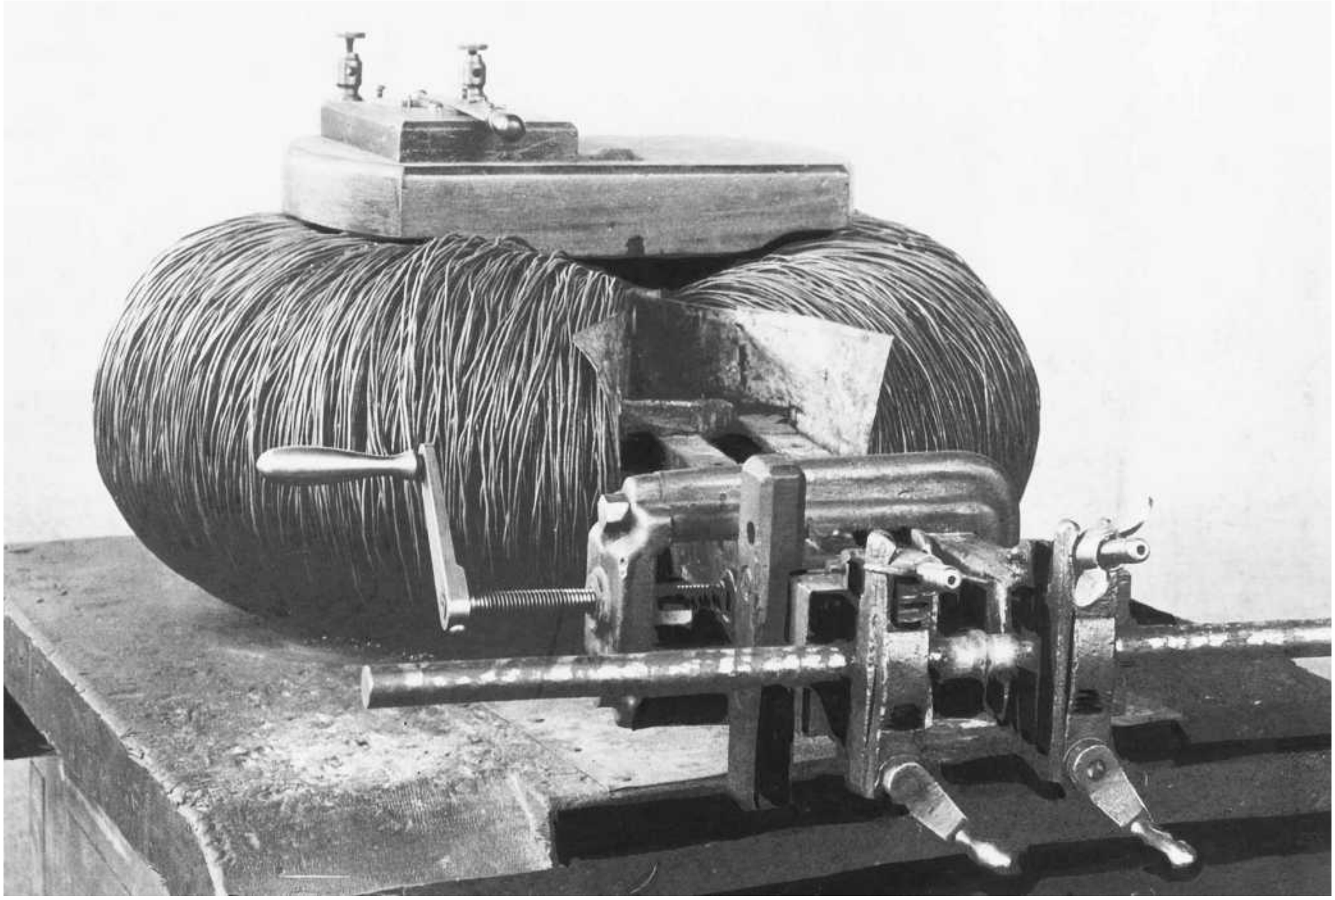
For any substance, the total thermal energy is the sum of the energies of all the molecules. In other words, thermal energy is equal to the energy per molecule multiplied by the number of molecules. A volume of air may have a high temperature, but does not necessarily have a lot of thermal energy because the number of molecules might be small. Conversely, a volume of air may have low temperature and significant thermal energy if many molecules are involved. When a gas is mixed with one at a higher temperature, the mixture will come to a temperature somewhere between the temperatures of the gases being mixed. A forced-air heating system works on this principle by mixing warmer air with the air existing in the room. Sometimes the mixing is uneven in a room producing temperature variations that are annoying to the occupants.

HOT-WATER HEATING SYSTEM

A hot-water heating system forces water into pipes, or arrangements of pipes called registers that warm from contact with warm water. Air in the room warms from contact with the pipes. Usually, the pipes are on the floor of a room so that warmer, less dense air around the pipes rises somewhat like a helium-filled balloon rises in air. The warmer air cools as it mixes with cooler air near the ceiling and falls as its density increases. This process is called convection and the moving air is referred to as convection current. The process of convection described here is pipe-to-air and usually does a better job of heating evenly than in an air-to-air convection system—the circulation of air by fans as in a forced-air heating system.

ELECTRICAL RESISTANCE HEATING

Rather than have pipes warmed by water, some heating systems employ coils of wire or other configurations of metal that are warmed by electric currents. An electric current is a flow of electric charge that may be either positive, negative or a combination of positive and negative. Both positive and negative electric currents are involved in the battery of an



The first electric welding transformer, a device which uses electricity to weld joints of metal using resistance heating. (Corbis Corporation)

automobile. But in a metal the electric current is due to the flow of electrons, which have negative charge. The electrons are components of atoms making up the structure of the metal. In a very similar way, electrons are forced to move through a wire by electrical pressure in somewhat the same way that water molecules are forced to move through a pipe by water pressure. Water molecules encounter resistance as they flow through the pipe and electrons encounter resistance as they flow through a metal wire. The resistance of both the pipe and the wire depends on the dimensions of and obstructions in the pipe and wire. The resistance increases as the length increases but decreases as the diameter increases.

The material selected makes a difference too. For the same length and diameter, a wire made of copper has less resistance than a wire made of aluminum. A current-carrying wire warms because of electrical resistance.

The resistance (R) of a conductor is measured in ohms and the rate of producing heat (power P) in watts. When the conductor is connected to a constant voltage source, as in a household electric outlet, the thermal power produced is given by $P = V^2/R$. Note that if the resistance halves, the power doubles. Some electric toasters produce heat from current-carrying wires that you usually can see. Because the voltage is fixed, typically 120 volts in a house, a desired thermal power is attained by tailoring the resistance of the heating element. The wire chosen must also be able to withstand the high temperature without melting. Typically, the wires are nichrome (an alloy of nickel and chromium) and the electrical resistance is about 15 ohms, making the thermal power about 1,000 watts. One thousand watts means 1,000 joules of heat are produced each second the toaster is operating.

A current-carrying wire converts electric energy to thermal energy with an efficiency of nearly 100 percent. In this sense, electric heating is very efficient. However, the electricity for producing the current in the heater was likely produced by burning coal in a large electric power plant. The efficiency for delivering electric energy to a consumer is about 32 percent due to energy losses in the plant and in transmission to the house. Therefore, the efficiency for converting the thermal energy from burning coal to thermal energy delivered by an electric heater is very low compared to the 80–90 percent efficiency for modern forced-air heating systems burning natural gas. Electric resistance heat is clean and convenient and a good backup for other systems, but as the main source of heat, the economics are very unfavorable.

UNWANTED HEAT PRODUCED IN ELECTRONIC COMPONENTS

Resistors are components of any electronic device such as a computer. If there is need for a resistance of 1,000 ohms, a designer can purchase a resistor having 1,000 ohms resistance. Heat will be produced in the resistor when a current flows through it. If this heat is not transferred away, the temperature will rise and damage the resistor. Usually the designer relies on heat being conducted to surrounding air to keep the resistor from overheating, and the most efficient transfer of heat is by increasing the surface area of the resistor. The physical dimensions of the resistor will be chosen so that the thermal power can be dissipated without damaging the resistor. For example, a 1,000-ohm resistor designed to dissipate 1 watt of heat will be about four times larger than a 1,000-ohm resistor designed to dissipate ¼ watt. In some cases the transfer of heat by direct conduction to the air is not sufficient and the resistor will be mounted onto a metal housing having substantial mass and surface area.

In addition to resistors, the electronic world of computers, calculators, television sets, radios, and high-fidelity systems involves a multitude of electrical components with names like diode, transistor, integrated circuit, and capacitor. Unwanted heat is generated in these components because of ever-present electrical resistance. If the heat is not transferred away, the temperature of the device will increase and, ultimately, be damaged. The heat generated is especially large in transistors in the final stage of a high-fidelity system where the speakers are connected. These so-called power transistors are mounted on a metal structure having substantial mass and surface area to disperse heat transferred to it by the transistor.

Scientists are forever searching for electronic components like transistors that will perform their function with minimum production of heat. In early versions of personal computers the heat produced by the components could not be dissipated by natural means and fans were used to force the heat to the surroundings. Most contemporary personal computers, including laptops, rely on removing heat by natural means and do not require fans.

TRANSMISSION OF ELECTRIC POWER

An electric generator in a modern coal-burning or nuclear-fueled electric power plant converts mechanical energy to electric energy at an impressive efficiency, about 99 percent. The 1 percent of mechanical energy not going into electric energy is lost as heat. When an electrical device is connected to the generator, the power delivered depends on the voltage of the generator and the current in the device. Specifically, electric power (watts) is equal to voltage (volts) times current (amperes). Typically, the voltage is 10,000 volts and the generator is capable of delivering around 1 billion watts of electric power. If the generator were connected directly to wires that transmitted electric power to consumers, the current would be 1,000,000,000 watts per 10,000 volts, which equals 100,000 amperes. The wires through which this current must flow can be tens or hundreds of miles long and have non-negligible electrical resistance. Therefore, heat will be produced and lost. Even if the resistance of the wires was as low as 1 ohm, the energy produced by the generator would be completely lost as heat. The power company uses a device called a transformer to reduce the current in the wires and thereby reduce the heat loss. The transformer is a device that accepts electric power at some voltage and current and then delivers essentially the same power at a different voltage and current. At the power plant the voltage is stepped up from 10,000 volts to around 1,000,000 volts. A voltage of 10,000 volts delivering 100,000 amperes would be changed to a voltage of 1,000,000 volts and current of 1,000 amperes. Because the power lost as heat depends on the square of the electric current, the lower current reduces the heat loss significantly. When the power arrives at a distribution center for consumers, the voltage is stepped down from its transmission value of 1,000,000 volts. For household use this voltage is 120 volts for lights and small appliances and 240 volts for electric stoves, electric clothes dryers, and electric water heaters.

A superconductor is a material having zero electrical resistance. An electric current in a superconductor would produce no heat. To achieve zero resistance the superconductor must be cooled. This temperature has gotten progressively higher over the years. At this writing it is about 100 K, which is about –173°C. As research progresses on superconducting materials there is hope that they can be used in the transmission of electric energy. Even though there would be an energy expenditure involved in cooling the transmission lines, it would be more than offset by the savings accruing from not having power lost to heat generated in the transmission lines.

COOLING TOWERS AND LOW-GRADE HEAT

You can do work by rubbing your hands together and all the work will be converted to heat. A food mixer can churn through water and do work and all the work will be converted to heat. But a heat engine can only convert a portion of the heat it takes in to work. Nowhere is this more evident than in the steam turbines driving electric generators in electric power plants. The clouds seen emanating from the giant towers so noticeable at electric power plants are graphic evidence of heat being transferred to the environment.

High temperature steam pounding on the blades of a turbine causes the blades to rotate. After passing by the blades the cooler steam condenses to liquid water. Condensation liberates energy and if this energy is not removed, the condenser part of the system warms up. The heat liberated at the condenser is removed by circulating water in pipes in contact with the condenser. Each second the water must remove more than a billion joules of heat, so there is a substantial amount of thermal energy absorbed by the cooling water. The purpose of a cooling tower is to transfer the thermal energy in the cooling water to the air environment by splashing the warm water on the floor of the tower. A portion of the water evaporates and is carried into the air environment by a natural draft created by the chimney-like structure of the tower. The vapor cloud seen at the top of a cooling tower is from the water that has been evaporated.

Although there is significant thermal energy in the water circulating from the condenser of a turbine, it is only 10–15°C higher than the input water. It is a case of having a lot of energy by having a lot of molecules. This relatively low-temperature water is not suitable for heating buildings. Furthermore, the electric power plant is usually several miles removed from buildings where the warm water could be used. By the time that the heated water would reach the building, most of the heat energy would be lost to the environment. Locating industries and communities near plants would make it feasible. One suggestion for using the warm water is to stimulate plant growth in nearby greenhouses.

Remember that heat is lost to the environment in virtually all energy conversion processes. The more heat that is lost the less desirable the form of energy and the less efficient the process. A 100-watt fluorescent lightbulb is more efficient than a 100-watt incandescent bulb because more of the electric energy goes into radiant energy and less into heat. Modern electronics using transistor technology is enormously more energy efficient than the original vacuum tube technology. The total elimination of heat loss can never be achieved, but scientists and engineers work diligently to find better ways of minimizing heat loss and successes have been achieved on many fronts.

HEAT PUMPS

A heat pump is a thermodynamic heating/refrigerating system used to transfer heat. Cooling and heating heat pumps are designed to utilize the heat extracted at a low temperature and the heat rejected at a higher temperature for cooling and heating functions, respectively.

The household refrigerator can provide a simple analogy. A refrigerator is actually a one-way heat pump that transfers heat from the food storage compartment to the room outside. In so doing, the inside of the refrigerator becomes progressively cooler as heat is taken out. In a closed room, the heat coming out of the refrigerator would make the room warmer. The larger the refrigerator is, the greater the potential amount of heat there is to transfer out. If the refrigerator door were open to the outdoors, there would be an almost unlimited amount of heat that could be transferred to the inside of a dwelling. Thus it is possible to design a refrigeration system to transfer heat from the cold outdoors (or any other cold reservoir, such as water or the ground) to the insides of a building (or any medium that it is desired to heat).

Heat pumps can move heat energy between any form of matter, but they are typically designed to utilize the common heating and cooling media, i.e., air or water. Heat pumps are identified and termed by transfer media. Thus terms air-to-air, water-to-air, or air-to-water are commonly used. Most heat pumps are designed to transfer heat between outside air and inside air, or, in the case of so-called geothermal or ground-source heat pumps, between the ground or well water and air. The principle application of heat pumps is ambient heating and cooling in buildings.

There are three types of heat pump applications: heating, cooling or heating and cooling. “Heating only” heat pumps are designed to transfer heat in one direction, from a cold source, such as the outdoors, to the inside of a building, or to a domestic hot water plumbing system, or to some industrial process. There is no term “cooling only heat pump,” as the term would simply be describing what is commonly referred to as an air conditioner or cooling system.

“Heating and cooling” heat pumps have refrigeration systems that are reversible, permitting them to operate as heating or cooling systems. An analogy would be a window air conditioner that was turned around in winter, so that it was cooling the outside and blowing hot air inside. Most heat pumps in use are of the heating and cooling type, and are used to heat residences, or commercial and industrial buildings. Residences consume the bulk of those sold: in 1999 about a quarter of new single-family homes were equipped with a heating and cooling heat pump.

Most heat pumps utilize a vapor-compression refrigeration system to transfer the heat. Such systems employ a cycle in which a volatile liquid, the refrigerant, is vaporized, compressed, liquefied, and expanded continuously in an enclosed system. A compressor serves as a pump, pressurizing the refrigerant and circulating it through the system. Pressurized refrigerant is liquefied in a condenser, liberating heat. Liquid refrigerant passes through an expansion device into an evaporator where it boils and expands into a vapor, absorbing heat in the process. Two heat exchangers are used, one as a condenser, and one as an evaporator. In the case of an air-to-air heat pump, one heat exchanger is placed outside, and one inside. In a ground-source heat pump, the outdoor heat exchanger is placed in contact with well water, a pond, or the ground itself. In both cases, the refrigerant flow is made reversible so that each heat exchanger can be used as an evaporator or as a condenser, depending on whether heating or cooling is needed. The entire system is electrically controlled. (See Figures 1 and 2.)

Some heat pumps, called thermoelectric heat pumps, employ the Peltier effect, using thermocouples. The Peltier effect refers to the evolution or absorption of heat produced by an electric current passing across junctions of two suitable, dissimilar metals, alloys, or semiconductors. Presently, thermoelectric heat pumps are used only in some specialized applications. They have not been developed to a point to make them practical for general heating and cooling of buildings.

The energy efficiency of heat pumps is measured by calculating their coefficient of performance (COP), the ratio of the heat energy obtained to the energy input. The capacity of modern heat pumps in the United States is rated in British thermal units per hour (Btu/h). The COP at a given operating point can be calculated by dividing the Btu/h output of the system by the energy input in Btu/h. Since system input for most heat pumps is electricity measured in watt-hours, the watt figure is multiplied by a conver-

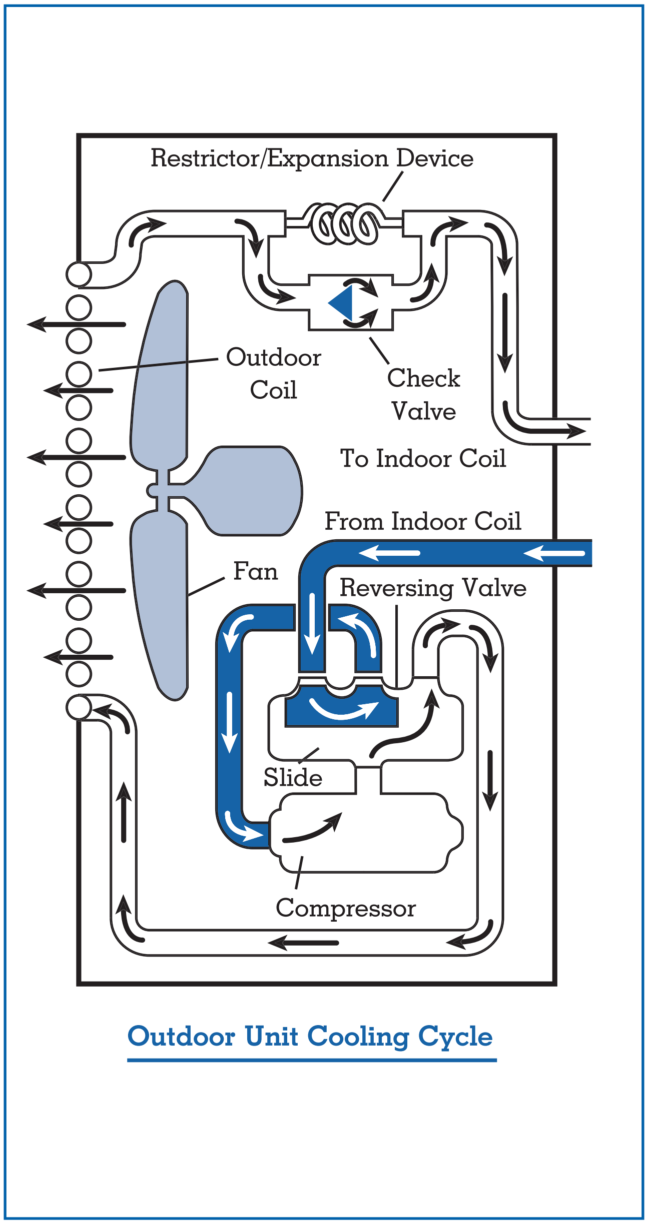

Figure 1.

SOURCE: Air Conditioning and Refrigeration Institute

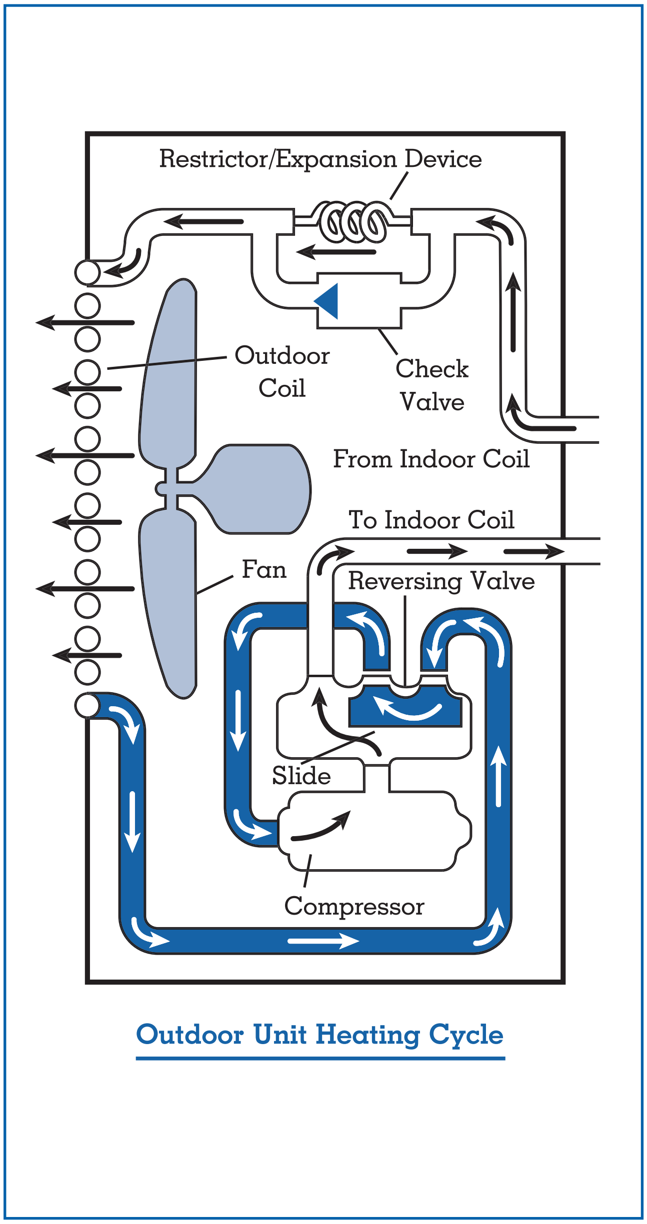

Figure 2.
Schematic of an outdoor heat pump's heating cycle.
SOURCE: Air Conditioning and Refrigeration Institute

sion factor of 3.412 to obtain the energy input in Btu/h.

There are two major factors that impact the COP: temperature difference and system component efficiency. A heat pump requires energy to move heat from a lower temperature to a higher one. As the difference in the two temperatures increases, more energy is required. The COP of a heat pump is higher when the temperature difference is less, and less energy is consumed to transfer a given amount of heat. Thus the COP of a heat pump varies during its operation, and is relative to the system operating point, the temperature of the medium heat is transferred from, and the temperature of the medium it is transferred to. Comparison of the COP of two different systems is meaningless unless the operating points are the same. For this reason, although heat pump efficiency continues to improve, specific historical comparisons of heat pump efficiencies are difficult because system operation data was recorded at different operating points.

Air-to-air heat pumps are particularly prone to varying COPs, due to fluctuating outdoor weather conditions. In the winter, the COP decreases as the outdoor temperature decreases, due to the need for the system to transfer heat energy at greater temperature differences. The heat output decreases as the outdoor temperature drops at the same time that the heating needs of the building are increasing. In fact, the COP may drop so low that the heat pump cannot meet the thermal needs of a building. For this reason an auxiliary heat source such as electric resistance heaters or a fossil-fueled furnace is needed in geographic areas that have cold winters. The COP of air-to-air heat pumps is further reduced by the use of defrost cycles needed to clear the outdoor heat exchanger of frost buildup when the air temperature drops below about 40°F. During defrost, the refrigeration system is reversed into comfort cooling mode, heating the outdoor heat exchanger to melt the frost. Since the defrost mode is cooling the indoor air, supplemental heat is usually necessary to maintain comfort levels, reducing the overall COP of the system. The reduction varies with the duration of the defrost.

In the summer, the COP of an air-to-air heat pump decreases as the outdoor temperature rises, reducing the cooling capacity. Normally the thermal needs of the building are met since it is common practice to size a heat pump so that it will deliver adequate cooling capacity in all but the most extreme summer conditions. The winter heating capacity of the system is then determined by this tradeoff, and if the heating capacity is inadequate, supplemental electric or fossil fuel heat is required.

Because deep ground temperature has little change, geothermal heat pumps using well water function at a fairly stable COP. Geothermal types using the ground for thermal mass will see some variance in COP depending on the dryness of the soil. Wet ground conducts more heat than dry and theoretical soil conductivity may vary up to 1,000 percent. For this reason the ground loop heat exchanger should be buried deep enough to minimize soil moisture fluctuations.

System components can affect the COP because their design and performance can vary. In vapor-compression systems, the transfer efficiency of the heat exchangers and the energy efficiency of the compressor, and how these components are matched, help determine the operating COP. Compressors are performance-optimized for narrow operating ranges. If the optimization is done for heating, cooling operation may suffer. The opposite is also true.

The operating condition of the components also affects the COP. For example, if the heat exchangers become clogged or corroded, or if a homeowner fails to change a furnace filter, the operating COP of a heat pump will decrease. Any heating and cooling system will suffer some performance degradation once it has been put into use. The amount of degradation depends on the conditions under which the system has to operate, as well as how carefully system components are maintained.

Most heat pumps for residences are unitary systems; that is, they consist of one or more factory-built modules. Larger buildings may require built-up heat pumps, made of various system components that require engineering design tailored for the specific building. Sometimes, multiple unitary units are used in large buildings for ease of zone control; the building is divided up into smaller areas that have their own thermostats.

HISTORY

Oliver Evans proposed the closed vapor-refrigeration cycle in 1805 in *The Young Steam Engineer's Guide*. Evans noted: "Thus it appears possible to extract the latent heat from cold water and to apply it to boil other water." By 1852 William Thompson (Lord Kelvin) had proposed that a refrigeration system be used to either cool or heat the air in buildings, and outlined the design of such a machine. In Austria after 1855 Peter Ritter Von Rittenger constructed working heat pumps that were said to be 80 percent efficient. These devices were used to evaporate salt brine, and similar devices were constructed in Switzerland after 1870.

A theoretical discussion of the heat pump appeared in the *Journal of the Franklin Institute* in 1886. T. G. N. Haldane of Scotland comprehensively pursued the application of heat pumps to the heating of buildings after the mid-1920s. Haldane tested air-to-water heat pump systems in his home and concluded that the vapor-compression refrigeration cycle could, under certain conditions, provide a more economical means to heat buildings and swimming pools than fossil fuels. Haldane further proposed using a reversed cycle so the heat pump could be used to cool buildings or make ice. Haldane's heat pump had a coefficient of performance (COP) between 2 and 3, depending on operating conditions.

During the 1930s and 1940s a number of residential and commercial heat pump installations were made in the United States. They were of all types, and the heating COPs of these systems, where results were known, seem to have ranged from 2 to 5. Hundreds of articles and papers were published discussing the theory, application, and installed examples of heat pumps. Despite this activity, most heating systems installed were conventional fossil-fuel furnaces and boilers due to their lower first cost, broad acceptance, and well-established manufacturing, sales, and service infrastructure.

Comfort cooling was one benefit of a heat pump that was typically cited in the literature of the 1930s and 1940s. However there was not a great consumer demand for general comfort cooling at that time, particularly for residences. True, there were isolated pockets of interest, as in movie theaters and some commercial buildings, but genuine mass consumer demand for comfort cooling did not develop until the mid-twentieth century. Thus, there was no financial incentive for mass production of unitary comfort cooling air conditioners in the 1930s and 1940s, and therefore no incentive to produce unitary heat pumps. There were a few isolated attempts, such as a package heat pump marketed by DeLaVergne in 1933, but the efforts were short-lived.

Electric utilities did have a vested financial interest in heat pumps, since most designs used electricity for heating and cooling. But utilities were not manufacturers or consumers. Despite their attempts to promote heat pumps with articles and showcase system installations, they failed to create the demand for the product.

By the 1960s, central residential air conditioning was becoming increasingly popular. Equipment had developed to the point that a number of manufacturers were producing and marketing unitary air conditioning equipment. Some of these manufacturers did attempt to resurrect the idea of applying the heat pump to residential, store, and small office heating and cooling. Systems were designed and marketed, but suffered dismally in the market. System components used did not stand up to the demands of summer and winter operation over wide weather conditions. Compressors and reversing valves in particular saw enough failures that most manufacturers withdrew their products from the marketplace. The air-to-air heat pumps of the 1960s used timed defrost cycles, initiating defrosts even when they were not necessary. Thus the system efficiency was unnecessarily reduced.

Spurred on by the energy crisis of the 1970s interest in heat pumps renewed. Rising price of fossil fuels caused manufacturers to take another look at heat pumps. Owners of "all electric homes," stung by the high cost of electric heat, were looking for a way to reduce heating costs with minimal existing heating system redesign. A heat pump could save 30 to 60 percent of the cost of electric resistance heating.

Remembering the problems of the 1960s, manufacturers redesigned system components. The system efficiency was generally higher than in the 1960s because system components were more efficient. Most air-to-air heat pumps of the period used a demand-controlled defrost cycle, further increasing overall energy efficiency. By the mid-1970s most of the major manufacturers of unitary air conditioning equipment were offering heat pumps. They were particularly popular in areas of moderate winters where air-to-air heat pumps could operate at higher COPs.

Conventional heat pumps continued to be available through the 1970s to the 1990s. The trend has been toward progressively higher energy efficiencies. The average efficiency of new heat pumps increased 60 percent (based on cooling performance) between 1976 and 1998. Minimum efficiencies were mandated for residential heat pumps in 1987 and for commercial equipment in 1992, a significant factor contributing to the rise in efficiency over the past twenty years. For heat pumps used in commercial buildings, the efficiency standards were derived from the model standards published by the American Society of Heating, Refrigerating and Air Conditioning Engineers (ASHRAE). The U.S. Department of Energy may review these standards in the next few years and setting more stringent standards (for both residential and commercial heat pumps) if technically and economically feasible.

CURRENT PRACTICE AND THE FUTURE

Heat pump systems are now rated with a Heating Seasonal Performance Factor (HSPF) and a seasonal energy efficiency ratio (SEER). The HSPF is calculated by the annual heating system output in BTU by the heating electricity usage in watt-hours. The SEER is an estimate of annual cooling output in Btu divided by the cooling electricity usage in watt-hours. The HSPF and SEER are calculated at specific rating points, standardized by the Air Conditioning and Refrigeration Institute (ARI), an industry trade organization that performs testing advocacy, and education. ARI conducts a certification program, participated in by almost all manufacturers of heat pumps. The program gives the consumer access to unbiased and uniform comparisons among various systems and manufacturers. Rating various systems at the same operating point allows accurate comparisons between systems. Heat pumps introduced in 1999 have an NSPF of 6.8 or greater and a SEER of 10.0 or greater, with high efficiency units having an HSPF of as much as 9 and a SEER of 13 or greater.

There is more interest than ever in the geothermal heat pumps. The cost of such systems has decreased with use of plastic piping for water or ground loops. Geothermal systems are proving particularly advantageous in colder winter areas, since ground temperature is much higher than outdoor temperatures. In addition, there is no efficiency-robbing defrost cycle that is necessary in air-to-air heat pumps.

New compressor technology employing rotary scroll type compressors is replacing previously-used reciprocating technology. Scroll compressors operate at higher efficiencies over wider operating conditions. Heat pumps employing scroll compressors use less supplemental heat at low outdoor temperatures. Electrical and electronic technology are making variable-capacity compressors cost-effective for the next century. Compressor performance can be optimized for a wider operation range, and matching compressor capacity to the actual demand for heating or cooling increases the system efficiency, saving energy. Application of microprocessors to control systems further permits fine-tuning of system operation. Energy efficiency is also being increased by development of higher efficiency electric motors for compressors and fans.

Increased environmental awareness will no doubt spur increasing interest in solar-assisted heat pumps in the future. Such systems can operate at higher heating COPs than more conventional heat pumps. A solar-assisted heat pump system uses a solar heating system in parallel with a conventional heat pump. The solar heating system reduces the operating time of the heat pump, and also reduces the need for supplemental electric or fossil-fuel heating during colder weather.

HEAT TRANSFER

Heat transfer is the energy flow that occurs between bodies as a result of a temperature difference. There are three commonly accepted modes of heat transfer: conduction, convection, and radiation. Although it is common to have two or even all three modes of heat transfer present in a given process, we will initiate the discussion as though each mode of heat transfer is distinct.

CONDUCTION

When a temperature difference exists in or across a body, an energy transfer occurs from the high-temperature region to the low-temperature region. This heat transfer, q, which can occur in gases, liquids, and solids, depends on a change in temperature, ΔT, over a distance, Δx (i.e., ΔT/Δx) and a positive constant, k, which is called the thermal conductivity of the material. In equation form, the rate of conductive heat transfer per unit area is written as

$$q/A = -k\Delta T/\Delta x$$

where q is heat transfer, A is normal (or perpendicular to flow of heat), k is thermal conductivity, ΔT is the change in temperature, and Δx is the change in the distance in the direction of the flow. The minus sign is needed to ensure that the heat transfer is positive when heat is transferred from the high-temperature to the low-temperature regions of the body.

The thermal conductivity, k, varies considerably for different kinds of matter. On an order-of-magnitude basis, gases will typically have a conductivity range from 0.01 to 0.1 W/(m–K) (0.006 to 0.06 Btu/h-ft-°F), liquids from 0.1 to 10 W/(m–K) (0.06 to 6 Btu/h-ft-°F), nonmetallic solids from 0.1 to 50 W/(m–K) (0.06 to 30 Btu/h-ft-°F), and metallic solids from 10 to 500 W/(m–K) (6 to 300 Btu/h-ft-°F). Obviously, gases are among the lowest conductors of thermal energy, but nonmetallic materials such as foamed plastics and glass wool also have low values of thermal conductivity and are used as insulating materials. Metals are the best conductors of thermal energy. There is also a direct correlation between thermal conductivity and electrical conductivity—that is, the materials that have a high thermal conductivity also have a high electrical conductivity. Conductive heat transfer is an important factor to consider in the design of buildings and in the calculation of building energy loads.

CONVECTION

Convective heat transfer occurs when a fluid (gas or liquid) is in contact with a body at a different temperature. As a simple example, consider that you are swimming in water at 21°C (70°F), you observe that your body feels cooler than it would if you were in still air at 21°C (70°F). Also, you have observed that you feel cooler in your automobile when the air-conditioner vent is blowing directly at you than when the air stream is directed away from you. Both of these observations are directly related to convective heat transfer, and we might hypothesize that the rate of energy loss from our body due to this mode of heat transfer is dependent on not only the temperature difference but also the type of surrounding fluid and the velocity of the fluid. We can thus define the unit heat transfer for convection, q/A, as follows:

$$q/A = h(T_i - T_\infty)$$

where q is the heat transfer per unit surface area, A is the surface area, h is the convective heat transfer coefficient W/(m^2 – K), T_i is the temperature of the body, and T_∞ is the temperature of the fluid.

Thus convective heat transfer is a function of the temperature difference between the surface and the fluid; the value of the coefficient, h, depends on the type of fluid surrounding the object, and the velocity of the fluid flowing over the surface. Convective heat transfer is often broken down into two distinct modes: free convection and forced convection. Free convection is normally defined as the heat transfer that occurs in the absence of any external source of velocity—for example, in still air or still water. Forced convection has some external source, such as a pump or a fan, which increases the velocity of the fluid flowing over the surface. Convective heat transfer coefficients range widely in magnitude, from 6W/(m^2 – K) (1 Btu/h-ft^2-°F) for free convection in air, to more than 200,000 W/(m^2 – K) (35,000 Btu/h-ft^2-°F) for pumped liquid sodium. Convective heat transfer plays a very important role in such energy applications as power boilers, where water is boiled to produce high-pressure steam for power generation.

RADIATION

Radiative heat transfer is perhaps the most difficult of the heat transfer mechanisms to understand because so many factors influence this heat transfer mode. Radiative heat transfer does not require a medium through which the heat is transferred, unlike both conduction and convection. The most apparent example of radiative heat transfer is the solar energy we receive from the Sun. The sunlight comes to Earth across 150,000,000 km (93,000,000 miles) through the vacuum of space. Heat transfer by radiation is also not a linear function of temperature, as are both conduction and convection. Radiative energy emission is proportional to the fourth power of the absolute temperature of a body, and radiative heat transfer occurs in proportion to the difference between the fourth power of the absolute temperatures of the two surfaces. In equation form, q/A is defined as:

$$q/A = \sigma\,(T_1^4 - T_2^4)$$

where q is the heat transfer per unit area, A is the surface area, σ is the Stefan-Boltzmann constant 5.67×10^{-8} W/(m^2 – K^4), T_1 is the temperature of surface one, and T_2 is the temperature of surface two.

In this equation we are assuming that all of the energy leaving surface one is received by surface two, and that both surfaces are ideal emitters of radiant energy. The radiative exchange equation has to be modified to account for real situations—that is, where the surfaces are not ideal and for geometrical arrangements in which surfaces do not exchange their energies only with each other. Two factors are usually added to the above radiative exchange equation to account for deviations from ideal conditions. First, if the surfaces are not perfect emitters, a factor called the emissivity is added. The emissivity is a number less than 1, which accounts for the deviation from nonideal emission conditions. Second, a geometrical factor called a shape factor or view factor is needed to account for the fraction of radiation leaving a body that is intercepted by the other body. If we include both of these factors into the radiative exchange equation, it is modified as follows:

$$q/A = F\varepsilon F_G\varepsilon\,(T_1^4 - T_2^4)$$

where $F\varepsilon$ is a factor based on the emissivity of the surface and F_G is a factor based on geometry.

The geometric factor can be illustrated by considering the amount of sunlight (or radiative heat) received by Earth from the Sun. If you draw a huge sphere with a radius of 150 million km (93 million miles) around the sun that passes through Earth, the geometric factor for the Sun to Earth would be the ratio of the area on that sphere's surface blocked by Earth to the surface area of the sphere. Obviously, Earth receives only a tiny fraction of the total energy emitted from the Sun.

Other factors that complicate the radiative heat transfer process involve the characteristics of the surface that is receiving the radiant energy. The surface may reflect, absorb, or transmit the impinging radiant energy. These characteristics are referred to as the reflectivity, absorbtivity, and transmissivity, respectively, and usually are denoted as ρ, α, and τ. Opaque surfaces will not transmit any incoming radiation (they absorb or reflect all of it), but translucent and clear surfaces will transmit some of the incoming radiation. A further complicating factor is that thermal radiation is wavelength-dependent, and one has to know the wavelength (spectral) characteristics of the material to determine how it will behave when thermal radiation is incident on the surface. Glass is typical of a material with wavelength-dependent properties. You have observed that an automobile sitting in hot sunlight reaches a temperature much higher than ambient temperature conditions. The reason is that radiant energy from the Sun strikes the car windows, and the very-short-wavelength radiation readily passes through the glass. The glass, however, has spectrally dependent properties and absorbs almost all the radiant energy emitted by the heated surfaces within the car (at longer wavelengths), effectively trapping it inside the car. Thus the car interior can achieve temperatures exceeding 65°C (150°F). This is the same principle on which a greenhouse works or by which a passively heated house is warmed by solar energy. The glass selectively transmits the radiation from the Sun and traps the longer-wavelength radiation emitted from surfaces inside the home or the greenhouse. Specially made solar glasses and plastics are used to take advantage of the spectral nature of thermal radiation.

R VALUES

Many everyday heat flows, such as those through windows and walls, involve all three heat transfer mechanisms—conduction, convection, and radiation. In these situations, engineers often approximate the calculation of these heat flows using the concept of R values, or resistance to heat flow. The R value combines the effects of all three mechanisms into a single coefficient.

R Value Example: Wall

Consider the simple wall consisting of a single layer of Sheetrock, insulation, and a layer of siding as shown in Figure 1. We assume it is a cool autumn evening when the room air is 21°C (70°F) and the outside air is 0°C (32°F), so heat will flow from inside the wall to the outside. Convective and radiative heat transfer occurs on both the inside and outside surfaces, and conduction occurs through the Sheetrock, insulation, and siding. On the outside, the convective heat transfer is largely due to wind, and on the inside of the wall, the convective heat transfer is a combination of natural and forced convection due to internal fans and blowers from a heating system. The room surfaces are so close to the outside wall temperature that it is natural to expect the radiative heat transfer to be very small, but it actually accounts for more than half of the heat flow at the inside surface of the wall in this situation. When treated using the R value concept, the total R value of the wall is the sum of individual R values due to the inside surface, the Sheetrock, the insulation, the siding, and the outer surface. Hence the heat flow through this wall may be written as

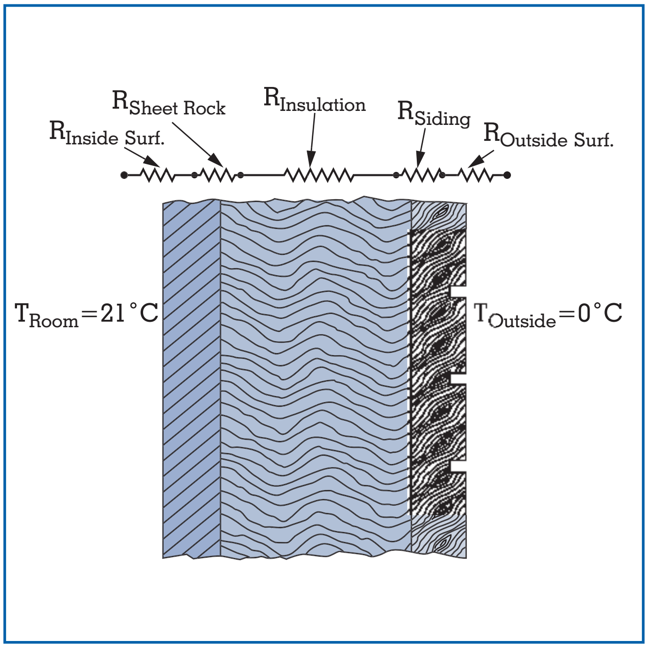

Figure 1.
Schematic diagram of a simple wall.

$$Q = A(T_{\text{room}} - T_{\text{outside}})/(R_{\text{inside surf.}} + R_{\text{Sheetrock}} + R_{\text{insulation}} + R_{\text{siding}} + R_{\text{outside surf.}})$$

The resistances of the Sheetrock, siding, and insulation may be viewed as conductive resistances, while the resistance at the two surfaces combine the effects of convection and radiation between the surface and its surroundings. Typical values for these resistances in units of $(\text{W/m}^2 - \text{W/m}^2\text{-°C})^{-1}$ $((\text{Btu/h-ft}^2\text{-°F})^{-1})$ are as follows:

$R_{\text{inside surf}}$	= 0.12	(0.68)
$R_{\text{Sheetrock}}$	= 0.08	(0.45)
$R_{\text{insulation}}$	= 1.94	(11.0)
R_{siding}	= 0.14	(0.80)
$R_{\text{outside surf}}$	= 0.04	(0.25)
R_{total}	= 2.32	(13.18)

For this case, the heat flow through the wall will be (21–0)°C/2.32 $(\text{W/m}^2\text{-°C})^{-1}$ = 9.05 W/m^2 (2.87

Btu/h-ft^2). While the surfaces, Sheetrock, and siding each impede heat flow, 80 percent of the resistance to heat flow in this wall comes from the insulation. If the insulation is removed, and the cavity is filled with air, the resistance of the gap will be 0.16 (W/m^2-°C)$^{-1}$ (0.9 (Btu/h-ft^2-°F)$^{-1}$) and the total resistance of the wall will drop to 0.54 (W/m^2-°C)$^{-1}$ (3.08 (Btu/h-ft^2-°F)$^{-1}$) resulting in a heat flow of 38.89 W/m^2 (12.99 Btu/h-ft^2). The actual heat flow would probably be somewhat different, because the R-value approach assumes that the specified conditions have persisted long enough that the heat flow is "steady-state," so it is not changing as time goes on. In this example the surface resistance at the outer wall is less than half that at the inner wall, since the resistance value at the outer wall corresponds to a wall exposed to a wind velocity of about 3.6 m/s (8 mph), which substantially lowers the resistance of this surface to heat flow.

If the wall in the example had sunlight shining on it, the heat absorbed on the outer surface of the wall would reduce the flow of heat from inside to outside (or could reverse it, in bright sunshine), even if the temperatures were the same.

R Value Example: Window

A window consisting of a single piece of clear glass can also be treated with R-value analysis. As with the wall, there is convective and radiative heat transfer at the two surfaces and conductive heat transfer through the glass. The resistance of the window is due to the two surface resistances and to the conductive resistance of the glass, R_{glass}. For typical window glass, R_{glass} = 0.003 (W/m^2-°C)$^{-1}$ (0.02 (Btu/h-ft^2-°F)$^{-1}$) so the total resistance of the window is R_{window} = (0.12 + 0.003 + 0.04) (W/m^2-°C)$^{-1}$ = 0.163 (W/m^2-°C)$^{-1}$ (0.95 (Btu/h-ft^2-°F)$^{-1}$). Thus the heat flow will be q = (21 – 0)°C/0.163(W/m^2-°C)$^{-1}$ = 128.8 W/m^2 (40.8 Btu/h-ft^2), or fourteen times as much as that through the insulated wall. It is interesting to note that the heat flow through an ancient window made from a piece of oilskin, or even a "window" made from a piece of computer paper, would not increase by more than 2 percent from that of the glass window, because the resistance of the glass is so small.

When sunlight is shining through a window, the heat transfer becomes more complicated. Consider Figure 2.

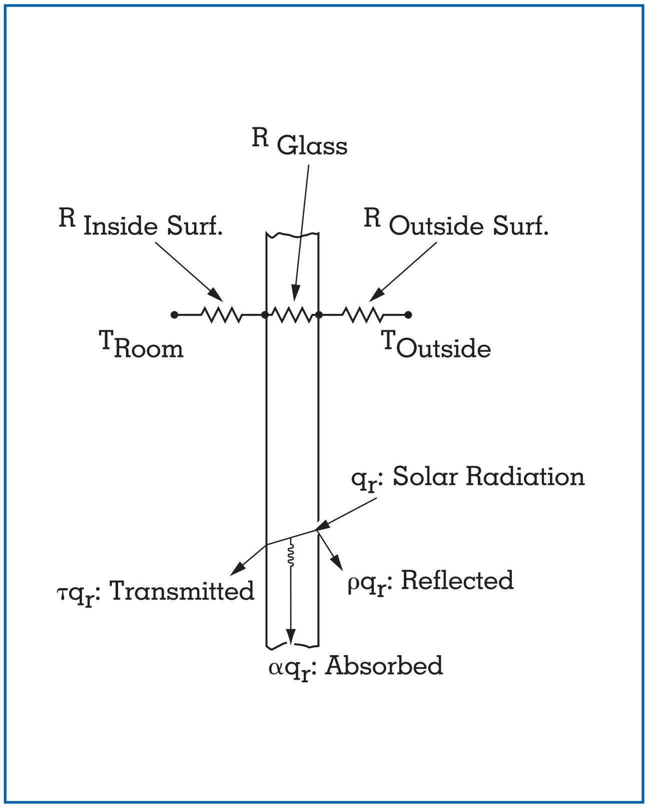

Figure 2.
Schematic diagram of a window.

Suppose the outdoor and indoor temperatures are still 0°C and 21°C, but the window now has 600 W/m^2 (190 Btu/ft^2-h) of sunlight striking it (q_r), typical of a fairly sunny window on an autumn day. About 8 percent (ρq_r) will be reflected back into the atmosphere, about 5 percent (αq_r), or 30 W/m^2, will be absorbed in the glass, and the remaining 87 percent (τq_r), or 522W/m^2, will be transmitted into the room, providing light before it strikes the walls, floor, ceiling, and furnishings in the room. Again, some will be reflected, providing indirect lighting, and the remainder will be absorbed and converted to heat. Eventually, all—except any that may be reflected back out the window—will be absorbed and converted to heat in the room. Thus the amount of sunlight coming through the window is about four times as great as the amount of heat flowing outward. The 30 W/m^2 that is absorbed in the glass heats the glass slightly, reducing the conductive heat flow through the glass to 121 W/m^2, so the net effect of the sunlight is to result in the window providing 401 W/m^2 of heating (522–121) to the room instead of losing 128 W/m^2.

In this example, we have assumed that the outside temperature is lower than inside; therefore the heat flow due to the temperature difference is from inside to outside. In the summer it will be hotter outside, and heat will flow from outside to inside, adding to the heat gained from the sunlight. Because windows represent a large source of heat gain or the heat loss in a building, a number of schemes are used to reduce the heat gains in summer and heat losses in winter. These include the use of double (two glass panes) or triple glazing for windows. The glass is separated by an air space, which serves as an added insulating layer to reduce heat transfer. Reflective films are used to reduce heat gain from sunlight. Some of these films also serve to reduce the heat transfer by longwave (nonsolar) radiation as well.

There are numerous other examples where heat transfer plays an important role in energy-using systems. One is the production of steam in large boilers for power production, where steam is boiled from water. Hot combustion gases transfer heat to the water by radiation, conduction through the pipe walls, and convection. The boiling of the water to produce steam is a special case of convective heat transfer where very high heat transfer coefficients are obtained during the boiling process. Another very practical example of convective cooling is in automobiles. The “radiator” is, in fact, a “convector” where pumped water is forced through cooling tubes and is cooled by air forced over the tubes and fins of the radiator. Forced convective heat transfer occurs at both the air side and the water side of the “radiator.” Cooling towers and air-conditioning coils are other practical examples of combined heat transfer, largely combined conduction and convection.

While heat transfer processes are very useful in the energy field, there are many other industries that rely heavily on heat transfer. The production of chemicals, the cooling of electronic equipment, and food preparation (both freezing and cooking) rely heavily on a thorough knowledge of heat transfer.

HEAVISIDE, OLIVER
(1850–1925)

Oliver Heaviside was born May 13, 1850, in London, England. He was a physicist and mathematician whose theoretical work played a large part in the understanding of radio transmission and long-distance telephony. Educated at Camden House School in London, Heaviside came fifth in the College of Preceptors examination out of five hundred pupils. He left school in 1866 and continued to study. He learned Morse code and studied electricity and languages. In 1868 he went to Denmark and became a telegraph operator, and in 1870 he was appointed Chief Telegraph Operator.

In 1871 Heaviside returned to England to take up a post with the Great Northern Telegraph Company dealing with overseas traffic. In 1875 he had to leave the job due to increasing deafness. Heaviside was encouraged to continue his electrical research by his uncle, Charles Wheatstone, who with W. F. Cooke patented the electric telegraph in 1837, and who later devised the Wheatstone bridge, an electrical network for measuring resistance.

In 1872 Heaviside's first paper, “Comparing of Electromotive Forces,” was published. Heaviside's second paper was published in 1873 and attracted the attention of Scottish physicist James Clerk Maxwell. In 1873 Heaviside was inspired by Maxwell's treatise on electricity and magnetism. It took Heaviside several years to fully understand Maxwell's book, which he then set aside to follow his own course of thinking. Finding Maxwell's conventional mathematics difficult to apply to practical matters, Heaviside introduced a simpler treatment that, in his opinion, did not impair accuracy. It proved to be controversial. His proofs did not conform to the standards of the time and his methods on partial differential equations had varying success.

In 1874 Heaviside established the ordinary symbolic method of analyzing alternating current circuits in common use today. It was a technique developed about fifteen years before AC came into commercial use. He emphasized the role of metallic circuits as guides, rather than conductors of AC currents. He discussed in detail causes of line distortion and suggested ways of alleviating it.

Between 1880 and 1887 Heaviside developed his operational form of calculus, a branch of mathematics that permits the manipulation of varying quantities applicable to practical problems, including such matters as electrical circuits with varying voltages and currents. Heaviside received a great honor in 1891 when he was elected a Fellow of The Royal Society in recognition of his work on electromagnetic waves. He was later the first recipient of the Society's Faraday Medal. The first volume of his great work "Electromagnetic Theory" was published in 1893 and a second volume in 1899. A third volume was published in 1912, but he died before completing the fourth.

In 1902 Heaviside's famous prediction about an ionized layer in the atmosphere that would deflect radio waves was published in an article titled "Telegraphy," in the tenth edition of "Encyclopaedia Britannica." The idea came when he was considering the analogy between the movement of electric waves along a pair of conducting wires and over a conducting earth. Discussing the possibility of radio waves being guided around a curved path he suggested: "There may possibly be a sufficiently conducting layer in the upper air. If so, the waves will, so to speak, catch on to it more or less. Then guidance will be by the sea on one side and the upper layer on the other." The layer was first named the Heaviside Layer and later the Kennelly-Heaviside Layer, as a similar prediction had been made around the same time by Arthur Kennelly at Harvard University. The hypothesis was proved correct in 1924 when radio waves received from the upper atmosphere showed that deflection of upward waves took place at a height of approximately 100 kilometers.

Heaviside made a significant contribution to electrical communications when he advocated the introduction of additional inductance in long-distance telephony cables although there was then no practical means to add it. His idea was eventually patented in 1904 by Michael Campbell of AT&T after Heaviside and George Pupin of Columbia University had shown it was possible to apply inductance in the form of uniformly spaced loading coils. By 1920 engineers had installed such loading on thousands of miles of cable, particularly in the United States.

During his lifetime, Heaviside made extensive contributions to pure mathematics and its practical applications to alternating current, vector analysis and telegraphy. He introduced new concepts that later became commonplace thinking and expressions for every electrical engineer, and invented much of the language now basic to communication engineering, including such words as "capacitance," "inductance," "impedance," and "attenuation."

Heaviside's last years were spent as an embittered recluse at Torquay, Devon where he allowed only a few people to visit him. For much of his life he suffered from recurring jaundice that was to prove fatal. He died on February 3, 1925. Heaviside's work has been an inspiration to countless electrical engineers and mathematicians. Time has enhanced the esteem in which he is held; succeeding generations have spent many hours studying his writings. As a lasting honor, craters on Mars and the Earth's moon were named after him.

HELMHOLTZ, HERMANN VON (1821–1894)

One of the most versatile scientists who ever lived, Hermann von Helmholtz was born in Potsdam, Germany, in 1821, the son of a "Gymnasium" (high school) teacher. From an early age he wanted to be a physicist, but his family could not afford the money required for his education. Instead, his father persuaded him to take up medicine, since his son's education as a physician would be subsidized by the state on the condition that he serve as a doctor in the Prussian army after he received his degree. Helmholtz attended the Institute for Medicine and Surgery in Berlin from 1838 to 1842 and fulfilled his obligation as an army surgeon from 1843 to 1848. His real interest, however, was always research; even in the army barracks he set up a small laboratory for research in physiology and physics.

On July 23, 1847, Helmholtz presented a paper on the conservation of energy at a meeting of the Berlin Physical Society. It was a talk at a reasonably high level of mathematical sophistication intended to convince physicists that energy was always conserved in any physical process. Although it was rejected by J. C. Poggendorf, the editor of the *Annalen der Physik*, as being too long and too mathematical for his readers, it eventually appeared in pamphlet form and was soon recognized as one of the most important papers in nineteenth-century science. This bold and path-breaking paper, written when he was only twenty-six, was Helmholtz's first and most fundamental statement of the conservation-of-energy principle. It came at a critical moment in the history of science when scientists and philosophers were waging a battle over whether conservation of energy was a truly universal principle. In his 1847 paper Helmholtz had shown convincingly that it was.

Helmholtz stated that his only purpose in his 1847 paper was to provide a careful investigation and arrangement of accepted facts about energy conservation for the benefit of both the physicists and the physiologists who attended his lecture. He never claimed priority for himself in this discovery, but later conceded that honor to J. R. Mayer and James Joule. When Helmholtz delivered this paper, however, he knew little about Joule's research, which was going on at about the same time, and nothing at all about Robert Mayer's 1842 paper, which had appeared in a journal not normally read by many scientists.

Some years later, in 1861, when Helmholtz was much involved in physiology, he realized that he had discussed physiology in only two paragraphs of his 1847 paper, and so supplemented it by a fuller consideration of energy transformations in organic systems. This he included in a talk before the Royal Society of London on April 12, 1861. Here he generously referred to the important contributions of Sadi Carnot, Mayer and Joule in establishing the principle of conservation of energy on a firm foundation.

On the basis of this work and other research, in 1849 Helmholtz was appointed professor of physiology at the University of Koönigsberg. There he devoted himself to the physiology of the eye, first explaining the mechanism of lens accommodation. In 1851 his invention of the ophthalmoscope, still the basic instrument used by eye doctors to peer at the retina of the eye, immediately made Helmholtz famous. In 1852 he also became the first experimentalist to measure the speed of nerve impulses in the human body.

Helmholtz did important research on another sense organ, the ear, and explained how it was able to detect differences in pitch. He showed how the quality of a sound depended on the number, nature and relative intensities of the harmonics present in the sound.

On the basis of his studies on the eye and ear, in 1858 Helmholtz was appointed Professor of Anatomy in Heidelberg. His thirteen years in Heidelberg gave him the opportunity to work closely with other gifted scientists including physicist Gustav Kirchhoff and chemist Robert Bunsen, in what was then called "an era of brilliance such as has seldom existed for any university and will not readily be seen again." In 1871 Helmholtz abandoned anatomy and physiology in favor of physics. He accepted the most prestigious chair of physics in Germany at the University of Berlin and spent the rest of his life there.

As he grew older, Helmholtz became more and more interested in the mathematical side of physics and made noteworthy theoretical contributions to classical mechanics, fluid mechanics, thermodynamics and electrodynamics. He devoted the last decade of his life to an attempt to unify all of physics under one fundamental principle, the principle of least action. This attempt, while evidence of Helmholtz's philosphical bent, was no more successful than was Albert Einstein's later quest for a unified field theory. Helmholtz died in 1894 as the result of a fall suffered on board ship while on his way back to Germany from the United States, after representing Germany at the Electrical Congress in Chicago in August, 1893.

It is difficult to exaggerate the influence Helmholtz had on nineteenth-century science, not only in Germany but throughout the world. It was during his lifetime that Germany gained its preeminence in science, which it was not to lose until World War II. His own research contributions, together with the impetus he gave to talented students by his teaching, research guidance, and popular lectures, had much to do with the scientific renaissance that Germany experienced during his lifetime.

Helmholtz was a sensitive and sickly man all his life, plagued by severe migraine headaches and fainting spells. He sought relief from his pain in music and the other arts, and in mountain climbing in the Alps. It is intriguing to imagine what he might have accomplished had he been in good health for all his seventy-three years. On the occasion of Helmholtz's death, Lord Kelvin stated: "In the historical record of science the name of Helmholtz stands unique in grandeur, as a master and leader in mathematics, and in biology, and in physics." Many scientists felt that Kelvin had shortchanged Helmholtz by this statement; Medicine, physiology, chemistry, and philosophy certainly deserved to be added to the list of fields Helmholtz had mastered during his long and productive scientific career.

HERTZ, HEINRICH RUDOLF (1857–1894)

Heinrich Hertz was born into a well-to-do German family in Hamburg on February 22, 1857. He was an exceptionally talented student, doing equally well in the humanities and sciences. He read extensively, tried his hand at sculpting, and even built scientific apparatus on a lathe at home. After a year of military service, Hertz studied structural engineering in Munich, but gave it up for physics when he realized he had the ability to contribute something substantial to that field. At the age of 20 he wrote to his parents: "… I would rather be a great scientific investigator than a great engineer, but I would rather be a second-rate engineer than a second-rate investigator."

In 1878 Hertz enrolled at the University of Berlin to study under Hermann von Helmholtz, the leading German physicist of the time. He obtained his degree *magna cum laude* in 1880 with a theoretical dissertation on the electromagnetic induction of currents in

Heinrich Rudolf Hertz. (Library of Congress)

conducting spheres rotating in a magnetic field. He remained at the Berlin Physics Institute as assistant to Helmholtz until 1883; during these years he published fifteen research papers on a great variety of topics in physics.

In 1883 Hertz was appointed *Privatdozent* for mathematical physics at Kiel, and after two years became a full professor at the *Technische Hochschule* in Karlsruhe. In 1889 Hertz left Karlsruhe to assume his last academic post as Professor of Physics at the Friedrich-Wilhelm University in Bonn. Five years later, following a long period of declining health and many painful operations, Heinrich Hertz died in Bonn of blood poisoning on January 1, 1894, a few months before his thirty-seventh birthday.

After Hertz's death Helmholtz paid tribute to his former student as a "consummate physicist," who uniquely combined mathematical ability, theoretical insight, and experimental skill. These qualities enabled Hertz to make many important contributions to physics, of which only those relating more directly to energy are outlined below.

Hertz's most direct involvement with all aspects of the energy question was the research he did to prepare his inaugural lecture to the faculty at the *Technische Hochschule* in Karlsruhe, delivered on April 20, 1885 and entitled: "On the Energy Balance of the Earth." The manuscript for this lecture has only recently been found and published in both German and English. Although written more than a century ago, this impressive document records both Hertz's insightful view of the Earth's energy situation at that time and his remarkably good order-of-magnitude estimates of the energy sources then known to be available to the Earth.

The most important contribution Hertz made in this inaugural lecture was his prediction, based on his estimates of the energy sources available, that ultimately the Earth was completely dependent on the Sun for the light and heat it needed to support life. Of course, this picture would change after Henri Becquerel discovered radioactivity in 1896, and thus introduced the nuclear age of physics.

The research that brought Hertz undying fame as a physicist was that on electromagnetic waves, performed in 1886–1889 in Karlsruhe. By his elegant experiments he confirmed the theoretical prediction of James Clerk Maxwell that electromagnetic waves in what are now called the microwave and radiowave regions of the spectrum travel through a vacuum at the speed of light. He also demonstrated that microwaves of 66-cm wavelength exhibit the same properties of reflection, refraction, interference and polarization as do light waves. Hertz's research also provided conclusive evidence that electromagnetic energy cannot be transmitted from place to place instantaneously, but only at a finite velocity, that of light. Hertz never considered the possibility of using electromagnetic waves for wireless communication over long distances. His sole interest was in understanding the world about him — "the intellectual mastery of nature," in the words of Helmholtz.

In the course of his research on electromagnetic waves Hertz discovered the photoelectric effect. He showed that for the metals he used as targets, incident radiation in the ultraviolet was required to release negative charges from the metal. Research by Philipp Lenard, Wilhelm Hallwachs, J. J. Thomson, and other physicists finally led Albert Einstein to his famous 1905 equation for the photoelectric effect, which includes the idea that electromagnetic energy is "quantized" in units of hν, where h is Planck's constant and ν is the frequency of the "bundle of energy" or "photon." Einstein's equation is simply a conservation-of-energy equation, stating that the energy of the incident photon (hν) is used partially to provide the energy needed to extract the negative particle (electron) from the metal, with the rest of the photon's energy going into the kinetic energy of the extracted electron. Hertz's discovery of the photoelectric effect in 1887 therefore led eventually to Einstein's energy-conservation equation for submicroscopic systems.

Hertz's last piece of experimental work was done when his health was deteriorating and he was devoting most of his research time to intensive theoretical work on the logical foundations of mechanics. In 1892 in his laboratory in Bonn, he discovered that cathode rays could pass through thin metallic foils. He published a short paper on the subject, but did not pursue the matter further. Instead he handed his apparatus and his ideas over to Philipp Lenard (1862–1947), his assistant in Bonn. Lenard pushed Hertz's suggested research so far that Lenard received the Nobel Prize in Physics in 1905 "for his work on cathode rays."

During his brief life Hertz moved back and forth with extraordinary ease and great dedication between intense theoretical study at his desk and equally demanding experimental work in his laboratory. As Robert S. Cohen wrote of Hertz in 1956, "His like is rare enough within science ... but his fusion of theory and experiment with a creative interest in philosophical and logical foundations [as revealed particularly in his *Principles of Mechanics*] is nearly unique."

HISTORICAL PERSPECTIVES AND SOCIAL CONSEQUENCES

As with so many other phenomena that define our civilization, we owe the idea of energy—from *en* (in) and *ergon* (work)—to ancient Greeks. In his *Metaphysics*, Aristotle gave the term a primarily kinetic meaning: "The term "actuality" (*energeia*) … has been extended to other things from motions, where it was mostly used; for *actuality* is thought to be motion most of all" (*Metaphysics*, Theta 3, p. 149).

For Greeks the word and its cognate terms filled a much larger conceptual niche than they do in modern scientific usage. In some of Aristotle's writings *energeia* stands in opposition to mere disposition, *hexis*; in others it carries the vigor of the style. The verb *energein* meant to be in action, implying constant motion, work, production, and change. The classical concept of *energeia* was thus a philosophical generalization, an intuitive expression embracing the totality of transitory processes, the shift from the potential to the actual. Although the perception was clearly holistic, it did not embrace the modern notion of the underlying commonality of diverse energies, the fact that their conversions can perform useful work.

This understanding was clearly formulated only by the middle of the nineteenth century; conceptualization of energy thus made hardly any advances during more than two thousand years following Aristotle's writings. Interestingly, even many founders of modern science held some dubious notions concerning energy. To Galileo Galilei, heat was an illusion of senses, an outcome of mental alchemies; Francis Bacon thought that heat could not generate motion or motion, heat.

But neither the absence of any unified understanding of the phenomenon nor the prevalence of erroneous interpretations of various energy conversions prevented a great deal of empirical progress in harnessing diverse energies and in gradually improving efficiencies of some of their conversions. Seen from a biophysical point of view, all human activities are nothing but a series of energy conversions, and so it is inevitable that different energy sources and changing conversion techniques have imposed obvious limits on the scope of our action—or opened up new possibilities for human development.

PREHISTORIC AND ANCIENT CULTURES

From the perspective of general energetics, the long span of human prehistoric development can be seen as the quest for a more efficient use of somatic energy, the muscular exertions used primarily to secure a basic food supply and then to gradually improve shelters, acquire more material possessions, and evolve a variety of cultural expressions. This quest was always limited by fundamental bioenergetic considerations: Fifty to ninety watts is the limit of useful work that healthy adults can sustain for prolonged periods of time (of course, short bursts of effort could reach hundreds of watts).

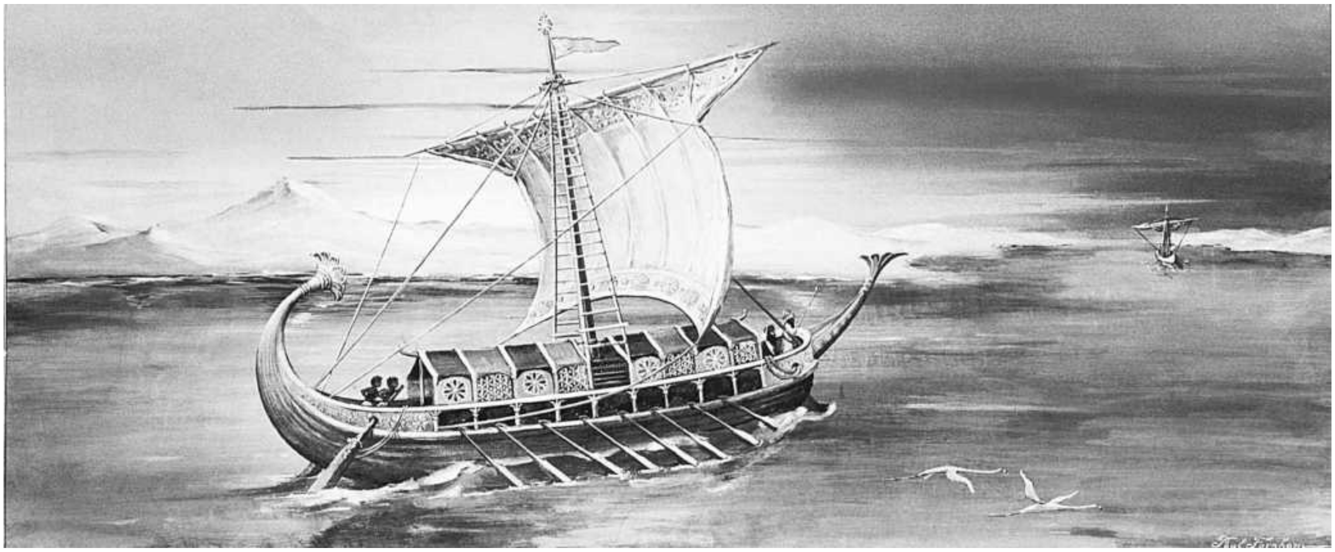
Human labor dominated all subsistence foraging activities, as the food acquired by gathering and hunting sufficed merely to maintain the essential metabolic functions and to support very slow population growth. Societies not very different from this ancestral archetype survived in some parts of the world (South Africa, Australia) well into the twentieth century: Because they commanded very little energy beyond their subsistence food needs, they had very few material possessions and no permanent abodes.

Simple wooden, stone, and leather tools—including digging sticks, bows, arrows, spears, knives and scrapers—were used to increase and extend the inherently limited musclepower in collecting, hunting, and processing tasks. The only extrasomatic energy conversion mastered by foraging societies was the use of fire for warmth and cooking. The earliest dates for controlled use of fire for warmth and cooking remain arguable: it may have been nearly 500,000 years ago, but a more certain time is about 250,000 years ago.

Energy returns in more diversified foraging (energy in food/energy spent in collecting and hunting) varied widely: they were barely positive for some types of hunting (particularly for small arboreal animals), high for gathering tubers (up to fortyfold), and very high for coastal collecting and hunting of marine species ranging from shellfish to whales. Some foraging societies able to secure high energy returns built permanent dwellings and also channeled the surplus energies into more elaborate tools and remarkable artistic expressions.

Energy returns actually declined when some foragers began practicing shifting cultivation, and they declined further with sedentary agriculture—but these modes of subsistence were gradually adopted because they made it possible to support much larger population densities. Carrying capacities of foraging societies were as low as 0.01 person per square kilometer in arid regions and almost as high as 1 person per square kilometer in species-rich coastal sites. In contrast, shifting agricultures would commonly support 20 to 30 people per square kilometer, and even the earliest, extensive forms of settled farming could feed 100 to 200 people per square kilometer (or one to two people from a hectare of cultivated land). Shifting agriculturalists extended the use of fire to the removal of forest vegetation and acquired a larger assortment of tools.

Human labor—with varying contributions by slave, corvee, and free work—continued to be the dominant source of mechanical energy throughout antiquity, and combustion of biomass fuels remained the most important conversion of extrasomatic energy in all ancient civilizations. Indeed, these two energy sources remained critically important until the creation of modern industrial civilization. But, in contrast to the prehistoric era, energetic perspectives on human history reveal a fascinating quest for harnessing extrasomatic energies combined with ingenious efforts to increase the efficiency of available energy conversions. Both the collective achievements



Painting of a Phoenician merchant galley, c. 7th century B.C.E., crossing the Red Sea. (Corbis Corporation)

of human societies and individual standards of living have always been highly correlated with success in diversifying energy sources and increasing efficiencies of their use.

With more ingenious tools (based on such fundamental mechanical principles as the lever and the inclined plane) and with thoughtful organization of often very complex tasks, societies commanding just musclepower were able to accomplish such feats as the building of admirably planned megalithic structures (such as Stonehenge and the colossi of Easter Island), pyramids (Egypt, Mesoamerica), and stone temples, walls, and fortresses on four continents. In contrast to this concerted deployment of human labor in construction—amounting to one to five kilowatts of sustained power in work gangs of ten to fifty people—no Old High culture took steps to the really large-scale manufacture of goods.

The use of fire was extended during antiquity to produce bricks and to smelt various metals, starting with copper (before 4000 B.C.E.) and progressing relatively rapidly to iron (the metal was used extensively in parts of the Old World after 1400 B.C.E.). Conversion of wood to charcoal introduced a fuel of higher energy density (about 50% higher than air-dried wood) and a superior quality. Being virtually pure carbon, charcoal was nearly smokeless, and hence much better suited for interior heating, and its combustion could produce high temperatures needed for smelting metal ores. But the inefficient method of charcoal production meant that a unit of charcoal's energy required commonly five to six units of wood.

ENERGY CONVERSIONS IN TRADITIONAL SOCIETIES

All ancient societies were eventually able to harness a variety of extrasomatic energies other than the combustion of biomass fuels and the use of pack animals for transport. Capturing wind by simple sails made seagoing transport much cheaper than moving goods or people on land, and it enabled many societies (most notably the Phoenicians and the Greeks, and later, of course, the Romans) to extend their cultural reach far beyond their core regions. However, simple square or rectangular sails were rather inefficient airfoils unsuitable for sailing in the open ocean. Transoceanic voyages had to wait for many centuries not only for the adoption of better sails but also for better keels, rudders, and compasses.

Cattle were the first animals used as sources of draft power in agriculture, and the coincidence of the first clearly documented cases of cattle domestication and plow farming are hardly surprising. Cattle were used in many regions also for lifting irrigation water and for processing harvested crops, and everywhere for transportation. Individual small animals could deliver no more than 100 to 300 watts of useful power, and a pair of good oxen (harnessed by head or neck yokes) could work at a sustained rate of 600 to 800 watts. A peasant working with a hoe would need 100 to 200 hours to prepare a hectare of land for planting cereals. Even with a simple wooden plow pulled by a single medium-size ox, that task could be done in just over 30 hours. Hoe-dependent farming could have never attained the scale of cultivation made possible by domesticated draft animals.

Because of their size and anatomy, horses are inherently more powerful draft animals than cattle: A good horse can work at a rate of 500 to 800 watts, an equivalent of eight to ten men. But this superiority was not translated into actual performance until the invention and general adoption of an efficient harness. The oldest preserved images of working horses do not show them laboring in fields, but rather pulling light ceremonial or attack carriages while using a throat-and-girth harness that is not suited for heavy fieldwork. The breastband harness was better, but only the invention of the collar harness (in China, just before the beginning of the common era) turned horses into superior draft animals.

By the ninth century an improved version of the collar harness reached Europe, where its use remained largely unchanged until horses were replaced by machines more than 700 years later. Millions of working horses worldwide use it still. Two other improvements that made horses into superior draft animals were the diffusion of horseshoes, and better feeding provided by cultivation of grain feeds. A pair of good horses could sustain one and a half kilowatts for many hours, and peak exertions of individual large animals surpassed two kilowatts. Horse teams of the late nineteenth century (with four to forty animals) were powerful enough to open up heavy grassland soils for pioneer farming and to pull the first mechanical harvesters and, later, the first modern combines.

Harnessing of wind by simple sails aside, the diversification of inanimate energy sources began about 2,000 years ago, and their slowly expanding contributions were limited by low efficiencies of prevailing conversion techniques as well as by their cost. Roman civilization, Islam, dynastic China, and premodern Europe came up with many ingenious solutions to convert kinetic energies of wind and water into useful work, easing many everyday tasks as well as allowing for previously impossible mechanical feats.

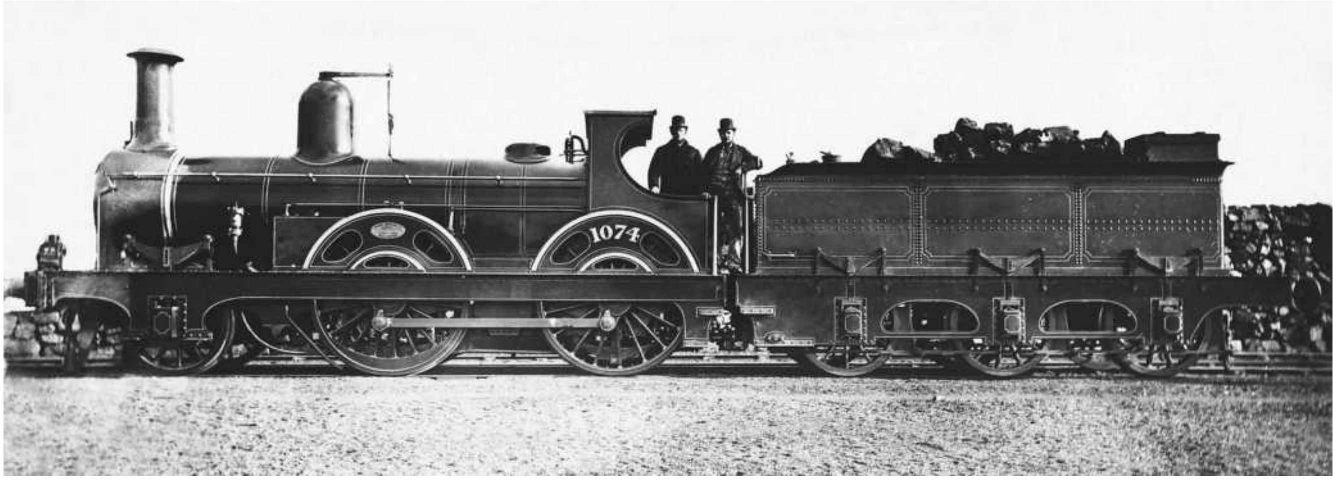
The first inanimate source of energy harnessed by a machine was flowing water. The origin of the earliest waterwheels remains uncertain. Vertical wheels, favored by the Romans, were much more efficient than the horizontal ones, and their first use was turning the millstones by right-angle gears. Use of waterwheels gradually expanded far beyond grain milling, and their power was used for sawing, wood turning, oil pressing, paper making, cloth fulling, tanning, ore crushing, iron making, wire pulling, stamping, cutting, metal grinding, blacksmithing, wood and metal burning, majolica glazing, and polishing.

Most of these tasks were eventually also done by windmills, whose diffusion began about a millennium after the wider use of waterwheels (the first clear European records come from the last decades of the twelfth century). While simple Asian machines had horizontally mounted sails, European mills were vertically mounted rotaries whose driving shafts could be turned into the wind. Useful power of both waterwheels and windmills continued to increase only slowly: Even during the early decades of the eighteenth century, European waterwheels averaged less than four kilowatts, and a typical large eighteenth-century Dutch mill with a thirty-meter span could develop seven and a half kilowatts (an equivalent of ten good horses).

Per capita consumption of biomass fuels in these premodern societies was commonly well below twenty gigajoules a year (an equivalent of less than one metric ton of wood). Radical changes came only with the widespread use of coal (and coke) and with the adoption of steam engines for many stationary and mobile uses. These changes were gradual and decidedly evolutionary: The notion of the eighteenth-century coal-based Industrial Revolution is historically inaccurate. Both in Europe and in North America it was waterpower, rather than coal combustion, that was the prime mover of rapidly expanding textile and other manufacturing industries, and in many countries charcoal-based smelting dominated iron production until the last decades of the nineteenth century.

EMERGENCE OF FOSSIL-FUELED ECONOMIES

In parts of Europe and northern China coal was mined, and used directly as household fuel and in small-scale manufacturing, for centuries preceding the first commercial use of Newcomen's inefficient



Two men stand on the Victoria Express Engine Series 1070, which was designed by Matthew Kirtly, the locomotive superintendent of Midland Railway in England during the early 1870s. (Corbis Corporation)

steam engine in the early decades of the eighteenth century. After 1770 James Watt transformed the existing steam engine into a prime mover of unprecedented power: Although his improved design was still rather inefficient, average capacity of steam engines built by Watt's company was about twenty kilowatts, more than five times higher than the mean for typical contemporary watermills, nearly three times larger than that for windmills, and twenty-five times that of a good horse.

During the nineteenth century the size, and the efficiency, of steam engines rose rapidly. The largest stationary machines designed during the 1890s were about thirty times more powerful (about one megawatt) than those in 1800, and the efficiency of the best units was ten times higher than during Watt's time. Railways and steamships greatly expanded and speeded up long-distance transport and international trade.

As the twentieth century began, two new prime movers were greatly extending the power of fossil-fueled civilization. Internal-combustion engines (Otto and Diesel varieties), developed and perfected by a number of French and German engineers between 1860 and 1900, opened the possibilities of unprecedented personal mobility, first when installed in cars, trucks, and buses, and later when used to propel the first airplanes. The steam turbine, invented by Charles Parsons, patented in 1884 and then rapidly commercialized by his company, made large-scale generation of electricity affordable. The closing decades of the nineteenth century also saw the emergence of a new fossil fuel industry: exploration, drilling, transportation (by pipelines and tankers), and refining of crude oil.

But at that time it was only North America and most of Europe that were in the midst of a radical shift from the combination of animate energies and low-power inanimate prime movers, to the dominance of fossil fuels converted by new, much more powerful, and much more efficient machines. Average annual per capita energy consumption had more than doubled, compared to the pre–fossil fuel era, with most of the fuel spent on industrial production and transportation of people and goods. Acting via industrialization and urbanization, growing rates of energy consumption were reflected in a higher standard of living.

In the early stages of economic growth, these benefits were limited because the fossil fuels were overwhelmingly channeled into building up an industrial base. Slowly increasing consumption of household goods—better cookware, clothes and furniture—were the first signs of improvement. Afterward, with better food supply and improving health care, a lower infant mortality and longer life expectancy.

Eventually, basic material and health advantages started spilling into the countryside. The educational levels of urban populations began to rise, and there were increasing signs of incipient affluence. The emergence of electricity as the most versatile and most convenient form of energy greatly aided the whole process of modernization.

These socioeconomic transformations were accompanied by a deepening understanding of basic principles underlying energy conversions. Practical advances in new machine design as well as new observations in the chemistry of plants and animals were behind some of the most fundamental theoretical breakthroughs of the late eighteenth and the nineteenth centuries that eventually created a unified understanding of energy.

THEORETICAL UNDERSTANDING OF ENERGY

James Watt's invention of a simple indicator, a recording steam gauge, opened the way for detailed studies of engine cycles that contributed immeasurably to the emergence of thermodynamics during the following century. During the 1820s Sadi Carnot used a purely theoretical approach to investigate the ways of producing kinetic energy from heat to set down the principles applicable to all imaginable heat engines, regardless of their working substance and their method of operation.

Not long afterward Justus von Liebig ascribed the generation of carbon dioxide and water to food oxidation, offering a basically correct view of human and animal metabolism. During the 1840s Julius Robert Mayer, a German physician, was the first researcher to note the equivalence of food intake and oxygen consumption. Mayer saw muscles as heat engines energized by oxidation of the blood and offered calculations proving the sufficiency of food's chemical energy to supply the mechanical energy necessary for work as well as to maintain constant body temperature. All of this led him to estimate that mammals are about 20 percent efficient as machines and to establish the mechanical equivalent of heat, and thus to formulate, in 1851, the law of conservation of energy, commonly known as the first law of thermodynamics.

Independent, and more accurate, quantification of the equivalence of work and heat came from an English physicist, James Prescott Joule, whose first publication in 1850 put the conversion rate at 838 foot-pounds and a later revision at 772 foot-pounds, a difference of less than 1 percent from the actual value. Soon afterward William Thomson (Lord Kelvin) identified the sun as the principal source of kinetic energy available to man and wrote about nature's universal tendency toward the dissipation of mechanical energy. Rudolf Clausius sharpened this understanding by showing in 1867 that heat energy at low temperature is the outcome of these dissipations; he named the transformational content entropy, a term derived from the Greek *trope*, for transformation. As the energy content of the universe is fixed, but its distribution is uneven, its conversions seek uniform distribution, and the entropy of the universe tends to maximum.

This second law of thermodynamics—the universal tendency toward heat death and disorder—became perhaps the most influential, and frequently misunderstood, cosmic generalization. Only at the absolute zero (-273°C) is the entropy nil. This third law completes the set of thermodynamic fundamentals. Josiah Willard Gibbs applied the thermodynamic concepts to chemistry and introduced the important notion of free energy. This energy actually available for doing work is determined by subtracting the product of temperature and entropy change from the total energy entering a chemical reaction.

The second law exercised a powerful influence on scientists thinking about energetic foundations of civilization during the closing decades of the nineteenth century. Edward Sacher viewed economies as systems for winning the greatest possible amount of energy from nature and tried to correlate stages of cultural progress with per capita access to fuels. The contrast of rising fuel demands and inexorable thermodynamic losses led to anxious calls for energy conservation. Wilhelm Ostwald, the 1909 Nobel laureate in chemistry, formulated his energetic imperative, admonishing to waste no energy but to value it as mankind makes the inevitable transition to a permanent economy based on solar radiation. Another Nobel laureate, Frederick Soddy (in 1921, in chemistry), investigated the magnitude of the earth's natural resources of energy and was the first scientist to make the often-quoted distinction between utilizing natural energy flows (spending the interest on a legacy) and fossil fuels (spending the legacy itself).

The twentieth century brought a fundamental extension of the first law, with Albert Einstein's follow-up of his famous special-relativity paper published in 1905. Soon after his publication Einstein, writing to a friend, realized that the principle of relativity requires that the mass of a body is a direct measure of its energy content, which means that light transfers mass. During the next two years Einstein formalized this “amusing and attractive thought” in a series of papers firmly establishing the equivalence of mass and energy. In the last of these papers, in 1907, he described a system behaving like a material point with mass

$$M_o = \mu + E_o c^2$$

and noted that this result is of extraordinary importance because the inertial mass of a physical system is equivalent with an energy content μc^2.

HIGH-ENERGY CIVILIZATION

The central role played by abundant, affordable, and varied energy conversions in sustaining and improving modern civilization is thus a matter of indisputable scientific understanding. That the public often ignores or overlooks this role is, in a way, a great compliment to the success of modern science and engineering, which have managed to make the conversions of extrasomatic energies so ubiquitous and so inexpensive that most people hardly give much thought to the centrality of fossil fuels and electricity in our civilization.

A variety of coals, crude oils, and natural gases supplies the bulk of the world’s primary energy, and these flows of fossil energies are complemented by primary electricity derived from flowing water, nuclear fission, wind, and solar radiation. Increasing shares of fossil fuels have been used indirectly, after being converted to electricity, the most versatile form of energy. While most of our prime movers—internal-combustion engines, steam and gas turbines, and electric motors—reached their growth plateaus in terms of their unit power, their overall capacity, and their efficiency, keep increasing.

Most of the citizens of affluent economies have been enjoying numerous benefits resulting from these large, and more efficient, energy flows for several generations, but the successive waves of the energy-driven revolution are only now diffusing throughout low-income countries. Although the process has been uneven in its spatial and temporal progress, there is no doubt that we are witnessing the emergence of a global civilization marked by mass consumption, with its many physical comforts (and frequent ostentatious displays), high personal mobility, longer periods of schooling, and growing expenditures on leisure and health.

Correlations of this sequence with average per capita energy consumption have been unmistakable. National peculiarities (from climatic to economic singularities) preclude any simple classification, but three basic categories are evident. No country with average annual primary commercial energy consumption of fewer than one hundred kilograms of oil equivalent can guarantee even basic necessities to all of its inhabitants. Bangladesh and Ethiopia of the 1990s were the most populous nations in this category, and China belonged there before 1950.

As the rate of energy consumption approaches 1 metric ton of oil equivalent (or 42 gigajoules), industrialization advances, incomes rise, and quality of life improves noticeably. China of the 1980s, Japan of the 1930s and again of the 1950s, and Western Europe and the United States between 1870 and 1890 are outstanding examples of this group. Widespread affluence requires, even with efficient energy use, at least 2 metric tons of oil equivalent (more than 80 gigajoules) per capita a year. France made it during the 1960s, Japan during the 1970s. During the 1990s mean per capita consumption rates were below 150 gigajoules (fewer than 4 metric tons of crude oil equivalent) in Europe and Japan, but more than 300 gigajoules in North America, reflecting the profligate use of liquid fuels for transport and the wasteful use of household energy.

A typical premodern family—that is, a peasant household of five to eight people—controlled no more than three to four kilowatts, roughly split between the animate energy of the working members of the family and a couple of draft animals, and the energy in wood used for heating and cooking. By flipping switches of their electric appliances and setting thermostats of their heating and cooling units, a modern American household of four people controls power of about fifteen to twenty-five kilowatts—and internal-combustion engines in their cars add ten times as much installed power. The average person in modern North American society thus controls about ten times as much power as his or her preindustrial ancestor—and given the much higher conversion efficiencies of modern processes (e.g., a simple wood

A Qantas Boeing 747–400 commercial airplane flies above the opera house in Sydney, Australia. (Corbis Corporation)

stove converts 10 to 15% of fuel to useful heat compared to 80 to 90% for high-performance natural-gas furnaces), the differences in terms of useful power are easily twenty to fiftyfold.

Maximum differences are even more stunning: Even when holding reins of a dozen large horses, a well-to-do traditional farmer controlled no more than about ten kilowatts of useful power. In contrast, a pilot of a Boeing 747 commands some sixty megawatts in the plane's four engines, a duty engineer of a large electricity-generating plant may be in fingertip control of more than one gigawatt, and a launch order by a U.S. president could unleash exawatts (10^{18} watts) in thermonuclear warheads. This immense concentration of power under individual control has been one of the hallmarks of modern high-energy society.

The grand transformation wrought by this surfeit of easily controllable energies defines modern civilization. Greatly increased personal mobility, a change that began with the application of steam power to land and water transport, has been vastly expanded thanks to the mass production of vehicles and airplanes powered by internal-combustion engines and gas turbines (the only notable twentieth-century addition to common prime movers). Wide-bodied jet airplanes in general, and the Boeing 747 in particular, have been among the leading agents of globalization. The latest stage of this energy-driven globalization trend is vastly enlarged access to information made possible by mass diffusion of personal computers, by electronic storage of data and images, and by high-volume wireless and optical fiber transmissions.

The easing of women's household work in the Western world is another particularly noteworthy social transformation wrought by efficient energy conversions. For generations rising fuel consumption made little difference for everyday household work; indeed, it could make it worse. As the standards of hygiene and social expectations rose with better education, women's work in Western countries often got harder. Electricity was the eventual liberator. Regardless of the availability of other energy forms, it was only its introduction that did away with exhausting and often dangerous labor: Electric irons, vacuum cleaners, electric stoves, refrigeration, washing machines and electric dryers transformed housework, beginning in the early decades of the twentieth century. Hundreds of millions of women throughout the poor world are still waiting for this energy-driven liberation.

Air conditioning has been another revolutionary application of electricity. The technique was first patented by William Carrier in 1902 but widespread adoption came only after 1960, opening up first the American Sunbelt to mass migration from northern states, then increasing the appeal of subtropical and tropical tourist destinations, and since the 1980s becoming also a common possession for richer urbanites throughout the industrializing world.

And yet the energy-civilization link should not be overrated. Basic indicators of physical quality of life show little or no increase with average per capita energy consumption rising above one hundred gigajoules per year—and it would be very unconvincing to argue that North American consumption levels, twice as high as in Western Europe, make Americans and Canadians twice as content, happy, or secure. Indeed, international and historic comparisons show clearly that higher energy use will not assure reliable food supply, does not confer political stability, does not necessarily enhance personal security, does not inevitably lead to a more enlightened governance, and may not bring any widely shared improvements in the standard of living.

CHALLENGES AHEAD

During the past generation, a number of poor countries moved to the intermediate energy consumption category. Still, in terms of total population, the distribution of global energy use remains extremely skewed. In 1950 only about 250 million people (one-tenth of the global population) consumed more than two metric tons of oil equivalent a year per capita, yet they claimed 60 percent of the world's primary energy (excluding biomass). By 1999 such populations were about a fifth of all mankind, and they claimed nearly three-quarters of all fossil fuels and electricity. In contrast, the poorest quarter of humanity used less than 5 percent of all commercial energies.

Stunning as they are, these averages do not capture the real difference in living standards. Poor countries devote a much smaller share of their total energy consumption to private household and transportation uses. The actual difference in typical direct per capita energy use among the richest and the poorest quarters of the mankind is thus closer to being fortyfold rather than "just" twentyfold. This enormous disparity reflects the chronic gap in economic achievement and in the prevailing quality of life and contributes to persistent global political instability.

Narrowing this gap will require higher substantially increased output of fossil fuels and electricity, but an appreciable share of new energy supply should come from more efficient conversions. Energy intensities (i.e., the amount of primary energy per unit of the GDP) of all affluent economies have been declining during most of the twentieth century, and some modernizing countries have been moving in the same direction even faster; perhaps most notably, China has more than halved its energy intensity since 1980!

Low energy prices provide little incentive for sustaining the efficiency revolution that flourished after OPEC's crude-oil price rises of the 1970s, but higher conversion efficiencies should be pursued regardless; in the absence of (highly unlikely) voluntary frugality, they are the only means of reducing overall energy throughput and hence minimizing the impact of energy use on the biosphere. Energy industries and conversions have many environmental impacts, but it now appears that the threat of relatively rapid global warming, rather than the shrinking resource base, will be the most likely reason for reducing our civilization's high dependence on fossil fuels.

So far we have been successful in preventing the use of the most destructive energy conversion, the explosion of thermonuclear weapons, in combat. Although the risk of armed superpower conflict has decreased with the demise of the Soviet empire, thousands of nuclear weapons remain deployed around the world. Our challenge during the twenty-first century will be fourfold: avoiding nuclear conflict; extending the benefits of high-energy society to billions of people in low-income countries; decoupling the development of rich societies from continuous growth of energy consumption; and preserving the integrity of the biosphere.

HOUDRY, EUGENE JULES (1892–1962)

EDUCATION AND WAR EXPERIENCE

Eugene Jules Houdry, one of the fathers of petroleum refining, was born in Dumont, France, outside of Paris, on April 18, 1892, and grew up during an era of rapid technological change and innovation. Houdry was blessed with considerable emotional and financial support from his family and encouraged to reach for lofty and risky goals.

With the urging of his father, a wealthy steel manufacturer, Houdry studied mechanical engineering at the École des Arts et Métiers in Chalons-sur-Marne near Paris. He earned the government's gold model for highest scholastic achievement in his class and captained its national champion soccer team. Graduating in 1911, Houdry briefly worked in his father's metalworking business, Houdry et Fils, but joined the army prior to the outbreak of World War I. As a lieutenant in the tank corps, Houdry was seriously wounded in 1917 in the first great tank battle, the Battle of Javincourt. He was awarded the Croix de Guerre, the French military decoration created in 1915 to reward feats of bravery, and membership in the Legion d'Honneur for extraordinary bravery.

FROM TANKS TO AUTOMOBILE RACING TO CATALYTIC CRACKING AND CATALYST DEVELOPMENT

After the war he rejoined Houdry et Fils, but his interest drifted from steel to car-racing and then to improving the fuel performance of car racing engines. Houdry recognized the need for more efficient motor fuels during a visit to Ford and while attending the Memorial Day Indianapolis 500 Race. In 1922 Houdry learned of a superior gasoline being produced from lignite by E. A. Prudhomme, a Nice chemist. Undeterred by unfamiliarity with catalysis or chemical engineering, Houdry enlisted Prudhomme in developing a workable lignite-to-gasoline process in a laboratory privately financed by a group of Houdry's friends. In their scheme, solid lignite would be initially broken down by heat (thermally cracked) to produce a viscous hydrocarbon oil and tars. The oil was then somehow further converted (actually, catalytically cracked) to gasoline by contacting the oil with various clays. Houdry's wartime experiences impressed upon him France's need for indigenous petroleum resources, which provided further impetus to his pursuing the project. With government support, the alliance built a plant that could convert sixty tons of lignite per day to oil and gasoline. The process was not economic, and the unit shut down in 1929. Across the ocean, a similar fate befell Almer McAfee at Gulf Oil in the same year. McAfee is credited with developing the first commercially viable catalytic cracking process using aluminum chloride as the catalyst.

The poor economics for McAfee's catalytic process lay in the substantial improvements being made in the technology of thermally cracking crude oil. Notable among these competing efforts were those of William Burton of Standard Oil (Indiana), whose high-pressure and high-temperature thermal technology more than doubled the potential yield of gasoline from crude oil and thereby substantially reduced the cost of thermal cracking.

Houdry was dejected by the failure of his process to compete against the more mature thermal cracking technology, but his seven-year effort was not in vain. Houdry had been devoting his attention initially to using a naturally occurring aluminosilicate clay, fuller's earth, as the catalyst and later to using more catalytically active hydrosilicates of aluminum prepared by washing clays, such as bentonite with acid. This approach ran contrary to the mainstream of catalytic cracking investigators, who were working unsuccessfully with nickel-containing catalysts, or to McAfee, who was using anhydrous aluminum chloride as the catalyst and making it practical by effecting tenfold reductions in its cost of manufacture.

The catalytic cracking activity of Houdry's catalysts and McAfee's aluminum chloride were puzzling to researchers at the time: It worked, but they could not understand why. As later determined by Hans Tropsch of UOP Research Laboratories, both silica-alumna and aluminum chloride behave as acid catalysts capable of donating protons or accepting electron pairs to form "carbonium ion" reaction intermediates. The concept of such active intermediates explained the propensity of catalytic cracking to favor formation of higher-octane branched chain paraffins and aromatics as compared with thermal cracking's disposition toward producing lower-octane straight chain paraffins. It also explained the greater yields of gasoline resulting from other hydrocarbon reactions occurring in the process, namely isomerization (e.g., conversion of zero octane n-pentane to isopentane), alkylation (e.g., conversion of isobutane and isobutene to "isooctane"), polymerization (e.g., propylene to hexene) and dehydrogenation (e.g., hexene to benzene).

Remarkably, seventy years after Houdry's utilization of the catalytic properties of activated clay and the subsequent development of crystalline aluminosilicate catalysts that are a magnitude more catalytically active, the same fundamental principles remain the basis for the modern manufacture of gasoline, heating oils, and petrochemicals.

COMMERCIALIZATION AND IMPACT

Houdry concentrated his personal efforts on developing a viable processing scheme, solving the engineering problems, scaling the process to commercial size, and developing requisite equipment. In 1930,

H. F. Sheets of Vacuum Oil Company, who learned of Houdry's work and shared his vision for converting vaporized petroleum to gasoline catalytically, invited him to the United States. After a successful trial run, Houdry moved his laboratory and associates from France to Paulsboro, New Jersey, to form a joint venture, Houdry Process Corporation, with Vacuum Oil Company. In that year Vacuum Oil Company merged with Standard Oil of New York to become Socony-Vacuum Company (much later Mobil Oil Corporation).

In 1933, a 200-barrel-per-day Houdry unit was put into operation. The financial strains of the Great Depression coupled with formidable technical problems necessitated inclusion of Sun Oil Company in a fruitful three-way codevelopment partnership. In the next few years the Houdry process underwent considerable changes, especially in developing an innovative method for periodically burning off a buildup of coke within the catalyst to restore catalyst activity lost after only ten minutes of usage and employing a molten salt heat exchanger to replace heat absorbed by the endothermic cracking reactions.

In 1936, Socony-Vacuum built a 2,000-barrel-per-day semicommercial Houdry unit at Paulsboro, closely followed the next year by Sun Oil's 15,000-barrel-per-day commercial plant in its Marcus Hook, Pennsylvania, refinery. With a capability to produce a higher-octane and thus better-performing gasoline, the new development was touted as "the new miracle of gasoline chemistry." The timing was fortuitous in giving the Allies a major advantage in World War II. During the first two years of the war Houdry units produced 90 percent of all catalytically cracked gasoline. Minimal additional refining, notably washing with sulfuric acid to remove low-octane straight-chain olefins and deleterious sulfur components, allowed the manufacture of exceedingly scarce high-test aviation gasoline. Allied planes were 10 to 30 percent superior in engine power, payload, speed and altitude during these critical early years of the war.

The Houdry fixed-bed cyclic units were soon displaced in the 1940s by the superior Fluid Catalytic Cracking process pioneered by Warren K. Lewis of MIT and Eger Murphree and his team of engineers at Standard Oil of New Jersey (now Exxon). Murphree and his team demonstrated that hundreds of tons of fine catalyst could be continuously moved like a fluid between the cracking reactor and a separate vessel for catalyst regeneration. Nevertheless, the fixed bed remains an important reactor type in petrochemicals, and the Houdry reactor remains a classic example of their high state of development.

BEYOND CATALYTIC CRACKING

Houdry's entire career was characterized by foresight, imagination, leadership, boldness, and persistence. He was a demanding individual, single-minded of purpose and a workaholic, yet with considerable charm. Houdry was one of twenty whose opposition to the Vichy government resulted in their French citizenship being revoked. Later during the war, when natural rubber supplies were cut off, Houdry invented a catalytic process for producing butadiene, an essential reactant in manufacturing synthetic rubber. Following World War II, motivated by a concern for the environment, Houdry showed foresight in turning his attention to the health hazards of automobiles and industrial pollution, well before they were widely acknowledged as major problems. He founded Oxy-Catalyst Company and holds one of the early U.S. patents for catalytically reducing the amounts of carbon monoxide and unburned hydrocarbons in automobile exhausts, anticipating the development of the catalyst processes now used with modern automobiles. He died on July 18, 1962, at age seventy.

HYBRID VEHICLES

INTRODUCTION

By incorporating into the driveline of the vehicle the capability to generate electricity onboard the vehicle from a chemical fuel, a hybrid-electric vehicle has the characteristics of both an electric vehicle and a conventional internal combustion engine (ICE) vehicle and can be operated either on wall-plug electricity stored in a battery or from a liquid fuel (e.g., gasoline) obtained at a service station. This essay discusses technologies for hybrid-electric vehicles that can attain significantly higher fuel economy and lower emissions than conventional ICE vehicles of the same size, performance, and comfort.

HYBRID-ELECTRIC VEHICLE DESIGN OPTIONS

There are a large number of ways an electric motor, engine, generator, transmission, battery, and other energy storage devices can be arranged to make up a hybrid-electric driveline. Most of them fall into one of two configurations—series and parallel. In the series configuration (Figure 1, Top), the battery and engine/generator act in series to provide the electrical energy to power the electric motor, which provides all the torque tot he wheel of the vehicle. In a series hybrid, all the mechanical output of the engine is used by the generator to produce electricity to either power the vehicle or recharge the battery. This is the driveline system used in diesel-electric locomotives. In the parallel configuration (Figure 1, Bottom), the engine and the electric motor act in parallel to provide torque to the wheel of the vehicle. In the parallel hybrid, the mechanical output of the engine can be used to both power the vehicle directly and to recharge the battery or other storage devices using the motor as a generator. In recent years, a third type of hybrid configuration, the dual mode, is being developed that combines the series and hybrid configurations. As shown in Figure 1b, the engine output can be split to drive the wheel (parallel mode) and to power a generator to produce electricity (series mode). This configuration is the most flexible and efficient, but it is also likely to be the most complex and costly.

A range-extended electric vehicle would most likely use the series configuration if the design is intended to minimize annual urban emissions. It would be designed for full-performance on the electric drive alone. The series hybrid vehicle can be operated on battery power alone up to its all-electric range with no sacrifice in performance (acceleration or top speed) and all the energy to power the vehicle would come from the wall plug. This type of hybrid vehicle is often referred to as a “California hybrid” because it most closely meets the zero emission vehicle (ZEV) requirement. The engine would be used only on those days when the vehicle is driven long distances.

Hybrid vehicles designed to maximize fuel economy in an all-purpose vehicle could use the series, parallel, or dual configurations depending on the characteristics of the engine to be used and acceptable complexity of the driveline and its control. Parallel hybrid configurations will require frequent on-off operation of the engine, mechanical components to combine the engine and motor torque, and complex control algorithms to smoothly blend the engine and motor outputs to power the vehicle efficiently. The parallel hybrid would likely be designed so that its acceleration performance would be less than optimum on either the electric motor or engine alone and require the use of both drive components together to go zero to sixty mph in 10–12 sec. Such a hybrid vehicle would not function as a ZEV in urban/freeway driving unless the driver was willing to accept reduced acceleration performance. The parallel configuration can be designed to get better mileage than the series configuration. A fuel cell hybrid vehicle would necessarily be a series hybrid because the fuel cell produces only electricity and no mechanical output. The dual mode hybrid is intended to maximize fuel economy and thus be designed like a parallel hybrid, but with a relatively small generator that could be powered by the engine. The engine in the dual mode hybrid would operate in

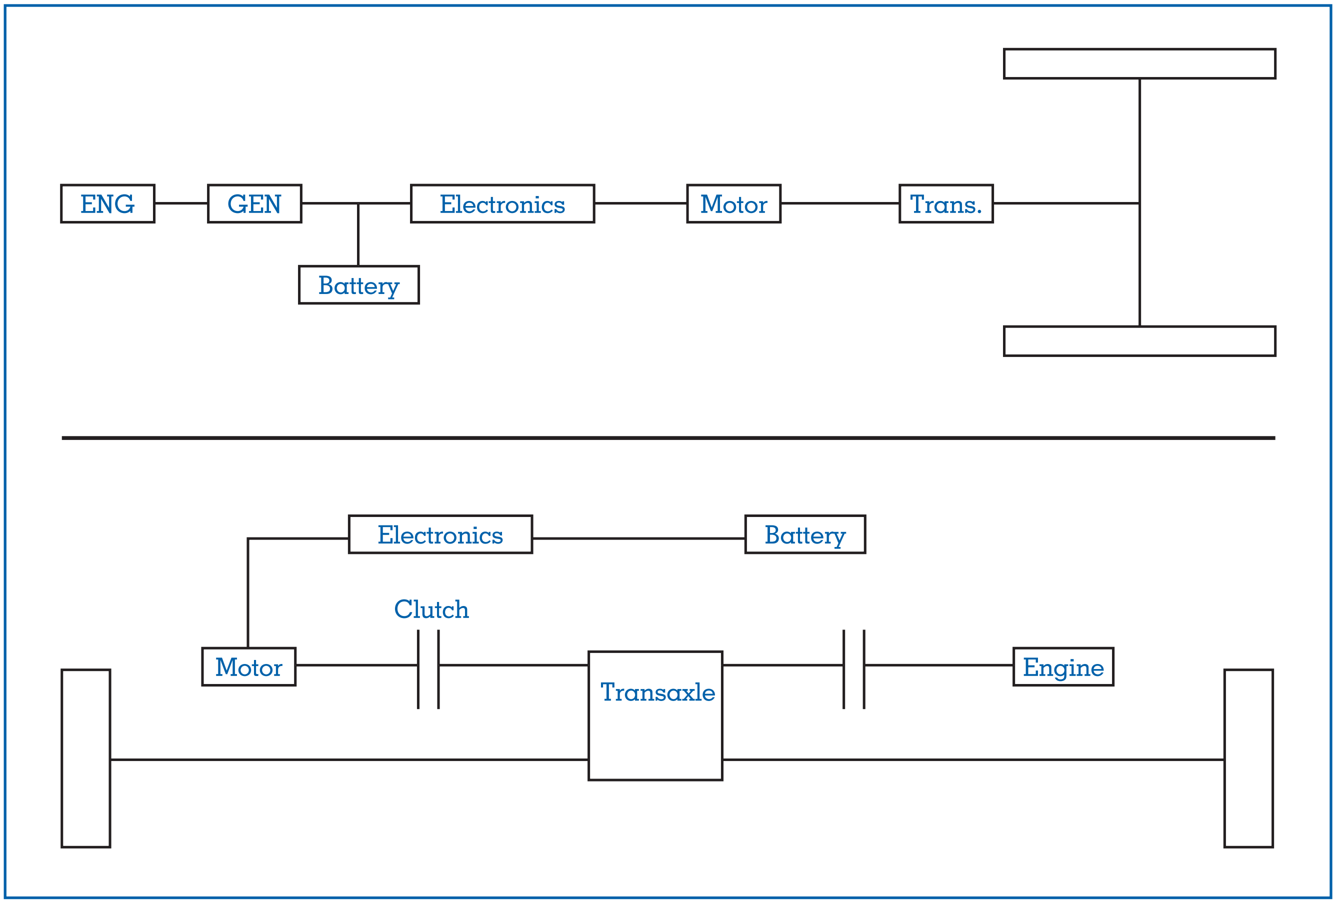

Figure 1.
Hybrid Vehicle Driveline Schematics.
NOTE: Top: Series; Bottom: Parallel

the on/off mode, but be cycled on and off less frequently than in the parallel configuration.

COMPONENT TECHNOLOGIES: STATUS AND PROSPECTS

Motor and Electronics

Recent advances in both motor and inverter electronics technologies have important implications for the design of high performance hybrid vehicles. In 2000 the size and weight of the motor and the electronics combined are significantly smaller (by a factor of two to three—see Table 1) than that of an engine and transmission of the same peak power in 1998. The size advantage of the electrical components will be even greater as the operating voltage of the electrical drive system is increased above the 300–400V that is common today. This means that in packaging the hybrid driveline, the electrical drive components take up only a fraction of the space available and finding room for the mechanical components, such as the engine, transmission or torque coupler, can present a difficult challenge.

Electrical Energy Storage

The key component in the hybrid driveline that permits it to operate more efficiently than the engine/transmission in a conventional car is the electrical energy storage unit. It must store sufficient energy (kWh) to provide the all-electric range of the vehicle or to permit the engine or fuel cell to operate near the average power required by the vehicle (in a load-leveled mode). It also must have sufficient power capability to meet on demand the peak power of the motor/electronics for vehicle acceleration or

Hybrid Vehicle Engine Characteristics

regenerative braking. In most cases, the energy storage unit in a hybrid vehicle is sized by the peak power requirement. Because the size (weight and volume) of the energy storage unit (often a battery) in the hybrid vehicle is smaller than the battery in a battery-powered electric vehicle (EV), the power density (W/kg and W/liter) requirements of the energy storage unit in the hybrid vehicle are greater than for the battery in an electric vehicle. For example, power densities of 200–300W/kg are satisfactory for use in an EV, but power densities of 500–1,000W/kg are needed for hybrid vehicles. Considerable progress has been made in the development of high power batteries (often referred to as pulse batteries) of various types. In hybrid vehicles, the energy density of the energy storage unit is of secondary importance; compromises in energy density have been made to reach the high power density of pulse batteries. For example, nickel metal hydride batteries designed for EVs have an energy density of 70Wh/kg and a power density of 250 W/kg, while those designed for hybrid vehicles have an energy density of 40–45Wh/kg and a peak power density of 600–700W/kg. Another important consideration for energy storage units for use in hybrid vehicles is the need to minimize the losses associated with transferring energy into and out of the unit, because in the hybrid, a reasonable fraction of the electrical energy produced onboard the vehicle is stored before it is used to power the vehicle. In order to minimize the energy storage loss, the round-trip efficiency (energy out/energy in) should be at least 90 percent. This means that the useable peak power capability of a battery is much less that the power into a match impedance load at which efficiency of the transfer is less than 50 percent. Useable power is only about 20 percent of the peak power capacity. This is another reason that the design of an energy storage units for hybrid vehicles is much more difficult than for battery-powered electric vehicles and energy storage technology is often described as the enabling technology for hybrid vehicles.

A new energy storage technology that is well suited for hybrid vehicles is the electrochemical ultracapacitor, often referred to as the double-layer capacitor. Ultracapacitors for vehicle applications have been under development since about 1990. The construction of an ultracapacitor is much like a battery in that it consists of two electrodes, a separator, and is filled with an electrolyte. The electrodes have a very high surface area (1,000–1,500 m^2/gm) with much of the surface area in micropores 20 angstroms or less in diameter. The energy is stored in the double-layer (charge separation) formed in the micropores of the electrode material. Most of the ultracapacitors presently available use activated carbon as the electrode material. The cell voltage is primarily dependent on the electrolyte used. If the electrolyte is aqueous (sulfuric acid or KOH) the maximum cell voltage is 1V; if an organic electrolyte (propylene carbonate) is used, the maximum cell voltage is 3V. As in the case of batteries, high voltage units (300–400V) can be assembled by placing many ultracapacitor cells in series.

Batteries have much higher energy density and capacitors have much higher power capacity. The technical challenge for developing ultracapacitors for vehicle applications is to increase the energy density (Wh/kg and Wh/liter) to a sufficiently high value that the weight and volume of a pack to store the required energy (500 Wh for a passenger car) is small enough to be packaged in the vehicle. Power density and cycle life are usually not a problem with ultracapacitors. The cost ($/Wh) of ultracapacitors is presently too high—being about $100/Wh. It must be reduced by at least an order of magnitude (a factor of 10) before this new technology will be used in passenger cars. Nevertheless, ultracapacitors are a promising new technology for electrical energy storage in hybrid vehicles.

Engines and Auxiliary Power Units

The characteristics of engines for hybrid vehicles are shown in Table 1. Most of the hybrid vehicles designed and built have used four stroke gasoline or diesel engines. Nearly all gasoline engines are now fuel-injected and both gasoline and diesel engines are computer controlled. Continuing improvements are being made in these engines in terms of size, weight, efficiency, and emissions. These improvements and the common use of computer control make it fairly easy to adapt the conventional engines to hybrid vehicle applications. The major difficulty in this regard is to find an engine of appropriate power rating for hybrid vehicle application. Most automotive engines have power of 60kW (75hp) and greater, which is too large for use in most hybrid vehicle designs. Experience has shown that good sources of engines for hybrid vehicles are the minicars designed for the small car markets on Japan and Europe.

Several advanced engines have been developed especially for hybrid vehicles. These include a high-expansion ration gasoline engine (Atkinson cycle) developed by Toyota for their Prius hybrid vehicle which they started to market in Japan in 1997. Stirling Thermal Motors (STM) under contract to General Motors (GM) designed and fabricated a Stirling engine (30kW) for use on GM's series hybrid vehicle built as part of the Department of Energy (DOE) hybrid vehicle program. Capstone Technology developed a 25kW recuperative gas turbine engine for use in a flywheel hybrid vehicle built by Rosen Motors. The characteristics of these engines are indicated in Table 1. The most successful of these engine development projects was the Prius engine of Toyota. The other two engines were too large and were not efficient enough to warrant further development for hybrid vehicle applications. The new Toyota engine in the Prius is a four cylinder (1.5 liter), four stroke gasoline engine that utilizes variable inlet valve timing to vary the effective compression ratio from 9.3 to 4.8 in an engine having a mechanical compression ratio of 13.5. Varying the effective volume of air during the intake stroke permits operation of the engine at part load with reduced pumping and throttling losses. This results in an increase in engine efficiency. The expansion ratio at all times is set by the high mechanical compression ratio of the engine. This new engine was optimized for operation in the hybrid mode and had a brake specific fuel consumption of about 235 gm/kWh for output powers between 10 and 40kW. This corresponds to an efficiency of 37 percent, which is very high for a four stroke gasoline engine of the same peak power rating.

The engine output in a hybrid vehicle can be utilized to generate electricity on board the vehicle or to provide torque to the driveshaft of the vehicle. In the first case, the engine output torque drives a generator and the combination of the engine and the generator is termed an auxiliary power unit (APU). The generator can be either an ac induction or a brushless dc permanent magnet machine. The size of the generator for a given power rating depends to a large extent on the voltage of the system and the rpm at which the generator rotates. For a 400V system and a maximum of 8,000–10,000, the size and weight of the APU are 0.7kg/kW and 0.8 liter/kW, respectively, including the electronic controls. The efficiency of the generator system will vary between 90 to 95 percent depending on the power output. The losses associated with the production and storage of the electrical energy onboard the vehicle in a series hybrid are significant (10 to 20%) and cannot be neglected in predicting the fuel economy of the vehicle.

Mechanical Components

The transmission, clutch, and other mechanical components needed in a hybrid vehicle to combine the output of the engine with the electric motor and generator and the main driveshaft of the vehicle are critical to the efficient and smooth operation of parallel and dual mode hybrid vehicles. The design of these components is relatively straightforward and not much different than that for similar components for conventional engine-powered vehicles. In a parallel hybrid (Figure 1b), the engine is connected to the drive shaft through a clutch that opens and closes as the engine power is needed. The speed ratio between the engine and the wheels is determined by the gear ratios in the transmission. Mechanical design of the engine clutch so that it has a long life and smooth operation is one of the critical tasks in the development of the parallel hybrid vehicle. Many hybrid vehicles are built with manual transmissions, because automatic transmissions with a torque converter have unacceptably high losses. A recent development is the use of a continuously variable transmission (CVT) in a parallel hybrid driveline. The operation of the CVT is like an automatic transmission from the driver's point-of-view with the advantages of lower losses and a wider range of continuous gear ratios, which result in efficient driveline operation in both the electric and hybrid modes. The disadvantages of the CVT are that control of the system is more difficult than with a manual transmission and the steel belt used in the CVT is much less tolerant of abuse (sudden changes in speed and torque). Nevertheless, it appears that in the future years CVTs will have application in parallel hybrid drivelines.

There are several arrangements of the dual mode hybrid driveline. In the simplest arrangement (Figure 2), the generator can be used as a motor to start the engine and/or supplemental torque of the traction motor to drive the vehicle. In this dual mode configuration, the batteries can be recharged either by the generator or by the traction motor acting as a generator. This simple dual mode system does not require a transmission. A second dual mode system utilizes a planetary gear set to couple the engine, generator, and main driveshaft. In this arrangement, the speed ratio between the engine and the main driveshaft depends on the fraction of the engine power that is applied to the generator. This second arrangement is used by Toyota in the Prius hybrid car. This system is less flexible and less efficient than the first system in which the engine and generator are directly connected on the same drive shaft, but it does not require a clutch, which must be opened/closed smoothly and reliably under computer control. Operation of the Toyota dual mode hybrid driveline has proven to be smooth and reasonably efficient.

Fuel Cells

Fuel cells can be utilized in electric hybrid vehicles as the means of converting chemical fuel to electricity. Rapid progress has been made in the development of fuel cells, especially proton exchange membrane (PEM) fuel cells, for transportation applications. This progress has resulted in a large reduction in the size and weight of the fuel cell stack and as a result, there is now little doubt that the fuel cell of the required power (20–50kW) can be packaged under the hood of a passenger car. The primary question regarding fuel cells in light duty vehicles is how they will be fueled. The simplest approach is to use high pressure hydrogen as has been done in the most successful bus demonstration to date. This approach is satisfactory for small test and demonstration programs, but the development of the infrastructure for using hydrogen as a fuel in transportation will take many years. Considerable work is underway to develop fuel processors (reformers) to generate hydrogen onboard the vehicle from various chemical fuels (e.g., methanol or hydrocarbon distillates). Most of the hydrogen used for industrial and transportation applications is presently generated by reforming natural gas using well-developed technology. A promising approach to fuel processing to hydrogen (H^+ and electrons) onboard the vehicle is direct oxi-

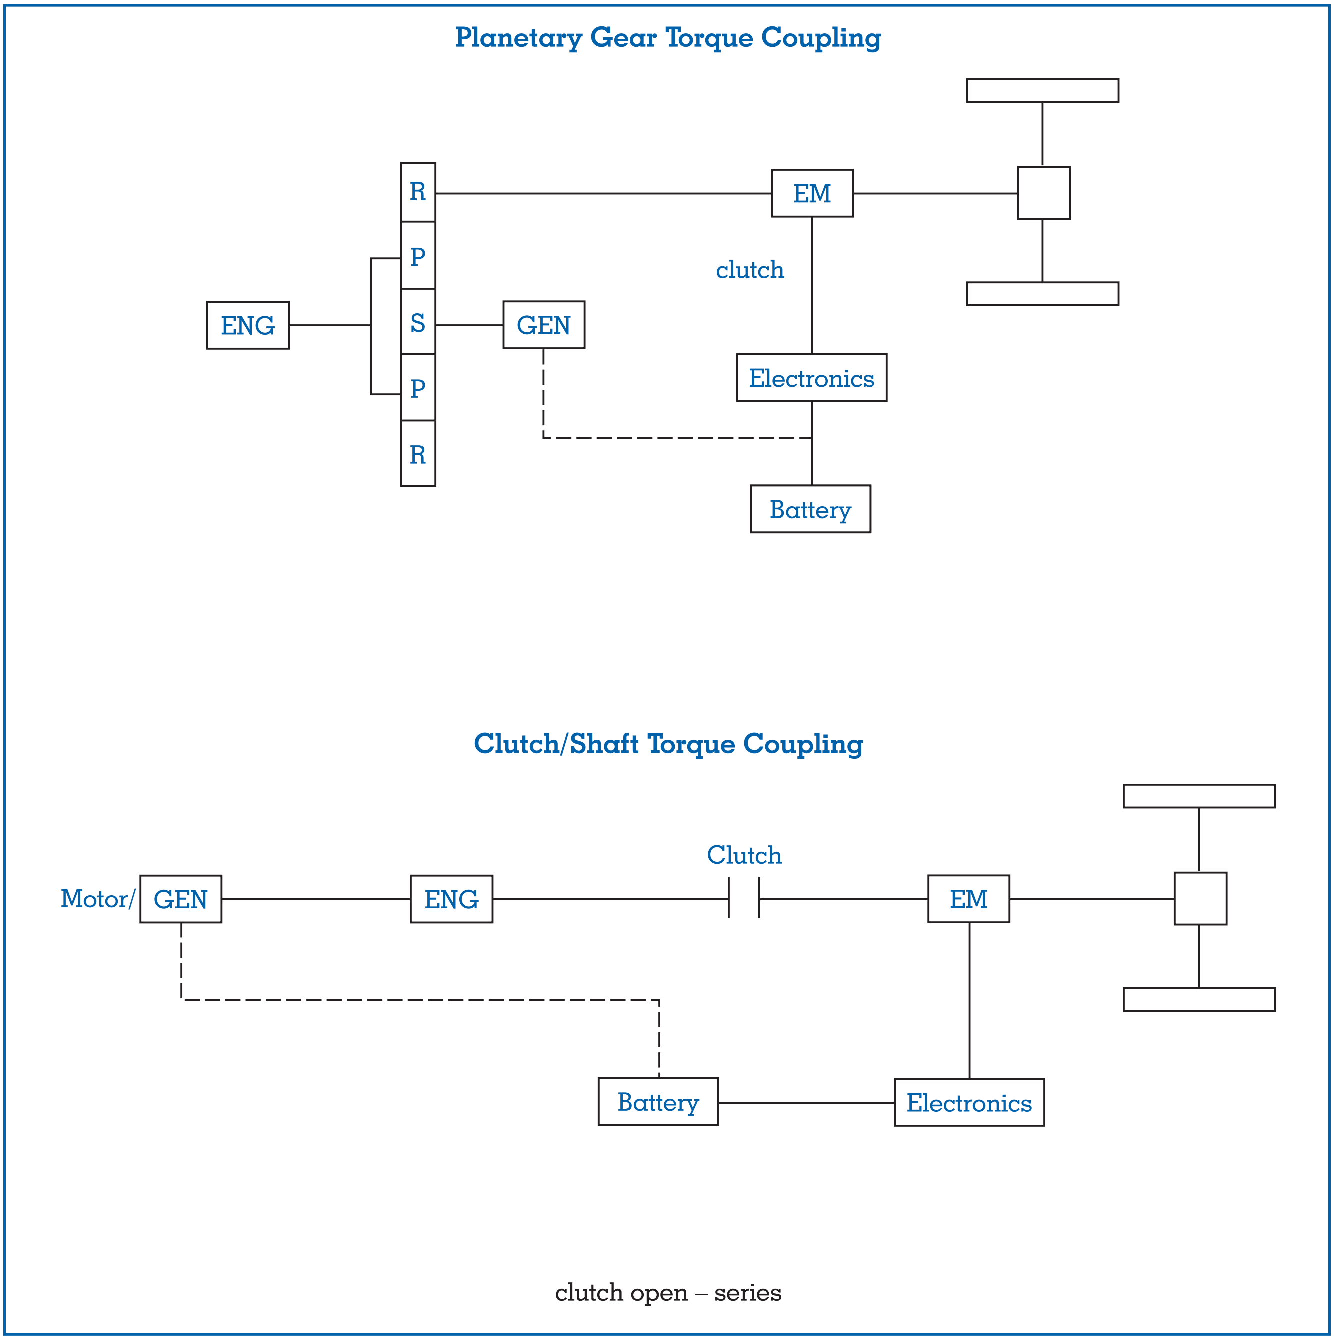

Figure 2
Dual Mode Hybrid Vehicle Driveline Schematics

dation of methanol within the fuel cell stack. When technology for the efficient, direct conversion of a liquid fuel to hydrogen within the PEM fuel cell is developed, the commercialization of fuel cells in light duty vehicles will occur rapidly.

CONTROL STRATEGIES

Control Strategies for Series Hybrid Vehicles

The intent of the control strategy is to maintain the state-of-charge of the energy storage unit within a prescribed range regardless of the driving cycle and the resultant power demand on the driveline. This should be done so that the onboard electrical generator (engine/generator or fuel cell) is operated at high efficiency and low emissions. This is done more easily when the energy storage capacity is reasonably large as with a battery than when it is small as using ultracapacitors. The strategy used for vehicles having a significant all-electric range is to discharge the battery to a prescribed state-of-charge (20 to 30%) and then to turn on the engine to maintain the battery within 10 to 20 percent of that condition. Electrical energy is generated at a rate slightly greater than the average power demand of the vehicle to account for losses associated with storing the energy. In the case of an engine/generator, a minimum power level is set so that the engine is never operated below it. Proper selection of this minimum power can have an important effect on fuel economy. When the battery charge reaches the maximum permitted, the engine is turned off and it remains off until the battery state-of-charge falls to the engine turn-on state-of-charge. When the series hybrid is operated so that the battery is permitted to discharge to a relatively low state-of-charge, it is termed a charge depleting hybrid. If the battery is maintained at a high state-of-charge (60 to 70%), it is termed a charge sustaining hybrid and the battery is seldom, if ever, recharged from the wall-plug. A significant fraction of the energy used by charge depleting hybrid vehicles is from the wall-plug and their average annual emissions and energy consumption are dependent on the use-pattern (miles of travel per day) of the vehicle and how the electricity used to recharge the batteries is generated.

Control Strategies for Parallel Hybrid Vehicles

The control strategies for parallel hybrid vehicles are more complicated than those for series hybrids primarily because they are dependent on both vehicle speed and state-of-charge of the energy storage unit and should include a criteria for splitting the driveline torque between the engine and the electric motor. The intent of the strategy is to permit the electric motor to provide the torque if it can at vehicle speeds below a prescribed value and permit the engine to provide the torque at higher speeds. If the vehicle is operating in the all-electric mode, the motor provides the torque and the engine is not turned on regardless of the torque demand or vehicle speed. Since the all-electric range of a hybrid vehicle is usually less than 80 km, operation of the vehicle should change automatically to the hybrid mode when the all-electric range is exceeded. The control strategy in the hybrid mode can be either charge sustaining or charge depleting. In the case of charge sustaining, the battery state-of-charge is maintained at a near constant value by a control strategy using electrical energy produced by the engine and the motor acting as a generator and consequently little electrical energy is used from the wall-plug. For the charge depleting case, the control strategy permits the battery state-of-charge to decrease as the vehicle is driven and the battery is then recharged from the wall-plug at night. Parallel hybrids usually have a multi-speed transmission so the control strategy must also include a gear shifting algorithm that depends on whether the motor or engine or both are producing torque. A continuously variable transmission (CVT) would be particularly attractive for use in a parallel hybrid driveline.

In order to achieve high fuel economy with a parallel hybrid, it is necessary to avoid engine operation below some minimum engine torque (or effective throttle setting) where the engine brake specific fuel consumption (gm/kWh) is relatively high and to manage engine turn on and off carefully to minimize emissions and wasted fuel. In urban driving, the control strategies for parallel hybrids often result in the engine being turned on and off frequently because the vehicle speed and power demands vary rapidly in stop-and-go driving. The effects of this on-off engine operation on fuel usage and emissions for the parallel hybrids are neglected in most simulations at the present time, so further analysis and vehicle testing is needed to determine whether the high fuel economy and low emissions projected for parallel hybrids can be attained. The control strategies for parallel hybrids are necessarily more complex than those for series hybrids and the uncertainty in the simulation results for parallel hybrids are greater.

Control Strategies for Dual Mode Hybrid Vehicles

The control strategies for dual mode hybrid vehicles are a combination of those used for series and parallel hybrids. There are so many possible hardware arrangements and associated control strategies, it is not possible to summarize them in a simple manner as was the case for series and parallel hybrids. The objective of the dual mode operation is to use the possibility of battery charging simultaneously with the use of the engine and electric motor to power the vehicle as a means of maintaining engine operation at high efficiency at all times. At highway speeds, the engine can be used directly to power the vehicle with the engine operating at high efficiency. This mode of operation is essentially that of a parallel hybrid. At low vehicle speeds, when the battery does not need charging (state-of-charge greater than a specified value), the driveline would operate in an electric-only mode if the electric motor can provide the power required by the vehicle. If the power demand is greater than that available from the electric motor, the engine is turned on to assist the electric motor. At low speeds when the battery requires charging, the engine output is split between powering the generator and the vehicle. The possibility of splitting the engine output in this way at low vehicle speeds is the distinguishing feature of the dual mode hybrid configuration. This permits the engine to be operated near its maximum efficiency at all times and the battery to be recharged, when needed, regardless of the vehicle speed and power demand. The dual mode arrangement also reduces the need for on-off engine operation as required in the series and parallel control strategies. Dual mode hybrids are operated with the battery state-of-charge maintained in a narrow range (charge sustaining) and thus require no recharging of the battery from the wall-plug. The Toyota Prius hybrid vehicle uses this dual mode operating strategy.

PERFORMANCE OF HYBRID VEHICLES

The added complexity of the various hybrid vehicle designs relative to battery-powered electric vehicles and conventional engine-powered vehicles is evident. In order to justify this added complexity, hybrid vehicles must be more marketable than pure electric vehicles and have higher fuel economy and lower emissions than conventional engine-powered vehicles. All the vehicle types (electric, hybrid, and conventional) can be designed to have the same acceleration performance and top speed by the proper selection of the driveline components. Acceleration times of 0–96 km/hr (60 mph) in less than 8 sec and top speeds in excess of 120 km/hr for passenger cars have been demonstrated for both pure electric and hybrid vehicles. The primary advantage of the hybrid vehicle compared to the electric vehicle is that its range and refueling time can be the same or better than the conventional vehicle because it is refueled in the same manner—at the fuel pump. The key comparisons of interest are the fuel economy, emissions, and costs of hybrid and conventional vehicles.

Computer simulations have been performed for both midsize and compact, lightweight vehicle designs for driving on the Federal Urban Driving Schedule (FUDS) and the Federal Highway Driving Schedule (FHWDS). These driving cycles (speed vs. time) are intended to simulate vehicle operation in city and highway driving. For each vehicle type, computer simulations were run using gasoline fuel injected engines, diesel engines, and Stirling engines. Electricity was generated on board the hybrid vehicles by coupling the engines to a generator or by utilizing a fuel cell fueled using compressed hydrogen. In all cases, electrical energy was recovered into the energy storage unit during braking using the traction motor as a generator. The control strategies used in the simulations were essentially those previously discussed in the section on control strategies. In all cases, the engines and fuel cell were operated in an on-off mode to maintain the energy storage unit in the state-of-charge range specified by the control strategy. The minimum power setting of the engines and fuel cell when they were "on" were set so their efficiency was not outside the high efficiency portion of their operating maps.

Fuel Economy

Fuel economy simulation results for various engines in series hybrids are compared in Table 2 for the FUDS and FHWDS driving cycles. For both the midsize and compact cars, fuel economy depends significantly on the technology used in the driveline. The use of diesel engines results in the highest fuel economy (miles per gallon of diesel fuel); however, from the energy consumption (kJ/mi) and CO_2 emission (gm CO_2/mi) points-of-view, the advantage of diesel engine relative to gasoline-fueled engines should be discounted to reflect the higher energy and the carbon content per gallon of diesel fuel compared to gasoline. These discount factors are 15 to 20 percent. The simulation results also indicate that for the same type of engine, the fuel economy can be 10 to 20 percent higher using ultracapacitors in place of batteries as the energy storage device. The highest fuel economics are projected for vehicles using fuel cells. The fuel economies (gasoline equivalent) of the fuel cell vehicles using compressed hydrogen are

Vehicle	*Engine*	*Energy Storage*	*Miles per Gallon* *FUDS*	*Highway*
Midsize	Honda Gasoline	Ni. Mt. Hy. Bat.	36.1	45.4
	Direct Injection Gasoline	Ni. Mt. Hy. Bat.	47.3	56.0
	Sw. Ch. Diesel	Ni. Mt. Hy. Bat.	49.7	56.8
	Direct Injection Diesel	Ni. Mt. Hy. Bat.	60.5	71.1
	Stirling	Ni. Mt. Hy. Bat.	50.0	57.2
	Honda Gasoline	Capacitor	44.3	47.3
	Sw. Ch. Diesel	Capacitor	62.3	65.7
	Fuel Cell (H_2)	Ni. Mt. Hy. Bat.	89.2	105.0
Lightweight Compact	Honda Gasoline	Ni. Mt. Hy. Bat.	69.6	71.4
	Direct Injection Gasoline	Ni. Mt. Hy. Bat.	82.9	84.9
	Sw. Ch. Diesel	Ni. Mt. Hy. Bat.	98.2	95.6
	Direct Injection Diesel	Ni. Mt. Hy. Bat.	107.3	110.4
	Stirling	Ni. Mt. Hy. Bat.	89.5	92.7
	Honda Gasoline	Capacitor	81.4	75.5
	Sw. Ch. Diesel	Capacitor	109.8	104.0
	Fuel Cell (H_2)	Ni. Mt. Hy. Bat.	16.3	17.9

Table 2.
Summary of Hybrid Vehicle Fuel Economy Results on the FUDS and Highway Driving Cycles using Various Engines and a Fuel Cell
(1) mpg diesel fuel for diesel engine and mpg gasoline equivalent for fuel cell powered vehicles

about twice those of hybrid vehicles with direct injected gasoline engines and about 80 percent higher than vehicles with diesel engines. All the fuel cell vehicle designs utilized a fuel cell load-leveled with a nickel metal hydride battery permitting it to operate at high efficiency at all times.

In comparisons between the fuel economies of conventional passenger cars and those using series hybrid divelines, the hybrid vehicles have the same weight and road load as the conventional cars. Still, the utilization of the hybrid driveline resulted in about a 50 percent improvement in fuel economy for the FUDS cycle and about a 10 percent improvement on the FHWDS (highway cycle). The fuel economy of the conventional cars was taken from the EPA Fuel Economy Guide corrected by 10 percent for the FUDS and 22 percent for the highway cycle. These corrections were made, because the actual dynamometer fuel economy test data had been reduced by those factors so that the published fuel economies would be in better agreement with values experienced in the real world.

The fuel economy of series and parallel hybrid vehicles are compared in Table 3 for both the compact, lightweight, and midsize cars. The series hybrids are assumed to operate only in the charge sustaining mode (no battery recharging from the wall plug), but the parallel hybrids can operate in either the charge sustaining or charge depleting mode. In the case of the parallel hybrid in the charge depleting mode, the fuel economy is given for gasoline alone and at the powerplant (pp) including energy needed to recharge the batteries from the wall plug. For hybrid vehicles using gasoline engines (port injected), the fuel economy of the parallel hybrid vehicles in the charge sustaining mode (batteries charged from the engine—not from the wall plug) is 9 to 12 percent higher than that of the series hybrids. For the powerplant efficiency (33%) assumed in the calculations, the parallel hybrids operating in the charge depleting mode (battery charged only from the wall plug) had only 1 to 4 percent higher equivalent fuel economy than the same vehicle operating in the charge sustaining mode. If the batteries were recharged using electricity from a higher efficiency powerplant, the fuel economy advantage of the parallel hybrid in the charge depleting mode would be lighter.

Vehicle	*Fuel Economy (mpg) Gasoline Engine* *FUDS*	*Highway*	*Fuel Economy (mpg) Swirl Chamber Diesel* *FUDS*	*Highway*
Small, lightweight				
Series Hybrid				
Charge Sustaining	62.4	71.1	75.7	85.2
Parallel Hybrid				
Charge Sustaining	68.2	79.5	75.9	88.8
Charge Depleting				
gasoline alone	90.1	86.1	95.6	94.0
Including power plant	71.1	80.5	75.8	88.1
Midsize (1995 materials)

Full Fuel Cycle Emissions

The full fuel cycle emissions of the hybrid vehicles are the total of all the emissions associated with the operation of the vehicle and the production, distribution, and dispensing of the fuel and electricity to the vehicle. The total emissions can be calculated for all the vehicle designs utilizing as inputs the vehicle simulation results for the electricity consumption, fuel economy, and exhaust emissions in the all-electric and hybrid modes and the upstream refueling, evaporative, and fuel production emissions based on energy usage—bothfuel and electricity. Both regulated emissions (nonmethane organic gases [NMOG], CO, NO_x) and CO_2 emissions can be calculated.

Regulated Emissions for Hybrid, Electric, and Conventional Cars

Hybrid vehicles operated in the charge depleting mode (battery charged from the wall plug) have total emissions comparable to those of electric vehicles if their all-electric range is 50 mi or greater. Hybrid vehicles operating in the charge sustaining mode have much greater NMOG emissions than electric vehicles when the refueling and evaporative emissions are included. The calculated total emissions of the electric vehicles are close to the equivalent zero emission vehicle (EZEV) emissions when the battery charging is done in the Los Angeles (LA) basin. These comparisons are based on the total NMOG, CO, and NO_x emissions for the FUDS and highway driving cycles for electric vehicles and conventional ICE vehicles as well as hybrid vehicles. A baseline use pattern of 7,500 miles per year random, city travel, and a round trip to work of 15 miles was assumed.

Total CO_2 Emissions

The difference in the CO_2 emissions between operating a hybrid vehicle in charge depleting and charge sustaining modes, regardless of its all-electric range, is not large using nickel metal hydride batteries. The CO_2 emissions of the gasoline and diesel engine powered hybrids vary only about 25%—not as much as might be expected based on the differences in their fuel economies—because of the higher energy content and the higher carbon-to-hydrogen ratio of the diesel fuel. The fuel cell powered, hydrogen fueled vehicles are projected to have the lowest CO_2 emissions by 25 to 30 percent when compared to the most efficient of the engine powered vehicles even when the hydrogen is produced by reforming natural gas. The CO_2 emissions of the conventional ICE vehicles are directly proportional to their fuel economy, which is projected to be significantly less than the hybrid vehicles. ICE powered vehicles will have low CO_2 emissions only when their fuel economy is greatly increased. CO_2 emissions of vehicles are highly dependent on the technologies used to power them and can vary by a factor of at least two for the same size and weight of vehicle.

TESTING OF HYBRID VEHICLES

There have been relatively few tests of hybrid vehicles in recent years. One example of such tests is that of the Toyota Prius by the EPA. Special care was taken in those tests to account for changes in the net state-of-charge of the batteries on the vehicle. The simulation results were obtained using the same hybrid vehicle simulation program used to obtain the fuel economy projections given in Table 2. There is good agreement between the measured and calculated fuel economies for the Prius. The EPA emissions data indicate that the CO and NO_x emissions of the Prius are well below the California ULEV standards and that the NMOG emissions are only slightly higher than the 0.04 gm/mi ULEV standard. The fuel economy of the Prius on the FUDS cycle (in city driving) is 56 percent higher than a 1998 Corolla (equipped with a 4-speed lockup automatic transmission) and 11 percent higher for highway driving. These two improvements in fuel economy for a hybrid/electric car compared to a conventional ICE car of the same size are consistent with those discussed earlier in the section on fuel economy.

PROSPECTS FOR MARKETING HYBRID CARS

The societal advantages of the hybrid-electric vehicles will come to fruition only when a significant fraction of vehicle purchasers decide to buy one of them. This will occur if the purchase of the hybrid vehicles makes economic sense to them and the vehicle meets their needs. Otherwise vehicle buyers will continue to purchase conventional ICE-powered vehicles. The key to any workable marketing strategy is the availability of hybrid driveline technologies that make the transition from engine-based to electric-based drivelines manageable and attractive to the consumer with only modest financial incentives. The state of development of the new driveline technologies at the time of introduction must be such that vehicles meet the needs of the first owners and they find vehicles to be reliable and cost-effective to operate. Otherwise the market for the new technologies will not increase and the introduction of the new technologies at that time will be counterproductive. Even after the technical and economic feasibility of a new technology is shown in prototype vehicles, a large financial commitment is needed to perform the preproduction engineering and testing of the vehicles before the vehicles can be introduced for sale.

Starting in the fall of 1997, Toyota offered for sale in Japan the Prius Hybrid at a price close to that of the comparable conventional car. The initial response of the public was enthusiastic and the production rate quickly rose to more than 1,000 vehicles per month. Toyota is planning to introduce a redesigned Prius in the United States in the fall of 2000. Honda began selling a subcompact hybrid/electric car, the Insight, in the United States in the fall of 1999 at a price of less than $20,000, which is about $5,000 higher than the Honda Civic. According the EPA tests, the corporate average fuel economy (CAFÉ) (combined city and highway cycles) of the Honda Insight is 76 mpg.

Recent advances in exhaust emission technologies have resulted in the certification by several auto manufacturers of conventional gasoline fueled cars that can meet the California ULEV and SULEV standards. It seems important that the driving force for the eventual introduction of the hybrid-electric and fuel cell cars will be improved fuel economy and lower CO_2 emissions and not lower regulated emission standards. It appears likely that a significant increase in the price of energy (either because of scarcity or higher taxes), regulation (for example, the CAFÉ standard), or financial incentives to purchase and license hybrid vehicles will be necessary before advanced technology hybrid vehicles become popular.

HYDROELECTRIC ENERGY

Hydroelectric energy—electric power created by the kinetic energy of moving water—plays an important role in supplying the world's electricity. In 1996, nearly 13 trillion kilowatt-hours of electricity were generated worldwide; almost one-fifth of this electricity was produced with hydroelectricity. On average hydropower provides about ten percent of the U.S. electricity supply, although the annual amount of electricity generated by hydroelectric resources varies due to fluctuations in precipitation. In many parts of the world, reliance on hydropower is much higher than in the United States. This is particularly true for countries in South America where abundant hydroelectric resources exist. In Brazil, for example, 92 percent of the 287 billion kilowatt-hours of electricity generated in 1996 were generated by hydroelectricity.

There are many benefits for using hydro resources to produce electricity. First, hydropower is a renewable resource; oil, natural gas, and coal reserves may be depleted over time. Second, hydro resources are indigenous. A country that has developed its hydroelectric resources does not have to depend on other nations for its electricity; hydroelectricity secures a country's access to energy supplies. Third, hydroelectricity is environmentally friendly. It does not emit greenhouse gases, and hydroelectric dams can be used to control floods, divert water for irrigation purposes, and improve navigation on a river.

There are, however, disadvantages to developing hydroelectric power. Hydroelectric dams typically require a great deal of land resources. In conventional hydroelectric projects, a dam typically is built to create a reservoir that will hold the large amounts of water needed to produce power. Further, constructing a hydroelectric dam may harm the ecosystem and affect the population surrounding a hydro project. Environmentalists often are concerned about the adverse impact of disrupting the flow of a river for fish populations and other animal and plant species. People often must be relocated so that a dam's reservoir may be created. Large-scale dams cause the greatest environmental changes and can be very controversial. China's 18.2 gigawatt Three Gorges Dam project—the world's largest hydroelectric—will require the relocation of an estimated 1.2 million people so that a 412-mile reservoir can be built to serve the dam.

Another potential problem for hydroelectricity is the possibility of electricity supply disruptions. A severe drought can mean that there will not be enough water to operate a hydroelectric facility. Communities with very high dependence on the hydroelectric resources may find themselves struggling with electricity shortages in the form of brownouts and black-outs.

This article begins with a description of how hydroelectricity works, from the beginning of the hydrological cycle to the point at which electricity is transmitted to homes and businesses. The history of the dam is outlined and how dams evolved from structures used for providing a fresh water supply to irrigation and finally to providing electricity. The history of hydropower is considered and the different hydroelectric systems (i.e., conventional, run-of-river, and pumped storage hydroelectricity) currently in use are discussed.

HOW DOES HYDROELECTRICITY WORK?

Hydroelectricity depends on nature's hydrologic cycle (Figure 1). Water is provided in the form of rain, which fills the reservoirs that fuel the hydroelectric plant. Most of this water comes from oceans, but rivers and lakes and other, smaller bodies of water also contribute. The heat of the sun causes the water from these sources to evaporate (that is, to change the water from its liquid state into a gaseous one). The water remains in the air as an invisible vapor until it condenses and changes first into clouds and eventually into rain. Condensation is the opposite of evaporation. It occurs when the water vapor changes from its gaseous state back into its liquid state.

Condensation occurs when air temperatures cool. The cooling occurs in one of two ways. Either the air vapor cools as it rises and expands or as it comes into contact with a cool object such as a cold landmass or an ice-covered area. Air rises for several reasons. It can be forced up as it encounters a cooler, denser body of air, or when it meets mountains or other raised land masses. It can rise as it meets a very warm surface, like a desert, and become more buoyant than the surrounding air. Air also can be forced to rise by storms—during tornadoes particles of air circling to the center of a cyclone collide and are forced up. When the water vapor collides with a cold object, it can become fog, dew, or frost as it condenses. The vapor cools as it rises into the atmosphere and condenses to form clouds and, sometimes, rain.

In order for rain to form, there must be particles in the air (i.e., dust or salt) around which the raindrop can form and which are at temperatures above freezing. When the particles are cooled to temperatures below the freezing point water condenses around them in layers. The particles grow heavy enough that they eventually fall through the clouds in the form of raindrops or— if the air temperature is below the freezing point all the way to the ground — as snow, sleet, or hail.

Much of the rain that reaches the ground runs off the surface of the land and flows into streams, rivers, ponds and lakes. Small streams lead to bigger ones, then to rivers, and eventually back to the oceans where the evaporation process begins all over again.

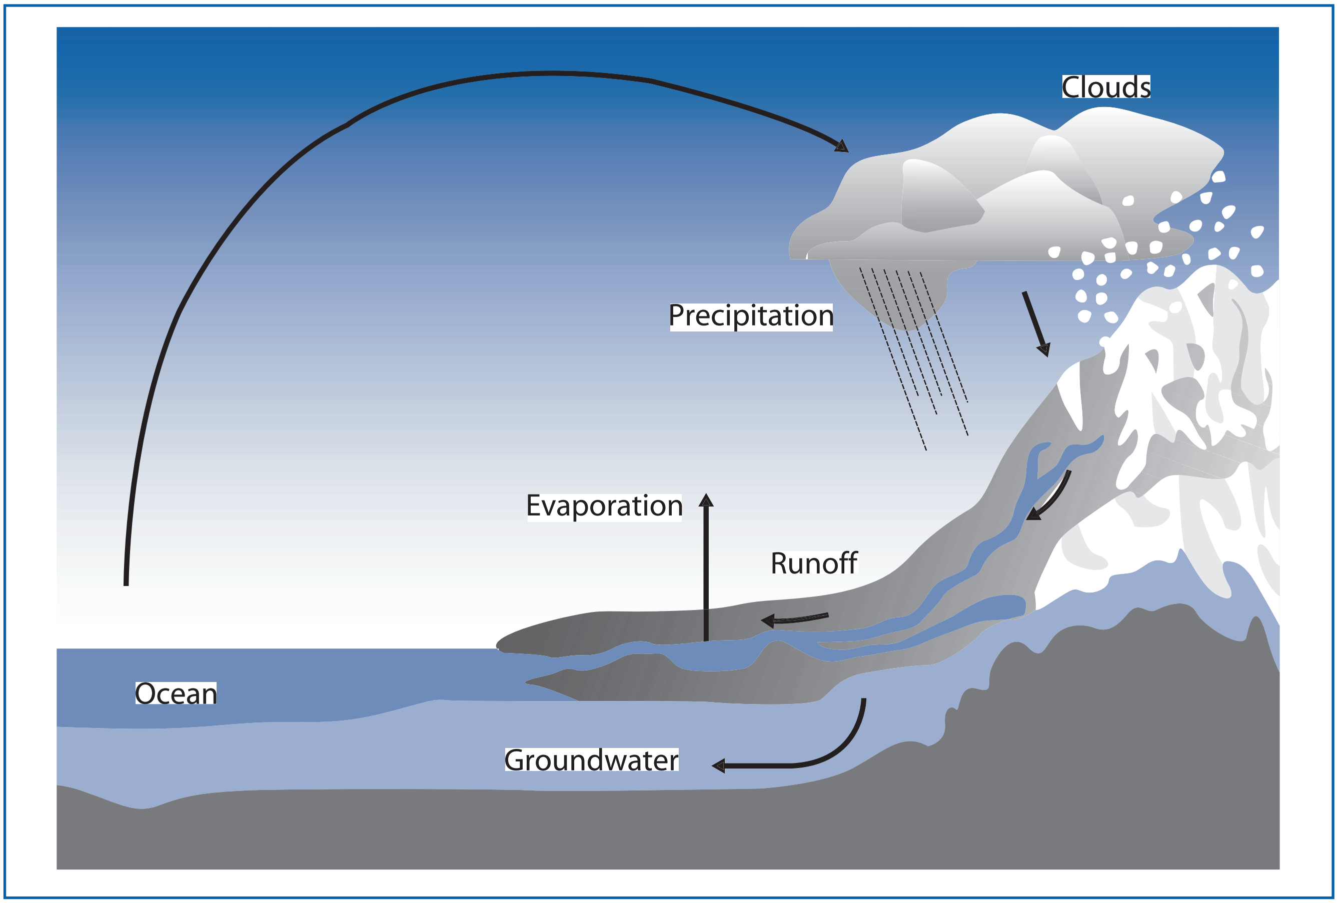

Figure 1.
The Hydrologic Cycle.
SOURCE: U.S. Department of Energy Hydropower Program.

Although water continuously changes from solid to liquid to gas, the amount of water on the earth remains the same; there is as much water today as there was hundreds of millions of years ago.

This water cycle—the process of moving water from oceans to streams and back again— is essential to the generation of hydroelectricity. Moving water can be used to perform work and, in particular, hydroelectric power plants employ water to produce electricity. The combination of abundant rainfall and the right geographical conditions is essential for hydroelectric generation.

Hydroelectric power is generated by flowing water driving a turbine connected to an electric generator. The two basic types of hydroelectric systems are those based on falling water and those based on natural river current, both of which rely on gravitational energy. Gravitational forces pull the water down either from a height or through the natural current of a river. The gravitational energy is converted to kinetic energy. Some of this kinetic energy is converted to mechanical (or rotational) energy by propelling turbine blades that activate a generator and create electricity as they spin.

The amount of energy created by a hydroelectric project depends largely upon two factors: the pressure of the water acting on the turbine and the volume of water available. Water that falls 1,000 feet generates about twice as much electric power as the same volume of water falling only 500 feet. In addition, if the amount of water available doubles, so does the amount of energy.

The falling water hydrosystem is comprised of a dam, a reservoir, and a power generating unit (Figure

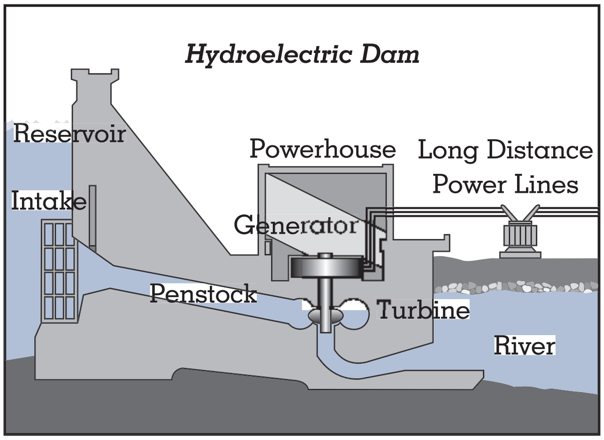

Figure 2.
Conventional, Falling Water Hydroelectric System.
SOURCE: U.S. Department of Energy Hydropower Program.

2). The dam is constructed so that a reservoir is created within which water accumulates and may be stored until it is needed. Water is released as required to meet electricity demands of customers. At the bottom of the dam wall is the water intake. The water intake controls when and how much water is moved into a steel called the "penstock." Gravity causes the water to fall through the penstock. This pipe delivers the running water to a turbine—a propeller-like machine with blades like a large fan. The water pushes against the turbine blades and the blades turn. Because the turbine is connected to an electric generator, as the turbine gains speed, it powers the generator and electricity is produced. The largest falling water facility in the United States is the Grand Coulee hydroelectric project on the Columbia River, in Washington State. Indeed, the largest power production facilities in North America are found at the Grand Coulee Dam project where an average 21 billion kilowatt-hours of electricity are produced each year.

The second type of hydroelectric plant is called a run-of-the-river system. In this case, the force of the river current applies pressure to the turbine blades to produce electricity. Run-of-the-river systems do not usually have reservoirs and cannot store substantial quantities of water. As a result, power production from this type of system depends on the river flow—the electricity supply is highly dependent upon seasonal fluctuations in output. Run-of-river projects are most successful when there are large flows in flat rivers or when a high natural geological drop is present, and when the required electricity output is below the maximum potential of the site.

Hydropower systems, as in all electricity-producing systems, require a generator to create the electricity. An electric generator is a device that converts mechanical energy into electric energy. The process is based on the relationship between magnetism and electricity. When a wire or any other electrically conductive material moves across a magnetic field, an electric current occurs in the wire. In a power plant, a strong electromagnet, called a rotor, is attached to the end of a shaft. The shaft is used to spin the rotor inside a cylindrical iron shell with slots—called a stator. Conducting wires are wound through the slots of the stator. When the rotor spins at a high rate of speed, an electric current flows through the conducting wires.

In a hydroelectric system, flowing water is used to propel a turbine that spins the shaft connected to the generator and creates the electric current. The kinetic energy of the moving water is changed into rotational energy and thereby causes the turbine blades to rotate. The turbine is attached to an electric generator and the rotational energy of the turbine is then converted to electric energy. The electricity then leaves the generator and is carried to the transformers where the electricity can travel through electric power lines and is supplied to residential, commercial, and industrial consumers. After the water has fallen through the turbine, it continues to flow downriver and to the ocean where the water cycle begins all over again.

Pumped storage hydroelectricity is an extended version of the falling water hydroelectric system. In a pumped storage system, two water sources are required—a reservoir located at the top of the dam structure and another water source at the bottom. Water released at one level is turned into kinetic energy by its discharge through high-pressure shafts that direct the downflow through the turbines connected to the generator. The water flows through the hydroelectric generating system and is collected in a lower reservoir. The water is pumped back to the upper reservoir once the initial generation process is complete. Generally this is done using reversible turbines—that is, turbines that can operate when the direction of spinning is reversed. The pump motors are powered by conventional electricity from the national grid. The pumping process usually occurs overnight when electricity demand is at its lowest. Although the pumped storage sites are not net energy producers—pumped storage sites use more energy pumping the water up to the higher reservoir than is recovered when it is released—they are still a valuable addition to electricity supply systems. They offer a valuable reserve of electricity when consumer demand rises unexpectedly or under exceptional weather conditions. Pumped storage systems are normally used as "peaking" units.

HISTORY AND EVOLUTION OF HYDROELECTRIC DAMS

Dams have existed for thousands of years. The oldest known dam, the Sadd el-Kafara (Arabic for "Dam of the Pagans"), was constructed over 4,500 years ago twenty miles south of Cairo, Egypt. The 348-feet wide, 37-feet high dam was constructed to create a reservoir in the Wadi el-Garawi. The dam was built with limestone blocks, set in rows of steps about eleven inches high. It appears that the dam was supposed to be used to create a reservoir that would supply drinking water for people and animals working in a nearby quarry. Scientists and archaeologists believe that the Sadd el-Kafara failed after only a few years of use because there is no evidence of siltation at the remains of the dam. When water flows into the reservoir created by a dam, the silt—sand and other debris carried with the stream—is allowed to settle, rather than be borne further downstream by the force of the flow of a stream or river. In the still water behind a dam this sediment is deposited on the bottom of the reservoir.

The earliest dams were built for utilitarian purposes, to create reservoirs for drinking supplies—as in the Sadd el-Kafara—or to prevent flooding or for irrigation purposes. Early dams were even used to create lakes for recreational purposes. In the middle of the first century, the Roman emperor, Nero, constructed three dams to create three lakes to add to the aesthetic beauty of his villa.

Today a variety of dam structures are utilized. These can be classified as either embankment dams or concrete dams. Embankment dams are constructed with locally available natural resources. There are several different types of embankment dams, including earth dams—which are constructed primarily of compacted earth; tailings dams—constructed from mine wastes; and rockfill dams—which are constructed with dumped or compacted rock. The shape of these dams is usually dependent on the natural settling angle of the materials used to build them. Concrete, bitumen, or clay is often used to prevent water from seeping through the dam. This can be in the form of a thin layer of concrete or bitumen facing which acts as a seal, or in the form of a central core wall of clay or other fine materials constructed within the dam, allowing water to penetrate the upstream side of the structure, but preventing it from moving beyond the clay core.

Concrete dams are more permanent structures than embankment dams. Concrete dams can be categorized as gravity, arch, or buttress. Because concrete is a fairly expensive material, different construction techniques were developed to reduce the quantity of concrete needed. This is highly dependent upon geological considerations. In particular, the rock foundations must be able to support the forces imposed by the dam, and the seismic effects of potential earthquakes. Gravity dams work by holding water back by way of their own weight. A gravity dam can be described as a long series of heavy vertical, trapezoidal structural elements firmly anchored at the base. It is generally a straight wall of masonry that resists the applied water-pressure by its sheer weight. The strength of a gravity dam ultimately depends on its weight and the strength of its base.

An arch dam, on the other hand, relies on its shape to withstand the pressure of the water behind it. The arch curves back upstream and the force exerted by the water is transferred through the dam into the river valley walls and to the river floor. They are normally constructed in deep gorges where the geological foundations are very sound. The United States's Hoover Dam is an example of a concrete arch dam.

The buttress dam uses much less concrete than the gravity dam, and also relies on its shape to transfer the water load. Buttress dams were developed in areas where materials were scarce or expensive, but labor was available and cheap. They have been built primarily for purposes of irrigation. The dams are particularly suited for wide valleys. They have a thin facing supported at an incline by a series of buttresses. The buttresses themselves come in a variety of shapes, including the multiple arch and the simple slab deck (see Figure 3). The weight of the concrete is transferred to bedrock through the downstream legs or "buttresses" of the structure. The Coolidge Dam near Globe, Arizona is an example of a buttress dam, constructed of three huge domes of reinforced concrete.

Using water as a source of power actually dates back more than 2,000 years when the Greeks used water to turn wheels to grind wheat into flour. The first recorded use of water power was a clock, built around 250 B.C.E. and since that time, falling water has provided power to grind corn, wheat, and sugar cane, as well as to saw mills. In the tenth century, water wheels were used extensively in the Middle East for milling and irrigation. One of these dams, built at Dizful—in what is now Iran—raised the water 190 feet and supplied the residents with water to grind corn and sugar cane.

The discoveries associated with electromagnetism in the early nineteenth century had a major impact on the development of hydropower. The development of electric power generators and the fact that electric power was the only form of energy in a "ready to use" state which can be transmitted over long distances has been particularly significant to hydroelectricity. Dams located away from population centers could be useful generators if there was a way to supply the consumers. Water turbines were also developed during the nineteenth century as a natural successor to the water wheel. The high performance and small size of the turbine relative to the water wheel were important advancements. Combining the technology of electric generators, turbines, and dams resulted in the development of hydroelectric power.

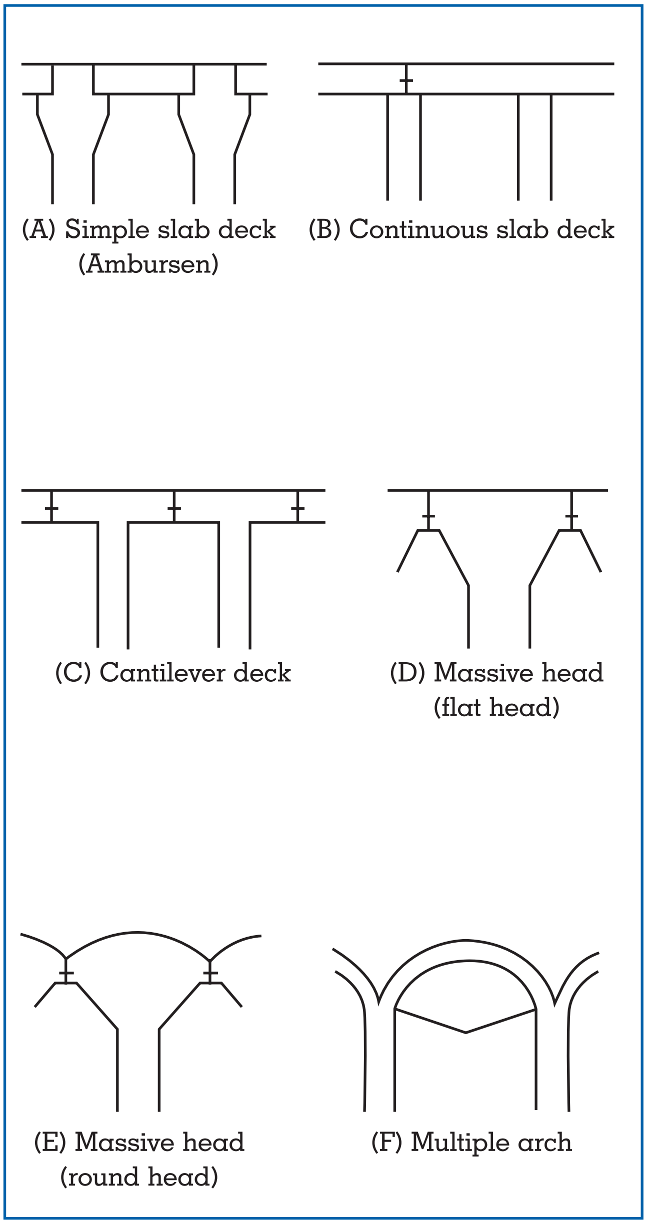

Figure 3.
Types of buttress dams.

Water was first used to generate electricity in 1880 in Grand Rapids, Michigan when a water turbine was used to provide storefront lighting to the city. In 1882—only two years after Thomas Edison demonstrated the incandescent light bulb—the first hydroelectric station to use Edison's system was installed on the Fox River at Appleton, Wisconsin. In 1881, construction began on the first hydroelectric generating station on the Niagara River in Niagara Falls on the New York-Canadian border. For twenty years, this project met the small electricity needs of the city. Water from the upper Niagara River fell 86 feet down a flume (a narrow gorge with a stream running through it) onto spinning water wheels on the lower river to generate electricity. The electricity was used to run the equipment of a paper company, other small factories, and sixteen open arc-lights on village streets. By 1896, the first long-distance transmission of electricity allowed the Niagara Falls project to provide electricity to Buffalo, New York—some 26 miles away.

By the early twentieth century, hydroelectric power was providing more than 40 percent of electricity generation in the United States. In 1940, hydropower supplied about three-fourths of all the electricity consumed in the West and Pacific Northwest, and still supplied about one-third of the total U.S. electricity supply. Although hydroelectricity's share of total electricity generation has since fallen to about 10 percent in the United States, hydroelectricity provides almost one-fifth of the world's total electricity generation today.

Hydroengineering has evolved over the past century so that it has become possible to build larger and larger hydroelectric projects. In 2000, the largest hydroelectric project in the United States was the Grand Coulee power plant on the Columbia river in Washington State. Grand Coulee is also the third largest currently-operating hydroelectric project in the world. The Grand Coulee project began operating in 1941 with 20 megawatts of installed capacity. The project has been expanded so that in 2000 it operated with an installed capacity of 6,180 megawatts.

The world's largest hydroelectric plant is the Itaipú power plant, located on the Paraná river separating Brazil and Paraguay. This 12,600-megawatt hydroelectric project is jointly-owned by Brazil and Paraguay. It is comprised of eighteen generating units, each with an installed capacity of 700 megawatts. The plant produces an estimated 75 billion kilowatt-hours each year. In 1994, Itaipú supplied 28 percent of all the electricity consumed in Brazil's south, southeast, and central-west regions, and 72 percent of Paraguay's total energy. Construction on this mammoth project began in 1975 and was not completed until 1991 at a cost of about $18 billion (U.S.). It required fifteen times more concrete than the Channel Tunnel that connects France and the United Kingdom; and the amount of steel and iron used in its construction would have built 380 Eiffel towers. The main dam of Itaipú is a hollow gravity type dam, but a concrete buttress dam and two embankment dams were also incorporated into the system design. At its highest point, the main dam is 643 feet—more than twice as high as the Statue of Liberty; it extends nearly five miles across the Paraná River.

The large-scale disruptions to the environment of projects like the Itaipú hydroelectric system are profound and this is one of the major disadvantages to constructing large-scale hydroelectric facilities. As a result of construction on Itaipú, over 270 square miles of forest land has been negatively impacted, mostly on the Paraguayan side of the Paraná River where an estimated 85 percent of the forest was destroyed during the early years of construction. Despite programs to minimize the environmental damage through migration to reserves of the wildlife and plants facing extinction, several plant species became extinct mostly because they did not survive the transplant process.

Itaipú no longer represents the upper limit of large-scale hydroelectric expansion. At the end of 1994, the Chinese government announced the official launching of construction on the Three Gorges Dam hydroelectric project. When completed in 2009, this 18,200-megawatt project will provide the same amount of electricity as thirty 600-megawatt coal-fired plants. Project advocates expect the dam to produce as much as 85 billion kilowatt-hours of electricity per year, which is still only about 10 percent of the 881 billion kilowatt-hours of electricity consumed by China in 1995. It will also be used to control flooding along the Yangtze River and will improve navigational capacity, allowing vessels as large as 10,000 tons to sail upstream on the Yangtze as far as Chongqing, 1,500 miles inland from Shanghai. It is a very controversial project that will require the relocation of an estimated 1.2 million people, and that will submerge thirteen cities, 140 towns, 1,352 villages, and some 650 factories in its 412-mile reservoir that is to be created to support the dam. Disrupting the flow of the river will place several rare plant and animals at risk, including the endangered Yangtze River dolphin. Some environmentalists believe the reservoir created for the Three Gorges Dam project will become a huge pollution problem by slowing the flow of the Yangtze River and allowing silt to build up, possibly clogging the planned harbor at Chongqing within a few decades. The World Bank and the U.S. Export-Import Bank have refused to help finance the project, primarily because of the adverse environmental effects this massive hydroelectric project might have. Opponents to the Three Gorges Dam project have stated that smaller dams built on Yangtze River tributaries could produce the same amount of electricity and control flooding along the river, without adversely impacting the environment and at a substantially lower price than this large-scale project.

Hydroelectric projects can have an enormous impact on international relations between surrounding countries. For instance, the controversy between Hungary and Slovakia over the Gabcĺkovo dam began at the dam's opening in 1992 and as of 2000 had not been completely resolved, despite a ruling by the International Court of Justice at The Hague in 1997. In its first major environmental case, the Court ruled that both countries were in breach of the 1977 treaty to construct two hydroelectric dams on the Danube River—the Slovakian Gabcĺkovo and, 80 miles to the south, the Hungarian Nagymaros. Hungary suspended work on its portion in 1989 due to protests from the populace and international environmental groups. In 1992, Czechoslovakia decided to complete Gabcĺkovo without Hungarian cooperation. Today, the $500 million, 180-megawatt project supplies an estimated 12 percent of the electricity consumed in Slovakia.

The Court stated that Hungary was wrong to withdraw from the treaty, but that Slovakia also acted unlawfully by completing its part of the project on its own. After almost a year of talks to resolve the differences between the two countries, Hungary and Slovakia agreed to construct a dam either at Nagymaros—the original site of the Hungarian portion of the project—or at Pilismarot. Unfortunately, soon after the agreement was signed, environmental protests began anew and little progress has been made to resolve the situation to everyone's satisfaction.

Another illustration of the political ramifications often associated with constructing dam projects concerns Turkey's plans to construct the large-scale Southeast Anatolia (the so-called GAP) hydroelectric and irrigation project. When completed, GAP will include twenty-one dams, nineteen hydroelectric plants (generating 27 billion kilowatthours of electricity), and a network of tunnels and irrigation canals. Neighboring countries, Syria and Iraq, have voiced concerns about the large scale of the hydroelectric scheme. Both countries argue that they consider the flow of the historic rivers that are to be affected by GAP to be sacrosanct. Scarce water resources in many countries of the Middle East make the disputes over the resource and the potential impact one country may have on the water supplies of another country particularly sensitive.

In the United States, in 2000 there were still over 5,600 undeveloped hydropower sites with a potential combined capacity of around 30,000 megawatts, according to estimates by the U.S. Department of Energy. It is, however, unlikely that a substantial amount of this capacity will ever be developed. Indeed, there is presently a stronger movement in this country to dismantle dams and to restore the natural flow of the rivers in the hopes that ecosystems damaged by the dams (such as fish populations that declined when dams obstructed migratory patterns) may be repaired. The U.S. Department of Interior (DOI) has been working to decommission many hydroelectric dams in the country and to restore rivers to their pre-dam states. In 1997, the Federal Energy Regulatory Commission (FERC) ordered the removal of the 160-year old Edwards Dam on the Kennebec River in Augusta, Maine and the demolition of the dam began in July 1999. Although Edwards Dam has only a 3.5-megawatt installed generating capacity and provided less than one-tenth of one percent of Maine's annual energy consumption, the event is significant in that it represented the first time that FERC had used its dam-removal authority and imposed an involuntary removal order.

In 1998, DOI announced an agreement to remove the 12-megawatt Elwha Dam near Port Angeles, Washington, but removal has been delayed indefinitely because Congress withheld the funds needed to finance the project. Some small dams in the United States have been successfully removed—such as the 8-foot Jackson Street Dam used to divert water for irrigation in Medford, Oregon and Roy's Dam on the San Geronimo Creek outside San Francisco, California. However, efforts to dismantle many of the larger dams slated for removal in the United States have been delayed by Congressional action, including four Lower Snake River dams and a partially built Elk Creek Dam in Oregon.

HYDROGEN

Hydrogen is a high-quality energy carrier that can be employed with high conversion efficiency and essentially zero emissions at the point of use. Hydrogen can be made from a variety of widely available primary energy sources, including natural gas, coal, biomass (agricultural or forestry residues or energy crops), wastes, solar, wind, or nuclear power. Technologies for production, storage, and transmission of hydrogen are well established in the chemical industries. Hydrogen transportation, heating, and power generation systems have been technically demonstrated, and in principle, hydrogen could replace current fuels in all their present uses. If hydrogen is made from renewable or decarbonized fossil sources, it would be possible to produce and use energy on a large scale system with essentially no emissions of air pollutants (nitrogen oxides, carbon monoxide, sulfur oxides, volatile hydrocarbons or particulates) or greenhouse gases during fuel production, transmission, or use. Because of hydrogen's desirable environmental characteristics, its use is being proposed to reduce emissions of air pollutants and greenhouse gases. However, technical and economic challenges remain in implementing a hydrogen energy system.

CHARACTERISTICS OF HYDROGEN AS A FUEL

Table 1 summarizes some physical characteristics of hydrogen relevant to its use as a fuel. Specifically,

- Hydrogen is a low-density gas at ambient conditions. It liquefies at –253°C. For storage hydrogen must be compressed or liquefied.
- Hydrogen has the highest heating value per kilogram of any fuel (which makes it attractive as rocket fuel), although it has the lowest molecular weight. The specific heat of hydrogen is higher than that of other fuels.
- Hydrogen has a wider range of flammability limits and a lower ignition energy than other fuels.

- Hydrogen can be used with very little or no pollution for energy applications. When hydrogen is burned in air, the main combustion product is water, with traces of nitrogen oxides. When hydrogen is used to produce electricity in a fuel cell, the only emission is water vapor.

HISTORICAL PERSPECTIVE

Although it is not considered a commercial fuel today, hydrogen has been used for energy since the 1800s. Hydrogen is a major component (up to 50% by volume) of manufactured fuel gases ("town gas") derived from gasification of coal, wood, or wastes. Town gas was widely used in urban homes for heating and cooking in the United States from the mid-1800s until the 1940s, and is still used in many locations around the world (including parts of Europe, South America, and China) where natural gas is unavailable or costly. Hydrogen-rich synthetic gases also have been used for electric generation. Hydrogen is an important feedstock for oil refining, and indirectly contributes to the energy content of petroleum-derived fuels such as gasoline. Liquid hydrogen also is a rocket fuel, and it has been proposed as a fuel for supersonic aircraft. Despite hydrogen's many applications, primary energy use of hydrogen for energy applications (including oil refining) is perhaps 1 percent of the world total.

The idea of boosting hydrogen's role—a "hydrogen economy" or large-scale hydrogen energy system—has been explored several times, first in the 1950s and 1960s as a complement to a largely nuclear electric energy system (where hydrogen was produced electrolytically from off-peak nuclear power), and later, in the 1970s and 1980s, as a storage mechanism for intermittent renewable electricity such as photovoltaics, hydroelectric and wind power. More recently, the idea of a hydrogen energy system based on production of hydrogen from fossil fuels with separation and sequestration (e.g., secure storage underground in depleted gas wells or deep saline aquifers) of by-product CO_2 has been proposed.

Concerns about global climate change have motivated new interest in low-carbon or noncarbon fuels. Recent rapid progress and industrial interest in low-temperature fuel cells (which prefer hydrogen as a fuel) for transportation and power applications have also led to a reexamination of hydrogen as a fuel.

Molecular weight of H_2 (g/mole)	2.016
Mass density of H_2 gas (kg/Nm^3) at standard conditions (P=1 atm=0.101 MPa, T=0°C)	0.09
Higher Heating Value (MJ/kg)	141.9
Lower Heating Value (MJ/kg)	120.0
Gas Constant (kJ/kg/°K)	4.125
Specific heat (c_p) (kJ/kg/°K) at 20°C	14.27
Flammability Limits in air (% volume)	4.0-75.0
Detonability Limits in air (% volume)	18.3-59.0
Diffusion velocity in air (meter/sec)	2.0
Buoyant velocity in air (meter/sec)	1.2-9.0
Ignition energy at stoichiometric mixture (milliJoules)	0.02
Ignition energy at lower flammability limit (milliJoules)	10
Temperature of liquefaction (°C)	-253
Mass density of liquid H_2 at -253°C (kg/Nm^3)	70.9
Toxicity	non-toxic

Table 1
Physical Properties of Hydrogen

HYDROGEN ENERGY TECHNOLOGIES

Hydrogen Production

Hydrogen is the most abundant element in the universe and is found in a variety of compounds, including hydrocarbons (e.g., fossil fuels or biomass) and water. Since free hydrogen does not occur naturally on earth in large quantities, it must be produced from hydrogen-containing compounds.

More than 90 percent of hydrogen today is made thermochemically by processing hydrocarbons (such as natural gas, coal, biomass, or wastes) in high-temperature chemical reactors to make a synthetic gas or "syngas," comprised of hydrogen, CO, CO_2, H_2O and CH_4. The syngas is further processed to increase the hydrogen content, and pure hydrogen is separated out of the mixture. An example of making hydrogen thermochemically from natural gas is shown in Figure 1.

Where low-cost electricity is available, water electrolysis is used to produce hydrogen. In water electrolysis

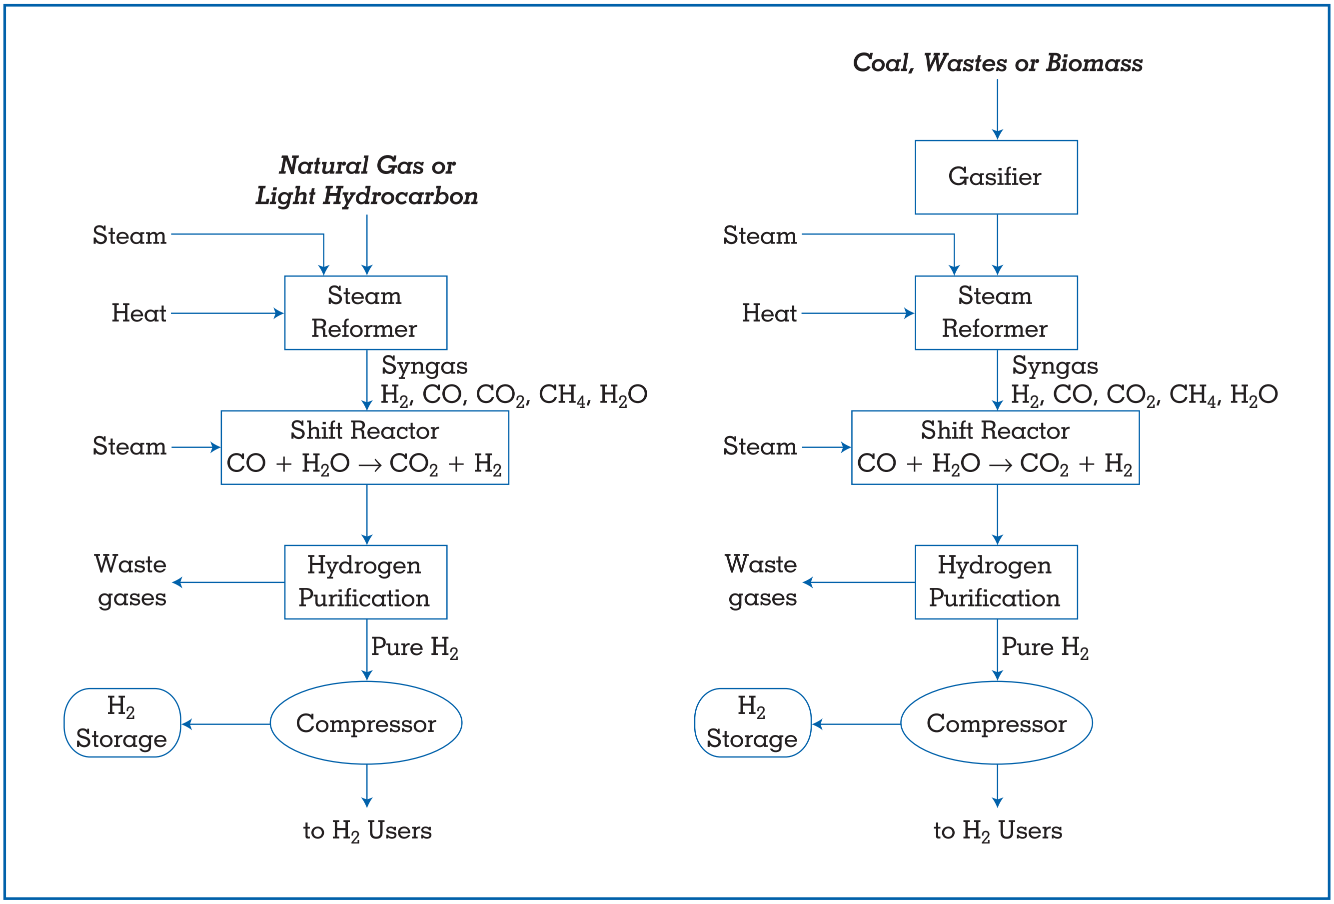

Figure 1.
Thermochemical Hydrogen Production Methods.

electricity is passed through a conducting aqueous electrolyte, breaking down water into its constituent elements, hydrogen and oxygen (see Figure 2). The hydrogen can be compressed and stored for later use. Any source of electricity can be used, including intermittent (time-varying) sources such as off-peak power and solar or wind energies. Fundamental research is being conducted on experimental methods of hydrogen production, including direct conversion of sunlight to hydrogen in electrochemical cells, and hydrogen production by biological systems such as algae or bacteria.

Hydrogen Transmission and Distribution

The technologies for routine handling of large quantities of hydrogen have been developed in the chemical industry. Hydrogen can be liquefied at low temperature (-253°C) and delivered by cryogenic tank truck or compressed to high pressure and delivered by truck or gas pipelines.

If hydrogen were widely used as an energy carrier, it would be technically feasible to build a hydrogen pipeline network similar to today's natural-gas pipeline system. It has been suggested that the existing natural-gas pipeline system might be converted to transmit hydrogen. With modifications of seals, meters, and end-use equipment, this could be done if pipeline materials were found to be compatible. However, hydrogen embrittlement (hydrogen-induced crack growth in pipeline steels that are subject to changes in pressure) could be an issue, especially for long-distance gas pipelines. Rather than retrofitting existing pipelines, new hydrogen pipelines might be built utilizing existing rights-of-way.

Hydrogen Storage

Unlike gasoline or alcohol fuels, which are easily handled liquids at ambient conditions, hydrogen is a

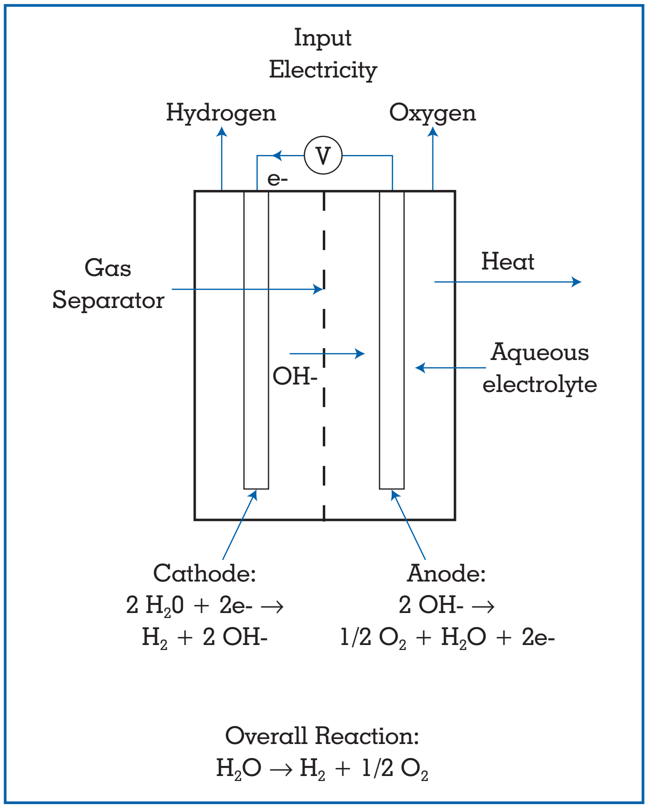

Figure 2.
Hydrogen Production Via Water Electrolysis.

lightweight gas and has the lowest volumetric energy density of any fuel at normal temperature and pressure. Thus hydrogen must be stored as a compressed gas (in high-pressure gas cylinders), as a cryogenic liquid at –253°C (in a special insulated dewar), or in a hydrogen compound where the hydrogen is easily removed by applying heat (such as a metal hydride). All these storage methods for hydrogen are well known in the chemical industry. Innovative storage methods such as hydrogen adsorption in carbon nanostructures are being researched.

Hydrogen onboard storage systems for vehicles are bulkier, heavier, and costlier than those for liquid fuels or compressed natural gas, but are less bulky and less heavy than presently envisaged electric batteries. Even with these constraints, it appears that hydrogen could be stored at acceptable cost, weight, and volume for vehicle applications. This is true because hydrogen can be used so efficiently that relatively little fuel is needed onboard to travel a long distance.

HYDROGEN FOR TRANSPORTATION AND POWER APPLICATIONS

Hydrogen Engines

Hydrogen engines resemble those using more familiar fuels, such as natural gas, gasoline, or diesel fuel. There are several key differences: (1) the emissions from a hydrogen engine are primarily water vapor with traces of nitrogen oxides, (2) the engine can be made more energy-efficient than with other fuels, and (3) there is much less need for postcombustion clean-up systems such as catalytic converters. Use of hydrogen in engines would substantially reduce pollutant emissions and would improve efficiency somewhat.

While hydrogen engines have some advantages over natural-gas engines, the hydrogen fuel cell offers a true “quantum leap” in both emissions and efficiency.

Hydrogen Fuel Cells

A fuel cell is shown in Figure 3. A fuel cell is an electrochemical device that converts the chemical energy in a fuel (hydrogen) and an oxidant (oxygen in air or pure oxygen) directly to electricity, water, and heat. The emissions are water vapor. The electrical conversion efficiency can be quite high. Up to 60 percent of the energy in the hydrogen is converted to electricity, even at small scale. This compares to 25 to 30 percent conversion efficiency for small fossil-fuel-powered engines.

The fuel cell works as follows. Hydrogen and oxygen have “chemical potential,” an attraction driving them to combine chemically to produce water. In a fuel cell hydrogen is introduced at one electrode (the anode) and oxygen at the other electrode (cathode). The two reactants (hydrogen and oxygen) are physically separated by an electrolyte, which can conduct hydrogen ions (protons) but not electrons. The electrodes are impregnated with a catalyst, usually platinum, which allows the hydrogen to dissociate into a proton and an electron. To reach the oxygen, the proton travels across the electrolyte, and the electron goes through an external circuit, doing work. The proton, electron and oxygen combine at the cathode to produce water.

Although the principle of fuel cells has been known since 1838, practical applications are fairly recent. The first applications were in the space program, where fuel cells powered the Gemini and Apollo spacecraft. In the 1960s and 1970s, fuel cells

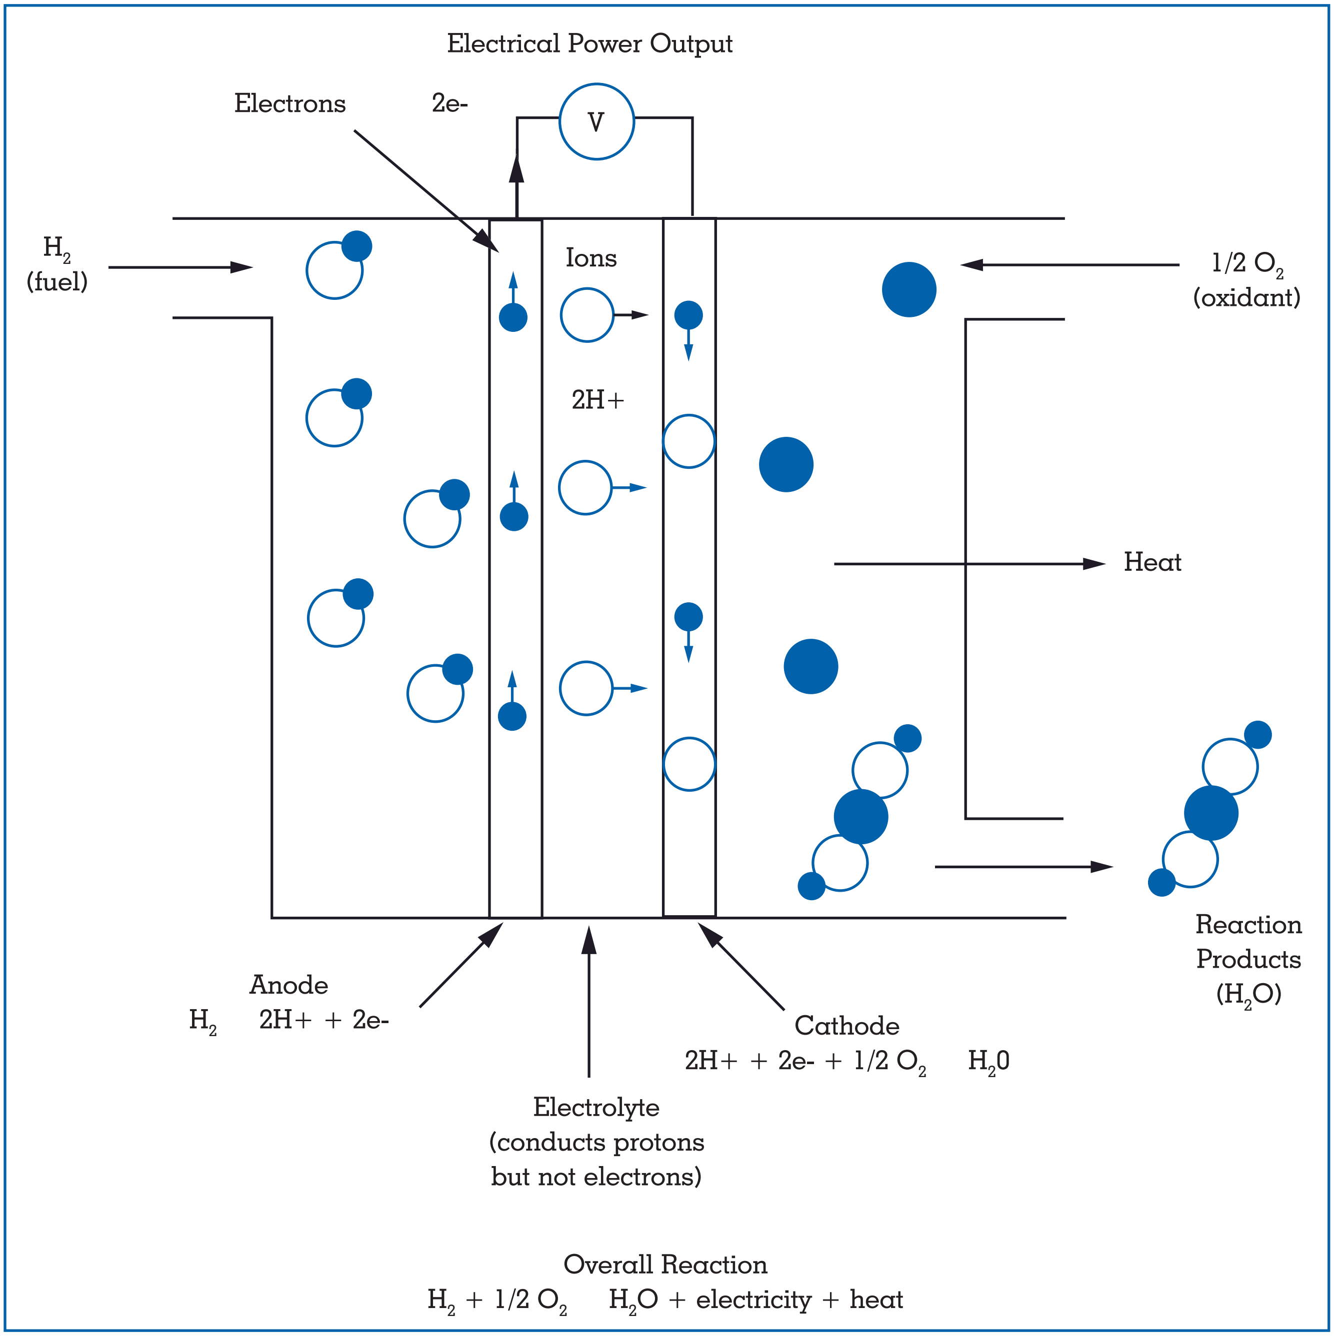

Figure 3.
Diagram of a Hydrogen-Oxygen Fuel Cell.

were used in space and military applications such as submarines. More recently fuel cells have been developed for low-polluting cogeneration of heat and power in buildings. In the past few years there has been a large worldwide effort to commercialize fuel cells for use in zero-emission vehicles.

Hydrogen for Transportation

A number of experimental hydrogen-powered vehicles have been built, dating back to the 1930s. Beginning in the early 1990s, "zero-emission-vehicle" regulations (enacted first in California and later in Massachusetts and New York) and government programs encouraging the development of high-efficiency automobiles (notably the Partnership for a New Generation of Vehicles) led to increased levels of R&D on fuel-cell and electric vehicles. Progress toward a commercial fuel cell vehicle is proceeding at a rapid pace. As of 1999, eight major automobile manufacturers were developing fuel-cell vehicles, and Ford, Daimler Chrysler, GM, and Toyota have announced their intent to commercialize a fuel-cell vehicle by 2005. Several oil companies (Mobil, Shell, Exxon, Texaco, and ARCO) are partners in demonstrations of fuel-cell-vehicle technologies. Shell has recently started a new business unit, Shell Hydrogen.

Hydrogen for Power Generation and Heating

Hydrogen also can be used to heat buildings and for power production. If low-cost fuel cells are commercialized, this could open the way for efficient combined heat and electric power systems for use in commercial and residential buildings. Because of ongoing deregulation, distributed, smaller-scale production of power may play an increasing role in future electric utilities. Several companies are developing fuel cell systems in a range of sizes. The economics are particularly attractive for buildings far from the existing electrical transmission grid, where resources for hydrogen production are present, such as remote sites or islands.

ENVIRONMENTAL AND SAFETY CONSIDERATIONS

Emissions from a Hydrogen Energy System

Hydrogen can be used with zero or near-zero emissions at the point of use. When hydrogen is burned in air, the main combustion product is H_2O, and there are traces of nitrogen oxides, which can be controlled to very low levels. No particulates, carbon monoxide, unburned hydrocarbons, or sulfur oxides are emitted. With hydrogen fuel cells, water vapor is the sole emission. Moreover, the total fuel cycle emissions of pollutants and greenhouse gases (such as CO_2, which could contribute to global climate change) can be much reduced compared to conventional energy systems, which vent all of the CO_2 in the flue gas.

Fuel cycle emissions are all the emissions involved in producing, transmitting, and using an alternative fuel. For example, for hydrogen made from natural gas, there would be emissions of CO_2 and nitrogen oxides at the hydrogen production plant, emissions associated with producing electricity to run hydrogen pipeline compressors (the nature of these emissions would depend on the source of electricity), and zero local emissions if the hydrogen is used in a fuel cell. The more efficient the end-use device (e.g., a fuel-cell vehicle), the lower the fuel cycle emissions per unit of energy service (e.g., emissions per mile traveled).

If hydrogen is made from decarbonized fossil fuels, fuel-cycle emissions can be cut by up to 80 percent. With renewable energy sources such as biomass, solar, or wind, the fuel cycle greenhouse gas emissions are virtually eliminated. It is possible to envision a future energy system based on hydrogen and fuel cells with little or no emissions of pollutants or greenhouse gases in fuel production, distribution, or use.

Resource Issues

In contrast to fossil energy resources such as oil, natural gas, and coal, which are unevenly distributed geographically, primary sources for hydrogen production are available virtually everywhere in the world. The choice of a primary source for hydrogen production can be made based on the best local resource.

Can hydrogen be produced sustainably? Over the next few decades, and probably well into the twenty-first century, fossil sources such as natural gas or coal may offer the lowest costs in many locations, with small contributions from electrolysis powered by low-cost hydropower.

In the longer term (or where locally preferred), renewable resources such as wastes, biomass, solar, or wind might be brought into use. It has been estimated that hydrogen derived from biomass produced on about two-thirds of currently idle cropland in the United States would be sufficient to supply transportation fuel to all the cars in the United States, if they used fuel cells (Ogden and Nitsch, 1993). Municipal solid waste could be gasified to produce transportation fuel for perhaps 25 to 50 percent of the cars in U.S. metropolitan areas (Larson, Worrell, and Chen, 1996). Solar power and wind power are potentially huge resources for electrolytic hydrogen production, which could meet projected global demands for fuels, although the delivered cost is projected to be about two to three times that for hydrogen from natural gas (Ogden and Nitsch, 1993).

Hydrogen Safety

When hydrogen is proposed as a future fuel, the average person may ask about the *Hindenburg*, the *Challenger*, or even the hydrogen bomb. Clearly, consumers will not accept hydrogen or any new fuel unless it is as safe as our current fuels.

Table 2 shows some safety-related physical properties of hydrogen as compared to two commonly accepted fuels, natural gas and gasoline.

In some respects hydrogen is clearly safer than gasoline. For example, hydrogen is very buoyant and disperses quickly from a leak. Experiments have shown that is it difficult to build up a flammable concentration of hydrogen except in an enclosed space, because the hydrogen disperses too rapidly. This contrasts with gasoline, which puddles rather than dispersing, and where fumes can build up and persist. Hydrogen is nontoxic, which also is an advantage.

Other safety concerns are hydrogen's wide flammability limits and low ignition energy. Hydrogen has a wide range of flammability and detonability limits (a wide range of mixtures of hydrogen in air will support a flame or an explosion). In practice, however, it is the lower flammability limit that is of most concern. For example, if the hydrogen concentration builds up in a closed space through a leak, problems might be expected when the lower flammability limit is reached. Here the value is comparable to that for natural gas.

The ignition energy (e.g., energy required in a spark or thermal source to ignite a flammable mixture of fuel in air) is low for all three fuels (hydrogen, gasoline, and natural gas) compared to commonly encountered sources such as electrostatic sparks from people. The ignition energy for hydrogen is about an order of magnitude lower for hydrogen than for methane or gasoline at stoichiometric conditions (at the mixture needed for complete combustion). But at the lower flammability limit, the point where problems are likely to begin, the ignition energy is about the same for methane and hydrogen.

Although safe handling of large quantities of hydrogen is routine in the chemical industries, people question whether the same safety can be achieved for hydrogen vehicle and refueling systems. According to a 1994 hydrogen vehicle safety study by researchers at Sandia National Laboratories, "There is abundant evidence that hydrogen can be handled safely, if its unique properties—sometimes better, sometimes worse and sometimes just different from other fuels—are respected." A 1997 report on hydrogen safety by Ford Motor Company (Ford Motor Company, 1997) concluded that the safety of a hydrogen fuel-cell vehicle would be potentially better than that of a gasoline or propane vehicle, with proper engineering. To assure that safe practices for using hydrogen fuel are employed and standardized, there has been a considerable effort by industry and government groups (within the United States and internationally) in recent years to develop codes and standards for hydrogen and fuel-cell systems.

ECONOMICS OF HYDROGEN PRODUCTION AND USE

If hydrogen technologies are available now and the environmental case is so compelling, why aren't we using hydrogen today? Part of the answer lies in the economics of hydrogen use. There are substantial capital and energy costs involved in hydrogen production. Comparing the delivered cost of hydrogen transporation fuel on an energy cost basis, we find that it is more costly than natural gas or gasoline. However, hydrogen can be used more efficiently than either natural gas or gasoline, so the cost per unit of energy service is comparable. Studies of the projected cost of hydrogen-fueled transportation have shown that if fuel-cell vehicles reach projected costs in mass production, the total life-cycle cost of transportation (accounting for vehicle capital costs, operation and maintenance costs, and fuel) will be similar to that for today's gasoline vehicles.

SCENARIOS FOR DEVELOPING A HYDROGEN ENERGY SYSTEM

The technical building blocks for a future hydrogen energy system already exist. The technologies for producing, storing, and distributing hydrogen are well known and widely used in the chemical industries today. Hydrogen end-use technologies—fuel cells, hydrogen vehicles, and power and heating systems—are undergoing rapid development. Still, the costs and the logistics of changing our current energy system mean that building a large-scale hydrogen energy system probably would take many decades.

Because hydrogen can be made from many different sources, a future hydrogen energy system could evolve in many ways. In industrialized countries,

	Hydrogen	*Methane*	*Gasoline*
Flammability Limits (% volume)	4.0-75.0	5.3-15.0	1.0-7.6
Detonability Limits (% volume)	18.3-59.0	6.3-13.5	1.1-3.3
Diffusion velocity in air (meter/sec)	2.0	0.51	0.17
Buoyant velocity in air (meter/sec)	1.2-9.0	0.8-6.0	non-buoyant
Ignition energy at stoichiometric mixture (milliJoules)	0.02	0.29	0.24
Ignition energy at lower flammability limit (milliJoules)	10	20	n.a.
Toxicity	non-toxic	non-toxic	toxic in concentrations > 500 ppm

Table 2
Safety-Related Properties of Hydrogen, Methane, and Gasoline

hydrogen might get started by "piggybacking" on the existing energy infrastructure. Initially, hydrogen could be made where it was needed from more widely available energy carriers, avoiding the need to build an extensive hydrogen pipeline distribution system. For example, in the United States, where low-cost natural gas is widely distributed, hydrogen probably will be made initially from natural gas, in small reformers located near the hydrogen demand (e.g., at refueling stations). As demand increased, centralized production with local pipeline distribution would become more economically attractive. Eventually hydrogen might be produced centrally and distributed in local gas pipelines to users, as natural gas is today. A variety of sources of hydrogen might be brought in at this time. In developing countries, where relatively little energy infrastructure currently exists, hydrogen from local resources such as biomass may be more important from the beginning.

IMPORT/EXPORT MARKET FOR ENERGY

The import and export of energy on the international market helps create world economic growth. Countries that need energy because they do not have very large domestic reserves must import energy to sustain their economies. Countries that have large reserves export energy to create growth in their energy industries. The export and import of energy also contributes to specialization and comparative advantage in the world economy, lowering costs of production, increasing productivity, and expanding world economic output.

Comparative advantage in energy trade creates more robust economic growth, similar to any economic trade. For example, an oil worker has a comparative advantage over the farmer in producing oil as a farmer has a comparative advantage over the oil worker in producing food. An oil worker who specializes in pumping oil out of the ground is better off trading the oil for food from a farmer. The oil worker could grow his own food, but he could better utilize his time by simply pumping oil and trading for food. He specializes in oil production because he can obtain more food that way, or more of other goods and services. The farmer likewise could try to produce his own oil, but would spend an enormous amount of time and resources exploring for and developing an oil field. Both the farmer and the oil producer gain from trade. The medium of exchange for this trading is money, and both the farmer and the oil worker make more money by specializing and trading than by being totally self-sufficient.

The dynamics of specialization and comparative advantage that apply to the individuals work similarly for nations as well. On the world market, energy exporters specialize in producing energy, and trade their energy to other countries for other goods and services. Energy importers specialize in producing other goods and services, and sell those goods and services for energy. Saudi Arabia, for example, obtains high-tech computers from the United States, automobiles from Japan, and manufactured goods from Europe in exchange for its oil. If Saudi Arabia had to produce all its own computers, their computers would cost a lot more and probably not be nearly as good. If Europe, Japan and the United States had to produce all their own oil by, for example, converting coal into oil, oil would be much more costly, and that cost would inhibit economic growth. The trade in energy therefore benefits both sides.

The largest international energy trading on a Btu basis is with oil, partly because oil is the world's most valuable and versatile existing energy resource. The international natural gas trade is also increasing but because of the portability problems with natural gas (far less energy content given volume making it more expensive and more difficult to transport) its greater potential is limited. But within geographical regions around the world. Electricity is traded internationally more frequently now that many countries have deregulated their utility markets. The Middle East is the most prolific energy exporter, exporting about five and a half billion barrels of oil a year in 1998, which was over 50 percent of all world oil exports, and one-third of all world energy exports. That share looks to increase in the future as many older oil-producing regions, including the United States and Russia, have declining production.

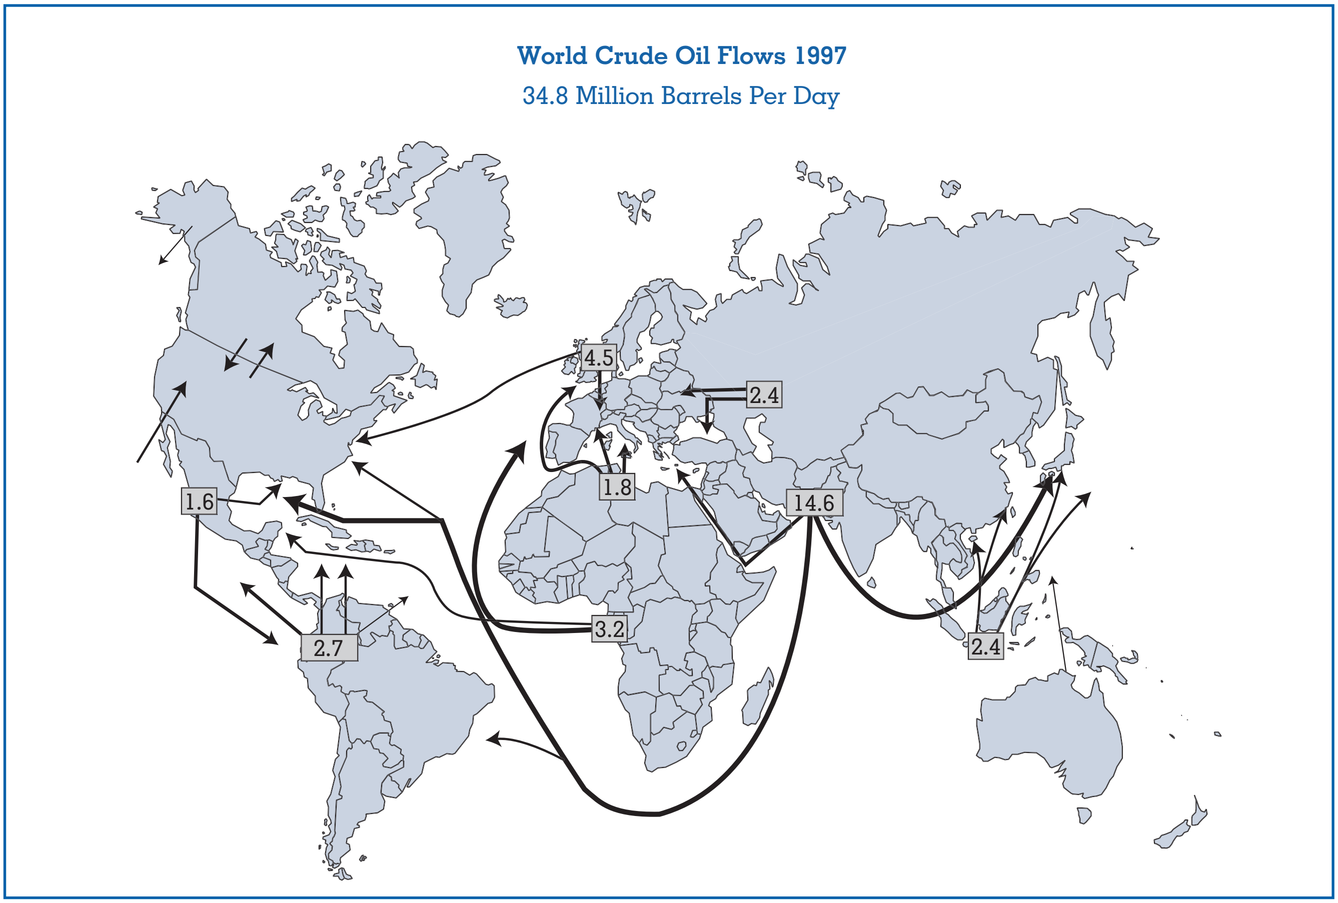

Figure 1.

SOURCE: Energy Information Agency, <http://www.eia.doe.gov/emeu/security/oilflow2.gif>.

MARKET POWER IN ENERGY TRADE

Energy exports not only depend on geological reserves of energy and internal consumption requirements of a country, but also on the market power of that country in energy markets. For example, in geological terms, 65 percent of world oil reserves reside in only five countries in the Middle East—Saudi Arabia, Iran, Iraq, Kuwait, and the United Arab Emirates—also called the big five Middle Eastern oil producers. The big five had proven oil reserves of more than 660 billion barrels of oil in 1998, with a theoretical potential to produce and export as much as 180 million barrels of oil a day (mbd), yet they produced and exported only 18 mbd on average in 1998. By restricting their oil exploration, production, and exports, the big five cause oil prices to rise on the world market. Therefore, it is not enough to look at world oil reserves and the theoretical potential oil production to determine how long oil will last or when an oil shortage will occur; market power must also be taken into consideration. World oil production will undoubtedly last for hundreds of years, but at low levels. Production will be restricted by the use of market power so that the price of oil on the world market will be exceptionally high, decreasing the demand for oil.

The percent of world oil production from the Middle East has changed over the years. In 1950, the Middle East produced about 16 percent of world production, but by 1975 it had a 35 percent market share of all production. That share declined to 25 percent by 1990 due to a decline in world demand, and stayed at that level through 1998. Eventually that share will rise. The big five Middle Eastern oil producers have the largest oil reserves in the world and therefore have the greatest potential to supply increasing world demand, giving them an increasing market share of world production, which in turn will give them enough market power to substantially increase prices by limiting their production. It is the share of total world production rather than the share of the export market itself that determines market power. Middle Eastern oil market power may be a good thing, however, since by raising oil prices and limiting production the world's oil reserves will last longer, albeit at a higher price.

THE HISTORY OF U.S. ENERGY IMPORTS

The United States became the world's first producer of deep crude oil from an oil well when in 1859 Colonel Edwin Drake successfully used a pipe drilled into the ground to obtain oil. From then until about 1970, the United States was virtually energy-independent with only some oil and gas imports from Mexico and Canada. While U.S. reserves of coal, natural gas and uranium continue to be large enough to supply internal demand with enough left over to export, the supply of oil took a sharp turn downward. After 1970, even while U.S. demand continued to increase at a steep 6.5 percent per year, the supply of U.S. oil began to decline, necessitating sharp increases in U.S. oil imports.

Suddenly there was a significant change in the import/export dynamics of the world. From 1970 to 1973 the United States increased its proportion of imported oil from 10 percent to 23 percent of domestic demand, a substantial 2 mbd increase in imports. At the same time, Saudi Arabia increased its exports by 120 percent, or about 4 mbd, to become the world's most important oil exporter. This change in the balance of exports on the international market gave Saudi Arabia and the rest of the Organization of Petroleum Exporting Countries (OPEC) tremendous market power. It was only a matter of time before they would use it.

The 1973 Yom Kippur war caused Arab oil producers to boycott oil exports to the United States and some allies. While the boycott may look like the culprit in the 1973 oil price shock, the cuts in exports actually did not last long, with the oil price increases continuing long after the Arab/Israeli war was over. The real reason why oil prices surged up and stayed there was because world oil demand was high, while Saudi Arabia and OPEC kept supplies low. OPEC used its market power to curtail its own oil exports in the face of surging world demand. The result was an incredible quadrupling of the international price for oil in only one year. The sharp increase in oil prices created an immediate call for energy independence.

After the first oil shock, world demand for oil began to subside somewhat, but then increased again. Exports by OPEC members increased simultaneously as imports by the United States and other countries also increased. In 1979 Iran had a revolution that cut exports of Iranian oil to virtually nothing. The Iranian supply cut pushed oil prices into another shock. Again oil prices jumped high, but this time the extremely high price pushed oil demand down. After 1980, world oil demand declined for awhile and then stayed low due to the structural changes in the world's economies. Firms began using less oil and more coal, natural gas and nuclear power. The resulting softening of demand cut oil exports by OPEC members, particularly Saudi Arabia.

By 1986, world demand for oil was so low, and non-OPEC oil producers were exporting oil so copiously, that the price of oil took a tremendous dive. The combination of low demand and more abundant supplies could not sustain a high world oil price. U.S. demand, for example, had reached 19 mbd in 1979, but fell to 15 mbd by 1984. At the same time, imports of oil fell from 8 mbd to 4.25 mbd (i.e., from 42 percent to 28 percent of demand). This same trend occurred in all the developed countries resulting in the price plunge. However, since the crash in oil prices, oil demand has turned up again. After 1984, U.S. demand increased at a rate of 1.5 percent per year to 22 mbd by 1998. Yet, U.S. oil supplies continued to fall, even taking into account the great Alaska North Slope oil fields. By 1996, the United States was importing 50 percent of its oil demand, or 8.5 mbd, which has created calls for energy independence for America.

ENERGY INDEPENDENCE

The idea behind energy independence is that if all energy production occurs within a country's borders, then that country's economy will be insulated from any energy supply disruptions. The country would then have less unemployment and less economic decline if and when the world's energy exporters, especially OPEC members, cut their supplies. France, has developed a strong nuclear power industry so that it would not have to import as much oil from the Middle East. A close policy alternative for energy independence is to have all imported energy come from friendly countries. In 1998, the United States imported much of its oil from Mexico and Venezuela rather than from Iraq, Libya, or Iran.

One of the problems with attaining energy independence has been the cost of alternative energies. In the late 1970s and early 1980s, the United States tried to produce oil from oil shale in order to become energy-independent. However oil from oil shale cost twice as much as oil from OPEC. The problem was that if the United States were to rely on shale oil, then the economy would have been worse off, with even more unemployment than if it imported relatively cheaper OPEC oil. The expansion of the oil shale industry itself would have caused an increase in employment in that particular industry, but at a drastically higher cost of energy to the economy as a whole. The higher cost of domestically produced energy would have caused the rest of the U.S. economy to go into more of a recession than it already was in. This is why a policy of energy independence has not been successful.

Another U.S. policy to attain energy independence was to force all Alaskan North Slope crude oil to be consumed inside the United States and not be allowed to be exported. The problem was that North Slope crude oil is relatively heavy and not suitable for west coast fuel needs. The mismatch of supply and demand caused California refineries to sell heavy distillate fuels abroad and import lighter fuel additives. Furthermore, the forced selling of Alaska crude oil on a very saturated west coast market caused Alaska crude prices to be $1 to $5 per barrel less than the international price, resulting in less oil exploration and development in Alaska. The upshot of all this was lower tax revenue, a loss of jobs in the oil fields, and less oil exploration and development on the North Slope. The United States actually exported heavy bunker fuel oil at a loss, as opposed to the profit that could have been attained by simply exporting crude oil directly.

FRIENDLY COUNTRY IMPORTS

According to some experts, the next best solution for energy independence is to make sure that all imported energy comes from friendly countries. The idea is to ensure a guaranteed source of energy in case a major energy exporter were to suddenly cut off its exports. The United States, for example, can buy all its oil from Mexico or Venezuela and be independent of crises in the Middle East. The problem with this strategy is that markets have a tendency to be independent of political expediency.

In a world market, oil is often bought by and sold to the highest bidder. Since all oil is fungible, the oil exporter usually does not care where the oil is sold as long as he receives top dollar for it. Oil import competitors such as Japan will always be ready to bid higher prices for oil no matter where it comes from. For example, the United States may import oil from Mexico. If a supply disruption occurred in Iran so that Japan could not get enough oil, Japan would immediately offer a higher price to Mexico for its oil. Even though Mexico is friendly to the United States it is not responsible for the U.S. economy. Mexico wants to get as much money as it can for its oil, and so will sell its oil to the highest bidder regardless of politics. In this case, Mexico would sell its oil to Japan if Japan were the highest bidder. This is how events in the Middle East can affect U.S. oil imports even if the U.S. imports its oil from somewhere other than the Middle East.

If Mexico did sell its oil to Japan rather than the United States, then the United States would immediately offer a high price for oil from another country, for example, Libya. Even though Libya has been a political foe of Americas, Libya would be willing to sell its oil to the United States if the United States paid more than European countries. In fact, events outside the United States have more to do with the price of oil than where the United States gets its oil. Whether U.S. oil is obtained from Alaska, Mexico, or Libya, it is the supply and demand for oil on the world market that determines the price of oil, not the location of supplies. Oil demand in East Asia, political tension in the Middle East, and lower oil production in the former Soviet republics, are much bigger determinants of U.S. energy prices than the source of imported oil. The world price of oil is independent of secure supplies from friendly countries, and as such it is the world oil market that affects the price of oil and brings about the economic instability caused by changing oil prices. The only way to ensure a stable low price for oil is to make sure that the international oil market stays competitive and free from supply disruptions caused by war or terrorist acts. This is why the United States, Europe, and the rest of the world defended Kuwait and Saudi Arabia in the Gulf War in 1991. However, as long as the United States or any other country is willing to pay the world price for oil, then it can purchase as much oil as it wants.

THE AMAZING INCREASE IN U.S. COKE IMPORTS

Coal is a very useful energy resource in the production of steel. However, before coal can be used in steel mills, it must be converted into another form called coke, which is the source of the carbon monoxide used in steel-making. The coal is heated up in a low-oxygen chamber and burned slightly to produce coke, which is similar to wood charcoal. The United States has a 200-year supply of coal, and therefore vast potential supplies of coke. Nevertheless, the United States imported more coke than it exported in 1998, mostly from Japan and China. Even though imported coke represents only eight percent of U.S. consumption, it is still surprising that the United States, which has the largest reserves of coal in the world, would import coke at all.

That imports of coke have increased in the United States is mostly due to the high cost of transportation within the United States and the lower cost of shipping by foreign firms. It is cheaper to extract coal in China, coke it and ship it to California than to buy coke from U.S. producers and transport it within the United States. The trade in coke doesn't hurt the U.S. economy any more than the trade in jet aircrafts to China hurts China. Mutual trade is always beneficial to trading partners.

HYDRO-QUEBEC CANADIAN ELECTRICITY

Quebec, Canada, has great hydroelectric generating potential. Hydroelectricity is a very cheap source of electric power and relatively environmentally benign. As the U.S. continues to deregulate its power industry, Quebec hydroelectricity can be marketed for export to the U.S. northeast where electricity is very costly. It is even possible for Quebec to obtain market power in the U.S. electric power market. However, electric power was much less regional in 1999 than it was in the 1980s and before. In 1999 the technology existed to transport electric power over high voltage power lines as far as two thousand miles. This means the lowest priced electric producer could compete in the power market from very far away. If Quebec begins exporting electric power to the U.S. northeast, it will compete with electric producers as far away as Texas and Oklahoma that can produce cheap electricity from natural gas.

The overriding concern for energy imports and exports should not be where energy comes from or whether an industrialized country should be completely self reliant for its energy needs. The overriding concern is simply the price of energy. Whether energy is produced inside a country or not, world supply and demand for energy, energy market power, and the costs of energy production are the biggest factors in determining energy prices. The price of energy then affects how well the world's economy grows. This is the reason the United States and the rest of the world are concerned about all economic and energy events around the world, including energy supply cutoffs, recessions, and a generally increasing world demand for energy.

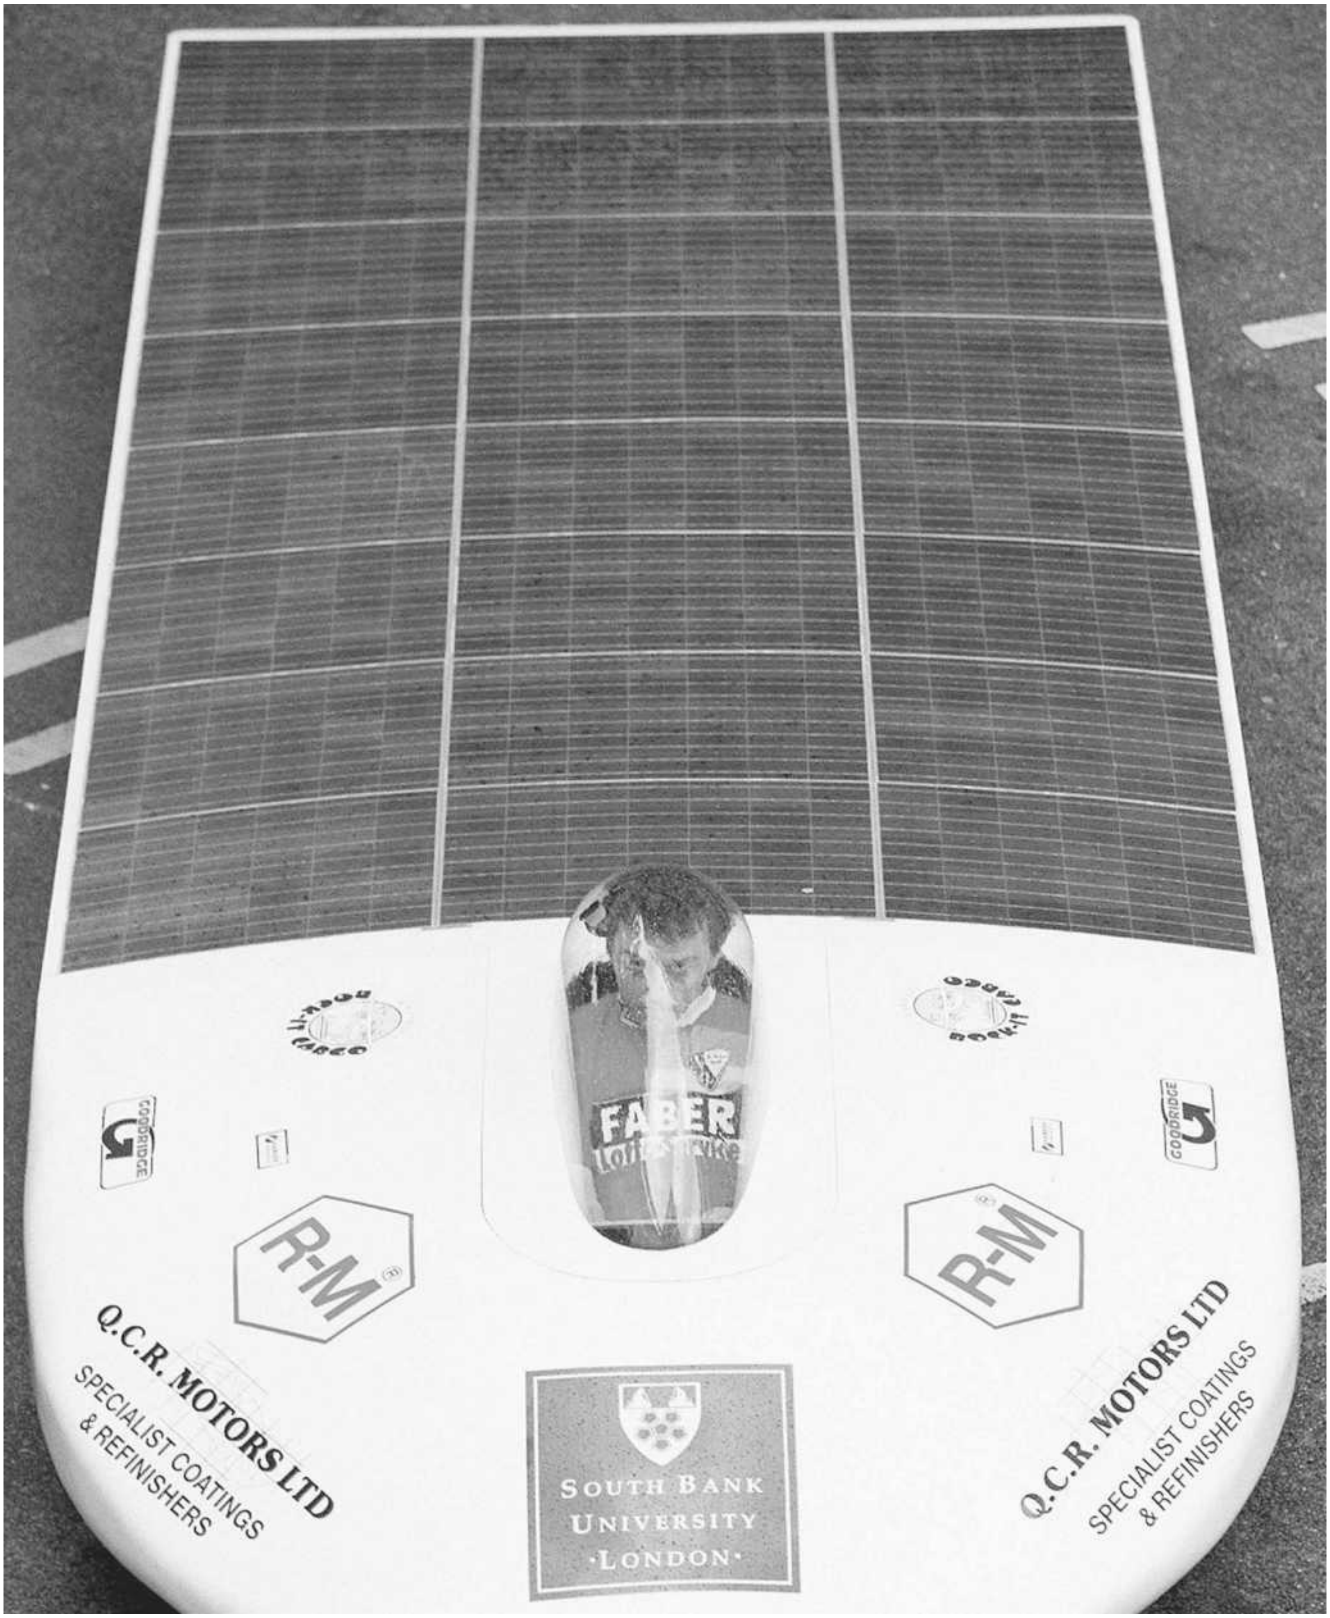
INDUSTRY AND BUSINESS, ENERGY AS A FACTOR OF PRODUCTION IN

The production of goods and services requires energy as an input, which is called a factor of production. Energy sources vary in their effectiveness as a factor of production, depending on their energy characteristics. The energy characteristics are measured in energy grades, which indicate the levels of usefulness of any given energy input. Low-grade energy resources are less useful to an economy than high-grade resources, because any given process will be able to produce more economic value from a high-grade energy resource than from a low-grade energy resource. For example, it is easier to fly a passenger jet aircraft using jet fuel rather than coal because jet fuel has more suitable energy characteristics.

ENERGY GRADES

There are four energy grades used to measure energy characteristics: weight, volume, area, and state. The weight grade is British thermal units (Btus) per pound of the energy resource. For example, coal has 10,000 Btus per pound, while oil has 20,000 Btus per pound, making oil the higher-grade resource. The volume grade is Btus per cubic foot of the energy resource. Oil has 1 million Btus per cubic foot while compressed natural gas, at 3,000 pounds per square inch, has 177,000 Btus per cubic foot, which makes oil the higher-grade resource. The weight and volume grades are important determinants for how easy energy is to transport. Light, compact energy sources are much easier to store and use than heavy, voluminous energy sources. The area grade is Btus per acre where the energy resource is found in its original state. Wood has 1 billion to 5 billion Btus per acre as a forest, whereas coal has 10 billion to 1 trillion Btus per acre in a mine. The area grade generally determines how costly it is to extract or produce energy. Energy that is diffuse over an area, such as trees in a forest, tends to require more capital and labor to extract each Btu of energy than concentrated sources. The state grade is the original physical state of the energy resource, such as a liquid, gas, or solid as measured at standard atmospheric temperature and pressure. The highest state grade is the liquid state, followed by the gas state, the solid state, and the field state. The liquid state is the highest state grade because liquids are easier to use than gases and solids. The field state is the lowest state grade, since energy from energy fields such as solar energy is difficult to store. The field state is any kind of energy field such as a magnetic field, an electric field, or a radiation field. Nuclear energy is a field state grade, since it derives its energy from a radiation field. The state grades are fundamental in determining how well various energy resources can produce economically valuable outputs.

High-grade energy resources can create higher-valued, lower-cost outputs. For example, oil is one of the highest-grade energy resources there is. It is a liquid that is a very high state grade. It has a high weight and volume grade, better than any other energy resource except nuclear fuels, making it cost-effective to carry with a mobile machine. For example, chain saws and automobiles work better with a light-weight fuel than with a heavy fuel, because there is less fuel weight to carry. Oil also has a high area grade—100



The solar-powered car Mad Dog III is put through its paces before it is packed up on August 26, 1999, to travel to Australia to compete in the World Solar Challenge. Its 760 solar cells generate 1,200 watts of power and give it a cruising speed of 75km/hr. (Corbis Corporation) billion to 1 trillion Btus per acre in oil fields—which makes it easier and cheaper to produce. Because oil is a liquid, it is easy to extract with no mining, and it is easy to convert into a refined liquid fuel. Finally, liquid fuels are the easiest of all energy resources to store and transport. Liquid fuels can be used in internal-combustion engines, which are lighter in weight and have more power per pound than external-combustion engines (steam engines) that operate on solid fuel (coal). And although internal-combustion engines can operate more cleanly on natural gas, the infrastructure needed to compress and store gas is much more complex and expensive.

THE ENERGY UTILIZATION CHAIN (EUC)

For any energy to produce goods and services, it goes through a sequence of usage called an energy utilization chain (EUC). The EUC determines how energy will be used to produce goods and services. Link 1 of the EUC is simply obtaining the energy source. This includes exploration and extraction of the energy or in some way producing it. Link 2 is energy conversion. More often than not, energy must be refined or converted into a more useful form of energy for consumption to occur. Link 3 is energy transportation and storage. All energy must be brought to the consumer or firm for use and if necessary be stored for later use. Link 4 is energy consumption. This is where energy is burned or used up. Conservation of energy resources is also a part of link 4—that is, consuming less energy resources in link 4 is conservation of energy. Link 5 is the energy service. The ultimate end of using and consuming any energy resource is to provide some sort of service to society. The service can be used directly by consumers or be an input into the production of other goods and services.

The use of oil for transportation, such as in automobiles and in aircraft, for example, is generally called the oil EUC. The chain of EUC links are the following: the exploration and production of oil; the transportation of the oil by pipeline or tanker; the refining of the oil in a refinery; the transportation of the gasoline to filling stations; the consumption of the gasoline in automobiles, which is sometimes conserved by the use of high-mileage cars; and finally the transportation service from driving the automobile. The EUC then explains the system for using energy. If an alternative energy resource is used to replace oil, then some or all of the EUC links must change. For example, replacing the oil EUC with coal converted into oil, requires only changing the first two links of the oil EUC. Using solar energy to replace the oil EUC may require all of the links to change. For example, gasoline-driven automobiles would be replaced with electric vehicles, which give different services than normal automobiles. Electric vehicles based on solar energy may have less range of operation, carry less cargo, and take longer to refuel than ordinary automobiles.

The oil EUC is one of the highest-value EUCs in the economy. Alternative EUCs for transportation are the natural gas EUC, the solar/electric EUC, the synthetic fuels EUC, and so on. The reason it is so costly to use these alternative EUCs to replace the oil EUC is because of the low energy grades of the energy sources for the alternative EUCs. For example, to replace the oil EUC with an ethanol alcohol fuel, the alcohol EUC would have to use industrial distilleries to convert grain into alcohol. However, grain has a low area grade of about 40 million Btus per acre, as compared to oil's 1 trillion Btus per acre. Oil has about five magnitudes greater energy per acre in its original state, making it much cheaper to produce. It takes about 100,000 acres of farmland planted in grain to equal one acre of an oil field. In terms of supply, it takes about three times as much capital and 10 times as much labor to extract a Btu of ethanol from farmland as to extract a Btu of gasoline from an oil field. If all U.S. farmland were used to make ethanol, it could replace only 35 percent of U.S. oil needs. In addition, the grain needs to be converted from a solid-state grade energy resource into a liquid. Because oil is already a liquid, this transition is much easier and cheaper.

ALTERNATIVE EUCS

In the future, as oil and other energy resources begin to deplete, the economy will need to use alternative EUCs. One alternative EUC is the solar EUC. Solar energy is a field grade—that is, it is and energy radiated in light waves similar to an electric field. Because it is a field, it cannot be stored easily. An acre of solar collectors can catch about 65 million Btus per hour. One hour of an oil field operation on one acre of land can produce 2 billion Btus. The oil requires much less capital to extract its energy than does solar energy. This is why it is cheaper to obtain energy from oil than from solar energy; in addition, it is easier to convert, store, and transport the oil energy, allowing it to produce cheaper and more useful energy services than solar energy can. Once oil supplies decline substantially, the economy may be forced to use the solar EUC, but at a substantially higher cost than for the oil EUC.

Alternative EUCs provide the economy with energy services such as transportation at a certain cost. Usually, low-cost, high-value EUCs are used wherever possible and are used before higher-cost, lower-value EUCs. However, as a high-grade energy resource declines, lower-grade energy resources must be used, meaning the economy must begin to use higher-cost, lower-valued EUCs—that is, the cost of energy as a factor of production may rise, at least in the short run. In the longer run, breakthroughs in advanced energy sources, such as from hydrogen, may actually lower energy costs. The cost structure of alternative EUCs, though, depends on the cost of inputs. Ironically, one of the inputs that goes into every EUC is energy itself. It takes energy to produce energy. For example in the case of the synthetic fuels EUC, oil shale is used as an energy source to replace crude oil. To produce oil from oil shale, the oil shale must be converted from a solid-state energy grade into a liquid energy grade, which requires much more capital and labor inputs than does converting crude oil into fuels. However, the capital and labor require energy to produce oil from oil shale. When the price of oil goes up, the costs of the labor and capital inputs also rise causing the price of the shale oil to go up. In 1970, before the first oil shock, oil from oil shale cost about $3 per barrel to produce, while oil cost $1.50 per barrel. However, by 1982, when oil was $30 per barrel, shale oil cost $60 per barrel to produce. The high cost of oil made other inputs into the synthetic fuels EUC cost more, creating a higher price for the synthetic fuel, which in turn resulted in an inflation cost spiral. The nature of energy grades and the inflation cost spirals of inputs into the EUCs tend to make it difficult to pin down the cost of energy.

In general and in the short run, alternative EUCs have higher costs and lower-valued services than currently used EUCs. As the economy begins to use alternative EUCs, they tend to cost more, possibly creating an inflationary cost spiral. Technology can help to make alternative EUCs cost less and create more value, but is not likely to change the physical characteristics of alternative energy resources in the short run, making alternative EUCs overall less valuable than currently used high-grade-energy EUCs. One way to deal with higher-cost, lower-value alternative EUCs is for society to change its lifestyle. The value of alternative lifestyles must be evaluated in comparison to the cost of alternative EUCs. Higher-cost EUCs may force society into changing lifestyles to be able to afford energy services.

In the longer run, perhaps new alternative EUCs, even superior to the current high-grade-energy EUCs, can be developed. This possibility offers the opportunity of defeating any energy-induced inflationary cost spiral that might have developed, and opening up new possibilities of economic expansion driven by inexpensive energy as a factor of production. Given the critical role of energy to the production process, our economic output in the future is dependent on further advances in energy technology.

INDUSTRY AND BUSINESS, PRODUCTIVITY AND ENERGY EFFICIENCY IN

Improving productivity is one of the central concerns of businesses. In buildings, energy-efficient technologies and design strategies can improve labor productivity (output of goods and services per hour worked) far in excess of the improvement in energy productivity (output per unit energy consumed). Similarly, in manufacturing, energy efficiency can improve total factor productivity (product output as a function of all labor, capital, energy, and materials consumed in its production) far in excess of the improvement in energy productivity.

OFFICE PRODUCTIVITY AND ENERGY EFFICIENCY

Offices and buildings are not typically designed to minimize either energy use or labor costs (by maximizing worker productivity). Almost everyone involved in building construction—such as the developer, architects, and engineers—is rewarded by the ability to minimize the initial cost of a building, as opposed to its life-cycle cost. Moreover, the designers are rarely the ones who will be paying the energy bill or the salaries of the people working in the building. The missed opportunity is revealed by the total life-cycle costs of a building (Table 1).

Initial cost (including land and construction)	2 percent
Operation & Maintenance (including energy)	6 percent
People Costs	92 percent

Table 1.
30-Year Life-Cycle Costs of a Building

A systematic approach to energy-efficient design can cost-effectively cut energy costs by 25 percent to 50 percent, as has been documented in both new construction and retrofit. The evidence on how energy-efficient design can increase worker productivity has been limited, so the issue has been a controversial one.

A growing body of international research suggests that specific design approaches can simultaneous save energy and increase productivity. The fundamental goal in productivity-enhancing design is to focus on the end users—workers—giving them the lighting, heating, and cooling they need for the job. This end-use approach maximizes productivity by ensuring, for instance, that workers don't have too much light or inadequate light quality for the job. It maximizes energy savings because, in most cases, this end-use approach eliminates excess and/or inefficient lighting, heating, and cooling, and because new technologies that provide higher quality services (such as better light quality) typically use far less energy than the technologies they replace.

Daylighting—use of natural light—is a key strategy because it is both the highest quality lighting and the most energy-saving, when it is systematically integrated into a design. In Costa Mesa, California, VeriFone achieved both large energy savings and productivity gains when it renovated a 76,000-square-foot building containing offices, a warehouse, and light manufacturing. The upgrade included energy-efficient air handlers, high-performance windows, 60 percent more insulation than is required by code, a natural-gas-fired cooling system, occupancy sensors, and a comprehensive daylighting strategy, including a series of skylights.

On sunny days, workers in the remanufacturing area construct circuit boards with only natural light and small task lighting. In the office area, on the other hand, the design minimizes direct solar glare on computers, while providing enough daylight to allow workers there to see changes associated with the sun's daily and seasonal variation.

The building beat California's strict building code by 60 percent, with a 7.5-year payback on energy-efficient technologies based on energy savings alone. Workers in the building experienced an increase in productivity of more than 5 percent and a drop in absenteeism of 45 percent, which brought the payback to under a year—a return on investment of more than 100 percent.

INDIVIDUAL CONTROL OVER THE WORKPLACE ENVIRONMENT

An increasingly popular strategy is to give individuals control over their workplace conditions. The benefits of this approach were documented at West Bend Mutual Insurance Company's 150,000-square-foot building headquarters in West Bend, Wisconsin. The design used a host of energy-saving design features, including efficient lighting, windows, shell insulation, and HVAC (heating, ventilation, and air conditioning).

In the new building, all enclosed offices have individual temperature control. A key feature is the

Environmentally Responsive Work-stations (ERWs). Workers in open-office areas have direct, individual control over both the temperature and air-flow. Radiant heaters and vents are built directly into their furniture and are controlled by a panel on their desks, which also provides direct control of task lighting and of white noise levels (to mask out nearby noises). A motion sensor in each ERW turns it off when the worker leaves the space, and brings it back on when he or she returns.

The ERWs give workers direct control over their environment, so that individuals working near each other can and often do have very different temperatures in their spaces. No longer is the entire HVAC system driven by a manager, or by a few vocal employees who want it hotter or colder than everyone else. The motion sensors save even more energy. The lighting in the old building had been provided by overhead fluorescent lamps, not task lamps. The workers in the new building all have task lights and they can adjust them with controls according to their preference for brightness. The annual electricity costs of $2.16 per square foot for the old building dropped to $1.32 per square foot for the new building, a 40 percent reduction.

The Center for Architectural Research and the Center for Services Research and Education at the Rensselaer Polytechnic Institute (RPI) in Troy, New York conducted a detailed study of productivity in the old building in the 26 weeks before the move, and in the new building for 24 weeks after the move. To learn just how much of the productivity gain was due to the ERWs, the units were turned off randomly during a two-week period for a fraction of the workers. The researchers concluded, “Our best estimate is that ERWs were responsible for an increase in productivity of about 2.8 percent relative to productivity levels in the old building.” The company’s annual salary base is $13 million, so a 2.8 percent gain in productivity is worth about $364,000—three times the energy savings.

FACTORY PRODUCTIVITY AND ENERGY EFFICIENCY

Just as in offices, energy efficiency improvements in manufacturing can generate increases in overall productivity far in excess of the gains in output per unit energy. This occurs in two principal ways: improved process control and systemic process redesign.

Process Control

Many energy-efficient technologies bring with them advanced controls that provide unique and largely untapped opportunities for productivity gains. In factories, probably the biggest opportunity is available in the area of variable-speed drives for motors. Variable- or adjustable-speed drives are electronic controls that let motors run more efficiently at partial loads. These drives not only save a great deal of energy, but also improve control over the entire production process. Microprocessors keep these drives at precise flow rates. Moreover, when the production process needs to be redesigned, adjustable drives run the motor at any required new speed without losing significant energy efficiency. Two examples are illustrative.

In Long Beach, Toyota Auto Body of California (TABC) manufactures and paints the rear deck of Toyota pickup trucks. In 1994, the company installed variable-speed motor drives for controlling the air flow in the paint booths. Applying paint properly to truck beds requires control over the temperature, air flow/balance, and humidity in the paint booths. Before the upgrade, manually-positioned dampers regulated airflow into the booths. Since the upgrade, the dampers are left wide open, while the fan motor speed changes automatically and precisely with touch screen controls, which also provide continuous monitoring of the airflow.

The improvements to the motor systems reduced the energy consumed in painting truck beds by 50 percent. In addition, before the upgrade, TABC had a production defect ratio of 3 out of every 100 units. After the upgrade, the ratio dropped to 0.1 per hundred. In 1997, the plant received a special award for achieving zero defects. The value of the improvement in quality is hard to put a price tag on, but TABC’s senior electrical engineer Petar Reskusic says, “In terms of customer satisfaction, it’s worth even more than the energy savings.”

The Department of Energy documented another typical case at the Greenville Tube plant in Clarksville, Arkansas, which produces one million feet of customized stainless steel tubing per month for automotive, aerospace, and other high-tech businesses. Greenville’s production process involves pulling, or “drawing,” stainless steel tubing through dies to reduce their diameter and/or wall thickness. The power distribution system and motor drive were inefficient and antiquated, leading to overheating, overloading, and poor control of the motor at low speed. A larger, but more efficient, motor (200 hp) was installed along with a computerized control system for $37,000. Electricity consumption dropped 34 percent, saving $7,000 a year, which would have meant slightly more than a five-year payback.

The greater horsepower meant that many of the tubes needed fewer draws: On average, one draw was eliminated from half the tubes processed. Each draw has a number of costly ancillary operations, including degreasing, cutting off the piece that the motor system latches on to, and annealing. Reducing the number of draws provided total labor cost savings of $24,000 a year, savings in stainless steel scrap of $41,000, and additional direct savings of $5,000. Thus, total annual savings from this single motor system upgrade was $77,000, yielding a simple payback of just over five months, or a return on investment in excess of 200 percent.

Process Redesign

The second principal way that energy efficiency can bring about an increase in industrial productivity is by achieving efficiency through process redesign. That process redesign could simultaneously increase productivity, eliminate wasted resources, and save energy has been understood as far back as Henry Ford. Perhaps the most successful modern realization and explication of the connection between redesigning processes to eliminate waste and boost productivity was achieved in the post-war development of the "lean production" system.

To understand lean production it is important to distinguish between improving processes and improving operations:

- An automated warehouse is an *operations* improvement: It speeds up and makes the operation of storing items more efficient. Eliminating all or part of the need for the warehouse by tuning production better to the market is a *process* improvement.
- Conveyor belts, cranes, and forklift trucks are *operations* improvements: They speed and aid the act of transporting goods. Elimination of the need for transport in the first place is a *process* improvement.
- Finding faster and easier ways to remove glue, paint, oil, burrs and other undesirables from products are *operations* improvements; finding ways not to put them there in the first place is a *process* improvement.

These examples show that when one improves the process, one does not merely cut out unnecessary operations, critical though that is to increasing productivity; one invariably reduces energy consumption as well as environmental impact. Reducing warehouse space reduces the need for energy to heat, cool, and light it. Reducing transportation reduces fuel use and exhaust fumes. Eliminating "undesirables" means no glue, paint, oil or scrap; it also avoids the resulting clean-up and disposal.

Thus, there is an intimate connection between redesigning processes to increase productivity (by eliminating wasted time, which is the essence of lean production) and eliminating wasted energy and resources. The most-time consuming steps in any process also tend to produce the most pollution and use the most energy. An integrated redesign can minimize everything.

For instance, in 1996, 3M company announced a breakthrough in the process for making medical adhesive tapes, a process that reduces energy consumption by 77 percent. The new process also cuts solvent use by 2.4 million pounds, lowers manufacturing costs, and cuts manufacturing cycle time by 25 percent. The proprietary process took researchers nine years from conception through final implementation.

The Sealtest ice cream plant in Framingham, Massachusetts, modified its refrigeration and air-handling system, cutting energy use by one third. The new system blew more air and colder air, and it defrosted the air handler faster. As a result, the time required to harden the ice cream was cut in half. The overall result was a 10 percent across-the-board increase in productivity, which is worth more to the company than the energy savings.

Process redesign drives a company toward a number of practices associated with productivity gain, including cross-functional teams, prevention-oriented design, and continuous improvement. One of the best programs for continuously capturing both energy and productivity gains was developed by Dow Chemical's Louisiana Division.

In 1982, the Division began a contest in which workers were invited to propose energy-saving projects with a high return on investment. The first year's result—27 winners requiring a capital investment of $1.7 million providing an average return on investment of 173 percent—was somewhat surprising. What was astonishing to everyone was that, year after year, Dow's workers kept finding such projects. Even

Reducing warehouse space reduces the need for energy to heat, cool, and light it. (Corbis-Bettmann)

as fuel prices declined, the savings kept growing. Contest winners increasingly achieved their economic gains through process redesign to improve production yield and capacity. By 1988, these productivity gains exceeded the energy and environmental gains.

Even after 10 years and nearly 700 projects, the two thousand employees continued to identify high-return projects. The contests in 1991, 1992, and 1993 each had in excess of 100 winners, with an average return on investment of 300 percent. Total energy savings to Dow from the projects of those three years exceeded $10 million, while productivity gains came to about $50 million.

CONCLUSION

Not all energy-efficiency improvements have a significant impact on productivity in offices or factories. Nonetheless, productivity gains are then possible from a systematic approach to design. The key features that simultaneously save energy and enhance productivity in office and building design are (1) a focus on the end user, (2) improved workplace environment, especially daylighting, and (3) individual control over the workplace environment. The key features that save energy and enhance productivity in factories are (1) improved process control, and (2) systematic process redesign.

INSULATION

The term "thermal insulation" refers to a material or combination of materials that slows the transfer of heat from high temperature (hot) regions to low temperature (cold) regions. Thermal insulation is placed between regions or surfaces having different temperatures to reduce heat flux—heat flow rate per unit area. In general, the heat flow increases as the temperature difference increases. The heat flux also depends on the type of material between the hot and cold surfaces. If the material between the surfaces is a thermal insulation—a material with relatively low values of a property called apparent thermal conductivity—then the heat flux will be small. As an added bonus, most building thermal insulation also function as effective sound or acoustical insulation.

The development of better thermal insulation is important since space heating and cooling account for the majority of energy consumption in the residential sector, and are second only to lighting in the commercial sector. Because of advances in insulation and more efficient heating systems, the U.S. Department of Energy projects that the energy used for space heating will drop at least 25 percent per household by 2020 relative to 1997 usage.

HISTORICAL DEVELOPMENT

The use of thermal insulation dates back to ancient times, when primitive man used animal skins for clothing and built structures for protection from the elements. Primitive insulation included fibrous materials such as animal fur or wool, feathers, straw, or woven goods. Bricks and stone, while not highly efficient thermal insulation, provided protection from the elements, reduced the loss of heat from fires, and provided large masses that moderate temperature changes and store heat.

Origins of the science associated with thermal insulations coincide with the development of thermodynamics and the physics associated with heat transfer. These technical subjects date to the eighteenth century. Early observations that a particular material was useful as thermal insulation were not likely guided by formal theory but rather by trial and error. Sawdust was used, for example, in the nineteenth century to insulate ice storage buildings.

MODERN DEVELOPMENT

Both building and industrial insulation experienced widespread use in the twentieth century. Because the use of thermal insulation in buildings significantly reduces the energy required to heat and cool living or working space, the use of thermal insulation has grown as expectations for comfort and the cost of energy have increased. The amount of insulation used in a particular application is economically justified by balancing the cost of the insulation against the value of energy saved during the lifetime of the insulation. For buildings, it depends on geographic location; for industry, it depends on the process temperature and safety considerations. The outside surface of insulation that is installed around a steam pipe, for example, will be cooler than the metal surface of the pipe.

Thermal insulation is available over a wide range of temperatures, from near absolute zero (–273°C) (–459.4°F) to perhaps 3,000°C (5,432°F). Applications include residential and commercial buildings, high- or low-temperature industrial processes, ground and air vehicles, and shipping containers. The materials and systems in use can be broadly characterized as air-filled fibrous or porous, cellular solids, closed-cell polymer foams containing a gas other than air, evacuated powder-filled panels, or reflective foil systems.

Thermal insulation in use today generally affects the flow of heat by conduction, convection, or radiation. The extent to which a given type of insulation affects each mechanism varies. In many cases an insulation provides resistance to heat flow because it contains air, a relatively low thermal conductivity gas. In general, solids conduct heat the best, liquids are less conductive, and gases are relatively poor heat conductors. Heat can move across an evacuated space by radiation but not by convection or conduction.

The characterization of insulation is simplified by the use of the term "apparent thermal conductivity" (k_a). Apparent thermal conductivity is used to signify that all three modes of heat transfer have been included in the evaluation of k_a. The k_a of an insulation can be determined by a standard laboratory test without specifying the heat transfer mechanism. The thermal resistivity (R^*) of an insulation is the reciprocal of k_a. R^* is the R-value per unit thickness of insulation, which is one inch in the inch-pound (IP) system. The ratio of insulation thickness over k_a is called the thermal resistance or R-value of the insulation. The property k_a is often referred to as the k-factor. In some cases the Greek letter λ is used. These terms are appropriate for fibrous or porous insulation containing air or some other low-thermal-conductivity gas or vacuum. Insulation such as cellulose, cork, fiberglass, foamed rubber, rock wool, perlite or vermiculite powder, and cellular plastics or glasses fall into this category of insulation sometimes called mass insulation. The thermal resistivity is useful for discussing insulations since the R-value is the product of thickness (in appropriate units) and k_a. Insulation in the building industry is commonly marketed on the basis of R-value while industrial users often prefer k_a, or k-factor. The greater the R-value or the smaller the k_a, the greater the insulation's effectiveness. The physical units commonly associated with the terms k_a, R^*, and R are listed in Table 1. The R-values of insulation of the type mentioned above are directly proportional to thickness as long as the thickness exceeds a minimum value, which is a few inches in most conditions.

In the case of thermal insulation that primarily reduces thermal radiation across air spaces, the term k_a is not used. This type of insulation is called reflective insulation, and R is not always directly proportional to thickness. The R-value of a reflective system is the temperature difference across the system divided by the heat flux.

Term	***Inch-Pound System (IP)***	***Scientific-International (SI)***
k_a	Btu·in./ft^2·h·°F	W/m·k
R^*	ft^2·h·°F/Btu in.	m·K/W
R	ft^2·h·°F/Btu	m^2·K/W
Thickness	in.	m
Heat flow rate	Btu/h	W
Heat flux	Btu/h·ft^2	W/m^2

Table 1.
Units Associated with Thermal Insulation

Fibrous, open-cell, and particulate insulations reduce heat flow because of the low thermal conductivity of the air in the insulation, which occupies a large fraction of the material's volume. The conduction across the material is limited because the air in the void fraction has low thermal conductivity. The structure provided by the solid restricts the movement of the air (convection) and limits radiation across the insulated space by intercepting and scattering thermal radiation. The type of "mass" insulation eliminates internal convection, reduces radiation, and increases conduction slightly because a small fraction of air volume is replaced by solid volume. The R-values of this type of insulation generally decrease with increasing temperature because the thermal conductivity of air increases with temperature. The R-value of mass-type insulation also depends on density, which is directly related to the amount of solid present. In fiberglass insulation at low density and 37.7°C (100°F), for example, R^* increases as density increases primarily because of reduced radiation. At high densities, R^* decreases because of increased solid conduction.

Closed-cell plastic foams such as polystyrene, polyurethane, and polyisocyanurate initially containing a gas other than air represent an important class of insulations. The gases that are used in the manufacturing process (blowing agents) usually have thermal conductivites less than that of air. Gases such as propane, carbon dioxide, and fluorinated hydrocarbons are examples of gases used as blowing agents. Closed-cell foams containing these or similar low-thermal-conductivity gases have R^* values up to about two times those of air-filled products. These products retain their relatively high R^* values as long as the blowing agent is not lost or unduly diluted by air. The lifetime average R-values for these products are less than the R-values of fresh products because air diffuses into the cells with time and the blowing agent diffuses out, thus changing the chemical composition and thermal conductivity of the gas mixture in the cells. Insulation board stock made of closed-cell polymeric foam are often faced with a gas-impermeable barrier material such as metal foil to reduce or prevent gas diffusion from taking place and thus maintain their R-values with time.

Fiberglass and rock wool insulations are produced by spinning and cooling to produce fine fibers. Fiberglass is produced from molten glass, binder or adhesive is added to produce batt-type insulation, and dye can be added for color. Rock wool insulation is produced from molten slag from iron or copper production. Cellulosic insulation is manufactured from recycled newsprint or cardboard, using equipment that produces small particles or flakes. Fire-retardant chemicals such as boric acid, ammonium sulfate, borax, and ammoniated polyphosphoric acid are added to reduce the smoldering potential and surface burning. Perlite and vermiculite particulate insulations are produced from ores passed through high-temperature furnaces. The high-temperature processing results in a lightweight particle with low bulk density. These particulate insulations are not flammable.

Reflective insulation and reflective insulation systems reduce the heat flux across enclosed air spaces using surfaces that are poor thermal radiators. These insulations have little effect on conduction across the air space, usually decrease the natural convection, and significantly reduce radiation. The R-values for reflective insulations like mass insulations depend on temperature. The terms k_a and R*, however, are not appropriate. The R-values for reflective systems depend on the number and positioning of the reflective surfaces, the heat flow direction, and the temperature difference across the system. The unique feature of reflective insulations is that they include low-emittance, high-reflectance surfaces. The low-emittance material commonly used is aluminum foil, with emittance in the range of 0.03 to 0.05. The emittance scale goes from 0 to 1, with 0 representing no radiation being emitted. The aluminum foil is commonly bonded to paper, cardboard, plastic film, or polyethylene bubble pack. The backing materials provide mechanical strength and support needed for handling and attachment. R-values for reflective insulations are generally measured for heat flow directions up, horizontal, and down.

Thermal insulations used in industrial applications include high-density fiberglass, high- density rock wool, particle insulations such as perlite and vermiculite, solids formed from perlite or calcium silicate, and occasionally reflective systems. The temperature range for industrial applications is much greater than that for buildings, so there is a wider variety of materials available. Fine perlite powder, for example, is used in low-temperature applications, while formed perlite or calcium silicate is used for high-temperature applications. Calcium silicate, perlite, high-density fiberglass, high-density rock wool, and foam glass are used for applications such as pipe insulation and furnace insulation. Each material has a range of temperatures in which it can be used, so it is important to match the material with the application. Reflective insulation produced from polished aluminum or stainless steel is also used for high-temperature applications.

Selected references that include thermal insulation data are listed in the bibliography at the end of this article. Table 2 contains nominal thermal resistivities of ten commonly used insulations. The thermal resistivities in Table 2 are at 23.9°C (75°F) and include the effects of aging and settling.

To obtain thermal resistance from R* multiply R* by the thickness of the insulation in the appropriate units, inches or meters. In the case of R* in IP units ($ft^2 \cdot h \cdot °F/Btu \cdot in.$), the thickness is in inches to give R_{IP} in $ft^2 \cdot h \cdot °F/Btu$, the units commonly used in the United States. For R_{SI}, the thickness is in meters to obtain units $m^2 \cdot K/W$. Conversely, the thickness required for a specific R-value is the ratio R_{IP}/R^*_{IP} or R_{SI}/R^*_{SI} . To obtain $R_{IP} = 30$, for example, a thickness of 10.3 inches of a fiberglass batt insulation with $R^*_{IP} = 2.9$ is required.

The R*s of a fibrous or cellular insulation like those in Table 2 generally decrease as the temperature increases. In the case of closed-cell polymeric foams like polyurethane or polyisocyanurate board, the R* may decrease if the insulation temperature drops below the condensation temperature of the blowing agent in the cells. This is because of changes in the gas- phase composition and therefore the gas-phase thermal conductivity. The R* of insulations also depends on density when all other factors are constant. The relationship between R* and density

Insulation Type	*R*(ft^2·h·°F/Btu·in.)$^{(a)}$*	*R*(m·K/W)$^{(b)}$*
Fiberglass batts (standard)	2.9 - 3.8	20.1 - 26.3
Fiberglass batts (high performance)	3.7 - 4.3	25.7 - 29.8
Loose-fill fiberglass	2.3 - 2.7	15.9 - 18.7
Loose-fill rock wool	2.7 - 3.0	18.7 - 20.8
Loose-fill cellulose	3.4 - 3.8	23.6 - 26.3
Perlite or vermiculite	2.4 - 3.7	16.6 - 25.7
Expanded polystyrene board	3.6 - 4.0	25.5 - 27.7
Extruded polystyrene board	4.5 - 5.0	31.2 - 34.7
Polyisocyanurate board, unfaced	5.6 - 6.3	38.8 - 43.7
Plyurethane foam	5.6 - 6.3	38.8 - 43.7

Table 2.
Nominal Values for R* at 23.9°C (75°F)
Note: (a) The values listed are for one inch of thickness.
(b) The values listed are for one meter of thickness.

depends on the type of insulation in question. In general, the compression or settling of an insulation results in a decrease in the R value.

Reflective insulations consist of enclosed air spaces bounded by low-emittance surfaces. The distance across the air spaces is set by the insulation designer. The spacing is generally in the range of 0.5 to 2.0 in, with one to seven air spaces provided by different products. The low-emittance (high-reflectance) surfaces serve as radiation barriers and, as a result, thermal radiation across the enclosed air spaces is dramatically reduced. The open air spaces, however, can have natural convection (air movement) occurring so the R-values depend on the heat-flow direction and the magnitude of the temperature difference across each air space in the system. The R-value of a reflective system is greatest when the heat-flow direction is downward, and least when the heat-flow direction is upward.

TRENDS

The design and manufacturing of cellulose, fiberglass, and rock wool are constantly being improved. The resulting increases in R*, however, are relatively small. The fiberglass and rock wool producers seek optimum fiber diameters and improved radiation attenuation. The cellulosic insulation producers have changed from hammer mills producing relatively high-density products to fiberizers that produce relatively low-density products. The result in most cases is improved R* with less material required. In some cases adhesives are added to building insulations to improve mechanical stability so that long-term settling of the insulation is reduced. Adhesives also have been added to loose-fill fiberglass insulation to produce a blow-in-blanket insulation (BIBS) widely used as insulation in cavity walls.

More advanced insulations are also under development. These insulations, sometimes called superinsulations, have R* that exceed 20 ft^2·h·°F/Btu·in. This can be accomplished with encapsulated fine powders in an evacuated space. Superinsulations have been used commercially in the walls of refrigerators and freezers. The encapsulating film, which is usually plastic film, metallized film, or a combination, provides a barrier to the inward diffusion of air and water that would result in loss of the vacuum. The effective life of such insulations depends on the effectiveness of the encapsulating material. A number of powders, including silica, milled perlite, and calcium silicate powder, have been used as filler in evacuated superinsulations. In general, the smaller the particle size, the more effective and durable the insulation packet. Evacuated multilayer reflective insulations have been used in space applications in past years.

Silica aerogels, a newly developing type of material, also have been produced as thermal insulations with superinsulation characteristics. The nanometer-size cells limit the gas phase conduction that can take place. The aerogels are transparent to visible light, so they have potential as window insulation. The use of superinsulations at present is limited by cost and the need to have a design that protects the evacuated packets or aerogels from mechanical damage.

IPATIEFF, VLADIMIR NIKOLAEVITCH (1967–1952)

Vladimir Nikolaevitch Ipatieff, one of the founding fathers of high-pressure catalysis, was the innovating force behind some of this country's most important petroleum processing technologies in the years leading up to World War II.

THE EARLY YEARS

Ipatieff was born in Russia in 1867. As a member of the privileged (i.e., noble) class, Ipatieff prepared for a military career. Early on in his education, Ipatieff gravitated toward the sciences, and in particular chemistry.

Ipatieff's formal training in chemistry began in earnest when, at the age of twenty-two, he entered the Mikhail Artillery Academy in St. Petersburg. The Academy was founded to give technical training to officers who were to serve as engineers and in other positions within the Russian military.

Chemical training at the Academy was particularly strong. The school taught Ipatieff how to apply textbook concepts to actual plant conditions. As a student, and then later as an instructor at the Academy, he regularly visited local metallurgical and chemical plants to examine first-hand industrial production.

While still a student at the Academy, Ipatieff began to make a name for himself in the Russian chemical community as he began to publish some of his laboratory findings. His first professional milestone as a chemist came in 1890 when he joined Russia's Physical-Chemical Society. Here he came into close contact with Russia's most famous chemists, including Dimitri Mendeleev, discoverer of the periodic table and one of the founders of the Society. In 1891, upon graduating from the school, he was appointed lecturer in chemistry at the Academy where he also continued to undertake original chemical research for his doctoral dissertation. In 1895, he was made assistant professor and, upon completion and acceptance of his dissertation in 1899, he became a full professor of chemistry.

Right up to World War I, Ipatieff, as part of his responsibilities at the Academy, traveled extensively to conferences and seminars throughout Europe and the United States. As a result, he made the acquaintance of some of the major chemists of the day.

During these years he gained an international reputation in the area of experimental chemistry in general and high pressure catalysis in particular. At the Academy he designed, built, and directed one of the first permanent high-pressure laboratories in Europe. Ipatieff investigated the composition and synthesis of numerous aliphatic compounds, including isoprene and the complex alcohols. He demonstrated for the first time the catalytic effect of the metal reactor walls on reactions, a result which would have important commercial implications. Ipatieff also undertook the first sophisticated experiments in catalytic polymerization, isomerization, and dehydrogenation of organic materials, including alcohols and petroleum.

He became intimately familiar with a wide range of catalytic materials—including aluminum oxide, silica, and clay, as well as nickel, platinum, zinc, and copper—and their role individually and as mixtures in effecting chemical transformation. One of Ipatieff's most important lines of research was his breakthrough work on the nature and mechanisms of catalytic promoters on organic reactions.

Although Ipatieff was dedicated to research, his practical training at the Academy prepared him well for applying his research to commercial problems. Ipatieff consulted to industry and government on a regular basis. He was often called upon to make commercial grade catalysts for a variety of applications. One of his most important early assignments, obtaining gasoline from Caspian sea petroleum, introduced Ipatieff to industrial research in fuels. He also used his expertise to undertake research for the government and helped expand Russia's explosives capacity during World War I.

THE POSTREVOLUTIONARY YEARS

Ipatieff's life changed dramatically with the Russian Revolution in 1917. The Bolsheviks were hesitant to retain in official positions those who were too closely allied with the old regime.

Ipatieff, however, remained loyal to Russia, even in its new form. He was also a pragmatist who understood that he must find a way to accommodate the new way of life in Russia, and gain the confidence of those currently holding power if he was to continue his chemical research.

Over the next few years, Ipatieff called upon the wide contacts he had made within Russian scientific and administrative circles before the revolution, and his growing international reputation, to negotiate with the Bolsheviks a favorable place for his research activity. An important element in his success was his ability to convince the government of the strategic importance of his work, which (he pointed out) had just been demonstrated during the war. Under Lenin, who knew of Ipatieff and his work, the scientist received government support. He remained at the Academy, which was retained to train future Bolshevik military officers. Most importantly, Ipatieff was given an official and prestigious research position as Director of the newly created Institute for High Pressures.

In this favorable environment, Ipatieff undertook some of his most important work in high pressure reactions. He studied the effect of catalysts and high pressures on reactions taking place in hydrogen atmospheres, and the effect of such metals as platinum and nickel on forming cyclic compounds from olefin-based materials. This was to become very important later in the 1930s and 1940s in the United States with the development of the platforming process.

When Stalin came to power, the political climate in Russia turned against the creative individuals—scientists, musicians, and writers—especially those who had strong roots in Czarist Russia. During the 1920s Ipatieff saw his colleagues and coworkers arrested, sent to labor camps, or executed.

THE LATER YEARS: AMERICAN PETROLEUM TECHNOLOGY

The opportunity for Ipatieff to emigrate to the United States came through a job offer by Dr. Gustav Egloff, Director of Research at the Universal Oil Products Co. (UOP). UOP, a Chicago-based firm, was a petroleum process development firm known in particular for its commercialization of the first continuous thermal cracking technology (i.e., the Dubbs Process). In the late 1920s, UOP wanted to go into catalytic cracking research. Having met Ipatieff in Germany while attending an international chemical conference, Egloff, who was familiar with Ipatieff's reputation, suggested that Ipatieff think of relocating to Chicago to direct UOP in these efforts.

Reluctantly, in 1929 Ipatieff left his homeland for the United States. He remained at UOP for the remainder of his life. Northwestern University, which had close ties to UOP, appointed Ipatieff to a professorship and directorship of the university's high-pressure research laboratory.

At UOP, Ipatieff had the opportunity to apply his former research in catalytic promoters and high-pressure technique to develop important catalytic petroleum processing technologies. In contrast to the way he conducted science, Ipatieff's technical efforts were conducted in teams comprised of a wide assortment of specialists.

Through the 1930s, Ipatieff led UOP in its effort to develop two catalytic processes for the production of high-octane fuel: alkylation and polymerization—the first, a reaction of a hydrocarbon with an olefin (double-bonded compound); the second, the formation of long molecules from smaller ones. Both processes produce high-octane blending compounds that increase the quality of cracked gasoline.

Ipatieff's work on promoted phosphoric acid and hydrogen fluoride catalysts, which extended his earlier research in Russia, provided the key to commercializing alkylation and polymerization technologies. Shell and other refiners quickly established industrial scale operations. These technologies, generally operating together and in tandem with cracking operations, created vast amounts of high quality aviation fuel. They were a vital part of the Allied war effort during World War II.

Ipatieff's final contribution to catalytic technology was more indirect but essential. His guidance and suggestions to Vladimir Haensel, a fellow Russian émigré who worked on catalytic reforming at UOP and studied under Ipatieff at Northwestern, were a significant contribution to Haensel's development of the high-pressure reforming technology known as platforming. An extension of Ipatieff's previous work involving platinum catalysts, high pressure, and hydrogen environments, platforming represents the first continuous catalytic reforming process. It produces large tonnages of ultra-high octane gasoline materials and critical organic intermediates (benzene, toluene, and xylene), previous obtained only in limited quantities from coal tar. Platforming, along with fluid catalytic cracking, is generally considered one of the great petrochemical innovations of the century.

Ipatieff never received the honor he coveted the most, the Nobel Prize. However, he continued to publish voluminously and, ever the practical scientist, he obtained numerous patents. He continued to receive honors in the United States and internationally. He became a member of the National Academy of Sciences and received the prestigious Gibbs medal for his many achievements. Ipatieff lived long enough to see the petroleum industry transformed with process technologies that he created and that were rooted in his early scientific research. The first platforming plant, the culmination of his life's work in catalytic research, came on line just shortly before his death in 1952.

JOULE

See: Units of Energy

JOULE, JAMES PRESCOTT (1818–1889)

James Joule was born in Salford, near Manchester, England, on December 24, 1818. He was the second son of a wealthy brewery owner and was educated at home by private tutors. For three years he was fortunate enough to have the eminent British chemist, John Dalton as his chemistry teacher. He never attended a university; as a consequence, while he was bright enough to learn a great deal of physics on his own, he remained, like Michael Faraday, unskilled in advanced mathematics.

Joule had the means to devote his time to what became the passion of his life — obtaining highly accurate experimental results in physics, for which he displayed a precocious aptitude. His genius showed itself in his ability to devise new methods, whenever needed, to improve on the accuracy of his quantitative results.

Joule had no real profession except as an amateur scientist, and no job except for some involvement in running the family brewery. Since his father was ill and forced to retire in 1833, his son had to become more involved in the affairs of the brewery from 1833 to 1854, when the brewery was sold by his family. While Joule was working at the brewery, he carried out his experiments before 9:00 A.M., when the factory opened, and after 6:00 P.M., when it closed. Because his father built a laboratory for him in his home, in 1854 he had the time and means to devote himself completely to physics research. Later in life, he suffered severe financial misfortune, but the Royal Society and Queen Victoria in 1878 each provided a £200 subsidy for Joule to continue his important researches.

In 1847 Joule married Amelia Grimes, and they had two children who survived them. Another son was born on June 8, 1854, but died later that month. This was followed by an even greater tragedy—within a few months Joule's wife also passed away. Joule never remarried, but spent the rest of his life with his two children in a variety of residences near Manchester.

Joule died in Sale, Cheshire, England, on October 11, 1889. He always remained a modest, unassuming man, and a sincerely religious one (even though he

James Prescott Joule. (Library of Congress)

was in the habit of falling asleep during sermons). Two years before his death he said to his brother, "I have done two or three little things, but nothing to make a fuss about." Those "two or three little things" were so important for the advancement of science that Joule was elected in 1850 as a fellow of the Royal Society of London, received the Copley Medal (its highest award) in 1866, and was elected president of the British Association for the Advancement of Science in 1872 and again in 1887. Joule is memorialized by a tablet in Westminster Abbey, and constantly comes to the attention of physicists whenever they use the unit of energy now officially called the joule (J).

JOULE'S CONTRIBUTIONS TO THE PHYSICS OF ENERGY

Joule's interest in the conservation of energy developed as a consequence of some work he did in his teens on electric motors. In 1841 he proposed, on the basis of his experiments, that the rate at which heat Q is generated by a constant electric current i passing through a wire of electrical resistance R is:

$$DQ/Dt = i^2R$$

now called Joule's Law.

From 1841 to 1847 Joule worked steadily on measuring the heat produced by electrical processes (Joule's Law), mechanical processes (rotating paddles churning water or mercury), and frictional processes (the rubbing of materials together, as Count Rumford had done in 1798). In each case he compared the amount of energy entering the system with the heat produced. He proved his mettle as a physicist by spending endless days ferreting out the causes of errors in his experiments and then modifying his experimental set-up to eliminate them. In this way he produced a remarkably precise and accurate value for the constant that relates the energy entering the system (in joules) with the heat produced (in calories). This constant is now called Joule's Equivalent, or the mechanical equivalent of heat.

In 1847 Joule published a paper that contained an overwhelming amount of experimental data. All his results averaged out to a value of 4.15 J/cal (in modern units), with a spread about this mean of only five percent. The best modern value of Joule's Equivalent is 4.184 J/cal, and so his results were accurate to better than one percent. This was truly amazing, for the heat measurements Joule performed were the most difficult in all of physics at that time.

At the British Association meeting at Oxford in June 1847, at which Joule presented his results, his audience's reaction was much more subdued and uninterested than he had expected. Joule fully believed that his paper would have passed unnoticed had not the 23-year-old William Thomson (later Lord Kelvin) asked a number of penetrating questions. These awakened his colleagues to the significance of Joule's work as a proof of the conservation-of-energy principle (now commonly called the first law of thermodynamics) under a variety of experimental conditions and involving many different types of energy.

This event marked the turning point in Joule's career. From 1847 on, when Joule spoke, scientists listened. His research results were one of the two major contributions to the establishment of the first law of thermodynamics, the other being that of the

German physician Julius Robert Mayer. Mayer's work, although historically important for its insights into the conservation-of-energy principle, was however tainted by errors in physics and an unacceptable reliance on philosophical arguments.

In addition to his work on the conservation of energy, Joule made a number of other important contributions to physics. In 1846 he discovered the phenomenon of magnetostriction, in which an iron rod was found to change its length slightly when magnetized. In 1852, together with William Thomson, he showed that when a gas is allowed to expand into a vacuum, its temperature drops slightly. This "Joule-Thomson effect" is still very useful in the production of low temperatures.

Joule believed that nature was ultimately simple, and strove to find the simple relationships (like Joule's law in electricity), which he was convinced must exist between important physical quantities. His phenomenal success in finding such relationships in the laboratory made a crucial contribution to the understanding of energy and its conservation in all physical, chemical and biological processes.

K

KAMERLINGH ONNES, HEIKE (1853–1926)

Heike Kamerlingh Onnes was born on September 21, 1853, in Groningen, the Netherlands, and died on February 21, 1926, in Leiden. His father owned a roof-tile factory. Heike Kamerlingh Onnes entered the University of Groningen to study physics. When the government threatened to permanently shut down the university for monetary reasons, he led a delegation to the seat of the government in the Hague as president of the student government. During his studies he won several prizes in physics; his Ph.D. thesis demonstrates superior mathematical abilities. Despite delicate health through much of his life, he showed an enormous capacity for work.

Kamerlingh Onnes does not fit the description of a loner; on the contrary, he created one of the first laboratories to be set up as if it were a factory. Per Dahl in his comparison between Kamerlingh Onnes and his British counterpart, James Dewar, states that Onnes, to be sure was paternalistic, opinionated, and a man of strong principles—traits not uncommon among the moguls of late nineteenth-century science—but that he proved to be a benevolent leader, kind and scrupulously fair in his relations with friends and pupils alike—behavior that was certainly within the norms of his time.

After Kamerlingh Onnes was appointed professor in experimental physics at the University of Leiden in 1882, he stated in his inaugural lecture that physics is capable of improving the well-being of society and proclaimed that this should be accomplished primarily through quantitative measurements. He laid out what he was going to do and, to the surprise of onlookers, that is what he did. He was an excellent organizer, and set out to equip his laboratory on a grand scale. The city of Leiden did not yet provide electricity, so he acquired a gas motor and generator and made his own electricity. Pumps and compressors were barely available, so he had them made in the machine shops of the laboratory. There was a need for measuring instruments, so he created an instrument makers' school. There was an even greater demand for glassware (Dewars, McLeod gauges and connecting tubes, etc.), so he created a glassblowers' school that became famous in its own right.

All currents that had to be measured were sent to a central "measurement room" in which many mirror galvanometers were situated on top of vibration-free columns that were separated from the foundations of the building. One should realize that the many announcements in the early literature of the liquefaction of specific gases pertained to not much more than a mist or a few drops; Kamerlingh Onnes planned to make liquid gases by the gallon. A separate hydrogen liquefaction plant was located in a special room with a roof that could be blown off easily.

The availability of large quantities of liquid helium as well as an excellent support staff led to the undertaking of many experiments at 8 K (the boiling temperature of helium) as well as the lower temperatures obtained by pumping. One subset was the measurement of the resistivity (conductivity) of metals, since this property was useful as a secondary thermometer. Although a linear decline was observed, various speculations were made as to what the result would be when zero absolute temperature was reached. In April 1911 came the surprising discovery that the resistivity in mercury disappeared. At first the sur-

Heike Kamerlingh Onnes. (Library of Congress)

prise was a sharp jump to what was thought to be a small value. The first reaction to this baffling result was to suspect a measurement error. All electrical machines in the laboratory were shut down to be sure that there were no unforeseen current leaks and the experiment was repeated several times. Very careful verifications finally showed that the effect was real and that the resistance was indeed unmeasurably small ("sinks below 10^{-4} of the resistance at 0°C"), and moreover it was found that the effect existed also in other metals, even those that could not be purified as well as mercury.

Initially there was speculation about building an "iron-less" magnet, but this hope was dashed when it was discovered that a small field destroyed the superconductivity. Not until 1960 when materials where found that could sustain high fields, did superconductivity show promise for building strong magnets. The other obstacle was the need for a low-temperature environment. Raising the critical temperature had been a goal for many years, and a spectacular breakthrough was made in 1986.

The result was called by Dutch physicist H. A. Lorentz "perhaps the most beautiful pearl of all [of Kamerlingh Onnes's discoveries]." However, as H. B. G. Casimir describes in his memoirs, he refused to give any credit to the graduate student who observed the phenomenon and who realized its importance.

Although the discovery can be called accidental, one may ask what led up to it. The decline in resistivity of metals when the temperature was lowered clearly invited further study. This program (J. van den Handel calls it Kamerlingh Onnes's second major field of research; liquefaction being the first) was both intrinsically interesting as well as relevant to the construction of a good secondary thermometer. It was known that the resistivity was a linear function of the temperature but was noticed to level off at lower temperatures. The height of this plateau was found to depend on the amount of impurities, using a series of experiments with gold, since the amount of admixture in this metal can be easily controlled. To lower this plateau, a metal of very high purity was needed. Since zone melting, in the modern sense, did not exist, the choice fell on mercury, because this metal could be purified by distillation, and the purified liquid was then placed in glass capillaries. When the liquid in these capillaries was frozen, it formed a "wire." Moreover, it became clear that these wires were free of dislocations, to use a modern term, because it was found that pulling of the wires resulted in increased values of the residual resistance. Hence mercury was the best bet to see how far the linear part of the resistivity curve could be extended to lower temperatures. The hope to have a linear resistor at very low temperatures was certainly a driving factor for the research that led to the discovery of superconductivity.

Heike Kamerlingh Onnes was awarded the Nobel Prize in physics in 1913.

KEROSENE

Kerosene is that fraction of crude petroleum that boils between about 330° to 550° F (183° to 305° C) (i.e. the distillate cut between gasoline and heavy fuel oil). What is usually thought of as kerosene, the domestic fuel or "range oil" commonly used for space heaters, is only a small part of this fraction. Diesel fuel, aviation jet fuel, and No. 1 and No. 2 heating oils also come from this general boiling range.

HISTORY

Petroleum was discovered by Drake in Pennsylvania in 1859. It is a mixture of hydrocarbon compounds ranging from highly flammable volatile materials like propane and gasoline to heavy fuel oil, waxes, and asphalt. It was soon discovered that crude oil could be separated by distillatoin in to various factions according to their boiling point (molecular weight). Kerosene, a middle distillate, was the first product made from petroleum that had a substantial commercial market. The Pennsylvania crudes happened to be low in sulfurous and aromatic components, so the straight run (unrefined) distillate was relatively odorless and clean-burning. The distillate rapidly replaced whale oil in lamps, and coal in home room heaters, and by 1880 kerosene accounted for 75 percent by volume of the crude oil produced. However, after the turn of the century, the advent of electric lights soon made kerosene lamps obsolete. Later, central home heating based on heating oil and natural gas largely replaced space heating based on kerosene, wood, and coal.

By 1980 production of "range oil" type kerosene was less than one percent of the crude oil refined. By the end of the twentiteth century, kerosene's use for space heating, water heating, cooking, and lighting was largely limited to camps, cabins, and other facilities remote from centralized energy sources. Kerosene is a relatively safe fuel, but to prevent fires care must be taken not to tip over operating kerosene appliances. While burner designs have been improved to minimize accidental upset, carbon monoxide formation is still a potential hazard. This deadly gas can result from use of dirty, poorly maintained burners or if the heater is used in a space with insufficient ventilation.

Kerosene is also used as a solvent for herbicides and insect sprays. However, most of the kerosene fraction in crude oils is used to make Diesel engine fuel and aviation jet fuel.

PROPERTIES

Kerosene is an oily liquid with a characteristic odor and taste. It is insoluble in water, but is miscible with most organic solvents. Structurally, it is composed mostly of saturated hydrocarbon molecules containing twelve to fifteen carbon atoms. When a sweet (low sulfur content) paraffinic crude oil is cut to the proper boiling range in a refinery's atmospheric pipe still, the resulting kerosene may only require a drying step before use. However, if the crude oil contains aromatic ring compounds like xylenes, they must be eliminated by solvent extraction because they burn with a smoky flame. Olefinic (unsaturated) molecules in this boiling range must also be removed by refining, usually by hydrogenation. These compounds tend to form color bodies and polymerize, thus imparting poor storage stability. Sulfur compounds are undesirable because of their foul odor and formation of air polluting compounds. They can also be removed by hydrogenation.

Other important properties include flash point, volatility, viscosity, specific gravity, cloud point, pour point, and smoke point. Most of these properties are related directly to the boiling range of the kerosene and are not independently variable. The flash point, an index of fire hazard, measures the readiness of a fuel to ignite when exposed to a flame. It is usually mandated by law or government regulation to be 120° or 130° F (48° or 72° C). Volatility, as measured

by the boiling range, determines the ease with which the fuel can evaporate in a burner or lamp. Viscosity measures the fuel's resistance to flow, and thus determines the ease with which it can be pumped or atomized in a burner nozzle. Specific gravity is the ratio of the weight of a given volume of fuel to the same volume of water. Denser, higher gravity fuels have higher heating values. Typical kerosenes have heating values of about 139,000 BTU per gallon. Cloud and pour points indicate the temperature at which the precipitation of waxy constituents affect performance in cold climates. As wax begins to form (cloud point) there is danger of plugging fuel nozzles and filters. At an even lower temperature (the pour point), enough wax has formed so that the fuel sets up and can no longer flow as a liquid. The smoke point is the flame height in millimeters at which a kerosene lamp begins to smoke.

Other properties of interest are carbon residue, sediment, and acidity or neutralization number. These measure respectively the tendency of a fuel to foul combustors with soot deposits, to foul filters with dirt and rust, and to corrode metal equipment. Cetane number measures the ability of a fuel to ignite spontaneously under high temperature and pressure, and it only applies to fuel used in Diesel engines. Typical properties of fuels in the kerosene boiling range are given in Table 1.

Because of its clean burning characteristics, kerosene commands a higher price than other fuels in its boiling range.

EQUIPMENT

The technology of kerosene burners is quite mature. The most popular kerosene heater is the perforated sleeve vaporizing burner or range burner (Figure 1). It consists of a pressed steel base with concentric, interconnected grooves and perforated metal sleeves, between which combustion takes place. Kerosene is maintained at a depth of about 1/4 inch in the grooves. As the base heats up, oil vaporizes from the surface, and the flame lights from asbestos wicks. Combustion air is induced by natural draft. The flame is blue, and the burner is essentially silent, odorless, and smokeless.

For larger capacity space heaters vaporizing pot burners are used (Figure 2). They consist of a metal pot perforated with holes for combustion air. Oil flows into the bottom of the pot by gravity, and is vaporized from the hot surface. Fuel vapors mix with primary air from the lower holes, then with additional secondary air in the upper section, and burn at the top of the vessel. Between periods of high demand, pot burners idle at a low fire mode. The flames burn in the bottom section of the pot, at a fraction of the high fire fuel feed rate, using only primary air. Thus no extraneous pilot light or ignition source is required for automatic operation.

Kerosene lamps have a flat cloth wick. Flame height is determined by the height of the wick, which is controlled by a ratchet knob. A glass chimney ensures both safety and a stable, draft-free flame.

KILOWATT

See: Units of Energy

KINETIC ENERGY

Energy is “capacity (or ability) to do work,” and work is “the result of a force acting through some distance.” A car running into the rear of a stalled car exerts a force on it, pushing it some distance, doing work in the process. The capacity of the moving car to do work is termed its kinetic energy. The greater a car's speed and/or mass, the greater its capacity to do work—that is, the greater its kinetic energy.

Formally, the kinetic energy (K) of a mass (m) moving with speed (v) is defined as $K=1/2\ mv^2$. Kinetic energy is measured in joules (J) when m and v are expressed in kilograms (kg) and meters per second (m/s). A 1,000-kg car traveling 15 m/s (about 30 miles per hour) has 112,500 J of kinetic energy. Kinetic energy depends much more on speed than on mass. That is because doubling the mass of an object doubles the kinetic energy, but doubling the speed quadruples the kinetic energy. A 4,000-kg tractor trailer traveling at 30 m/s has the same kinetic energy as a 1,000-kg car traveling at 60 m/s.

Invariably, energy of use to a society is kinetic. A car is useful when it is in motion. Water in motion is useful for driving turbines in a hydroelectric plant. Electricity, the most versatile of all forms of energy, involves electric charges (electrons) in motion. And thermal energy, which provides energy for a steam turbine, is associated with the kinetic energy of molecules.

Most energy converters convert sources of potential energy to forms of kinetic energy that are useful. Gasoline in the tank of an automobile has potential energy. When burned, potential energy is converted to heat, a form of kinetic energy. Uranium in the core of a nuclear reactor has nuclear potential energy. Conversion of nuclear potential energy through nuclear fission reactions produces nuclei and neutrons with kinetic energy. This kinetic energy is the source for the electric energy produced by the nuclear power plant. Water atop a dam has gravitational potential energy. Flowing toward the bottom of the dam, the water continually loses potential energy but gains kinetic energy (and speed). The potential energy the water had at the top of the dam is converted entirely to kinetic energy at the bottom of the dam.

Every molecule in the air around you has kinetic energy because each has mass and is in incessant motion. According to the kinetic theory of gases, each of the molecules has average kinetic energy given by $E=3/2\ kT$ where k is the Boltzmann constant, having a value of 1.38×10^{-23} joules per Kelvin, and T is the Kelvin temperature. Interestingly, the average kinetic energy is independent of the mass of the molecule. Thus, nitrogen molecules and oxygen molecules in the air we breathe have the same average kinetic energy. On the other hand, their average speeds differ because their masses differ. When considering the fundamental meaning of temperature, it is appropriate to think of temperature as measuring the average kinetic energy of a molecule in a gas.

Flywheels of reasonable size and speed can store energy comparable to that of batteries and have promise for storing energy for electric vehicles. When a car is brought to rest by braking, the kinetic energy of the car is converted into heat that dissipates into the environment. Conceivably, the car could be brought to rest by transferring the linear kinetic energy of the car to rotational energy in a flywheel, with very little lost as heat during the conversion. The rotational energy then could be recovered by allowing the flywheel to operate an electric generator.

KINETIC ENERGY, HISTORICAL EVOLUTION OF THE USE OF

Historically humans have used three natural sources of kinetic energy: wind, water, and tides.

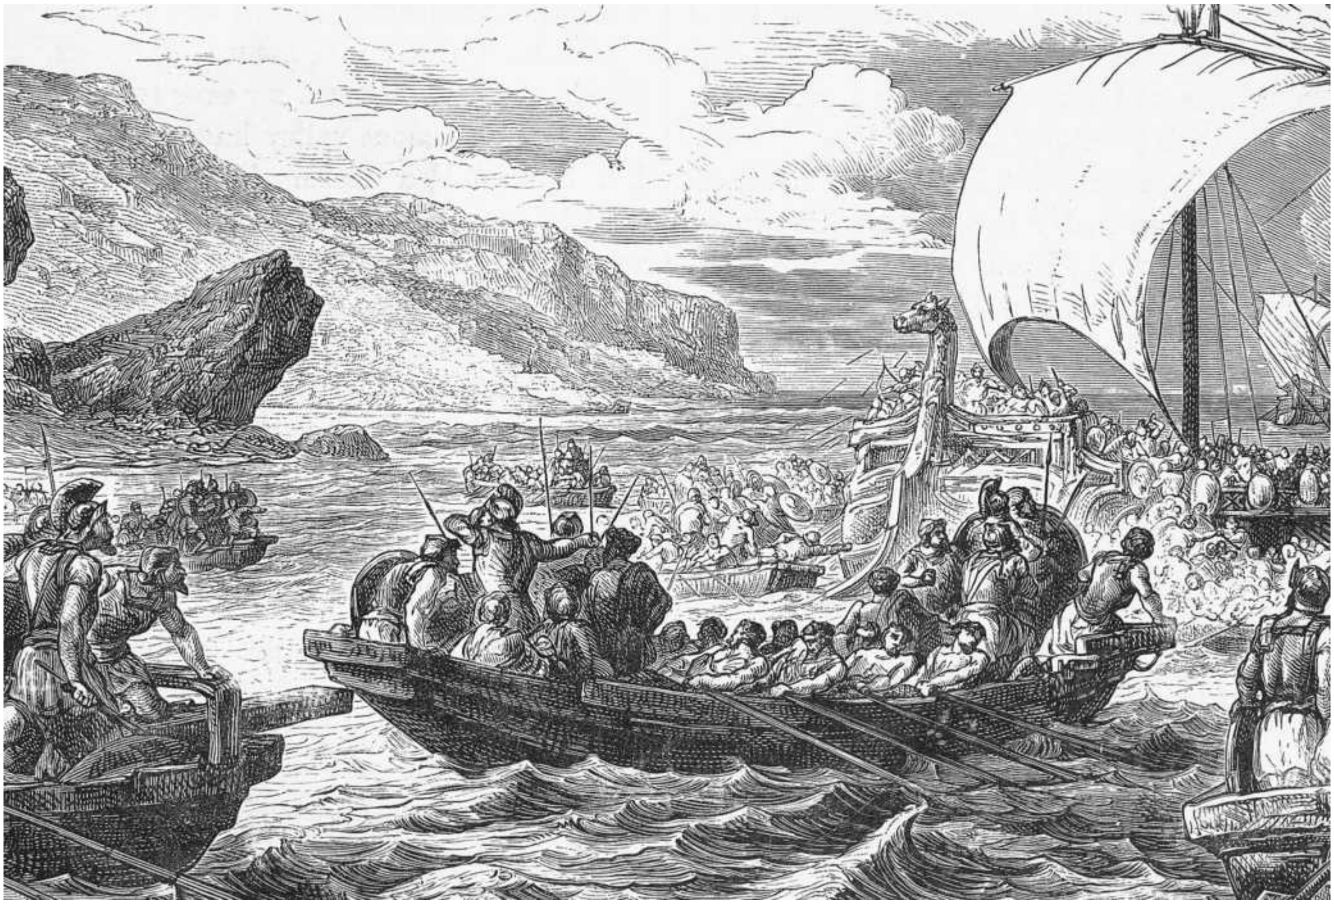
THE ANCIENT WORLD (TO 500 C.E.)

Although early humans often inadvertently tapped into the kinetic energy of moving air or water to do things such as separate grain from chaff or float downstream, the deliberate use of kinetic energy to power machinery came only in the historical era.

Only one machine in classical antiquity made deliberate use of the kinetic energy of wind: the sailing vessel. As early as 3000 B.C.E., paintings illustrated Egyptian vessels using sails. By the first millenium B.C.E., the use of sails was common for long-distance, water-borne trade. However, ancient sails worked poorly. The standard sail was square, mounted on a mast at right angles to the ship's long axis. It was effective only if the wind was dead astern. It was barely adequate if the wind was abeam, and totally inadequate in head winds. As a result, ancient mariners usually timed sailings to correspond with favorable wind direction and often averaged only 1 to 1.5 knots.

Very late in the ancient period the square sail was challenged by a more effective design: the triangular lateen sail, aligned with the vessel's long axis (i.e., fore-and-aft). The origin of this rigging is uncertain; unlike square sails, lateen sails operated as fabric aerofoils and permitted vessels to sail more closely into headwinds.

The only evidence for the use of wind in antiquity to power other machinery occurs in the *Pneumatica*



The sails on these Phoenician ships exhibit an early use of naturally occuring kinetic energy. (Corbis Corporation)

of Hero of Alexandria dating from the first century C.E. Hero described a toy-like device with four small sails, or blades, attached perpendicularly to one end of a horizontal axle. Wind struck the blades and turned the device. Pegs mounted on the opposite end of the axle provided reciprocating motion to a small air pump feeding an organ. There is no evidence that the idea was expanded to a larger scale, and some experts are suspicious of the authenticity of this portion of the *Pneumatica*.

Water, the other source of kinetic energy used in antiquity, saw wider application to machinery than did wind. The first evidence of the use of waterpower comes from the first century B.C.E., simultaneously in both China and the Mediterranean region. In China the preferred method of tapping the power of falling water was the horizontal water wheel, named after the plane of rotation of the wheel. Around the Mediterranean, the preferred form was the vertical water wheel. The vertical wheel came in two major forms: undershot and overshot. An undershot wheel had flat blades. Water struck the blades beneath the wheel and turned it by impact. The overshot wheel emerged later—the first evidence dates from the third century C.E. The overshot wheel's periphery consisted of containers, called buckets. Water, led over the top of the wheel by a trough, was deposited in the buckets; weight rather than impact turned the wheel.

The diffusion of waterpower was initially slow—perhaps due to its relatively high capital costs, its geographical inflexibility, and the abundance of manual labor in both the classical Mediterranean world and in China. Only in the declining days of the Roman Empire, for example, did watermills become the standard means of grinding grain in some areas, displacing animal- and human-powered mills.

THE MEDIEVAL WORLD (500–1500 C.E.)

Knowledge of how to tap the energy of wind and water was passed by both the Romans and Han Chinese to their successors. In the conservative eastern realm of the old Roman Empire (the Byzantine Empire), little was done to develop either wind power or water power, although Byzantine vessels did make increased use of lateen sails after the eighth century. On the other hand, the western part of the old Roman Empire, perhaps due to labor shortages, saw a very significant increase in the use of both wind and water power, especially between 900 and 1300.

The expansion of medieval Europe's use of natural sources of kinetic energy was most significant in waterpower. Although many Roman watermills were destroyed during the collapse of centralized authority in the fifth through seventh centuries, recovery and expansion beyond Roman levels was relatively rapid. By the eleventh century, sparsely populated England had over 5,600 watermills, a level of dependence on nonhuman energy then unparalleled in human history. Nor was England unusual. Similar concentrations could be found elsewhere. The Paris basin, for example, had around 1,000 watermills in the same era, and canal networks around medieval European cities were often designed to benefit mills.

In coastal estuaries, European craftsman by the twelfth century or earlier had also begun to use water wheels to make use of the movement of the tides. The usual arrangement required impounding incoming tides with a barrier to create a reservoir. During low tide, this water was released through a gate against the blades of a watermill.

With few exceptions, waterpower had been used in classical antiquity for only one purpose—grinding grain. By the tenth, and definitely by the eleventh century, European technicians had begun significantly to expand the applications of waterpower. By 1500 waterpower was used to grind not only wheat, but mustard seed, gunpowder, and flint for use as a glaze. It was used to crush ore, olives, and rags (to make paper). It was used to bore pipes, saw wood, draw wire, full (shrink and thicken) wool, pump water, lift rocks, shape metal, and pump bellows.

Nor was Europe the only civilization to make increased use of waterpower in this era. Although not blessed with the same abundance of stable, easy-to-tap streams, the Islamic world also increased its use of waterpower. Medieval travelers mention numerous mills and water-lifting wheels (norias) along rivers near Islamic cities such as Baghdad, Damascus, Antioch, and Nishapur. China, too, saw the expanded use of waterpower, for powering metallurgical bellows, grinding grain, spinning hemp, driving fans, crushing minerals, and winnowing rice.

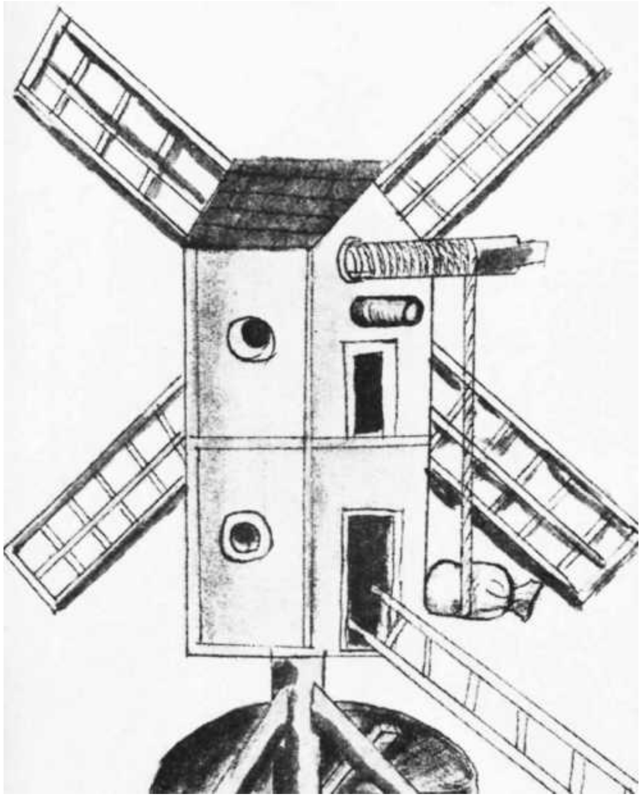
The wood water wheels used in the medieval period were, by modern standards, inefficient. Medieval undershot and horizontal wheels probably had an efficiency of about 15 percent to 25 percent, medieval overshot wheels about 50 percent to 60 percent. Commonly, their power output was only about 2–5 hp. But relative to the alternatives available at the time—human or animal power—they offered a very substantial gain in power.

Water provided a more reliable source of energy than the winds, but labor shortages in medieval Europe also encouraged the further development of wind power. The sailing vessel continued to be the most important wind-powered machine, and it saw significant improvement. Between 1000 and 1500, Chinese and European shipbuilders began to use multiple masts, stern post rudders, and deeper keels to tap larger volumes of air more effectively, and Europeans by 1500 were making effective use of combined square and lateen riggings.

The first solid evidence of the use of air to provide mechanical power to something other than sailing vessels comes from tenth-century Islamic travel accounts that describe wind-powered mills for grinding grain in eastern Persia. These were horizontal windmills, so named because the plane of rotation of their sails, or blades, was horizontal. The rotors were two-story devices, surrounded by walls with openings facing the prevalent wind direction. Wind passed through these orifices, struck the exposed blades, and exited through other orifices in the rear. In heavy winds they might produce as much as 15 hp, but more typically their output was about 2 to 4 hp.

Diffusion was very slow. The earliest clear Chinese reference to a windmill occurs only in 1219. The Chinese adopted the horizontal rotor used in Central Asia, but equipped it with pivoted blades, like venetian blinds. These windmills did not require shielding walls like Central Asian mills, and could tap wind from any quarter.

European technicians departed much more radically from Central Asian designs. Drawing from close experience with the vertical watermill, by 1100–1150



An early wind mill (c. 1430), with an automatic elevator for lifting flour bags. The post was designed to turn in accordance with the direction of the wind. (Corbis Corporation)

they had developed a vertical windmill called a post mill. The blades, gearing, and millstones/machinery of the post mill were all placed on or in a structure that pivoted on a large post so operators could keep the mill's blades pointed into the wind. European windmills typically had four blades, or sails, consisting of cloth-covered wooden frames. They were mounted on a horizontal axle and set at a small angle with respect to their vertical plane of rotation.

The European windmill diffused rapidly, especially along the Baltic and North Sea coasts. By the fourteenth century they had become a major source of power. Eventually, England had as many as 10,000 windmills, with comparable numbers in Holland, France, Germany, and Finland. In some areas of Holland one could find several hundred windmills in a few square miles.

Around 1300, Europeans improved on the post mill by devising the tower mill. In the tower mill, only a cap (containing the rotor axle and a brake wheel), mounted atop a large, stationary tower, had to be turned into the wind. The tower design allowed the construction of larger windmills containing multiple pairs of millstones, living quarters for the miller and his family, and sometimes machinery for sawing wood or crushing materials.

By the end of the medieval period, growing European reliance on wind and waterpower had created the world's first society with a substantial dependence on inanimate power sources.

THE EARLY MODERN ERA (1500–1880)

Dependence on wind or waterpower does not seem to have grown substantially in other civilizations after the medieval era, but this was not the case in Europe. By 1700, most feasible sites along streams convenient to some mercantile centers were occupied by water-powered mills, making it difficult for newer industries, such as cotton spinning, to find good locations. Moreover, European colonists carried waterpower technology with them to North and South America. By 1840 the United States, for example, had nearly 40,000 water-powered mills.

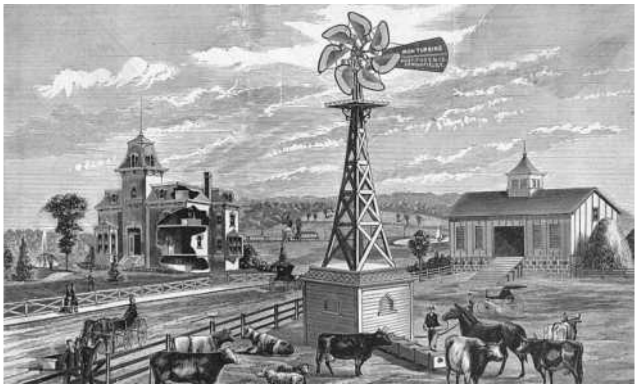
Pressure on available, easily tapped streams pushed the development of waterpower in several different directions simultaneously between 1700 and 1850. One direction involved the application of quantitative techniques to analyze wheel performance. In 1704 Antoine Parent carried out the first sophisticated theoretical analysis of water wheels. Erroneously believing that all wheels operated like undershot wheels, he calculated the maximum possible efficiency of water wheels at an astoundingly low 4/27 (15%). When John Smeaton in the 1750s systematically tested model undershot and overshot wheels, he discovered Parent's error. Smeaton found the optimum efficiency of an undershot vertical wheel was 50 percent (his model wheels actually achieved around 33 percent), and that of a weight-driven overshot wheel was much higher, approaching 100 percent (his model wheels achieved about 67–70%). Smeaton thereafter made it his practice to install overshot wheels where possible. Where impossible, he installed an intermediate type of vertical wheel called the breast wheel. With breast wheels, water was led onto the wheel at or near axle level. A close-fitting masonry or wooden casing held the water on the wheel's blades or buckets so it acted by weight (as in an overshot wheel) rather than by impact.

The mechanization of various elements of textile production, especially carding, spinning, and weaving, after 1770 created important new applications for waterpower. As textile factories grew larger, engineers modified the traditional wooden water wheel to enable it to better tap the kinetic energy of falling water. In addition to following Smeaton's example and using weight-driven wheels as much as possible, they replaced wooden buckets, with thinner sheet-iron buckets and used wrought iron tie-rods and cast iron axles to replace the massive wooden timbers used to support traditional water wheels. By 1850 iron industrial water wheels, with efficiencies of between 60 percent and 80 percent, had an average output of perhaps 15–20 hp, three to five times higher than traditional wooden wheels. Moreover, iron industrial wheels developing over 100 hp were not uncommon, and a rare one even exceeded 200 hp. The iron-wood hybrid wheel erected in 1851 for the Burden Iron works near Troy, New York, was 62 feet (18.9 m) in diameter, by 22 feet (6.7 m) wide, and generated around 280 hp.

Despite these improvements, in the more industrialized parts of the world the steam engine began to displace the waterwheel as the leading industrial prime mover beginning around 1810–1830. Steam was not able, however, to completely displace waterpower, in part because waterpower technology continued to evolve. Increased use of mathematical tools provided one means of improvement. In the 1760s the French engineer Jean Charles Borda demonstrated, theoretically, that for a water wheel to tap all of the kinetic energy of flowing water, it was necessary for the water to enter the wheel without impact and leave it without velocity.

In the 1820s, another French engineer, Jean Victor Poncelet, working from Borda's theory, designed an undershot vertical wheel with curved blades. Water entered the wheel from below without impact by gently flowing up the curved blades. It then reversed itself, flowed back down the curved blades, and departed the wheel with no velocity relative to the wheel itself. Theoretically the wheel had an efficiency of 100 percent; practically, it developed 60 percent to 80 percent, far higher than a traditional undershot wheel.

In the late 1820s another French engineer, Benoit Fourneyron, applied the ideas of Borda and Poncelet to horizontal water wheels. Fourneyron led water into a stationary inner wheel equipped with fixed, curved guide vanes. These vanes directed the water against a mobile outer wheel, also equipped with curved blades. These curved vanes and blades ensured that the water entered the wheel with minimum impact and left with no velocity relative to the wheel itself. Moreover, because water was applied to the entire periphery of the outer wheel at once, instead of to only a portion of the blades, Fourneyron's wheel developed much more power for its size than a comparable vertical wheel could have. This new type of water wheel was called a water turbine. Its high velocity and the central importance of the motion of the water on the wheel (water pressure) to its operation distinguished it from the traditional water wheel.



The "Iron Turbine" windmill is a more modern example of windpower. (Corbis Corporation)

By 1837 Fourneyron had water turbines operating successfully on both small falls and large ones. At St. Blasien in Germany, a Fourneyron turbine fed by a pipe, or penstock, used a fall of 354 feet (107.9 m), far more than any conventional water wheel could hope to. It developed 60 hp with a wheel only 1.5 foot (0.46 m) in diameter that weighed less than 40 pounds (18.2 kg).

Engineers quickly recognized that turbines could be arranged in a variety of ways. For example, water could be fed to the wheel internally (as Fourneyron's machine did), externally, axially, or by a combination. Between 1830 and 1850 a host of European and American engineers experimented with almost every conceivable arrangement. The turbines that resulted—the most popular being the mixed-flow 'Francis' turbine—quickly demonstrated their superiority to traditional vertical wheels in most respects. Turbines were much smaller per unit of energy produced, and cheaper. They could operate submerged when traditional wheels could not. They turned much faster, and they did all of this while operating at high efficiencies (typically 75% to 85%). By 1860 most new water-powered wheels were turbines rather than vertical wheels.

The continued growth and concentration of industry in urban centers, however, most of which had very limited waterpower resources, meant that steam power continued to displace water power in importance, even if the development of the water turbine delayed the process.

European engineers and inventors also made significant improvements in windmills between 1500 and 1850, but windmills fared worse in competition with steam than water wheels and water turbines.

The sails of the windmills that emerged from Europe's medieval period were inclined to the plane of rotation at a uniform angle of about 20°. By the seventeenth century, millwrights in Holland had improved the efficiency of some mills by moving away from fixed angles and giving the windmill blades a twist from root to tip (i.e., varying the inclination continuously along the blade's length) and by putting a camber on the leading edge, features found on modern propeller blades. Another advance was the fantail. Developed by Edmund Lee in 1745, the fantail was a small vertical windmill set perpendicular to the plane of rotation of the main sail assembly and geared so that a change in wind direction would power the fantail and rotate the main sails back into the wind. In 1772 Andrew Meikle developed the spring sail, which used hinged wooden shutters mounted on the blades, operating like venetian blinds, to secure better speed control. Other inventors linked governors to spring sails to automatically control wind speeds.

As with water wheels, engineers also began to carry out systematic, quantified experiments on windmills to test designs. In 1759 John Smeaton published a set of well-designed experiments on a model windmill. Since he had no means of developing a steady flow of air, he mounted 21-inch (53-cm) long windmill blades on a 5.5-feet (1.54-m) long arm that was pulled in a circle in still air to simulate the flow of air against a windmill. His experiments refuted prevalent theory, which recommended that the blades of windmills be inclined at a 35° angle. They confirmed that the 18–20° angle generally used in practice was far better. Smeaton's work also confirmed the even greater effectiveness of giving the blades a twist, that is, inclining sails at a variable angle like a propeller. By 1800 a large, well-designed Dutch windmill might develop as much as 50 hp at its axle in exceptional winds (normally 10–12 hp), although gearing inefficiencies probably reduced the net output at the machinery during such winds to around 10–12 hp.

Despite the empirical improvements in windmill design and attempts to apply quantitative methods to its design, the energy that could be tapped from winds was too erratic and had too low a density to compete with newly developed thermal energy sources, notably the steam engine. Following the development of an effective rotary steam engine by James Watt, and the introduction of mobile, high-pressure steam engines (locomotives) in the early-nineteenth century, that brought the products of steam-powered factories cheaply into the countryside, windmills began a rapid decline.

Only in limited arenas did the windmill survive. It continued to produce flour for local markets in unindustrialized portions of the world. It also found a niche—in a much-modified form—as a small power producer in isolated agricultural settings such as the Great Plains of North America. The American farm windmill of the nineteenth century was a vertical windmill, like the traditional European windmill, but it had a much smaller output (0.2-1 hp in normal breezes). Consisting of a small annular rotor usually no more than 6 feet (2 m) in diameter, with a very large number of blades to produce good starting torque, American windmills were mounted atop a high tower and usually used to pump water. By the early twentieth century several million were in use in America, and the technology had been exported to other flat, arid regions around the world, from Australia to Argentina to India.

THE MODERN ERA (1880–2000)

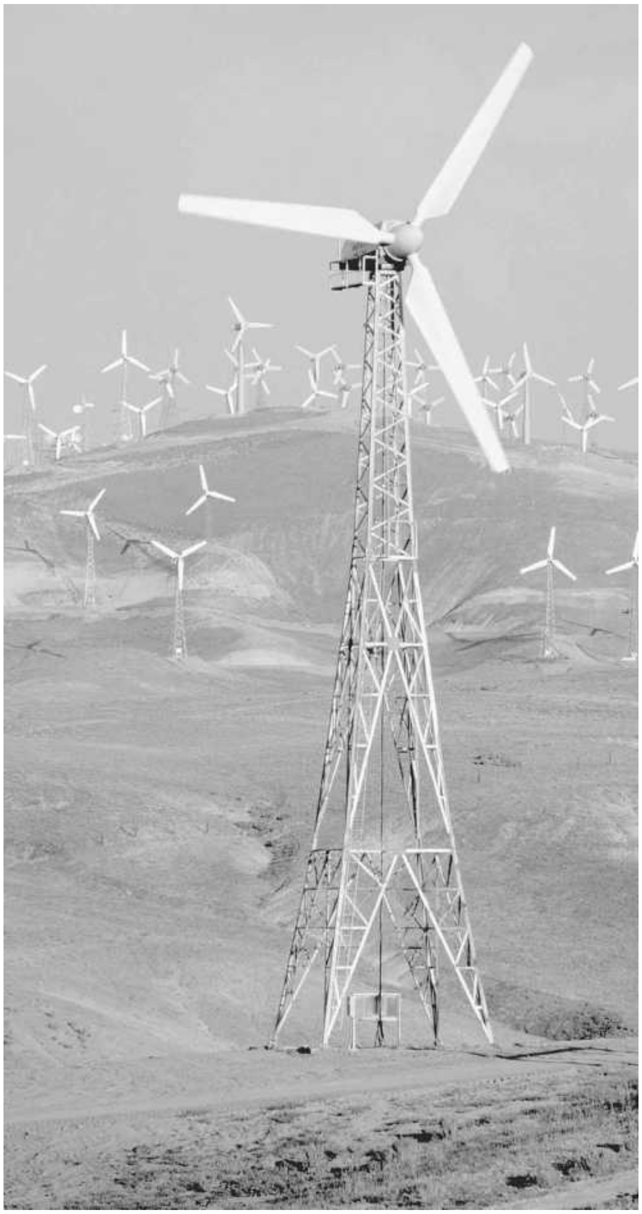
By the late nineteenth century, both wind and water were in decline as power producers almost everywhere. Steam-powered vessels had, in the late nineteenth century, begun to rapidly replace sailing vessels for hauling bulk merchandise. Only in isolated regions did sailing vessels continue to have a mercantile role. Increasingly, sailing vessels became objects of recreation, not commerce. In areas such as Holland, traditional windmills continued to pump away here and there, but they were on their way to becoming historical relics more than anything else. In the twentieth century even the American windmill went into decline as electric power lines belatedly reached rural areas and electric pumps replaced wind-powered pumps. Meanwhile, growing dependence on steam engines steadily reduced the importance of waterpower in all but a few favorable locations.

The emergence of electricity as a means of transmitting power late in the nineteenth century offered new life to devices that tapped the kinetic power of wind and water, since it offset one of the greatest advantages of steam power: locational flexibility. With electricity, power could be generated far from the point at which it was used.

Around 1890 Charles Brush erected a wind-powered wheel over 56 feet (17 m) in diameter to test the possibilities of wind as an economical generator of dc electricity. Coal- and waterpower-poor Denmark provided much of the early leadership in attempts to link wind machinery with the newly emerging electrical technology. The Danish engineer Poul LaCour, for example, combined the new engineering science of aerodynamics with wind tunnel experiments and new materials such as steel to try to develop a wind engine that would be a reliable and efficient generator of electricity. By 1910 he had several hundred small wind engines operating in Denmark generating dc electricity for charging batteries, but he had few imitators.

The development of the airplane stimulated intensive research on propeller design. In the 1920s and 1930s, a handful of engineers began to experiment with fast-moving, propeller-shaped windmill rotors (wind turbines), abandoning traditional rotor designs. For example, Soviet engineers in 1931 erected a 100 kW (about 130 hp) wind turbine on the Black Sea. In 1942 the American engineer Coslett Palmer Putnam erected the first megawatt-scale wind turbine designed to feed ac into a commercial electrical grid—a very large, two-blade rotor—at Grandpa's Knob in Vermont. It failed after 1,100 hours of operation, and cheap fuel prices after World War II limited further interest in wind-generated electricity.

The fuel crises and environmental concerns of the 1970s revived interest in the use of wind to produce electricity. Governmental subsidies, especially in the United States, supported both the construction of wind turbines and research, and led to the erection of large arrays of wind generators (wind farms) in a few favorable locations. By the 1990s, over 15,000 wind turbines were in operation in California in three mountain passes, generating a total of about 2.4 million hp (1,800 mW), but wind's contribution to total electrical energy supplies remains miniscule (<1%).



Modern wind turbine on a hill. (Corbis Corporation)

Waterpower fared better. When electrical engineers demonstrated the possibility of long-distance transmission of electrical power between 1875 and 1885, waterpower suddenly assumed new importance. Many of the best waterpower sites had been untapped because they were in remote regions far from manufacturing centers. As long as power had to be directly transmitted by mechanical shafts and belts, the locational flexibility of steam power made it the overwhelming first choice of industry. Electric power transmission made low-cost hydropower more competitive.

The first experiments with commercial water-generated electricity took place in the 1880s, but applications were limited since the predominant form of electricity generated, low voltage dc suffered large power losses in transmission. The introduction of high voltage ac around 1890, with its sharply reduced transmission losses, led to the first hydroelectric plants of significant scale. The spectacular success of the first hydroelectric plant at Niagara Falls in 1895, which used multiple turbine generator units, each developing 5,000 hp (3,750 kW) under a 136-foot head, and transmitting that power via high voltage ac some 22 miles to Buffalo, attracted enormous capital into the field. Between 1895 and 1930 large hydroelectric plants sprang up all across the United States and Europe. In some regions such as Norway and California, hydroelectricity became the dominant form of energy used.

The move toward gigantic hydroelectric developments accelerated in the 1930s, especially in the United States and the Soviet Union, as government-sponsored projects replaced privately funded projects. The Dnieprostroy hydroelectric plant in the Soviet Union, completed in 1932, was equipped with nine 85,000 hp turbine-generator units. The seventeen turbine-generators installed at Hoover Dam in the mid-1930s were even more powerful: rated at 115,000 hp (~86 MW each). More recent hydroelectric plants have grown even larger. For example, Itaipú (1984–1991) on the Paraná River in South America has eighteen turbine-generator units, each with a capacity of around 940,000 hp (700 MW), for a total capacity of around 17 million hp (12,600 MW).

Although the continued growth of energy consumption and the fixed amount of energy available from waterpower has prevented it from returning to its position as humanity's primary source of inanimate power, waterpower, unlike wind power, continues to be an important producer of energy. Today, waterpower is responsible for nearly 20 percent of the world's electrical energy. In some regions where hydrological and terrain conditions are appropriate, for example in Canada, Norway, and New Zealand it supplies a much higher proportion.

The technologies that enabled waterpower to remain important in the twentieth century—turbines, high voltage ac, and large dams—were also applied to harness the tides. In a few select estuaries where tidal variations were significant and construction conditions appropriate, large dams with embedded turbine-generators impounded high tides and used the outflow during low tides to generate electricity. The largest of these was placed in operation in 1966 on the Rance River on the coast of Brittany in France, where an average tidal range of around 28 feet was available. At Rance, a 0.4 mile long dam equipped with twenty-four turbines, generates around 320 MW of electric power. The high capital cost of tidal plants, the very limited number of sites with sufficient tidal variation and suitable construction conditions, and environmental concerns sharply limit the use of this form of kinetic energy. Thus, tides do not produce a significant portion of the world's energy (much less than 1%).

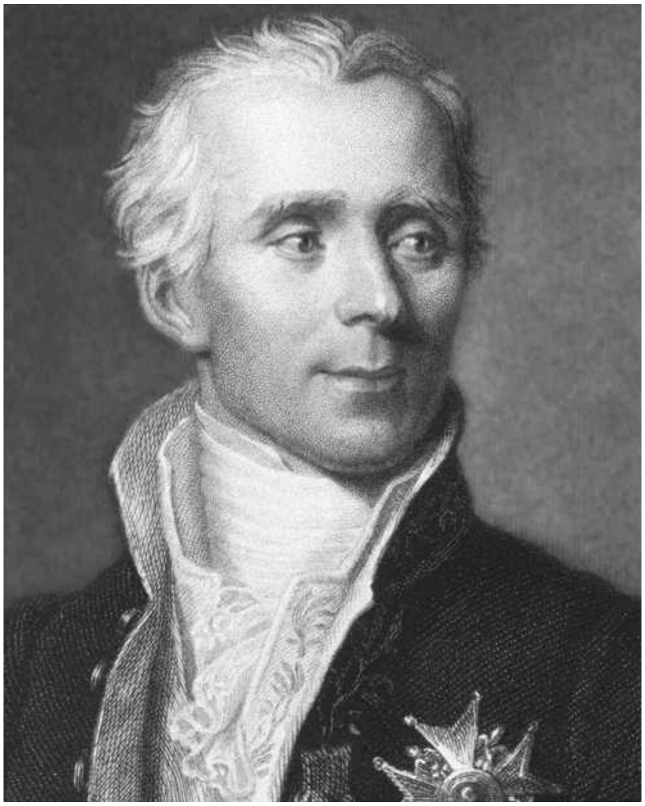
LAPLACE, PIERRE SIMON (1749–1827)

Pierre Simon Laplace, the most influential of the French mathematician-scientists of his time, made many important contributions to celestial mechanics, the theory of heat, the mathematical theory of probability, and other branches of pure and applied mathematics. He was born into a Normandy family of well-to-do peasant farmers and merchants. Intended for an ecclesiastical career, he matriculated at the University of Caen in theology but, discovering his aptitude for mathematics, departed for Paris at age nineteen bearing a letter from his instructors to the mathematician d'Alembert, a leading intellectual figure in prerevolutionary France.

D'Alembert, impressed by Laplace, took him on as his protégé and obtained an appointment for him as a professor of mathematics at the École Militaire, where he taught mathematics to teenage cadets. In this position, Laplace was also expected to present his work to the Académie Royal des Sciences, which was under royal patronage. He presented thirteen papers to the Academy in his first three years in Paris. In 1773, his fifth year in Paris, he was elected an adjunct member of the Academy. By the 1780s he was regarded as one of its leading figures and was appointed to important royal committees, largely based on his published papers on probability, astronomy, and geophysics. In 1785 he was promoted to the rank of senior pensioner in the Academy. However, Laplace was far from a popular figure. He rightly considered himself to be the leading mathematician in France and presumed upon it, pronouncing judgment on matters in other sciences. Even when he was correct, his abrasive manner created enemies. Nevertheless, he played a preeminent role in the Academy committee to reform the system of weights and measures. During this period (1782–1793) he also collaborated with Lavoisier in a series of investigations on the nature of heat and the phenomena of combustion and respiration. The collaboration terminated during the Reign of Terror, when the Academy was suppressed. Toward the end of 1793, probably in fear for his safety, Laplace left Paris until after the fall of Robespierre in the following year.



Pierre Simon Laplace. (Library of Congress)

The functions of the Académie Royal des Sciences were assumed in 1795 by a branch of the newly formed National Institute. Laplace was elected vice president of this reincarnated Academy and then elected president a few months later, in 1796. The duties of this position put him in contact with Napoleon Bonaparte. Three weeks after Napoleon seized power in 1799, Laplace presented him with copies of his work on celestial mechanics. Bonaparte quipped that he would read it "in the first six weeks I have free" and invited Laplace and his wife to dinner. Three weeks later, Napoleon named Laplace his minister of the interior. After six weeks, however, he was replaced; Napoleon thought him a complete failure as an administrator. However, Napoleon continued to heap honors and rewards upon him, regarding him as a decoration of the state. He made Laplace a chancellor of the Senate with a salary that made him wealthy, named him to the Legion of Honor, and raised him to the rank of count of the empire. Laplace's wife was appointed a lady-in-waiting to the Italian court of Napoleon's sister. Laplace responded with adulatory dedications of his works to Napoleon. When Napoleon fell from power, however, Laplace carefully dissociated himself from the emperor. In the Senate, Laplace voted for the return of the Bourbon monarchy and absented himself from Paris in 1815 during Napoleon's brief hundred-day return from Elba. In 1817 Louis XVIII raised Laplace to the rank of marquis. Laplace remained loyal to the Bourbons for the rest of his life, and his 1826 refusal to sign a petition supporting freedom of the press condemned him as far as the liberals in the Academy were concerned.

Laplace's lifelong work was the successful application of Newtonian gravitation to the entire solar system, accounting for all the observed deviations of the planets and satellites from their theoretical orbits. He began this work in 1773. His five-volume work on celestial mechanics (1798–1827) provided a complete mechanical description of the solar system. During the course of his investigations, Laplace discovered that the force on a body in a gravitational field could always be derived as the gradient of a potential function, a discovery that had profound implications in other branches of physics.

In mathematics, Laplace's name is most often associated with the "Laplace transform," a technique for solving differential equations. Laplace transforms are an often-used mathematical tool of engineers and scientists. In probability theory he invented many techniques for calculating the probabilities of events, and he applied them not only to the usual problems of games but also to problems of civic interest such as population statistics, mortality, and annuities, as well as testimony and verdicts.

In the first and second decades of the nineteenth century, Laplace exercised a powerful influence on physics in France, not only through his publications but also through the power to direct the research of others by virtue of his prestige and his position in the Academy. The genius of Laplace lay in his skill in surmounting mathematical difficulties. However, unlike other great scientists, he never attempted to go beyond the view of the world that existed when his career began. Laplace was an apostle of Newtonian mechanics. He believed, for example, that phenomena such as the behavior of light in material media could be understood on the basis of Newton's corpuscular theory of light and short-range molecular forces acting on the corpuscles of light; he directed research to strengthen this approach. As the weight of evidence in favor of the wave nature of light grew larger, Laplace's influence and power waned. In his last years he developed an elaborate caloric theory of heat, again based on a theory of short-range mechanical forces, but the theory was greeted with indifference and generated no further research.

LASERS

It is said that necessity is the mother of invention. This adage says volumes about the early development of the laser. During World War II, U.S. military and civilian scientists searched frantically for improved radar. While these researchers met with only mixed success, their efforts spurred basic research. After the war, using knowledge gained from this line of inquiry, the first successful laser was developed in 1960.

Applications of the laser were found in numerous fields, including science, medicine, industry, and entertainment. By the 1980s, with the widespread use of lasers in industry and in commercial devices such as compact disk players and retail store price scanners, lasers were affecting the daily lives of nearly everyone in the developed world, whether they realized it or not. In a few decades, the laser has gone from a new cutting-edge technology to one that is so pervasive it is difficult to imagine many fields even existing without it.

WHAT IS A LASER?

The word "laser" is an acronym for "light amplification by the stimulated emission of radiation." Lasers of all kinds consist of several basic components: an active medium, an outside energy source, and an optical cavity with carefully designed mirrors on both ends. One of the mirrors is 100 percent reflective while the other is somewhat less reflective, so a beam can be emitted. The active medium is inside the optical cavity and is excited with an external energy source (typically electricity). For the cavity to emit laser radiation, the active medium has to achieve an unusual energy state called "population inversion."

All atoms consist of electrons orbiting around a nucleus. Normally these electrons prefer to remain in their lowest energy state, or orbit, which is known as ground level. When excited, however, electrons will jump to a higher orbit and then drop back down by radiating energy in the form of light at a discrete wavelength. This release of energy is called spontaneous emission. The energy or wavelength of the emitted light determines its color. Spontaneous emission occurs all by itself and is the source of virtually all light we see from natural sources (stars) and man-made ones (television sets, fluorescent lamps.)

Unlike these light sources, laser technology relies on a concept known as stimulated emission. When an excited atom is stimulated by a photon, light is emitted at precisely the same wavelength and precisely in phase with the light wave that stimulated it.

As energy is added and photons collide with other atoms, more and more electrons gain energy and jump orbits. The excited atoms all emit photons at the exact same wavelength. At some point there are more atoms with electrons in excited states than at ground level. This is population inversion.

As the emitted radiation bounces back and forth between the two mirrors, it becomes coherent. Some of the energy traveling back and forth through the optical cavity is transmitted though the less reflective mirror and becomes a laser beam.

The coherence of the beam makes a laser extremely powerful. The beam is light if a single frequency or color in which all the components are in step with one another. Normal radiation (such as the light from the sun) consists of many different wavelengths of light traveling in different directions. A laser's energy is concentrated, traveling in one direction, and traveling at the same wavelength, so its effect on other matter is extraordinary. A 100-watt lightbulb, for example, can barely light a living room, but a pulsed, 100-watt laser can be used to cut or drill holes in metal.

Another feature of many (though not all) lasers is a cooling system to dissipate energy wasted in the form of heat. Although some are much more efficient than others, all lasers waste significant amounts of energy. For example, a CO_2 laser (the most popular laser for industrial uses) operates at approximately 20 percent efficiency. To produce 100 watts of coherent light, these lasers require 500 watts of input power. A ruby laser is even less efficient, at about 0.1 percent; it would require 100,000 watts of electricity to produce that same 100 watts of laser light. Conversely, one company introduced a semiconductor laser in 1998 that operates at 56 percent, the most efficient up to that time.

DEVELOPMENT OF THE LASER

The first known laser was made by Theodore Maiman at Hughes Research Laboratories in Malibu, California, in 1960, but the seeds of this breakthrough were planted years before. In 1917 Albert Einstein, through his work on the quantum theory of light, theorized that stimulated emission of light radiation could occur. The idea was forgotten, though, until the middle of the century.

In the 1940s, researchers were working on better military radar. Radar is used to locate and track objects using pulses of long-wavelength microwave radiation created according to similar principles as laser radiation. Scientists knew that if they could achieve shorter wavelengths, more accurate images can be obtained using more compact equipment. The race was on to reach the infrared and visible portions of the spectrum. Although technical stumbling blocks prevented researchers from achieving this goal during the war, the pursuit continued during peacetime. The war had taught U.S. military and government officials the importance of technological superiority. Worldwide political tensions kept research grants flowing into America's scientific laboratories.

In 1948 Charles Townes was a professor of physics at Columbia University, working with microwaves. During the early 1950s he speculated that stimulated emission could generate microwaves, but he also knew that a population inversion was necessary. By combining the work done by researchers at Harvard University on this concept as well as his own radar-related work on amplifying a signal, Townes came up with the idea for a closed cavity in which radiation would bounce back and forth, exciting more and more molecules.

By 1954 Townes, with the help of graduate students Herbert Zeiger and James Gordon, developed the maser, an acronym for microwave amplification by stimulated emission of radiation. The maser had all the components of a laser—the resonator cavity and an active medium (Townes used ammonia)—but the wavelengths produced were much longer. In 1957 Townes developed the equation showing that much smaller wavelengths (in the infrared and visible-light range) were possible. Townes collaborated with Arthur Schawlow, a physicist at AT&T Bell Laboratories, and the two worked together to achieve a laser.

Theodore H. Maiman with a ruby that was used in early laser studies in the 1960s. (Corbis Corporation)

Others had similar ideas. R. Gordon Gould, a graduate student at Columbia, had come to the same conclusions. In November 1957 he wrote up his notes on a possible laser. In 1958 Townes and Schawlow patented a similar idea. Theodore Maiman learned of this research in September 1959 at a conference on quantum electronics that Townes had organized. Afterward he began his own research on a laser, using a pink ruby as the active medium. Ironically, Schawlow had rejected ruby because he felt it would require too much energy. By pumping the ruby with the light from a photographer's flash lamp, however, Maiman created the world's first laser, in June 1960.

The floodgates were now open. Lasers using calcium fluoride, helium-neon, glass, and cesium vapor as active media followed within two years. Others substances followed throughout the early 1960s. By 1962 about 400 companies had some kind of laser research. U.S. government spending on laser development soared, from $1.5 million in 1960 to $20 million in 1963. Scientific journals became inundated with papers, and meeting rooms at conferences overflowed with inquisitive attendees.

Lasers were still tools of elite scientists, though. Moving the technology from the lab and into the marketplace took years. The first devices produced in significant quantities were military systems in the early 1970s, followed by a small but growing number of industrial and medical lasers. The laser's time had finally come.

LASERS AND THEIR APPLICATIONS

Different lasers use different materials as the active medium. The medium can be either solid, liquid, or gas, and there are advantages for each in the amount of energy that can be stored, ease of handling and storage, secondary safety hazards, cooling properties, and physical characteristics of the laser output.

Solid-State Lasers

The term "solid-state laser" refers to lasers that use solids as their active medium. However, two kinds of materials are required: a "host" crystal and an impurity "dopant." The dopant is selected for its ability to form a population inversion. The Nd:YAG laser, for example, uses a small number of neodymium ions as a dopant in the solid YAG (yttrium-aluminum-garnet) crystal. Solid-state lasers are pumped with an outside source such as a flash lamp, arc lamp, or another laser. This energy is then absorbed by the dopant, raising the atoms to an excited state. Solid-state lasers are sought after because the active medium is relatively easy to handle and store. Also, because the wavelength they produce is within the transmission range of glass, they can be used with fiber optics.

Diode (Semiconductor) Lasers

Also using solids but considered separately because of their unique characteristics, diode lasers are the most common lasers in use. Compact size and reliability are the chief benefits of this kind of laser. The two common families of diode lasers contain active mediums composed of GaAlAs (gallium-aluminum-arsenite) or InGaAsP (indium/phosphorus). These media emit radiation in the infrared range. Much like those working with radar in the 1940s and '50s, researchers in the 1980s and '90s found ways to shorten wavelengths of lasers produced by diodes to reach into the range of blue visible light.

Liquid (Dye) Lasers

The common liquid lasers utilize a flowing dye as the active medium and are pumped by a flash lamp or another laser. These are typically more complex systems requiring more maintenance. They can be operated as either CW (continuous wave) or pulsed. One advantage liquid lasers have is they can be tuned for different wavelengths over a 100-nm range.

Gas Lasers

Gas lasers are not unlike fluorescent light bulbs and neon signs. Gas is confined to a hollow tube, and electricity passing through it excites the atoms. The most common gas lasers use carbon dioxide, argon, and helium-neon. Gas lasers are relatively inexpensive and can produce very high-powered beams.

Excimer Lasers

Excimer lasers use gases, but because of their special properties are usually considered as a class of their own. Excimer is short for "excited dimer," which consists of two elements, such as argon and fluorine, that can be chemically combined in an excited state only. These lasers typically emit radiation with very small wavelengths, in the ultraviolet region of the electromagnetic spectrum. This shorter wavelength is an enormous advantage for many applications.

There are literally thousands of uses for lasers. One of the largest applications is telecommunications—sending a signal through fiber optic cables, for example. This application grew rapidly in the 1990s with the phenomenal increase in traffic on the Internet. Optical data storage, such as on compact disks, CD-ROMs, and DVDs, is another important use for lasers. The information age was obviously a boon to this application, and as researchers obtained smaller wavelengths with diode lasers, they were able to fit more information on smaller storage devices.

Another group of applications is collectively known as materials processing. This includes the processes used in manufacturing. Production facilities use lasers to cut, weld, drill, mark, and heat-treat numerous materials such as metals, plastics, wood, ceramics, and even diamonds. Lasers are much more precise than other mechanical means used to process materials, and lasers make it possible to build devices with tiny, even microscopic, dimensions. A subgroup of this category, medical device manufacturing, relies on lasers to machine stents and other devices for implantation into the human body.

Lasers are used for medical procedures as well. The laser has been called a bloodless scalpel because it can be used to simultaneously cut and cauterize tissue. Photodynamic therapy is a cancer treatment that relies on lasers, and laser eye surgery can correct vision, eliminating the need for glasses and contact lenses. Plastic surgeons use lasers for hair removal, skin resurfacing, tattoo removal, and many other applications. New medical imaging and diagnostic methods have been devised thanks to the laser.

Military uses for lasers are abundant, from rangefinding to guided munitions to laser aiming devices on firearms. Warfare has been revolutionized by the laser. Law enforcement uses lasers to lift hard-to-recover fingerprints and in laser radar speed guns.

Laser printers, bar code readers, unmanned freeway tollbooths, laser pointers—none of these very common devices would be possible without laser technology. This is just a minor sampling; the list of laser applications goes on and on.

The laser has revolutionized many aspects of science and other disciplines, as well as the daily lives of millions of people. When it was first invented, the laser was referred to by some as a solution looking for a problem because it came about mostly from basic research rather than the active solution to a particular concern. At the time, no one could have predicted the far-reaching effects it would have in the second half of the twentieth century, or that it would come to be considered by many as one of the most influential technological achievements of that time.

LEWIS, WARREN K. (1882–1975)

INTRODUCTION

As a central figure in twentieth century petrochemical technology, Warren K. Lewis is widely viewed as the father of American chemical engineering. His work opened up an entirely new and powerful engineering discipline applicable across a broad range of manufacturing industries, including chemical synthesis, steel production, and power generation.

Lewis had an enormous influence on the energy industries. Along with the Russian, Vladimir Ipatieff, Lewis was pivotal in advancing petroleum refining technology. As an instructor and mentor, Lewis left his mark on three generations of chemical engineering students, many of whom entered and influenced the U.S. petroleum and petrochemical industry. As a consultant and technological innovator, Lewis directly applied his principles of chemical engineering, an essentially American development, to revamping and extending the production capability of U.S. catalytic cracking facilities. Lewis' greatest single engineering achievement was his central role during World War II in the design of the fluid catalytic cracking process, an innovation of strategic and economic importance.

THE EARLY YEARS

Warren K. Lewis was born in 1882 on a small farm in southern Delaware. Farm life exerted a strong early influence on the future engineer. Believing that after college he would return to manage the family farm, his academic goal was to learn the fundamentals of agricultural science in order to apply them in a rational manner to improve the farm's productivity. To Lewis, this meant employing a thorough understanding of the mechanical operations of advanced (i.e., efficient) equipment and tools. In 1901 Lewis entered MIT as an undergraduate with a major in mechanical engineering.

THE MIT YEARS

Soon after entering MIT, Lewis came under the influence of Professor William H. Walker, who was instituting a new and innovative program in chemical engineering. In his sophomore year, Lewis transferred to the chemical engineering program, which at that time was part of the chemistry department.

After graduation, and at the urging of Walker, Lewis won a two-year fellowship for study in Germany. Studying under the great physical chemist Abegg at the University of Breslau, Lewis obtained his doctorate in 1908 while developing a thorough grounding in the theories of and mathematical structures associated with phenomena underlying numerous industrial engineering processes.

Spending only a brief period in industry, Walker urged Lewis back to MIT in 1910 to become an assistant professor of chemical engineering. Both Walker and Lewis sought to form closer ties between the chemical engineering program and industry. To this end, and with the cooperation of the great industrial chemist A. D. Little, they established in 1916, MIT's School of Chemical Engineering Practice. The Practice School, a successor to Walker's Research Laboratory of Applied Chemistry (established at MIT in 1908), centered around practical chemical engineering instruction within operating plants in and around the New England area.

In addition to being (by all accounts) a brilliant and riveting teacher, Lewis was an innovative administrator in the cause of furthering chemical engineering at MIT. In 1920, largely due to the efforts of Walker and Lewis, MIT's chemical engineering program became a separate department, with the Practice School becoming part of the newly-formed department. In that year, Lewis became the first head of the chemical engineering department. During his nine years as department head, Lewis fought successfully for a strong, independent chemical engineering program. In their path breaking text, The Principles of Chemical Engineering (1923), Lewis and Walker for the first time systematized the engineering study of unit operations and provided a model of instruction for burgeoning chemical engineering departments. Eventually, Lewis secured for the department approval by MIT to develop a curriculum leading to a B.S. in chemical engineering, one of the first such programs in the country.

ENGINEERING, CONSULTING AND PETROLEUM PROCESSING

Lewis' influence on the U.S. energy sector evolved from his career as a consultant to the petroleum refining industry, and in particular Standard Oil of New Jersey (currently Exxon). Lewis' success as a consultant rested in large part on his ability to apply to practical problems his knowledge of and experience in industrial chemical engineering. Between 1919 and 1927, Lewis virtually restructured Jersey Standard's manufacturing operations. His work spanned both oil production and refining.

One of Lewis' first assignments was to make the distillation process more precise and continuous. By the early 1920s, Lewis introduced to Jersey Standard the use of vacuum stills. These were able to operate at lower temperatures that limited coking and fouling of equipment. Thus production engineers did not have to periodically clean out and repair equipment, which in turn facilitated the transformation of distillation from batch to continuous operations.

Lewis directed subterranean reservoir studies to improve the efficiency of extracting oil from the ground. He designed the first bubble tower to effect more precise and efficient fractionation operations and provided important assistance in developing one of the first continuous thermal cracking process.

In 1927, Lewis and Frank A. Howard, head of the Development Department at Jersey Standard, established a research center at Jersey's Baton Rouge plant to research and commercialize advanced petrochemical technology. This development marks the beginning of the Southwest as a center of petroleum-based technology. Lewis populated the facility with colleagues and graduates from MIT's Chemical Engineering Department and the Practice School. These included Robert Haslam, the head of the Practice School, who became director of Baton Rouge R&D and Eger Murphree, a protégé of Lewis, who was made Manager of Development and Research for Jersey Standard's Development Department.

In the years leading to World War II, Lewis and Haslam hired fifteen additional MIT-affiliated chemical engineers to work at the Baton Rouge plant. These men felt great loyalty to Lewis who they considered their mentor. They were instrumental in championing Lewis and his style of chemical engineering at Jersey Standard. Through the 1930s and during World War II, Lewis and Jersey's R&D people at Bayway and Baton rouge worked closely together to develop some of the most important innovations in the history of petrochemical technology. The most significant of these was fluid catalytic cracking.

WORLD WAR II, FLUID CRACKING, AND THE LATER YEARS

Fluid cracking, which began operations in 1942 and was responsible for providing the Allies with sufficient supplies of aviation fuel and synthetic rubber, was Lewis' last and greatest engineering achievement. Its successful development depended on Lewis' engineering genius, on the close relationship established between Jersey Standard and MIT by Lewis, and the ability of his protégés both within MIT and Jersey Standard to transform his core ideas and designs into commercial reality.

In addition to his work on fluid cracking, Lewis served as Vice Chairman of the Chemistry Division of the National Defense Research Committee during World War II. In this capacity, he directed chemical engineering research on problems associated with the development of the atomic bomb. Lewis officially retired from teaching in 1948, although he continued to meet with students at MIT well into his eighties. Lewis died at the age of 92 in 1975. The American Institute of Chemical Engineers, in honor of his achievements in the academic arena, established an annual award in his name for those who have made significant contributions to education in the field.

LIGHTING

Light is essential for human life. Modern societies have created homes, schools, and workplaces that rely on electric light sources. Some of the electricity used to generate the light in these spaces is wasted, largely owing to ignorance. The efficient application of electric, as well as natural, light sources to the human condition is a sophisticated effort, but one that is essential to a sustainable and enjoyable future.

WHAT IS LIGHT?

Humans are a diurnal species, which means that we are active in the day and asleep at night. Indeed, daylight is the primary stimulus to the photobiological system that regulates our sleep-awake cycle. Of course, while we are awake, we see, and we depend a great deal on seeing. Approximately 80 percent of the human brain devoted to sensing the environment is devoted to vision. It is not surprising, then, that from the beginning of human history we have strived to produce and control light.

Until very recent human history, the Sun had been our primary source of light for both seeing and waking. Over the past two millennia, and particularly over the past two centuries, our direct reliance on the Sun for light has diminished. Today it can be argued that large segments of affluent human societies are exposed to light from the Sun only rarely. Many people spend virtually all of their active lives under manufactured light sources of various types.

These manufactured light sources are, perhaps ironically, largely dependent on the Sun. The radiant energy from the Sun has been stored in the fossilized remains of billions of creatures over millions of years and is used to power the electric light sources created by modern humans. The power generated by hydroelectric sources also is a result of solar evaporation and subsequent rainfall. Only nuclear reactors provide power independent of the Sun, which is, of course, the largest nuclear reactor in the solar system.

Ironically, too, without humans there cannot be "light." In other words, we formally define light in human terms. Radiation from the Sun and from other sources varies in frequency. These different frequencies have been categorized for convenience into different bands. The highest frequencies are in a band known as cosmic rays, and the lowest are in the radio frequency band. Between these two extremes is a very small band of radiant energy known as visible radiation, or light. Only radiation in the narrow region of the electromagnetic spectrum visible to humans can be called light. All other radiation, *even that seen by other species* outside this band, cannot technically be referred to as light. We measure the frequency of radiation within the visible band in terms of wavelength. By convention, the visible band ranges from 380 to 780 nanometers; one nanometer is one billionth (10^{-9}) of a meter.

Photoreceptors in the eyes convert radiation in the visible band into neural signals that reach the brain. Photoreceptors are located throughout the retina, a sensory membrane that covers the entire back of the

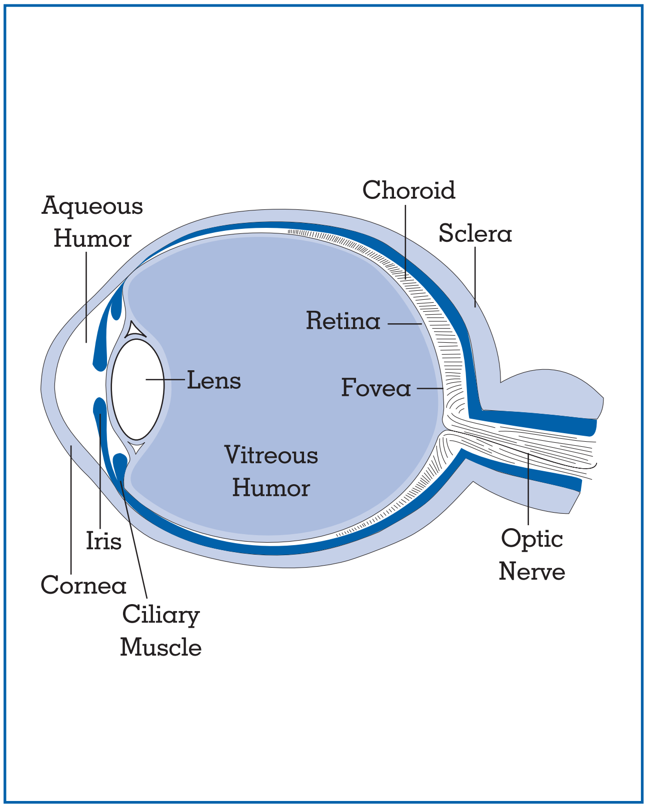

Figure 1.
Cross section of the human eye.

human eye, as shown in Figure 1. One eye contains approximately 130 million photoreceptors. We have, however, two distinct classes of photoreceptors, rods and cones. Rods are more sensitive to light and are used primarily for nighttime vision, whereas cones, of which there are three types, are used for daytime vision. These two classes of photoreceptors enable human vision to comfortably span light levels from a sunny, snow-capped mountain to faint starlight, a billion-to-one range. The three cone types provide us with the ability to convert light into color. Indeed, color is not an inherent property of light. Rather, the human brain "calculates" color from the neural signals generated by the three cone types.

MEASUREMENT OF LIGHT AND COLOR

Light is measured in several ways. Until about 1960, most light measurements were obtained by visual comparison. A standard light source of known, but adjustable, brightness was compared by a trained technician to another light source of unknown, but fixed, brightness. When the two lamps were seen to be equally bright, they were said to produce the same amount of light. Naturally, this technique was fraught with problems of inconsistency and inconvenience. Today photosensitive electronic detectors are used to measure light accurately and reliably. They convert radiant energy into a measurable electrical signal that can be used to quantify the amount of light generated by a source.

The measurement of light is known as photometry. (Color measurement is known as colorimetry; see below.) Photometry can be performed in several different ways, depending on the geometric relationship between a light source and a detector. Most light measurements are based on the flux (photon) density on a detector. This quantity is known as illuminance and represents the rate of photon absorption by a detector of known area. From an illuminance measurement other photometric quantities can be derived. Flux, measured in lumens, is simply the total amount of light generated by a source. Intensity, measured in candelas (cd), is the amount of light projected in a given direction and within a two-dimensional (solid) angle. Luminance, measured in candelas per square meter, is comparable to the human perception of brightness because it accounts for both the amount of light reaching a surface and the amount of light reflected from that surface back to the eye. For many years luminance was known as photometric brightness, but this term is no longer used.

Photometric measurements do not weight all wavelengths in the visible band equally. Rather, a specific weighting function for the electromagnetic spectrum is employed to define "light" (see Figure 2). This function, known as the photopic luminous efficiency function, is not based on the responses of all of the photoreceptors in the eyes. Rather, it is based on the spectral sensitivity of only two cone types found only in the small region of the retina known as the fovea. Responses by the photoreceptors in the fovea enable us to read and see fine detail, but they represent only about 4 percent of all the photoreceptors in the retina. The photopic luminous efficiency function was established by international agreement in 1924 and has been used as the standard weighting function for light ever since.

Light also can be defined in other ways, even though these definitions are rarely used. For exam-

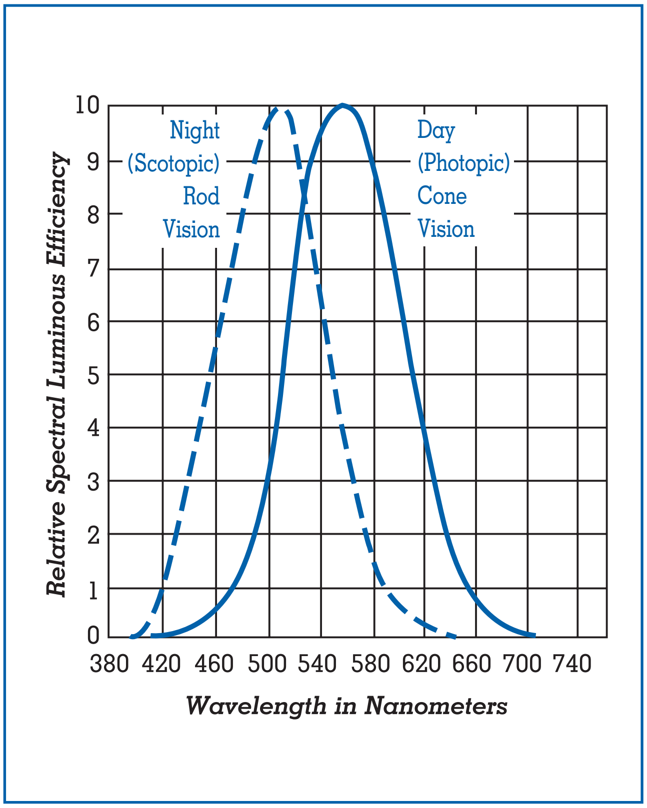

Figure 2.
Photopic (right) and scotopic (left) luminous efficiency functions.

ple, the scotopic luminous efficiency function was established in 1951 by international agreement to represent the spectral sensitivity of rods (see Figure 2). This function is rarely if ever used in photometry because the presence of almost any light source, including moonlight, will raise light levels to a point where some cones also function for vision.

Light sources vary in their ability to produce light—that is, to produce radiation within the photopic luminous efficiency function. In general the efficiency of extracting energy from fossil fuels or other energy sources and converting it into light is very low. For example, the efficiency of light extraction by an open gas flame is only about 0.04 percent. Not until very recently, with the advent of electric light sources, was it possible to substantially increase extraction efficiency. The conversion efficiency of the most efficacious electric light source presently manufactured (low-pressure sodium) is, however, only about 30 percent.

All electric light source efficacies are measured in terms of their ability to generate light per unit electric power, measured in lumens per watt (lm/W). However, efficacy is only one consideration in selecting a light source. For example, the most efficacious light source, low-pressure sodium, essentially produces a single wavelength of light (589 nanometers), making every object color appear as different shades of yellow. For some human activities the absence of color information is not important, but for others it is not only unpleasant but also dangerous (e.g., in surgery). It is beyond the scope of this article to compare light source cost, maintenance, safety, flexibility, and operating conditions, but all of these factors, not just efficacy, are extremely important in selecting the right light source for a particular application.

However, two points about energy efficiency need to be stressed. First, power and energy are two different quantities, and second, high light source efficacy (lm/W) does not always indicate good energy efficiency.

Power is the rate at which a source generates energy, measured in ergs per second. Obviously, then, because energy is the product of power and time, energy conservation techniques can either reduce the power required to generate light or the total time that the power is being supplied to the light source. Many electric light sources can be used with associated electrical dimming circuits to reduce light output by reducing the power supplied to that source. Photosensors, for example, can be used to dim electric lighting levels when daylight enters a room through a window or a skylight. Time clocks, occupant sensors, and even manually operated switches are effective techniques for turning lights off when a room or a building is unoccupied. Both strategies reduce the energy used for lighting; dimming matches the light source intensity with the needs of the people, and switching extinguishes light when no one needs it. Dimming and switching should be used to reduce only wasted lighting energy. It should be reemphasized that light is necessary for human activity. Our societal goal should not be simply to reduce energy consumption but rather to reduce energy wasted by too much light and by lighting that meets no human need.

Light sources are only rarely used without a fixture to house the light source. A fixture makes handling and operating the light source safer and helps provide

Common Lamp Types	*Typical CCT*	*Typical CRI*
Incandescent		
household A-lamp	2800	100
tungsten-halogen	3190	100
photoflood	3400	100

light where it is needed by controlling the direction of light emitted by the source. As already noted, electric lamp efficacy is measured in lumens per watt. However, the total flux generated by a source is measured without regard to direction. Because light should be directed toward an object or an area to achieve a purpose, flux emitted from a fixture is not necessarily the most useful photometric quantity to assess efficacy in a given application. An automobile headlamp, for example, should direct as much of the light generated by the lamp as possible onto the road in front of the automobile. The light directed into the night sky cannot be used, and thereby this lost light reduces the fixture (headlamp) efficacy. Therefore, efficacy measured in terms of lumens per watt does not provide a true measure of fixture efficacy because all the flux from the fixture are not always useful for a given application. The photometric quantity, intensity, is the amount of light flowing within an imaginary cone connecting the illuminated object and the light source. Intensity, measured in candelas, is a measure of how much light generated by the light source actually arrives where it is needed. The amount of light arriving at a specific location is critical for headlamp design, for example. In general, intensity per watt is a valuable measure of efficacy for any lighting system because, ultimately, light must arrive at a specified location to be useful. Other light is wasted, and this wasted light should be reflected in a measure of low fixture efficacy. Different fixtures are produced by manufacturers for different applications using a variety of light sources. The most efficacious light fixture for a given application should be used, but the most efficacious light fixture (cd_{max}/W)

does not always employ the most efficacious light source (lm/W).

The term "color" can be used in two ways to describe the light generated by a source or reflected from an object. As already noted, color appearance is a perceptual phenomenon that, despite much scientific investigation, defies precise quantification. For example, the same physical light may look brown or orange depending on its brightness. Further, this same light may look more or less red, yellow, or brown depending on the apparent color adjacent to it. At present we have only a qualitative understanding of these color appearance phenomena. Color can, however, be quantified very precisely in terms of color matching. This system of quantifying color is known as colorimetry. Any light can be matched in appearance with the right combination of idealized, but quantifiable, red, green, and blue lights. These three lights are known as primary colors or, simply, primaries. Color televisions are practical examples of color matching. They can produce a wide gamut of colors through adjustments of three color pixels: red, green, and blue. Thus, although we can predict precisely what colors will match in terms of these three primaries, we have no precise way to predict whether the pixels will be seen as, for example, brown or orange. Through manual adjustments of the color television pixels, however, each person can reach an acceptable appearance of a televised image.

The color of light generated by a source can be precisely described by colorimetry. From a colorimetric description of the light, other color measures can be derived. Two derived measures—correlated color temperature (CCT) and color rendering index (CRI)—are commonly used to characterize light generated by manufactured sources. It is very important to emphasize that both CCT and CRI are derived from the science of color matching but are used, incorrectly, to describe different aspects of color appearance. Despite the technical error, both CCT and CRI have been found to be practically useful by the lighting industry for color appearance.

CCT refers to the appearance of the light generated by a very hot (i.e., incandescent) object, the temperature of which is measured in kelvins (K). As a body is heated, it begins to produce a reddish-yellow, and then a yellow-white light. As temperature increases, the apparent color of the light changes to blue-white. In astronomy, for example, older, cooler stars appear yellow or red, whereas younger, hotter stars look blue. Paradoxically, electric light sources with CCTs between 2,700 K and 3,200 K generate a yellowish-white light and are termed "warm"; those with CCTs between 4,000 K and 7,500 K produce a bluish-white light and are termed "cool." This paradox seems to have originated from the association between yellow light and a hot fire. The association between apparent color and tactile temperature seems to have been reinforced by the cold feel of glass admitting blue light from the sky on a clear day.

CRI is a measure of how "true" or "natural" colors will appear when illuminated by a light source. Light sources that generate light evenly throughout the visible spectrum, such as daylight, have high values of CRI (maximum CRI = 100); those that have gaps in the visible spectrum (e.g., clear mercury) have low CRI. Electric light sources, particularly fluorescent lamps, have undergone a great deal of development in recent years and now have much higher CRI values than were available in 1970. Although real improvements have been made to the color-rendering properties of these lamps, to some extent these lamp developments are only a game of numbers. Given the technical flaws inherent in CRI for describing color appearance, this measure should not be expected to precisely characterize the color-rendering properties of these lamps. For example, a ten-point difference in CRI values is probably unimportant.

TYPES OF LIGHTING

Much of the history of electric light sources (see Figure 3), fixtures (see Figure 4), and control technologies (dimming and switching) centers around improving energy efficiency. It is often assumed that incandescent lamps were the first electric light source. Actually, carbon arc lamps were the first practical electric light source, preceding the incandescent lamp by almost half a century. Carbon arc lamps employ two carbon electrodes separated by a gap. When current is supplied to the electrodes, the lamp produces a very bright, blue-white arc. These lamps literally burn the electrodes while the lamp is operating, so a clock device is required to continuously feed carbon into the arc to keep the gap width constant.

Carbon arc lamps were first developed in the 1840s, and sometimes elaborate towers were created to provide illumination to streets in a few European

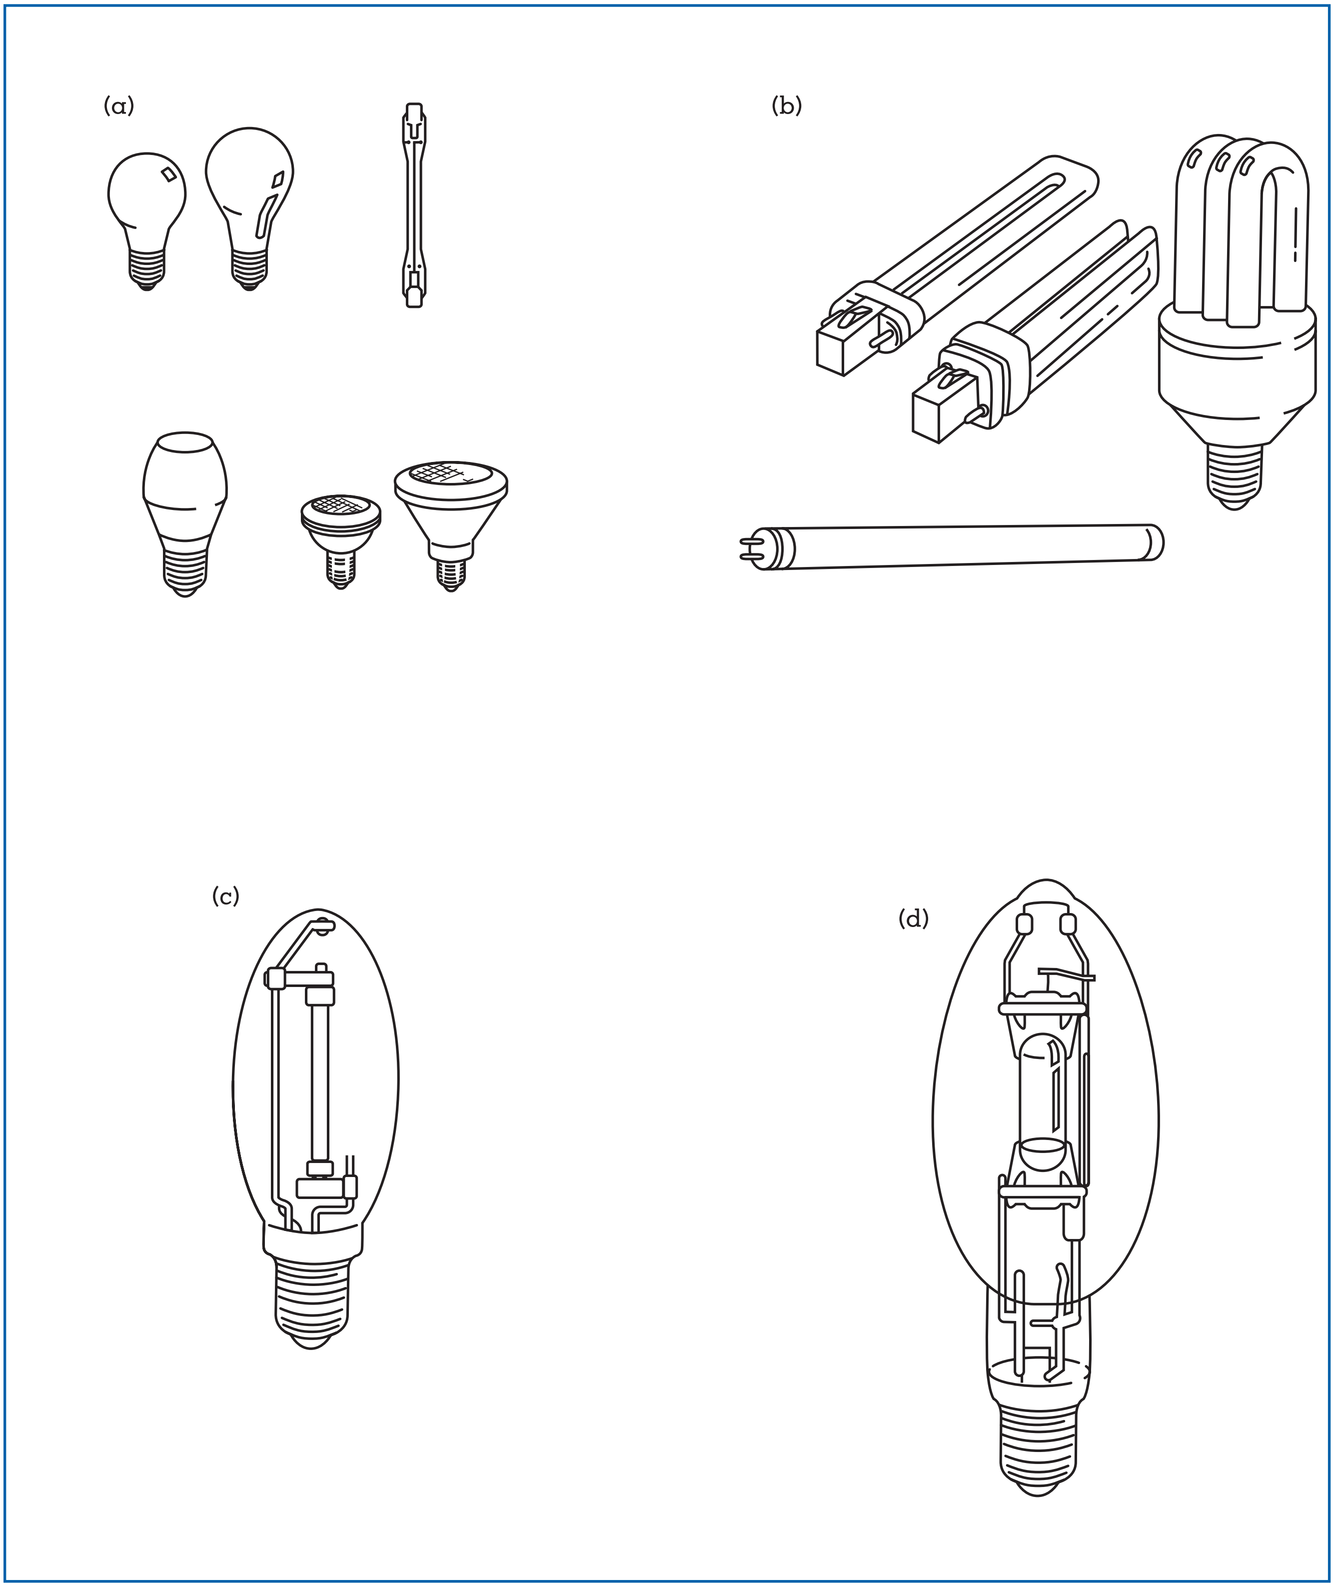

Figure 3.

cities. Carbon arc lamps are still used today for searchlights because they produce the very bright, concentrated point of light needed for a high-intensity beam. These lamps are impractical for other purposes, however, because it is difficult to segregate and distribute this concentrated light into many small packages useful for human activities indoors. Also, cost and the pollution generated by these lamps make them unacceptable by modern standards.

Incandescence means to heat an object to the point of producing light. The incandescent lamp, then, is a lamp with a filament heated to the point of glowing. The trick accomplished by Thomas Edison and his team at Menlo Park, New Jersey, in 1879 was to produce an inexpensive lamp with a carbon filament that would glow for several hundred hours. After more than a year of experimenting, Edison was able to demonstrate an incandescent lamp producing approximately 2 lumens per watt and lasting several hundred hours. Incremental improvements in that basic design, especially the use of the metal tungsten in filaments, have increased the efficacy of commercially available incandescent lamps to between 10 and 15 lumens per watt. More significantly, perhaps, these lamps are easy to install and cost as little as fifty cents each.

It has been argued that Edison's greatest vision was not the invention of the incandescent lamp but rather his insight two years earlier into the possibilities of providing small "packages" of light where people needed them. A high-voltage power supply with a high resistance light source was required to meet his vision; the incandescent lamp was, therefore, a logical outcome of that insight. The incandescent lamp and the associated electrical distribution system changed human history forever. An inexpensive, manageable light source not only illuminated the night but also made it possible to build the large windowless buildings so prevalent today.

One of the major innovations in incandescent lamps has been the tungsten-halogen lamp, developed in 1959. As the tungsten filament of an incandescent lamp glows, some of it evaporates and is deposited on the inside surface of the bulb. This evaporation not only shortens lamp life, but also the deposited tungsten reduces the light output from the lamp. Iodine, bromine, and chlorine are within the family of elements called halogens. These molecules will combine with the evaporating tungsten and, rather than be deposited on the bulb wall, will deposit the combined molecules back onto the filament. At this point the halogen molecule disassociates from the tungsten molecule, and the cycle begins again. The halogen cycle prolongs incandescent lamp life and keeps the lamp burning brightly. Special bulb shapes and materials are needed for tungsten-halogen lamps because very high temperatures are required for their operation. The high temperatures increase efficacy so that most tungsten-halogen lamps available to the market produce approximately 15 to 30 lumens per watt.

Probably every reader has heard of the mythical incandescent lightbulb that has burned for more than fifty years. Because we are all susceptible to believing conspiracy theories, we are suspicious that manufacturers could make all lightbulbs last that long, if only they would. Most inexpensive incandescent lamps available in stores are rated for 750 hours of operation. In reality, an incandescent lamp can be made to last a very long time, certainly longer than 750 hours, but there is no "free lunch." Incandescent lamp life can be prolonged considerably if the lamp is operated at low temperatures. Lamps operated at low temperatures, however, produce relatively more heat than light, so the efficacy drops below the rated 10 to 12 lumens per watt. Lamp life could also be improved if the lamp were more expensive. Incandescent lamps used in traffic signals are rated at about 8,000 hours of operation but are approximately five to ten times as expensive as the conventional household incandescent lamp, because of their more durable filament construction. An incandescent lamp can have long life, high efficacy, or low cost, but not all three at the same time. So although the mythical lamp may exist, and indeed it can be made, physics demands that it must either produce light expensively or inefficiently, and probably both.

Fluorescent lamps were the next major innovation in lamp technology. Introduced commercially in 1938, they were a radical improvement in lighting energy efficiency. At nearly 50 lumens per watt, the first fluorescent lighting systems immediately replaced those using incandescent lamps in large industrial and commercial applications. Even today, fluorescent lamp technologies are arguably the most cost-effective, energy-efficient, and reliable source of illumination for interior applications.

Fluorescent lamps are termed a low-pressure discharge lamp. An electric current passes through mercury contained at normal vapor pressure within the bulb. The current vaporizes the mercury and liberates electrons from the molecules. The liberation of electrons from mercury molecules produces radiation, much of which cannot be seen by humans. Phosphors that coat the inside of the bulb absorb the nonvisible radiation. The irradiated phosphor molecules are themselves excited to liberate electrons that *do* emit radiation within the visible band of the electromagnetic spectrum. This multistage process sounds inefficient, but fluorescent lamps can be made to operate at nearly 100 lumens per watt, with lamp life greater than 20,000 hours. New lamp designs as well as improvements to the electrical device needed to start and operate the fluorescent lamp, known as a ballast, have improved system efficacy by more than 40 percent since 1980. Not only has efficacy been improved, but also the color characteristics are better, and the audible noise generated by the ballast has been reduced. Moreover, smaller, compact fluorescent lamps have been introduced and are beginning to replace some of the less efficacious incandescent lamps used most commonly in homes.

Many consumers continue to complain about fluorescent lamps, however, arguing that they "buzz," distort the color of natural objects, and cause headaches. These attitudes are barriers to societal goals for energy efficiency, particularly in the home. As stated above, however, most of the technical issues leading to these complaints have been resolved. Nevertheless, these negative attitudes toward fluorescent lamps persist and are, in fact, reinforced by exposure to the older technologies still in operation and by low-cost, inefficient products being introduced by manufacturers from developing countries. A major barrier to widespread introduction of fluorescent lamps is initial price. Fluorescent lighting systems are much more expensive to purchase than incandescent systems. In the long run, however, the energy savings associated with the fluorescent lighting system would more than pay for its higher initial cost.

The flip side of consumer bias is that some people argue that only fluorescent lamps should be used in buildings. This attitude, while well intentioned, is based on an unsophisticated knowledge of the performance of lighting systems. As previously discussed, the efficacy of a lighting system cannot be characterized by lamp efficacy alone. For example, although a fluorescent lamp and ballast may produce 80 lumens per watt compared to a tungsten-halogen lamp at 20 lumens per watt, the system efficacy of a recessed open downlight ceiling fixture may, in fact, be better with a tungsten-halogen source than with a fluorescent source. This perhaps surprising result is due to the fact that the tungsten-halogen filament is very compact. The light from the small tungsten-halogen filament can be optically controlled much easier than it can from the relatively large fluorescent lamp. Where little or no optical control is necessary, as with general illumination from a standing floor-lamp fixture, fluorescent lighting systems are much more efficacious than tungsten-halogen lighting systems in producing the same visual effect. Again, the application is important for selecting the most efficacious lighting system.

Low-pressure sodium lamps, another low-pressure discharge lamp, produce very bright, monochromatic light at relatively high wattage. These lamps are used exclusively for outdoor applications where a high-light-output lamp can distribute light over a relatively large area. Low pressure sodium lamps have the highest efficacy (180 lumens per watt), but as discussed above, provide people with no color perception. Despite its high efficacy, this monochromatic source has made little inroads into the outdoor lighting market, except in the United Kingdom, which consumes approximately half of all low-pressure sodium lamps manufactured.

High pressure can be used to expand the spectral emission of the sodium gas. Although expanding the sodium spectrum reduces the lamp efficacy to between 60 and 120 lumens per watt, it significantly improves the color characteristics of the lamp. High-pressure sodium lamps were introduced in 1965, and the yellow-orange light produced by these lamps is now found throughout modern societies in roadway, security, and parking lot applications. Newer, color-corrected high-pressure sodium lamps can be found in some indoor applications but have still lower efficacies.

High pressure can also be used to expand the spectral emission of mercury gas. High-pressure, clear mercury lamps are no longer widely used because, even under high pressure, they are relatively inefficient and do not provide good color perception. By mixing halides with the mercury under high pressure, however, good color can be produced at relatively high efficacies ranging from 60 to 110 lumens per watt. These metal halide lamps have been gaining steadily in popularity since they were introduced in 1964, particularly as an outdoor light source associated with retail spaces (e.g., shopping centers, gas stations, and facade lighting). These lamps also are being used in many indoor applications, such as warehouses and shopping malls. They are even being used in modern automobile headlamps as a replacement for tungsten-halogen headlamps.

Perhaps the most radical new development in light sources has come from the electronics industry rather than the traditional lighting industry, established in the nineteenth century. Light-emitting diodes (LEDs) were invented in the 1960s, but only since 1997 have these sources become an important light source for widespread applications. Before then, LEDs were used as indicator lights on electronic equipment and were largely restricted to a few colors, the first being the red LED. Today many colors, including white, can be produced economically with efficacies ranging from 5 to 25 lumens per watt. It has been projected that efficacies of some colored LEDs may approach 100 lumens per watt in the near future.

LEDs are a highly directional light source, ideally suited to applications such as automobile taillights and traffic signals. In architectural applications, LEDs have already proven successful in exit sign applications. The high visibility necessary for transportation applications is also a positive attribute in emergency egress fixtures. In addition, the low power requirements of LEDs in exit signs (fewer than 5 or 6 watts per face) compared to other technologies provide substantial energy savings when multiplied by hours of operation typical of exit signs (usually twenty-four hours per day every day). The long life of LEDs also provides the reliability needed for transportation and egress applications.

In the future, LED fixtures will be produced for architectural applications by clustering the individual LEDs. Coupled with electronic controls, the LED fixtures will enable the color and intensity distribution of light to be customized and easily changed. These systems will provide cost-effective and energy-efficient lighting solutions to future lighting artists, designers, and engineers. Indeed, this technology may change architecture in ways not seen since the time of Edison.

The efficient application of lighting technologies to a residential, commercial, or industrial space is much more than simply picking the lamp with the highest lumens per watt. As described above, it is important to have light where you need it and when you need it. Color, cost, ease of maintenance, heat, and durability—as well as how people will use, operate, and maintain the space—are among the other factors to consider in selecting the right lighting equipment for an application.

FUTURE TRENDS

The world population continues to expand. Fuel reserves continue to be depleted. Pollution associated with power generation continues to increase. Technical advances in light sources, fixtures, and controls as well as those in power generation provide a modestly optimistic picture of the future. In 1850 the extraction efficiency of light from carbon-based fuels such as open gas flames was about 0.04 percent. Today we have increased that efficiency more than a hundredfold. Estimates from the U.S. Department of Energy in 1999 suggest that efficiency improvements in lighting technologies will reduce the required energy for lighting in commercial buildings, although the amount of commercial floor space will continue to grow in the United States. Even if this projection is correct for the United States, the need for light by people around the world will outpace the increased extraction efficiency offered by new lighting technologies in the decade 2000 to 2010.

Our societal ambition to reduce energy consumption is, without any doubt, both correct and urgent. It must always be remembered, however, that humans always will need light. Our goal, then, should be to reduce wasted lighting energy, energy expended on lighting that meets no real purpose. The technological advances in light source efficacy must also be coupled with technological advances in controls—both optical control to deliver light where it is needed, and power control to deliver the right amount of light when it is needed. Lighting control systems are slowly becoming more sophisticated, utilizing both automatic and manual controls, to tune lights to occupant needs. Estimates made in the late 1990s suggest that lighting energy used in offices can be reduced by as much as 80 percent using controls relative to static lighting systems (Maniccia 1999). We must also strive to better understand exactly what humans need. Recommended illumination levels in North America, for example, have been reduced by roughly two-thirds since the oil embargo of 1972, with no noticeable loss in human productivity or satisfaction.

Arguably, a reason why lighting energy is still being wasted is ignorance of policymakers, building owners, and developers. Well-intentioned policymakers legislate power but not energy, failing to consider the importance of lighting controls in meeting our societal goals. They also regulate lamp efficacy rather than lighting system efficacy, implicitly failing to recognize that light should be directed to a location where it can be used. Another reason lighting energy is being wasted is the emphasis on the purchase price of lighting equipment. Often the cheapest lighting products are the most energy-wasteful. A lighting system will be operated for many years, and the cost of energy, even at current low prices, far exceeds the initial cost of even the most expensive lighting equipment.

LIQUEFIED PETROLEUM GAS

Propane is the most widely used commercial term to describe a family of liquefied petroleum gases (LP-gas or LPG) that also includes ethane and butane.

Name and Formula	*Ethane* C_2H_6	*Propane* C_3H_8	*N-butane* C_4H_{10}
Vapor pressure @ 100 d.F			
lbs/sq. in. absolute	780.0	190.0	51.6
Boiling point of liquid at			
atmospheric pressure-F	-127.5	-43.7	31.1
Weight of liquid @ 60 d.F			
Pounds per gallon	3.11	4.23	4.86
Specific gravity	0.374	0.508	0.584
Gross heat of combustion			
Btu per pound	22,329	21,670	21,315
Btu per cu. ft. @ 60 d.F	1,783	2,558	3,368
Btu per gallon @ 60 d.F	69,433	91,044	103,047
Flammability limits			
Lower % in air	3.0	2.2	1.9
Upper % in air	12.5	9.5	8.5
Freezing point of liquid at			
atmospheric pressure F	-297.8	-305.9	-216.9
Gallons per pound mol @ 60 d.F	9.64	10.41	11.94
Molecular weight	30.07	44.09	58.12

Table 1.
Physical Constants of Selected Hydrocarbons Found in LP Gas.
SOURCE: Handbook/Butane-Propane Gases

Propane is a nontoxic, colorless, odorless hydrocarbon that occurs naturally in natural gas streams and crude oil. At normal atmospheric pressure and temperature, it is a gas; under moderate pressure propane becomes liquid. The ratio of liquid to gas is 270—one unit of liquid expands to 270 units of vapor.

HISTORY

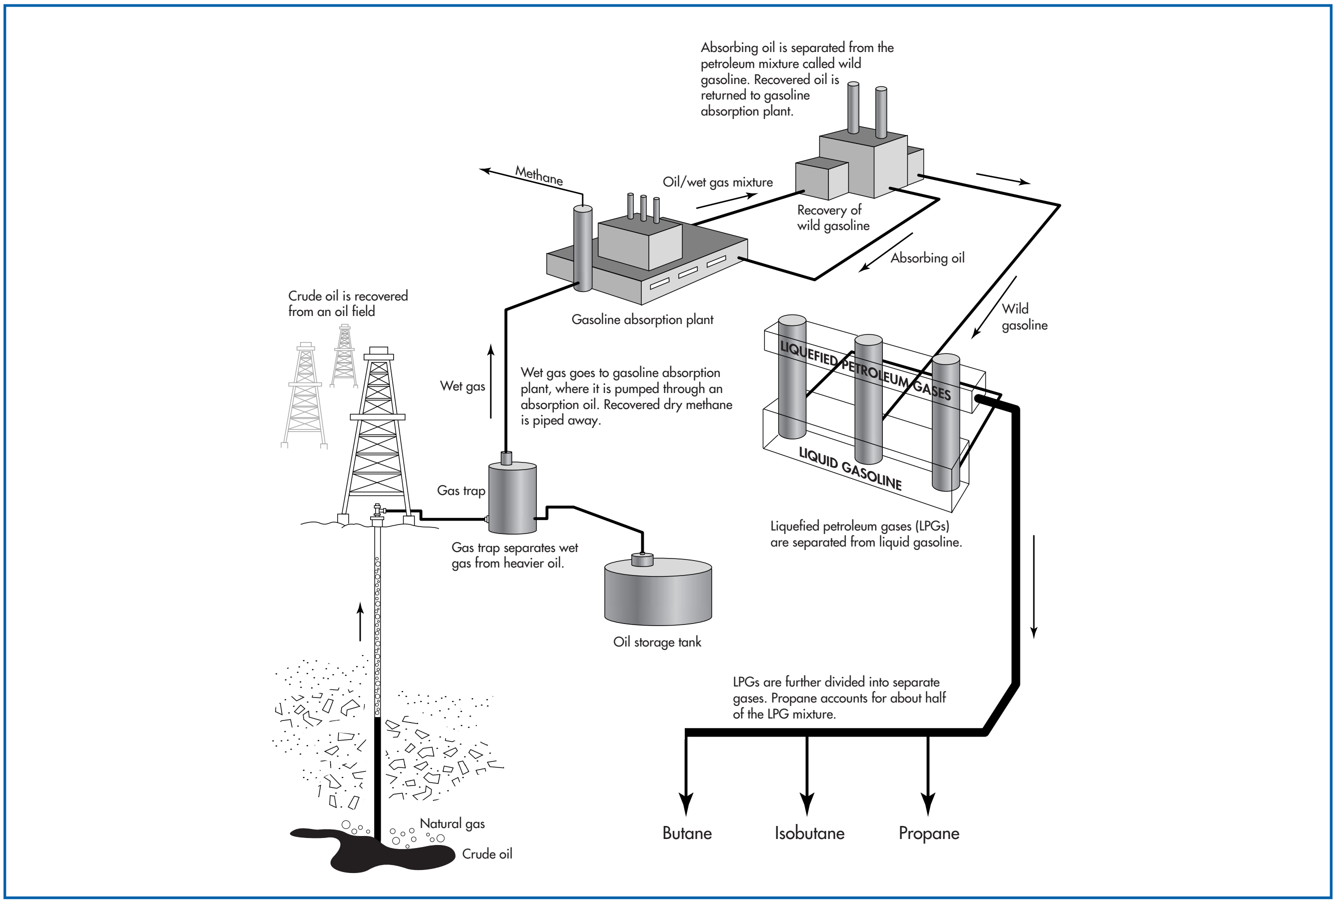
The process of separating "liquefied gases" from natural gasoline was developed in 1912 by Walter O. Snelling, a chemist for the U.S. Federal Bureau of Mines. He wanted to develop better reading light for rural people than the then commonly used candles and kerosene. The first houses were piped for use of this "gasol" in Pennsylvania in 1912. Later, propane was used for cooking and refrigeration. Space heating use soon followed.

Propane became popular as a cutting fuel replacing more expensive acetylene. Another of its first uses was motor fuel. City buses began using it in the 1930s, new farm uses were added in the 1940s including flame weeding, crop drying, hog farrowing, and chicken brooding, and even a locomotive was powered with propane. Recreational uses for barbecues and campers became popular. In the 1950s LP-gas farm tractors and trucks began production. Chicago Transit began converting their city buses to propane.

In the 1960s, use extended to hot air balloons and industrial burners. Residential and commercial use expanded because of new construction without access to natural gas pipelines and the growing popularity of camping. In the 1970s, propane became a popular supplement for natural gas utility systems that were experiencing shortages of natural gas. Refrigerated import terminals were built. When government price controls were imposed in response to the oil embargo, massive vehicle conversions took place to take advantage of the lower-priced and price-controlled propane. Gasoline prices were approaching 100 percent higher and were expected to keep rising.

PHYSICAL PROPERTIES

Propane (C_3H_8) is one of the saturated open-chain hydrocarbons that form the paraffin or alkane series



The process of making propane. (Gale Group)

(C_nH_{2n+2}). The parent compound of this family is methane. The propane molecule, with three carbon and eight hydrogen atoms, is third in the series after ethane (C_2H_6). The specific gravity is 0.508–0.510 at 60°F (15.6°C). The melting point is –309.8°F (–189.9°C). (See Table 1 for other selected properties of LP-gases.)

When liquefied, propane has a Btu content of 91,044 per gallon (higher heating value). At ordinary temperatures, propane is relatively unreactive with other chemicals such as acids, alkalis, or oxidizers.

COMMERCIAL PROPERTIES

Upon release from a pressurized container, propane vaporizes immediately. This property makes liquid propane economical to store and to transport by pipeline, rail, barge, or truck. Because they are relatively light, propane tanks and canisters can be carried by hikers or wheeled to outdoor sites for barbecuing, lighting, and campfires. Propane has been nicknamed “the portable gas.”

Although propane is nontoxic, exposure to liquefied propane can cause skin burns. In gas form, propane is a simple asphyxiant that can displace oxygen. The gas is highly flammable but has a relatively narrow flammability range of 2.2 to 9.5 percent concentration in air. Numerous safety features are incorporated into propane equipment. Storage tanks are constructed to withstand pressures a minimum of four times actual normal operating pressures. Relief valves are integrated into the tanks to relieve extreme pressures that might occur when the tank is subjected directly to fire. To aid in detection of a leak an odorant such as mercaptan is added to the fuel. Although heavier than air, a propane leak readily dissipates into the atmosphere as it reverts from the liquid phase inside the tank to its normal vapor state.

Propane is desirable as a fuel because of its clean-burning properties, its portability, closed-to-atmosphere storage, and availability even in remote locations. It is an approved alternative fuel listed in the 1990 Clean Air Act Amendments and the National Energy Policy Act of 1992. Current factory-produced propane vehicles meet the U.S. Environmental Protection Agency (EPA) ultralow emission vehicle (ULEV) standards and prototype vehicles meet the even more stringent super ultralow emission (SULEV) standards. Because propane does not contaminate soil or water supplies it is exempt from EPA's leaking underground storage regulations.

Compared with other alternative motor fuel options (reformulated gasoline, compressed or liquefied natural gas, ethanol from corn or coal, methanol and electricity), propane has the lowest greenhouse gas emissions except for natural gas. According to a 1998 study by the Institute of Transportation Studies, greenhouse emissions from propane vehicles are 21.8 percent less than from gasoline or diesel.

PRODUCTION AND DELIVERY

There are two primary sources of commercial propane: natural gas processing (55 percent) and crude oil refining (45 percent). A typical natural gas raw stream is comprised of about 90 percent methane and 3 percent propane, and a remainder of other gases such as ethane, butane and pentane. Ninety percent of the propane used in the United States is produced domestically. Ten percent is imported with 50 percent of imports originating in Canada and Mexico. Domestic production comes from several hundred refineries and gas processing plants. From the production source, propane is transported to bulk storage plants in pipelines, railroad tank cars, trucks and barges. Combinations of several types of transportation may be used depending on distance and economics of each transportation type. From the bulk plant, deliveries are made to end users in delivery trucks of 2,500-3,000 gallon capacity. Imports are by pipeline and refrigerated ships.

CONSUMPTION

Worldwide consumption of propane in 1998 was about 96 billion gallons, of which 15 billion gallons were used in the United States by some 60 million consumers. This represents about 4 percent of the total United States energy market. (Each year an additional 8-22 billion gallons of propane are used by the petrochemical industry where it is reformulated into basic building blocks for the production of a variety of polymeric products and chemicals.)

Homes and commercial establishments are the largest users of propane as a fuel where it is used for space heating, water heating, cooking and clothes drying. Fuel storage tanks can be located underground or above ground. Residential, commercial and industrial appliances and equipment can generally operate on either propane or natural gas with only slight modifications to accommodate the different heating values and fuel/air ratios of the fuels.

Industries use propane for space heating, concrete drying, steel cutting, process heat, and asphalt laying, and to power forklifts. Farms use it for crop drying, irrigation engines, animal barn heating and flame cultivation.

LOAD MANAGEMENT

See: Electric Power, Generation of

LOCOMOTIVE TECHNOLOGY

A machine designed to convert the potential energy stored in fuel to tractive effort needed for pulling unpowered wheeled vehicles (usually in a train on railway tracks) is called a "locomotive." The complexity of this definition reflects the fact that "railroads" are a composite technology made up of tracks, locomotives, and trains. There were "trains" of wheeled vehicles pulled by animals or gravity on "tracks" laid to reduce rolling resistance before there were locomotives, but there were no "railroads" until all three components were brought together. The final link was the locomotive—one of the most useful inventions ever made. Within decades of its development locomotives had multiplied overland travel speeds and freight tonnages more than tenfold—in the process revolutionizing land transportation for all time.

HISTORY

Historians usually credit the invention of the locomotive (and hence the innovation of the railroad) to Richard Trevithick, a Cornish mining engineer. In 1804 he assembled a steam-powered locomotive employing used cylinder steam to increase stack draft for a hotter boiler fire, with the resultant puffing smoke and sound characteristic of steam locomotives. Trevithick then used his effective little engine to pull some ten tons of iron and about seventy persons in railed wagons for a distance of nine miles on the Penydarren Iron Works tramroad in South Wales. The Frenchman Nicholas Cugnot had devised a steam-powered, self-propelled street wagon as early as 1769, but before Trevithick's demonstrations there was much disbelief that a locomotive could pull heavy loads without its wheels spinning uselessly on the iron rails.

The word "locomotive" means, literally, "power for moving from one place to another." Early locomotives were given the nickname "iron horse" because of their material and function. Most European languages use similar nomenclature for "railroads," as in the French *chemin de fer*, Italian *ferrovie*, Spanish *ferrocarril* and German *eisenbahn*, all of which mean "iron way" in literal English.

Work is movement of mass through distance, and *power* is work accomplished or energy transferred at a given rate or in a given time. Horsepower is a measure of power—first used, so it is said, by one of the pioneers of steam engine development, James Watt. One horsepower is, approximately, the work a good draft horse could accomplish in a minute—now given as 33,000 foot pounds/minute or 746 watts. A locomotive's power is often rated by the horsepower generated by its prime mover (the engine for converting fuel to power and motion), and the pulling force it can give to the first car in its train (drawbar horsepower). The difference between engine horsepower and drawbar horsepower is power used or lost in the locomotive's transmission, wheel slippage, and auxiliary functions such as producing air pressure for braking or electric current for lighting and other onboard train devices, plus the power needed to move the locomotive itself. A locomotive's tractive effort (work performed by wheel torque at the rails) is estimated in pounds. Actual tractive effort can be directly measured with the use of a wheel dynamometer. What is most important to a railroad, however, is drawbar pull, which equals tractive effort minus the force necessary to move the locomotive.

POWER GENERATION

Locomotives are often classified into three basic types derived from the kind of prime mover and the fuel or energy conversion system employed. These three main types are steam, diesel-electric, and electric (in which the prime mover is actually an off-board power generating station). By historical usage, steam locomotives are often called "engines" and electric locomotives or powered passenger cars are often referred to as "motors" or "traction." Locomotives with internal combustion or turbine prime movers are usually identified further by the type of transmission apparatus, thus "diesel-electric," "LNG diesel," "gas-electric," "turbine-electric," "diesel-hydraulic," or "diesel-mechanical," etc. Innovations in each generic type of locomotive gradually improved its energy efficiency, but inherent features of each type limited technology improvements and ultimately determined (along with other capital and operating cost factors) its success in the marketplace. *Dual mode* or *hybrid* locomotives refer to designs enabling operation with more than one prime mover, such as diesel-electric plus third-rail electrification (see Table 1).

	Steam	*Electric*	*Diesel - DC*	*Diesel - AC*
OUTPUT SIDE:

- Shops and Line-side Infrastructure	Very High	High	Low	Low

Table 1.
Technical and Economic Characteristics of Locomotive Types.

Wood was the easiest fuel to use in early steam locomotives, but it was soon realized that the logistics of wood fuel were limiting. Steam engines were developed that could burn coal, peat, or (later) oil where those fuels were more abundant. For intercity railroads (especially in the Americas, Asia, Australia, and Africa), coal remained the fuel of choice for one hundred years. Despite impressive technology development, steam locomotives never could achieve thermal efficiencies greater than about 6 to 8 percent.

As electric and internal combustion motors were developed and improved in the second half of the nineteenth century, railroads began to look at alternatives to steam locomotion. In most urban transit applications, electric traction overtook horse-drawn and cable-drawn cars, as well as any remaining coal burners. Electrification offered smoke-free locomotive operation, the ability to tap hydroelectric energy supplies (important in Europe and Japan), and the benefit of drawing peak power levels when needed for climbing steep mountain grades or rapid acceleration of passenger trains. With regard to intercity rail applications as opposed to urban transit, however, more often than not initial construction costs for electric power distribution systems were prohibitive. The most important extension of intercity rail electrification in many decades has been completed between New Haven, Connecticut and Boston.

Dual mode locomotives offer the ability to operate beyond electrified territory without changing locomotives, but at a cost of deploying additional on-board equipment and incurring consequent suboptimal performance in both modes. Hybrid locomotives have been used for many years in the approaches to New York City commuter terminals.

In America and elsewhere, coal powered steam locomotives gave way to diesel electric traction over the period 1925 to 1960. This three-decade-plus process of "dieselization"—from first innovation to universal application—became a textbook case in the study of the diffusion of new industrial technology. Professor Edwin Mansfield has demonstrated that the economics of dieselization were akin to those of stimulus and response in psychology; railroads that could benefit the most from diesel power implemented the new technology most expeditiously. Consequently (and like jet engines later replacing piston aircraft), dieselization followed a typical logistics curve—slow initial acceptance in the face of skepticism and uncertainty, then rapid deployment as benefits were understood, and finally tapering of demand as opportunities became saturated.

A diesel-electric locomotive uses as its prime mover a large, self-igniting, internal combustion engine of the type invented by Rudolf Diesel and first successfully demonstrated in 1897. Thermal efficiency of these engines exceeded 30 percent, compared

Table 2 (continued).
Technological Development of the Locomotive.

with about 17 percent for contemporary low pressure oil engines and about 14 percent for a steam turbine. Locomotives use "medium speed" (typically 16 cylinders and 800 to 1200 rpm) diesel engines—in contrast to the "high speed" engines in trucks or "low speed" diesels in ships. Older locomotives powered an electric direct current (DC) generator, which in turn fed electric energy to DC traction motors mounted one to an axle, usually four or six in total, under the frame of the locomotive. Newer locomotives almost always generate alternating current (AC) in an alternator, and then rectify it to DC. If AC traction motors are to be used, the power is then inverted to AC of precisely variable frequency (see below).

Diesel engine output is controlled by throttle settings for the diesel engine ("notch eight" usually means full power), and is automatically balanced to the electrical load on the generator or alternator. Most large diesel-electric locomotives employ a turbo-supercharger, which uses exhaust from the engine to compress air for injection, along with additional fuel, to increase the combustion rate and thus the horsepower of the engine. This action is also automatic, in that the harder the engine runs, the more exhaust, the more power for compression of air, and hence the more oxygen injected for combustion of more fuel. Turbochargers are precision machines and require special maintenance, but they approximately double the engine's horsepower compared with naturally-aspirated diesels. Design improvements in diesel-electric locomotives continue to result in impressive gains in fuel efficiency. Revenue ton-miles per gallon of fuel have nearly doubled since 1975 (see Figure 2).

Top speeds achievable by locomotives depend on their mass, horsepower, gearing, and the quality of track on which they run. Steam and diesel-electric locomotives have been operated at more than 100

mph, and electric locomotives in France first exceeded 200 mph in 1955. The Federal Railroad Administration is currently sponsoring development of a turbine-electric locomotive designed to operate at up to 150 mph.

TRACTIVE EFFORT

After the power rating of the prime mover, a second limitation to any locomotive is the tractive effort it can deliver to the unit's driving wheels without slipping on the rail. The proverbial "inherent advantage" of railroads due to low rolling resistance of steel wheels on steel rails now becomes a limitation, in that a positive coefficient of friction is needed to maintain pulling force at the face of the rail. In the old days, steam locomotive engineers developed great skill at adjusting steam admission to the cylinders and sanding of the rails to minimize slipping. To start a long train, the engineer would back the engine into the train in order to bunch the train's slack, then accelerate—causing each car in succession to jerk to a roll. This is unnecessary with an appropriately powered diesel locomotive consist.

In 1939 General Motor's Electro-Motive Division sent its famed demonstrator FT-103 diesel-electric units on a triumphant tour of America. One purpose was to show skeptical railroaders that this 5400 hp, four-unit diesel locomotive developed more low speed tractive effort than competitor steam engines, which meant smooth starts and excellent performance on long mountain grades. The effect was much like Trevithick's demonstrations 130 years earlier, and a new generation of railroad locomotive power was assured.

Modern locomotives have sensors that detect

when the wheels of any powered axle are about to spin; the microprocessor-based slip control then reduces energy to that traction motor to enable smooth application of maximum pulling power from all wheels. Traditionally, locomotives could achieve (for dry, sanded rail) an adhesion factor of about 25 percent of their weight on driving wheels, but the refinement of wheel slip controls allowed increases in the adhesion factor to about 32 percent. Also to increase torque at the rail, DC locomotive traction motors are wired in series at low speeds, spreading generator voltage and maximizing tractive effort. When speed increases to a certain point, the motors are switched to a parallel connection permitting increased traction motor voltage; this allows the motors to run faster and cooler.

The newest AC locomotives use microprocessor controls and instrumentation that compares ground speed with traction motor rotation to control tractive effort and wheel slip with great precision. These locomotives have equipment that can change the phase angle of the three phase power supplied to the traction motors, and a device called a thyristor (a high speed solid state switch that can handle large ratios of controlled to controlling amperage) to adjust the frequency and amplitude of alternating current cycles. AC locomotives with single axle control will actually reallocate power from a slipping wheelset to those with greater adhesion.

The arrangement of diesel engine, on-board electric power generation, and axle-mounted traction motors also allows dynamic braking—the ability to reduce speed by converting train momentum back through torque developed between rail and wheel to the locomotive axles and traction motors. The motors, thus converted to electric power generators, resist the kinetic energy of the train and produce electric current, which must be carried away to prevent overheating. In electric locomotives (where it is known as regenerative braking) the current is returned to the catenary or third rail, while in diesel-electric engines the electric power is wasted as heat energy through ventilated grid resistors on the top of the locomotive.

OPERATIONAL CONTROL

The third limitation on performance of any locomotive is the ability, whether through the skill of the engineer or by good design of the technology, to control its overall operation effectively. Steam engines were tricky to operate, to the point of taking on almost humanoid characteristics in popular lore. Getting the boiler fire to burn just right, for example, required hard work and experience. Until the mechanical stoker was invented, the fireman's simple physical limitations constrained performance. An advantage of the diesel-electric power configuration is that loads balance nearly automatically between the engine, generator, and traction motors—making operation by the locomotive engineer or driver much simpler than on a steam engine. The "marriage" and self-correcting nature of the diesel engine, its generator (or alternator), and the traction motors was invented by Herman Lemp of General Electric in 1923–1925, and continues to be used today in all diesel-electric locomotives.

With use of electric and diesel-electric locomotives also came the ability to control power and tractive effort, not just for the unit in which a crew rides, but for multiple units (MU) coupled together in a locomotive consist—and this without need of additional crews in the following units. (A "consist" is the make-up of the train, in this case the full set of locomotives used.) With MU operation, locomotive managers had flexibility to size horsepower of the consist to operating requirements of a particular train and its territory or specific assignment.

In time, other aspects of operational control of the locomotive were made possible by electric and diesel-electric power. One important technology advance

represents a logical extension of the principle of MU operation—remote control of additional locomotives placed deep in the train or at its end. This distributed power has proven highly effective in reducing drawbar forces in long, heavy trains, or indeed, in allowing safe handling of longer trains by the locomotive engineer. Experiments were made with distributed power in the 1960s and 1970s, but it was only with the development of reliable microprocessor controls and data radio communications in the 1990s that the concept proved widely effective.

Train control in a different sense of the term is a powerful potential breakthrough technology for railroads. In this concept, accurate knowledge of train position and dispatcher authorities interpreted by an on-board locomotive computer is used to prevent train collisions, overspeed accidents, and incursions into track territory reserved for maintenance crews. The Global Positioning System (GPS), digital data radio communications to and from locomotives, and computer display screens for crews are among the enabling technologies to be used in advanced train control systems, increasingly called positive train control (PTC). The on-board locomotive electronic networks and radio communications systems developed for applications such as power and train control will increasingly be used for locomotive health monitoring, event recording, train dispatching efficiency, on-time (scheduled) train movement, and more responsive customer service. Some of these other business functions are already being deployed on locomotives by railroads, and the Association of American Railroads has developed locomotive systems integration (LSI) standards to promote compatibility of devices from different suppliers.

EMISSIONS

Locomotive emissions have become an important aspect of performance in recent years. While overall fuel efficiency of railroad freight service has been shown by several detailed studies to be approximately three times better than highway motor carrier service, and while rail passenger advocates point out the energy use, congestion mitigation, and superior emissions performance of rail compared with other modes of transportation, environmental protection authorities are interested in reducing major sources of manmade pollution. The 1990 Clean Air Act Amendments specifically mandated extension of emission regulations to locomotives, which the U.S. Environmental Protection Agency (EPA) currently estimates to be responsible for nearly five percent of nationwide emissions of oxides of nitrogen.

In April of 1998, the EPA published a final rule for emission of oxides of nitrogen (NOx), hydrocarbons (HC), carbon monoxide (CO), particulate matter (PM), and smoke opacity for newly manufactured and remanufactured locomotives. The rulemaking took effect in 2000 and is estimated by the EPA to cost the railroads $80 million per year—about $163 per ton of NOx reduced, according to EPA figures. The emissions standards for the several pollutants will be implemented in three tiers—for locomotives manufactured or remanufactured from 1973 to 2001, from 2002 through 2004, and in or after 2005, respectively. The emission levels are based on achievability with reasonable technology and cost outlays. EPA has adopted fleet averaging and banking and trading provisions to provide flexibility in meeting goals more efficiently. The two largest railroads serving the Los Angeles Basin have entered into a separate agreement with California authorities to address the special air quality issues in that area.

LOOKING BACK AND AHEAD

After decades of economic decline and company bankruptcies from the end of World War II through the 1970s, American railroads were largely deregulated in the Staggers Act of 1980. Since then the industry has achieved an unprecedented renaissance in productivity, financial performance, and economic value to customers, due in part to significant technology advances facilitated by deregulation. Because of their labor and energy efficiency, favorable environmental characteristics relative to competing transportation modes, and remarkable ability to absorb and spawn new technologies, railroads have a bright future. Expected increases in traffic volumes in coming decades will require large investments in railroad capacity, including new locomotives. Continuing improvements in locomotive performance, together with the contributions of "intelligent systems" riding these powerful machines, will lead the procession into railroading's third century, as they did its first.

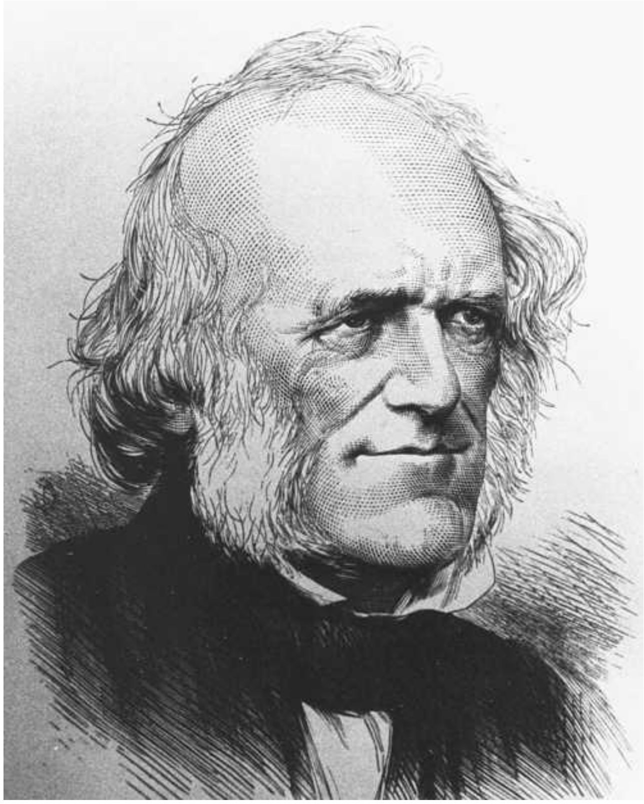
LYELL, CHARLES (1797–1875)

Charles Lyell was a founder of modern British geology. One of his most important contributions to science concerned the rates at which the earth's internal energy was released to affect the shape and form of its crust and thus to create the landscape we know today. Geological changes such as creation of valleys, mountain formation, deposition of sediments, and the like were not in his view caused by occasional "catastrophes" but rather the results of ordinary geological processes operating over an immense period of time. In other words the release of energy to produce geological change has occurred at a rate similar to that of the present time, and is largely uniform over the earth's long history. This doctrine of uniformitarianism has been rightly attributed to Lyell, though others before him (e.g., James Hutton) had expressed similar views.

Lyell was born on November 17, 1797, at Kinnordy near Forfar in Scotland. His father was a wealthy landowner with passions for both Italian literature and natural history. His mother came from Yorkshire and while he was still very young the family moved to England, taking a lease of a large house on the fringe of the New Forest in Hampshire. The boy was sent to schools in the locality, though he showed little evidence of scholastic promise. In 1816 he went to Exeter College, Oxford, to read classics, but he also attended lectures by William Buckland, a professor of geology. The effects of these lectures were reinforced by books from his father's ample library and by an encounter with Gideon Mantell, a doctor in the neighboring county of Sussex, renowned for his study of the fossils then being discovered in the chalkbeds and on the coast of southern England.



Sir Charles Lyell. (Library of Congress)

Lyell's 1819 Oxford degree was in classics, and he then began to study law at Lincoln's Inn, London. However, weak eyesight precluded much reading at that time, and this gave him a reason for further geological study in lectures, field studies, tours, and so on. He became a fellow of the Geological Society in 1819, and four years later was made one of its joint secretaries. He undertook geological tours in France, the west country of England, and the Scottish Highlands. A visit with Buckland to Glen Roy revealed to them the now famous Parallel Roads, three raised seabeaches now believed to be of glacial origin but even then posing great problems for conventional geology.

The central problems that Lyell was to address in the next few years involved detailed mechanisms of geological change, the age of the earth; and rates of energy release. The most popular view of geological history had proposed a series of great convulsions or "catastrophes" involving immense amounts of energy, alternating with longer periods of relative quiescence. Most famously, the biblical Flood of Noah was invoked to explain the present crust of the earth, including the regular strata of fossil beds. People who favored water as the chief agent of change ("diluvualists") had to contend with others who thought that fire was chiefly responsible ("vulcanists"). But each believed in a relatively short period of time for it all to happen, and sometimes drew confirmation from certain biblical data that *could* be interpreted to suggest a date of creation a mere few thousand years ago. Much support for this view was given by Buckland and by his Cambridge counterpart Adam Sedgwick, though both were later to change their minds. The opposite views of James Hutton were less popular, though Lyell was increasingly inclined toward them. One of several events that proved critical in his experience was a visit to Sicily in 1828. Before crossing the volcano Etna he had observed strata at the base of the mountain that seemed comparatively recent. Discovering similar deposits on the opposite side he concluded that the vast bulk of Etna rested on what were, in geological terms, recently recent rocks. Hence a vast age for the whole earth was indicated, and he embarked on a crusade for his uniformitarian ideas, publishing his monumental *Principles of Geology* in the early 1830s (and many subsequent editions thereafter). This work brought him lasting fame.

His legal practice largely forgotten, Lyell now devoted the rest of his life to promoting his doctrines and to traveling extensively. In 1832, at the new King's College, London, he became the first professor of geology, a post he occupied for only two years. He received from the Royal Society its Royal Medal in 1834, and a year later he became president of the Geological Society. He became much involved with the Great Exhibition in London in 1851 and in the British Association. He received a knighthood in 1848 and a baronetcy in 1864.

The influence of Charles Lyell on science was profound. Among the recipients of his *Principles* was a young naturalist embarking on a long sea voyage. This was Charles Darwin, who came to develop a strong interest in geology. He also accepted much of Lyell's arguments and, while his own theory of evolution was being formed, relied extensively on Lyellian arguments for an immensely old earth. He became a good friend as well as a disciple, though even in the 1860s Lyell was reluctant to give Darwin his public support, as he saw how thin the fossil evidence really was for transmutation of species. Not all scientists became enthusiastic Lyellians, however. William Thomson (Lord Kelvin) opposed him over the age of the earth, arguing on largely thermodynamic grounds for a shorter time span than Lyell or Darwin wanted. Only with the discovery of subterranean radioactivity were Kelvin's estimates shown to be erroneous and a Lyellian time scale rendered more credible. However, that of all the uniformitarians in the nineteenth century Lyell was the most extreme, and no one identified completely with a literal interpretation of uniformitarian change. There was too much evidence of catastrophic releases of energy in volcanic eruptions, flash flooding, and earthquakes for most people to deny their massive influence of earth history. Today a modified, and reduced, uniformitarianism seems more likely to fit the facts. Lyell's extreme views were probably related to a religious inclination to Unitarianism, which denies God's intervening activity in history through Christ, just as uniformitarianism cannot allow catastrophic interventions in geology. However, Lyell outwardly remained a member of the Church of England.

In 1842 he married Mary Horner, daughter of Leonard Horner, warden of the University of London. Lyell died in London on February 22, 1875.

MACHINES, SIMPLE

See: Mechanical Transmission of Energy

MAGNETIC LEVITATION

The term “maglev” was coined by Howard Coffey in the 1970s as a shortened form of “magnetic levitation” for transportation. One dictionary defines maglev as “having to do with a railroad system using magnets to float a swiftly moving train above its tracks.” This is a poor definition since there are no tracks, no need for a train of vehicles, and maglev can work at any speed. A better definition is “a transportation system in which the vehicles are suspended, guided and propelled by magnetic forces without any contact with the guideway.”

Maglev is a recent name for an old idea: support a moving vehicle with magnetic fields so there is no contact between the vehicle and a guideway. This apparently simple idea has long inspired inventors, but in spite of sustained efforts by hundreds of people, publication of thousands of technical papers and the expenditure of billions of dollars, there is no commercial maglev system in operation at the start of the Twenty-First Century. This is due to the formidable technical and nontechnical problems that must be solved, the inability to find a design and application that are well matched, and the complexity of the maglev puzzle. This article discusses the past, present, and probable future for this fascinating technology.

EARLY HISTORY: SIMPLE IDEA, A HARD REALITY

The dream of maglev may be as old as the discovery of permanent magnets, such as ones used in magnetic compasses by the Chinese in about 1250 C.E. Permanent magnets can attract or repel each other and it would seem that one might arrange magnets so that a body floats freely in space. The earliest history of maglev is not well known, but in 1839 Earnshaw proved an important theorem which, in simplified form, states that any arrangement of bodies that have attractive or repulsive forces that obey an inverse power law is unstable. For maglev this means that no configuration of permanent magnets, electromagnets with constant current excitation, and ferromagnetic material can be stable, with or without the presence of gravitational forces. If the magnetic field can change, such as via a feedback control mechanism, stability can be achieved. It is also possible to achieve stability by virtue of motion between interacting bodies or by using superconductors arranged so that their persistent currents change appropriately in response to changing position.

A major problem is the design of a propulsion system for a vehicle that has no contact with a guideway. The only reasonable choice is a linear motor that uses magnetic fields to propel the vehicle. The development of a linear motor and its control system is at least as formidable a challenge as the development of a maglev suspension system.

Magnetic scaling laws favor large systems. It takes strong and heavy magnets to suspend a vehicle with any significant spacing between a vehicle and a guideway, and this has made it difficult to build small maglev systems. We have many toy cars, planes, and trains, but no comparable maglev toys that can be used to explain the key ideas.

A train that operates by magnetic levitation, at a railroad research center in Japan. (Corbis-Bettmann)

TECHNOLOGICAL ALTERNATIVES FOR SUSPENSION AND PROPULSION

There are four competing maglev technologies: electromagnetic suspension, electrodynamic suspension, linear synchronous motor, and linear induction motor.

Electromagnetic Suspension (EMS)

Figure 1a shows an EMS system in which an array of magnets is attracted upwards to a steel rail. It is possible to design the magnets so that there is an upward force produced by magnetic attraction that cancels the downward gravitational force: the magnets are suspended in space! If steel beams were mounted on either side of a "guideway," then a vehicle with magnets on both sides could move along the guideway and be supported and guided by the steel rails. If permanent magnets, or electromagnets with constant current excitation, were used in the design, the system would be unstable: any disturbance from equilibrium would cause the magnets to move in the direction of the disturbance. The difference between stable and unstable equilibrium is like the difference between balancing a cone on its base and balancing it on its point. EMS was pioneered by B. Graeminger in 1911.

Earnshaw's theorem proves that some instability is inherent. Ideally there is neutral stability in the fore and aft direction, so that we have a choice: the vehicle can be stable laterally and unstable vertically, or vice versa. The usual approach is to use a design similar to Figure 1a and use electromagnets with power controllable current. Position and velocity sensors are used in conjunction with controllers to regulate the magnet currents and thereby achieve vertical stability, and lateral stability can be achieved passively or, possibly, with help from controlled magnetic forces. This approach is called "Electromagnetic Sus-pension" (EMS) and has been used in many designs.

EMS vehicles have operated at speeds from 0 to 440 km/h (270 mph).

EMS requires about 1 to 2 kW of magnet power for every ton of vehicle mass. At modest and high speeds this power loss is small compared with the power loss due to aerodynamic drag. EMS is the favored approach for urban maglev and is suitable for high speeds if the use of a minimal 10 mm air gap is acceptable.

Electrodynamic Suspension

Figure 1b shows an array of magnets moving over a conducting sheet and being pushed upwards by forces due to induced currents. This electrodynamic suspension that was pioneered by Gordon Danby and James Powell in the 1960s, can not work at zero speed, but at higher speeds it can be inherently stable.

The virtue of EDS designs is their ability to operate with larger air gaps than is feasible with EMS designs. Vehicles suspended in this way have operated at speeds from about 50 to 552 km/h (31 to 343 mph).

All EDS designs are highly underdamped and can even be negatively damped, the equivalent of the instability found in EMS designs. Many maglev designers have underestimated the importance of this damping problem, the equivalent of building a car with solid tires and no shock absorber.

A well designed EDS suspension will create 5 to 10 kW of power dissipation in the guideway for every ton of vehicle mass. This is almost an order of magnitude higher than the power required for EMS. Since the suspension power comes from the linear motor, at low speeds the motor must provide high thrust, and even at moderately high speeds, the suspension power is comparable to aerodynamic drag losses. The high losses can cause serious overheating of the guideway at low speeds. These factors, taken together, make EDS a questionable technology for urban maglev but quite appropriate for high speeds.

Linear Synchronous Motor

One propulsion alternative is to have a powered guideway in which a magnetic field is made to appear to move via electronic means, and it pushes on a magnetic field created by the vehicle. This is called a long stator linear synchronous motor, generally referred to as an LSM. It is possible to have magnets on the guideway and supply the moving field from the vehicle, but this is not a favorable design for maglev. The LSM creates forces by attractive and repulsive magnetic forces, much as an EMS design creates suspension via these forces. The rotary synchronous motor was invented more than 100 years ago and the linear version was pioneered by Henry Kolm and Richard Thornton at MIT in the 1970s.

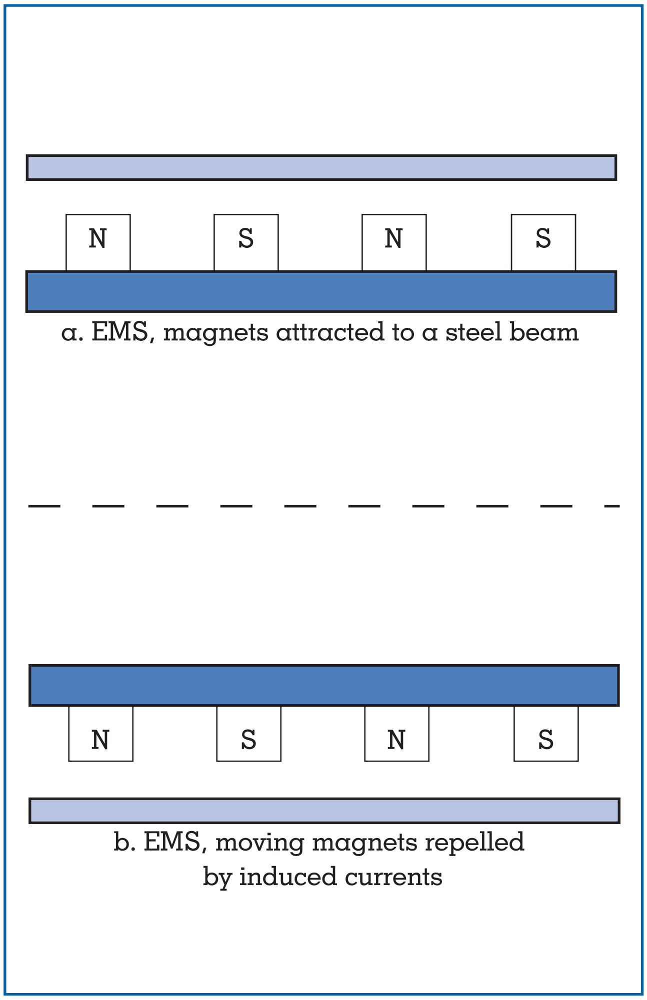

Figure 1.
Electromagnetic suspension: two views.

The advantage of this design is the simplified nature of the vehicle's portion of the propulsion system. In the simplest case the vehicle has a linear array of permanent magnets and is totally passive. This passive vehicle approach has been used successfully for material handling equipment and is probably the best design for small and moderate size vehicles. For larger vehicles the permanent magnets are usually replaced with electromagnets, that also provide the suspension force. This dual use of vehicle magnets for both suspension and propulsion has much merit for high speed transportation systems. The long stator design also has the major advantage that there is no need to transfer large amounts of power to the vehicle and that there is no bulky and heavy power conditioning equipment on the vehicle. Also, the guideway-based power conditioning can be sized according to terrain, with lower power controllers used in regions where high forces and velocity are not required.

A disadvantage of the long stator LSM is the higher cost of the guideway winding as compared with a simple conducting strip that can be used with a linear induction motor. If there are many closely spaced vehicles, each fairly small, then this cost is well justified, but it becomes a problem for some maglev designs.

A second disadvantage is the need to maintain synchronism. Unlike rotary synchronous machines, linear versions are difficult to operate "open loop" with the vehicle automatically maintaining synchronism with a moving field. In practice it is necessary to have a separate controller for each vehicle, and therefore not more than one vehicle can be in one block of guideway. For operation up to a few meters per second, it is possible to use a "stepping mode" with the vehicle following the moving field without feedback, but this method will not work at higher speeds because of inherent "mid frequency resonance" phenomenon. The solution is to use position sensors and electronically synchronize the vehicle with the moving magnetic field.

Linear Induction Motor

A propulsion alternative is to transfer power to the vehicle and then have a magnetic structure on the vehicle that can create a moving field that, in turn, interacts with a conducting guideway to provide propulsion. This is called a short stator linear induction motor (or linear asynchronous motor), generally referred to as a LIM. It is possible to put the powered winding on the guideway and induce currents in a conductor on the vehicle, in which case it would be a long stator design, but this turns out to be an expensive and inefficient approach to maglev propulsion. The LIM creates forces via induced current much as an EDS design creates suspension via induced currents. The rotary induction motor was invented by Nikola Tesla in 1886 and the linear version for transportation was pioneered by Eric Laithwaite in the 1950s.

The advantage of the LIM is the reduced cost of the guideway and the ability to operate closely spaced vehicles without the block limitation of the LSM. The LIM has been used for propelling both wheel based vehicles and magnetically suspended vehicles over a very wide range of speeds.

The principal disadvantage of the short stator design is the need to transfer power to the vehicle. If this is done with sliding contacts, as with conventional electric trains, then some of the advantages of maglev are lost. If it is done via inductive transfer, then the guideway cost is increased.

A second disadvantage is the need to have substantial amounts of power conditioning on the vehicle. This equipment must be sized to match the highest force and speed for the entire system, even if it rarely needs such high peak power. If the air gap is large this power conditioning equipment can be heavy and expensive.

Note that the popular press often misuses terms like "induction" and "synchronous" when applied to linear motors.

RECENT SYSTEMS

England

A low speed EMS maglev system was constructed in Birmingham in 1984. This design had an air gap of 10 mm and used short stator LIM propulsion with power delivered to the vehicle via sliding contacts and a third rail. It provided transportation between an airport and a train station and worked nearly flawlessly for more than twelve years. When problems did develop there was no one with interest and ability to repair it, so it was removed.

Japan

The Japanese constructed a high-speed maglev system in Yamanashi Prefecture using superconducting technology. This was the successor to several smaller and lower speed vehicles that had been tested in Miyazaki Prefecture starting in 1980. The Yamanashi system uses the null-flux version of EDS and a long stator LSM for propulsion. The latest test facility consists of a two-way, 42.8 km (27 mi.) long guideway, most of it in tunnels. In April 1999 a manned five-car train, MLX01, achieved a speed of 552 km/h (343 mph). In November 1999 two trains passed each other at a relative speed of 1,003 km/h (623 mph). This system shows the potential of EDS, but is relatively expensive to construct and operate and it is questionable whether it will ever become a commercially viable design.

Germany

The Germans constructed a 31.5-km (19.6-mile) test loop in Emsland, starting in 1974. This was the culmination of a research effort started in 1970 and involving experiments with both EDS and EMS and with various types of linear motors. The latest design, called Transrapid 08, has an EMS with 9 to 10 mm (3/8 in.) air gap and LSM propulsion using the same magnets for both suspension and propulsion. It achieved a top speed of 450 km/h (280 mph) in June 1993. Although the air gap is relatively small, the success of the Emsland tests makes it clear that this technology is usable for higher speeds than are ever likely to be commercially feasible with conventional railroad technology. A comparison of Transrapid with the Germany ICE high speed train indicates that maglev consumes 30 percent less energy and the differences are much larger when comparing maglev with automobiles and commercial aviation. There are plans to construct a 292-km (181-mi.) operational system between Hamburg and Berlin. The design calls for five stations and a travel time of less than one hour. The construction cost is estimated to be about the same as for a new ICE high speed rail line, but there is still some doubt whether this project will ever be completed. There are active proposals to construct Transrapid systems in the United States but it is too early to tell whether such a system will ever be built.

A second German effort, designated HSST, has been underway since 1974. This is a lower speed EMS design and uses a LIM with power transfer via sliding contacts. This system has been demonstrated on several occasions and there are pending plans for implementation, but past plans have never been carried out and the future is uncertain.

United States

In 1966 Danby and Powell at Brookhaven National Laboratory conceived of using vehicle-mounted superconducting magnets that induced current into their novel “null-flux” winding on the guideway. This concept helped precipitate maglev research efforts in the early 1970s, but these were soon terminated by political action. In 1987 Senator Patrick Moynihan created the U.S. National Maglev Initiative that was managed by the Federal Railway Administration. It led to four preliminary designs, but the effort was terminated by political action. In the late 1990s a maglev effort was reinitiated, but the combination of political and technical dispute makes the future uncertain.

There is an effort by the U.S. Federal Transit Administration to develop an Urban Maglev system that can be an alternative to urban rail-based transit systems. The objective is to achieve speeds up to 161 km/h (100 mph) with lower noise, lower energy consumption and lower operating cost that any other fixed guideway system. Based on the success of the Birmingham, England system it is likely that a viable urban system can be built. If the lower speed design was well conceived it could evolve into a design suitable for operation at higher speeds, just as the railroad system evolved.

Web Sites for More Information

The best and most up-to-date references are Internet websites. Most of these can be reached via links from the U.S. Department of Transportation site: <http://www.dot.gov>. This site has links to the Federal Railroad Administration and the Federal Transit Administration, each of which has links to other national and international maglev sites. Additional maglev sites can be reached from the *Innovative Transportation Technologies* site: <http://faculty.washington.edu/~jbs/itrans/maglevq.htm>. More details on EMS, LSM, and LIM can be found on the German *Transrapid* and Japanese *HSST* sites. More details on EDS and LSM can be found on the Japanese *Railroad Technical Research Institute* (RTRI) site.

A word of caution: Any publication that claims major advantages for a particular breed of suspension or propulsion should be viewed with skepticism.

PROS AND CONS OF MAGLEV

Advantages

Following are advantages that have been proven by actual tests on working system.

- *More efficient.* Maglev vehicles can operate at a given speed with less energy consumption than for almost any other transportation mode, particularly for short to medium distances. This is because the vehicles can be lighter and more streamlined than is possible for any wheel-based design and commercial aviation is very inefficient for short trips. It has frequently been proposed that the vehicles can operate at very high speeds in a partially evacuated tunnel with dramatic savings in energy and time, and several studies have shown that this is not as far-fetched as it might sound.

- *Less noisy.* Maglev vehicles are quiet. Transrapid test data shows 5 to 10 dB less noise than for a train at the same speed or the same noise for speeds that are 100 km/h (62 mph) higher. Some newer maglev designs with more streamlining have even lower noise.
- *Safer.* The system can be as safe or safer than any other system. If it is well designed with dedicated rights of way, a high level of automation and no physical contact, then the most common cause of accidents will have been eliminated. There have been no significant accidents in all of the maglev tests that have been run. If maglev attracts people away from other modes it could save many lives.
- *Environmentally friendly.* The reduced noise and lack of air pollution is environmentally desirable, and so also is the ability to climb steep grades and operate in smaller diameter tunnels. This combination is unbeatable by any other mode.
- *Faster.* The system can be designed to operate safely at very high speeds. But speed is relative so that 161 km/h (100 mph) operation in an urban area will be dramatically faster than alternatives. Some people believe that maglev designers have put too much emphasis on speed and this has made the designs expensive.
- *Reduced operating cost.* The elimination of bearings and wheel contact will reduce the maintenance time and cost. This is borne out by the high reliability of the Birmingham, England maglev shuttle and the reliability of the Transrapid test system in Emsland, Germany. The lower energy consumption and potential for complete automation creates additional savings.

Disadvantages and Problems

There are several disadvantages and problems that must be solved:

- There is a perception that maglev is too expensive. Part of the problem is a focus on very high speeds where any system would be expensive, if not impossible. For many new construction projects a well designed maglev system need be no more expensive than wheel-based designs, and lower maintenance and energy cost will provide additional savings. But this potential cost advantage must be proven before it is can be used to sell maglev.
- Transportation planners and managers can point to financial disasters in the early application of new technology. They feel, with justification, that no commitment for a commercial system should be made until there is a good demonstration system that proves the technology.
- There are many barriers to innovation in the transportation sector. Large corporations dominate the design and construction of guided systems and they have little incentive to change. They could lose by either failing to deliver a viable system or because another company is stronger in the new technology. There are many government regulations that pertain to any transportation system, and political involvement in transportation decision making tends to favor the status quo.
- There are too many inventors and little cooperation in finding the best combination of suspension, guidance, propulsion, and control. A national competition would be very helpful, such as the locomotive competition in 1829 when George Stephenson's *Rocket* beat several competing designs by hauling a coach of passengers at 39 km/h (24 mph).

PROGNOSIS FOR THE FUTURE

Future success will require a significant group to make a long-term commitment to develop an integrated maglev system. There should be a reduced emphasis on new inventions and increased attention to the myriad problems of integrating suspension, propulsion, guidance, and control. Some group must be willing to fund the development to the point that a potential buyer of a maglev system can clearly see that the advantages outweigh the disadvantages. The probability of this happening is good; the major question is "When, where, and how will maglev reach commercial fruition?"

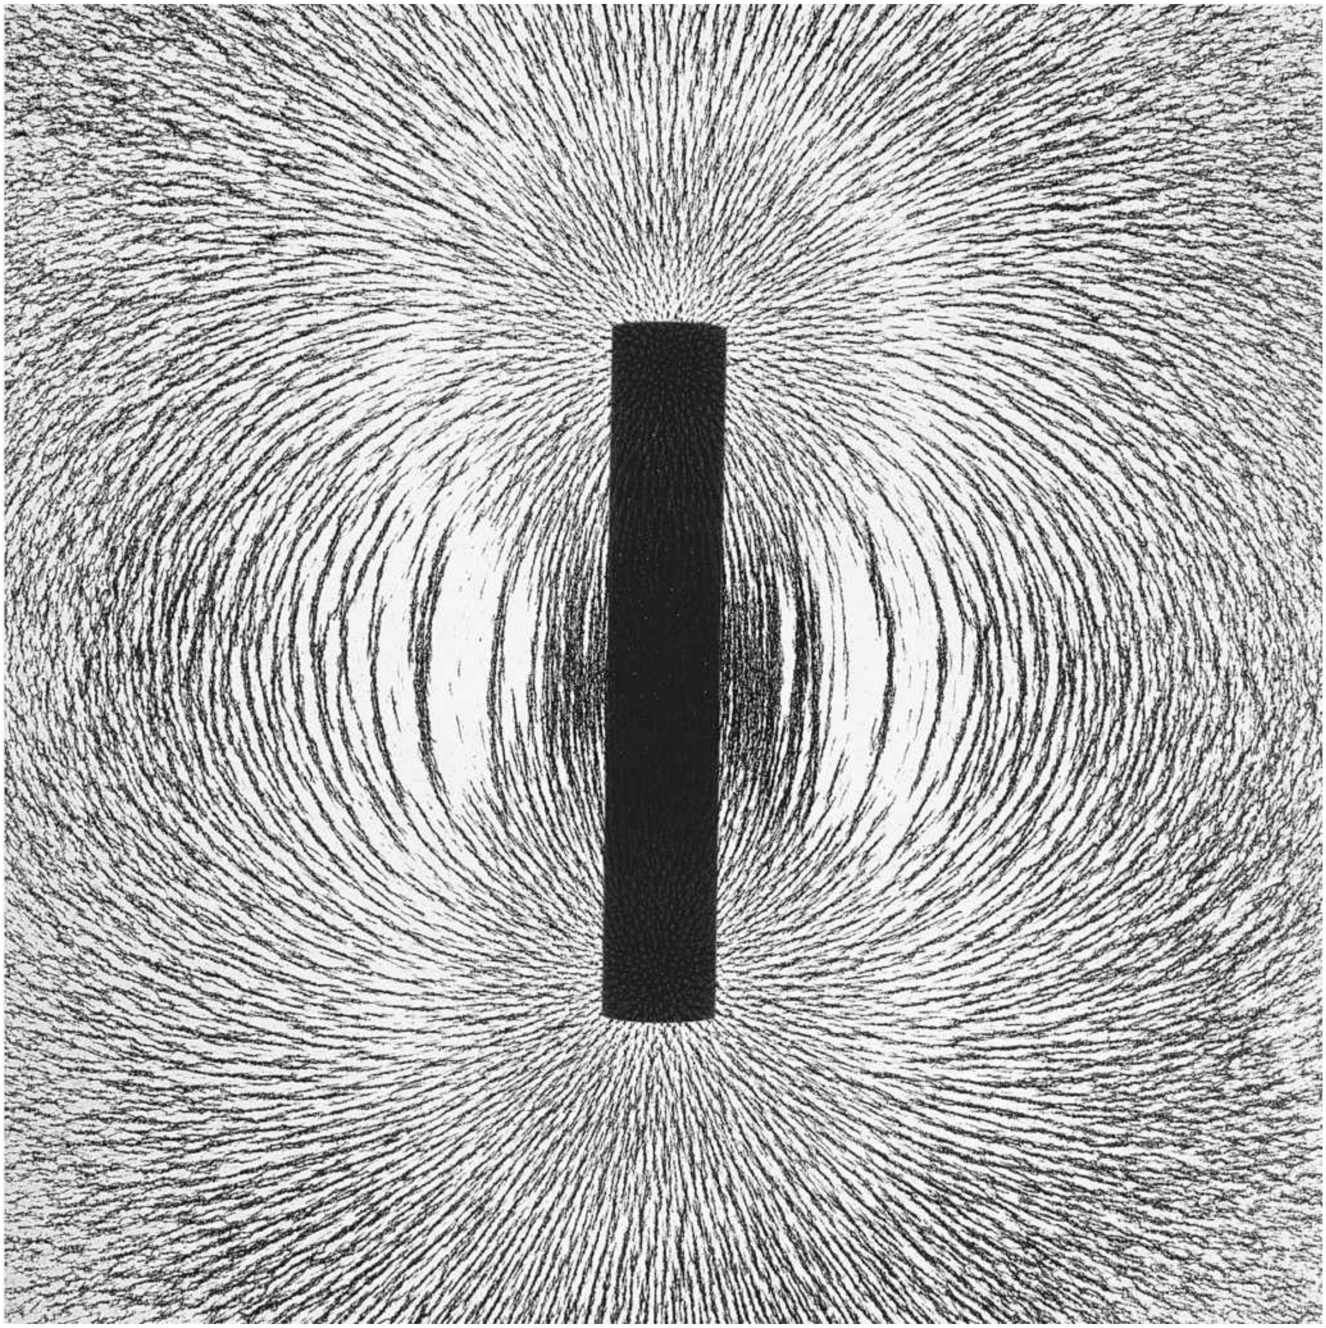
MAGNETISM AND MAGNETS

Magnetism is the phenomenon in which iron is attracted to a natural material called lodestone, the properties of which are similar to a magnet.



Metal filings form a magnetic field pattern around the poles of a magnet. (Corbis-Bettmann)

LODESTONE AND MAGNETS

Lodestone is a crystalline oxide of iron called magnetite. Until the 1800s, lodestones and the earth were the only sources of magnetism. Iron-based materials are attracted to a lodestone as well as to any other magnet. It is the attraction between a magnet and the iron in a refrigerator door that pins a photograph to the door. Bringing an iron-based material in contact with a magnet or lodestone will make a magnet of the material. Unfold a paperclip and rub it with a magnet. The clip becomes magnetized, with the magnetic properties concentrated near the ends of the clip. These end regions are called poles. Magnetize two unfolded paperclips and, in one parallel orientation, the ends or poles attract each other. Change the orientation of one clip and the poles repel each other. Attach a thread to the middle of one of the clips, suspend it, and one pole will point in the general direction of geographic north. The one pointing north is called an N-pole; the opposite pole is an S-pole. We observe, and say, “unlike poles attract, like poles repel.” It is an instructive experiment to cut the magnetized clip into two pieces in an effort to isolate a pole. Interestingly, each of the two pieces has an N-pole and an S-pole. Regardless of how many times a clip is cut in two, magnetic poles always occur in pairs of N-poles and S-poles.

MAGNETIC FIELD

A magnet does not materially change the space around it. Yet, if the magnet were not there, another magnet would not experience a force when brought into the space. Magnetically, the space around the magnet is altered and the modification is thought of as producing a magnetic field. When another magnet is brought into the magnetic field and experiences a force, the magnetic field is the mechanism for exerting the force. The concept of a field applies to gravitational and electric forces as well, and is an extremely important aspect of many energy applications.

Magnetic fields are measured in units of teslas, symbol T. A strong permanent magnet, such as might be found in a physics laboratory, produces a magnetic field of about 0.3 T. Such a magnet is capable of lifting several kilograms of iron. For comparison, the magnetic fields produced by other systems include

10^{8} T	neutron stars
10^{3} T	short bursts of electric current
10^{1} T	strong laboratory superconducting magne
10^{-5} T	Earth’s magnetic field
10^{-9} T	interplanetary magnetic fields
10^{-12} T	magnetic field associated with the human body

In 1819, Hans Christian Oersted, professor of physics at Copenhagen University, discovered that a magnet experiences a force when in the vicinity of a wire carrying an electric current. The fact that the magnet experiences a force is evidence that the electric current produces a magnetic field, which eventually led to the development of innumerable devices—electric motors, electric generators, speakers for hi-fidelity amplifiers, and electromagnets, to name a few—based on this principle.

ENERGY APPLICATIONS

Electric motors

Electric motors are found in nearly every room of a typical house. They power everything from the washing machine, refrigerator, and vacuum cleaner, to the hair dryer, fan, garage door opener, and disk drive in a computer. In an automobile, motors adjust seats, raise an antenna, operate windshield wipers, adjust mirrors, run fans, start the engine, and someday may replace the internal combustion engine under the hood. There is probably no device more useful for doing work than electric motors, and their pervasiveness will surely grow.

Fundamentally, an electric motor converts electric energy to rotational energy. Rotation results from magnetic forces between a rotating part (the rotor) and a stationary part (the stator). There are many designs. In the simplest, the rotor is an electromagnet that rotates between the poles of a permanent magnet (Figure 1). The N-poles and S-poles of the electromagnet are determined by the direction of current flow. In the illustration, attraction and repulsion between poles on the rotor and stator cause the electromagnet to rotate clockwise. When the unlike poles approach each other, the direction of current flow is reversed, causing the poles on the electromagnet to change. The alternating magnetic attraction and repulsion between poles keeps the electromagnet rotating in the same direction.

Electric Generators

An electric generator for operating lights is a common sight on many bicycles. The generator has a coil of wire that rotates between the poles of a magnet and looks very much like a motor. Whereas a motor converts electric energy into rotational energy, a generator converts mechanical energy to electric energy. On a bicycle, the tire rubs against a wheel attached to the rotating coil. Some agent, in this case the cyclist pedaling, does the work to turn the coil with the reward being electric energy. In a large electric power plant an electric generator working on the same physical principle is driven by a large steam turbine.

Electric generators are based on the principle that an electric charge experiences a force when it moves in a magnetic field. Electrons in the metallic wires of

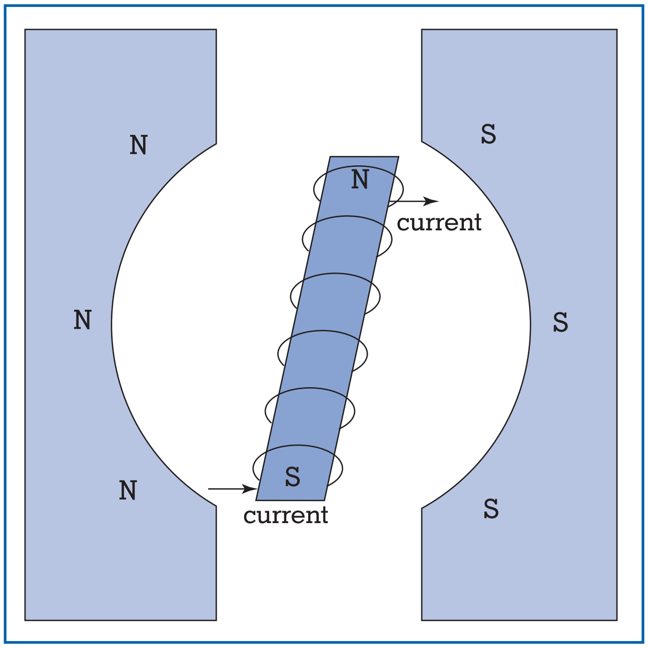


Figure 1.
An elementary motor consists of a rotating electromagnet and a fixed permanent magnet.

the rotor of a generator experience a force when the coil is rotated in a magnetic field. An electric current is produced in a light bulb, for example, when it is connected to the open ends of the wires making up the coils of the rotor.

Magnetic Levitation of Vehicles

Whereas electric motors utilize both attraction and repulsion of magnetic fields, there are energy applications that rely only on attraction or repulsion. Magnetic levitation of vehicles is a good example. A vehicle riding on a track or roadway experiences frictional forces that oppose the movement. Any scheme that can reduce the frictional forces offers improved energy economy. Magnetic levitation involves magnetic forces that hold a vehicle above a roadbed so that the vehicle appears to float on a cushion of air. It does not. It floats on a "magnet" cushion. One method of suspension capitalizes on the idea that like poles repel. The poles are produced by electromagnets rather than using permanent magnets. Another scheme is based on the principle that a metal experiences a force when in the magnetic field of an electromagnet that is energized by an electric current that changes rapidly with time.

Once a vehicle is levitated, it is not in material contact with a track, so cannot be propelled by wheels. The propulsion system, like the levitating system, is based on magnetic principles that are identical to the principles in an ordinary electric motor. The road bed is appropriately configured so that the magnetic field exerts a force on a current-carrying coil secured to the vehicle. In a real sense, the vehicle and magnetic road bed constitute a motor, albeit a linear motor (as opposed to the rotational motor shown in Figure 1). This is called a linear indication motor (LIM). The National Aviation and Space Administration (NASA) believes that this scheme could also be used to launch spacecraft into orbit. A magnetically levitated space vehicle accelerated to a speed of about 600 miles/hour would be catapulted from the ground. Once aloft, a rocket engine would take over and propel the spacecraft into orbit.

Magnetic controls

A magnetic field due to an electric current can be turned on and off simply by turning the current on and off. A piece of iron attached to the end of a spring having the other end fixed can be moved with a magnetic field and returned to its initial position by the spring. The iron piece can then be used to actuate a switch or move a lever on a valve. Applications of this principle include electrically controlled valves in a washing machine and an electrically controlled switch for the starter in an automobile.

Superconducting Magnets

The magnetic field produced by an electric current is proportional to the current; doubling the current doubles the magnetic field. It would seem that an experimenter could achieve any desired magnetic field by creating the necessary electric current in a coil of wire. But wires like those in an electric toaster offer resistance to electric currents, resulting in the production of heat. If the heat is not removed, the wires will melt. Solving this problem is the driving force behind the effort to develop superconducting materials that offer zero electrical resistance to electric current.

Until 1987, achieving zero resistance required cooling electrical conductors to around the temperature of liquid helium (4.2 K or -268.8°C). Nevertheless, practical electromagnets using superconducting wires cooled to around 4 K have been used in the laboratory for several decades. A new class of superconducting materials requiring cooling to around 77 K (-196ºC) was discovered in 1987. These materials are difficult to fabricate, but are very attractive because of their substantially higher superconducting temperature. Superconducting materials could be used for wires for transmission lines bringing electricity from an electric power plant to a city. Electromagnets made from superconducting wires can carry much more electric current, and so generate much stronger magnetic fields.

Magnetic Materials

Because magnetic poles occur in N and S pairs, a magnet is referred to as a magnetic dipole. The net magnetic field produced by two magnetic dipoles depends on their orientations. If the N-poles of each point in opposite direction, their contributions to the net magnetic field tend to cancel. If the N-poles of each point in the same direction, their contributions to the net magnetic field tend to add, and the net magnetic field is larger than that of one alone. The more magnets there are with their N-poles pointing in the same direction, the greater is the net magnetic field. In a real sense, iron atoms are like tiny magnetic dipoles. In an unmagnetized piece of iron, the tiny atomic magnetic dipoles are randomly oriented and there is no net magnetic field produced by the iron. But if the dipoles are given a preferred orientation, a net magnetic field around the iron results. The preferred orientation can be achieved by putting the iron in a magnetic field caused by a magnet or an electric current. This is a way of producing a permanent magnet.

Magnetic Recording

The binary system of numbers requires only two numbers, usually designated 0 and 1. Any device having two distinct states can be used to represent the two numbers. A finger pointed up could represent 1; pointing down it could represent 0. Zero and one can be represented with the N-poles of a magnetic dipole pointing in opposite directions. Information is recorded on a floppy disk or magnetic tape in binary fashion. The disk or tape is coated with a magnetizable material. Tiny local areas are magnetized with either the N-pole up or down to represent 0 or 1 . The device that reads the information detects the orientations and translates the information.

Magnetic Resonance Imaging

Magnetic Resonance Imaging (MRI) is a revolutionary diagnostic tool for producing images of the interior of a human body. It works because a proton, the sole constituent of a hydrogen atom, behaves like a tiny magnetic dipole. There is a copious source of hydrogen atoms in the body because many components contain water, and every water molecule has two hydrogen atoms. Normally, the atomic dipoles are oriented randomly, but they align when in a strong magnetic field. When stimulated by a short burst of radio frequency electromagnetic radiation, the atomic dipoles are deflected away from the direction of the magnetic field. Following the short burst of radiation, the dipoles rotate (precess) in ever-decreasing circles around the direction of the magnetic field, and in doing so emit a detectable signal before returning to a state of equilibrium. The detected signal can be converted into an image using computer technology. The technique has revolutionized the diagnosis of problems associated with muscles and joints in the human body.

MAGNETOHYDRODYNAMICS

Magnetohydrodynamics (MHD) is a promising technology for electric bulk power generation. MHD is accomplished by forcing an electrically conducting fluid or a plasma through a channel with a magnetic field applied across it and electrodes placed at right angles to flow and field (Figure 1). An MHD plant can be directly fired with coal and there are no moving parts. To achieve extra high efficiencies, MHD is combined in a binary thermodynamic cycle with a conventional steam plant to add an extra 40 percent to the total power output and to boost the overall combined efficiency into the 60 percent range. The high temperature MHD process extracts part of the heat energy in the plasma at the high temperature end. The gas leaving the MHD generator, still at relatively high temperatures, is then used in a conventional bottoming steam plant.

A schematic coalfired MHD generator in Figure 2 is shown using a combustion plasma at up to 3,000 K, seeded with alkali salts for high conductivity, fed directly into the generator with a superconducting magnet providing up to 7 tesla. The combustion products, still at about 2,000 K, then pass through an air preheater, where the hot gas exhausted from the MHD generator preheats the air for the combustor leading to the high temperatures required to create the plasma.

To use lower gas temperatures (under 1,500 K), noble gases like argon and helium offer very high electrical conductivities. Recycling the noble gas leads to the "closed cycle" MHD process.

Nuclear reactors have been used for small generators providing the high temperature and pressure plasma to drive an MHD process, and a nuclear plant could offer a considerable reduction in pollution because of high overall efficiency without CO_2 emission.

EXPERIMENTAL DEVELOPMENTS

In the early part of the nineteenth century Michael Faraday (1832) conducted MHD experiments using

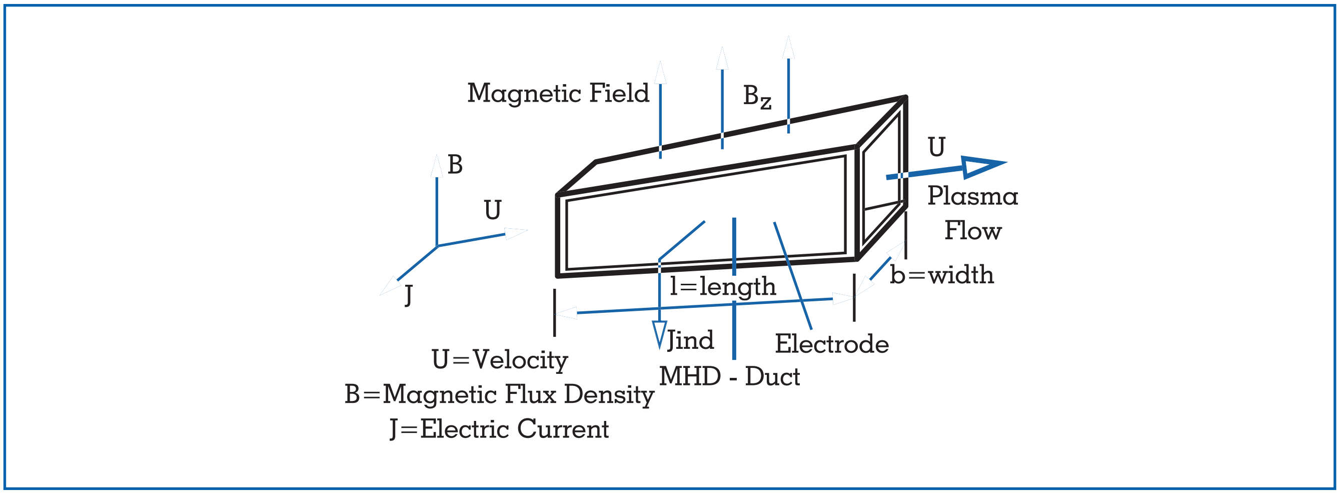

Figure 1.
Linear MHD Generator Channel.

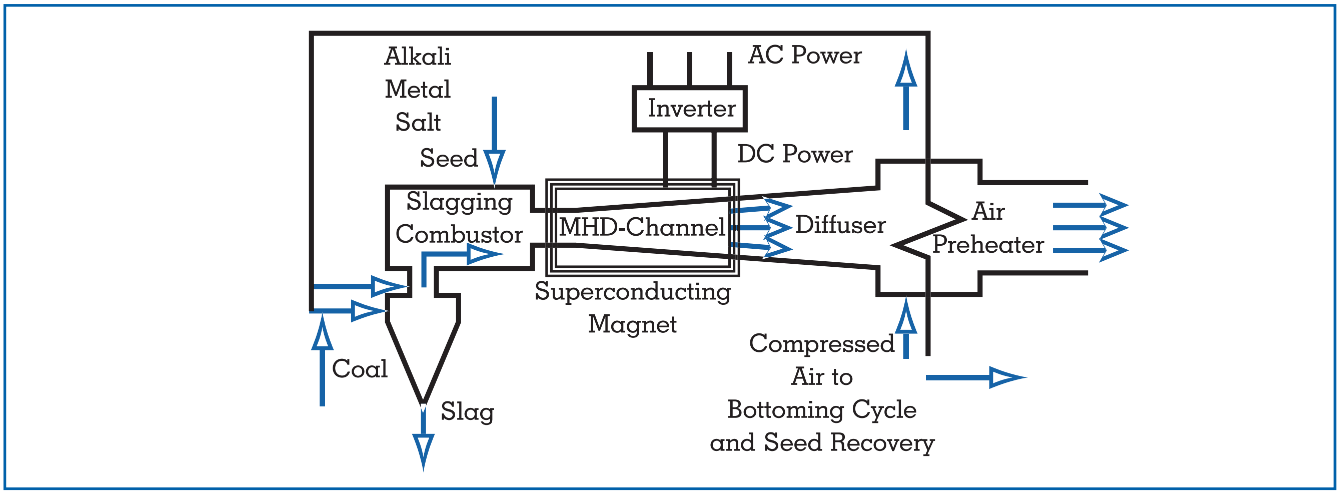

Figure 2.
MHD Linear Generator Flow Chart.

the brackish water of the river Thames flowing through the Earth's magnetic field. The first successful power generation experiment, developed by Richard Rosa in 1959, generated 10 kW with a timber walled channel on the AVCO "Mark 1" facility in Boston, Massachusetts. This success and the possibility of cheap MHD power led in the 1960s to national programs in Britain, the Soviet Union, The Netherlands, France, Germany, Poland, Italy, India, Australia and Israel. In 1965 the AVCO "Mark 5" generator successfully generated 32 MW over a one minute run using alcohol at 45 kg/sec fired with oxygen. AVCO later developed a sophisticated coal fired MHD channel for a 2,000 hour test program and demonstrated technical feasibility under the most stringent conditions.

In 1972 in Moscow, a large experimental facility, the "U-25," used a 250 MW natural gas combustor and generated 20 MW. The Soviets have been using very successfully mobile, pulsed MHD generators throughout the Soviet Union, for seismic studies.

MHD programs in the United States are concentrated in two major facilities. A "Component Development and Integration Facility" is located in Butte, Montana, and a "Coal Fired Flow Facility" at the University of Tennessee to studies coal fired MHD, slag processing, seed handling and downstream systems.

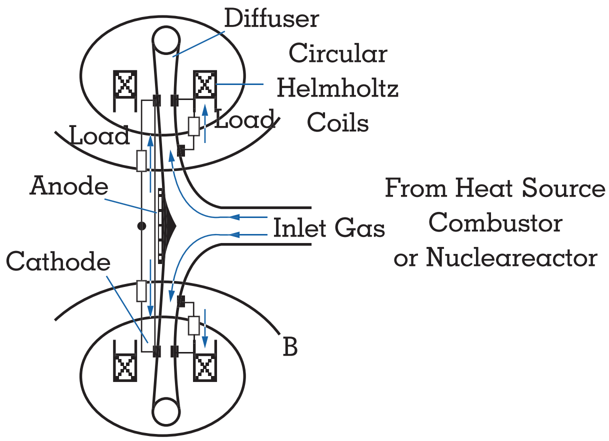

Figure 3.
MHD Disc Generator.

A circular disk MHD generator geometry requires a lower cost circular ring magnet structure as shown in Figure 3. Work in the United States using shock tunnels with large discs proved the feasibility of very high enthalpy extraction. Continuous operation on a fossil fuel fired disk facility was demonstrated at the University of Sydney, Australia. The potential advantages offered by closed cycle disc systems was made evident in the 1980s and 1990s by the Japanese MHD research effort and by the Dutch team at the University of Eindhoven.

A great deal of work has been done in the United States, Russia, Israel, and France showing that low temperature operation is possible using liquid metal as the MHD driver. A liquid metal MHD-generator can be very much smaller because of the much higher conductivity of liquid metal.

POWER SYSTEM REQUIREMENTS

Studies carried out in the United States, Russia, and Japan indicate that a combined cycle MHD-steam plant should be able to achieve an overall power station efficiency of at least 60 percent which is about 20 percent more than offered by a conventional steam plant. This should be possible at capital costs comparable with existing steam plants.

As shown in Figure 4, the operating temperature range for MHD is beyond that of any other generating technology. MHD could still add up to 15 percent at the top end of other combined cycles. MHD is potentially a natural choice for conversion of high temperature energy output from future nuclear power plants whether fission or fusion driven. A combined Nuclear-MHD system design with high efficiency does offer two advantages: (1) a reduction in thermal pollution and (2) no CO_2 emission as with fossil fuel-driven plants.

MHD efforts in many countries, including the United States, have declined substantially, in Russia because of lack of funds and in general because the high costs envisioned in setting up a full-scale power station. If funds become available to set up full-scale power stations and with the advent of high temperature nuclear heat sources, the many advantages provided by MHD may be realised.

MANUFACTURING

Industrial production is the backbone for economic output in almost all countries. Over the past decades, manufacturing industrial production has been growing in most economies. The industrial sector is dominated by the production of a few major energy-intensive commodities, such as steel, paper, cement, and chemicals. In any given country or region, production of these basic commodities follows the general development of the overall economy. Rapidly industrializing countries will have higher demands for infrastructure materials, and more mature markets will have declining or stable consumption levels. The regional differences in consumption patterns (expressed as consumption per capita) will fuel a further growth of consumption in developing countries. In addition to labor costs and costs for raw materials in these "heavy" industries, energy is a very important production cost factor in the effort to achieve higher energy efficiency (see Table 1). Markets in the industrialized countries show a shift toward more service-oriented activities and hence non energy-intensive industries. Because of the great difference in energy intensity between energy intensive industries and all others, changes in output shares of these industries can have a major impact on total industrial energy use. Many commodities (e.g., food and steel) are traded globally, and regional differences in supply and demand will influence total industrial energy use. Production trends also depend on regional availability of resources (e.g., scrap) and capital. Manufacturing energy use also will depend on the energy efficiency with which the economic activities are done. In this article we will assess trends in industrial energy use and energy intensities, followed by a discussion of energy services, uses, and industrial technologies.

GLOBAL MANUFACTURING ENERGY USE

In 1990, manufacturing industry accounted for 42 percent (129 exajoules, EJ) of global energy use. Between 1971 and 1990, industrial energy use grew at a rate of 2.1 percent per year, slightly less than the world total energy demand growth of 2.5 percent per year. This growth rate has slowed in recent years and was virtually flat between 1990 and 1995, primarily because of declines in industrial output in the transitional economies of Eastern Europe and the former Soviet Union. Energy use in the industrial sector is dominated by the industrialized countries, which accounted for 42 percent of world industrial energy use in 1990. Industrial energy consumption in these countries increased at an average rate of 0.6 per year between 1971 and 1990, from 49 EJ to 54 EJ. The share of industrial sector energy consumption within the industrialized countries declined from 40 percent in 1971 to 33 percent in 1995. This decline partly reflects the transition toward a less energy-intensive manufacturing base, as well as continued growth in transportation demand, resulting in large part from the rising importance of personal mobility in passenger transport use.

The industrial sector dominates in the economies in transition, accounting for more than 50 percent of total primary energy demand, the result of the emphasis on materials production, a long-term policy promoted under years of central planning. Average annual growth in industrial energy use in this region was 2.0 percent between 1971 and 1990 (from 26 EJ to 38 EJ), but dropped by an average of -7.3 percent per year between 1990 and 1995.

In the Asian developing countries, industrial energy use grew rapidly between 1971 and 1995, with an annual average growth rate of 5.9, jumping from 9 EJ. It also accounted for the greatest share of primary energy consumption, between 57 percent and 60 percent. The fastest growth in this sector was in China and in other rapidly developing Asian countries. Growth in other developing countries was slightly lower.

The nature and evolution of the industrial sector vary considerably among developing countries. Some economies that are experiencing continued expan-

Sector	1973 Energy Intensity (primary energy)	1973 Energy Costs (share of production costs)	1985 Energy Intensity (primary energy)	1985 Energy Costs (share of production costs)	1994 Energy Intensity (primary energy)	1994 Energy Costs (share of production costs)
Iron & Steel	30.5 GJ/t	7%	27.8 GJ/t	11%	25.4 GJ/t	8%
Pulp & Paper	43.1 GJ/t	6%	42.7 GJ/t	6%	32.8 GJ/t	6%
Cement	7.3 GJ/t	40%	5.2 GJ/t	36%	5.4 GJ/t	33%
Primary Aluminum	N/A	14%	17.6 MWh/t	19%	16.2 MWh/t	13%
Petroleum Refining	6.2 GJ/t	4%	4.3 GJ/t	3%	4.5 GJ/t	3%

Table 1.
Energy Intensities and Energy Costs in Selected U.S. Industries.
NOTE: Energy intensity is expressed in primary energy, where the efficiency of electricity generation is assumed to be 33 percent. Energy intensity of primary aluminum production is given in MWh (1000 kWh).

sion in energy-intensive industry, such as China and India, show relatively unchanging shares of industrial energy use. In other countries, such as Thailand and Mexico, the share and/or growth of the transportation sector dominate. Many smaller countries have remained primarily agrarian societies with modest manufacturing infrastructure.

ENERGY INTENSITY TRENDS

In aggregate terms, studies have shown that technical efficiency improvements of 1 to 2 percent per year has been observed in the industrial sector in the past, Between 1975 and 1983 during and after the years of major oil price increases, U.S. industrial energy intensity declined by 3.5 percent per year. Between 1984 and 1994 industrial energy intensity declined by less than 1 percent on average (Brown et al., 1998). Figure 1 gives an overview of energy of economic intensity trends in the industrial sector in industrialized countries.

The trends demonstrate the capability of industry to improve energy efficiency when it has the incentive to do so. Energy requirements can be cut by new process development. In addition, the amount of raw materials demanded by a society tends to decline as countries reach certain stages of industrial development, which leads to a decrease in industrial energy use. The accounting of trends in structural shift, material intensity, and technical energy efficiency and their interactions can be extremely difficult. To understand trends in energy intensity it is important to analyze the structure of the industrial sector. Industrial energy use can be broken down into that of the energy-intensive industries (e.g., primary metals, pulp and paper, primary chemicals, oil refining, building materials) and the nonenergy intensive-industries (e.g., electronics and food). Reduction of energy intensity is closely linked to the definition of structure, structural change, and efficiency improvement. Decomposition analysis is used to distinguish the effects of structural change and efficiency improvement. Structural change can be broken down into intra-sectoral (e.g., a shift toward more recycled steel) and intersectoral (e.g., a shift from steel to aluminum within the basic metals industry). A wide body of literature describes decomposition analyses and explains the trends in energy intensities and efficiency improvement. Decomposition analyses of the aggregate manufacturing sector exist mainly for industrialized Western countries, but also for China; Taiwan; and selected other countries, including those in Eastern Europe. The results show that different patterns exist for various countries which may be due to specific conditions as well as differences in driving forces such as energy prices and other policies in these countries. More detailed analyses on the subsector level are needed to understand these trends better. Changes in energy intensities also can be disaggregated into structural changes and efficiency

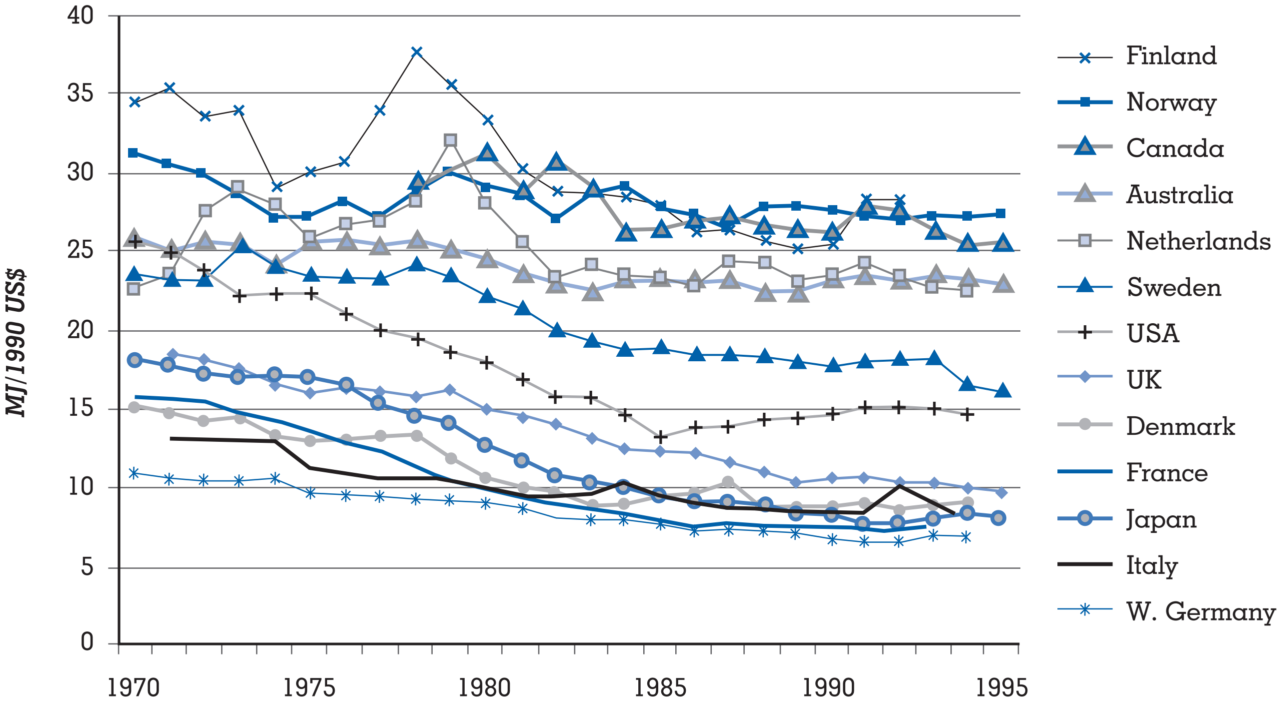

Figure 1.
Industrial sector economic energy intensity trends in selected industrialized countries, 1970–1995.
SOURCE: Lawrence Berkeley National Laboratory, Berkeley, California.

improvements at the subsector level. In the iron and steel industry, energy intensity is influenced by the raw materials used (i.e., iron ore, scrap) and the products produced (e.g., slabs, or thin rolled sheets). A recent study on the iron and steel industry used physical indicators for production to study trends in seven countries which together produced almost half of the world's steel. Figure 2 shows the trends in physical energy intensity in these countries, expressed as primary energy used per metric ton of crude steel. The large differences in intensity among the countries are shown, as well as the trends toward reduced intensity in most countries. Actual rates of energy efficiency improvement varied between 0.0 percent and 1.8 percent per year, while in the case of the restructuring economy of Poland, the energy intensity increased.

ENERGY SERVICES AND ENERGY EFFICIENCY

Energy is used to provide a service (e.g., a ton of steel) or to light a specified area. These services are called energy services. Energy efficiency improvement entails the provision of these services using less energy. About half of industrial energy use is for specific processes in the energy-intensive industries. On the other hand, various general energy conversion technologies and end uses can also be distinguished, such as steam production, motive power, and lighting. Hence, energy use in manufacturing can be broken down to various uses to provide a variety of services. A common breakdown distinguishes energy use for buildings, processes and utilities and boilers. The boilers provide steam and hot water to the processes, and the buildings. Due to the wide variety of indus-

trial processes, we will limit our discussion to two energy intensive sectors—iron and steel, and the pulp and paper industries, as well as boilers, to illustrate important cross-cutting energy-consuming processes in industry.

Iron and Steel Industry

The first record of the use of iron goes back to 2500-2000 B.C.E., and the first deliberate production of iron began in about 1300 B.C.E. Small furnaces using charcoal were used. Evidence of such furnaces has been found in Africa, Asia, and Central Europe. The relatively low temperatures in the furnace lead to low-quality iron, and the slag had to be removed by hammering the iron. High-temperature processes started to be introduced in Germany in about 1300 C.E. The design of these furnaces is essentially the same of that of modern blast furnaces. The furnaces still used charcoal, and in 1718 the first use of coke is reported in the United Kingdom. The higher strength of coke allowed larger furnaces to be built, increasing energy efficiency. By 1790 coke iron making contributed to 90 percent of British iron production. Between 1760 and 1800, energy use declined by about 2 percent per year, mainly through the use of steam engines permitting higher blast pressures. During the nineteenth century, coke demand was further reduced by 1 percent per year. The development of the modern blast furnace after World War II resulted in an annual reduction of energy intensity of 3 to 4 percent a year, due to the use of improved raw materials, ore agglomeration, larger blast furnaces, and higher air temperatures. Today the blast furnace is the main process to make iron, and provides the largest raw material stream in steelmaking.

Steel is made by reducing the carbon content in the iron to levels below 2 percent. This reduces the brittleness of the material and makes it easier to shape. The first steelmaking process was invented in 1855 by Bessemer, and was in commercial operation by 1860. In the Bessemer converter air was blown through the hot iron, which oxidizes the carbon. This principle is still followed in modern steelmaking processes. In the United States the last Bessemer converter was retired in the 1960s. In the late nineteenth century the open-hearth furnace (OHF) or Siemens-Martin furnace was invented, which uses preheated air and fuels to oxidize the carbon and melt the steel. This process is currently found only in developing countries and in Eastern Europe. The United States was one of the industrialized countries that phased out OHF at a very late stage. In the 1980s the dominant process became the basic oxygen furnace (BOF), using pure oxygen instead of air. The BOF process was developed in Austria in the 1950s. The productivity of this process is much higher than that of OHF, as is the energy efficiency. An alternative process is the electric arc furnace (EAF). The EAF process is mainly used to melt scrap. Performance of EAFs has improved tremendously; fuel and oxygen are starting to be used besides electricity. In the future it is expected that the BOF and EAF processes will follow similar developmental paths.

Liquid steel is cast into ingots or slabs and shaped in rolling mills to the final product. Although most energy use is concentrated in ironmaking and steelmaking, reduced material losses and productivity gains in casting and shaping (e.g., continuous casting and, currently thin slab casting) have contributed to dramatic increases in the energy efficiency of steelmaking.

Today, the U.S. iron and steel industry is made up of integrated steel mills which produce pig iron from raw materials (iron ore, coke) using a blast furnace and steel using a BOF, and secondary steel mills (minumills), which produce steel from scrap steel, pig iron, or direct reduced iron (DRI) using an EAF. The majority of steel produced in the United States is from integrated steel mills, although the share of minimills is increasing, growing from 15 percent of production in 1970 to 40 percent in 1995. There were 142 operating steel plants in the United States in 1997, of which 20 were integrated steelmills and 122 were minimills. The integrated mills are most often located near or with easy access to the primary resources; for example, in the United States these are concentrated in the Great Lakes region, near supplies of coal and iron ore and near key customers such as automobile manufacturers.

The worldwide average energy intensity of steelmaking is estimated at gigajoules (GJ) per metric tone, although large variations occur among countries and plants (see Figure 2). Today the most energy-efficient process would use 19 GJ/per metric ton for integrated steelmaking, and 7 GJ/per metric ton for making steel out of scrap. Analyses have shown that many technologies exist that could improve energy efficiency further. For example, in the United States the potential for energy efficiency improvement is estimated at 18 percent, using proven and cost-effective practices and technologies. Under development are new technolgies that could considerably lower the energy intensity of steelmaking. Smelt reduction in ironmaking would integrate the production of coke and agglomerated ore with that of ironmaking, leading to reductions in production costs and energy use. The development of direct casting techniques that abandon rolling would increase productivity while reducing energy use further. Combined, these technologies could reduce the energy intensity of primary steelmaking to 12.5 GJ/per metric ton of steel, and for secondary steelmaking to 3.5 GJ/ per metric ton reductions of 34 percent and 50 percent, respectively. In the highly competitive and globalizing steel industry, manufacturers must continuously look for ways to lower their energy intensity and costs.

Pulp and Paper Industry

Paper consists of aligned cellulosic fibers. The fibers may be from wood or other crops, or from recycling waste paper. Starting with wood fibers, the fibers need to be separated from the wood, which is done by pulping the wood. The separation can be done by chemicals, by heat, or by mechanical means. In the chemical pulping process chemicals and hot water are used to separate the cellulosis from the ligno-cellulosis. The amount of pulp produced is about half the amount of wood used. Chemical pulping results in high-quality paper. In the mechanical process the wood is ground under pressure, separating the fibers from each other. In mechanical pulping the ligno-cellulosis is generally not removed, resulting in a lower quality of paper (e.g., paper used for newsprint) but a higher recovery (about 90%) of the used wood. In chemical pulping a lot of steam is used to heat the water and concentrate the chemical by-products. However, recovery of the by-products to be recycled in the process can actually produce sufficient steam for the whole paper mill. The mechanical process uses large quantities of electricity, while some processes can recover steam from the grinding process. Chemical pulp can be bleached to produce white paper. Waste paper is being pulped by mixing with water, after which ink is removed and the pulp refined. Paper recycling reduces the energy needs of the pulping process. Waste paper use in the production of paper varies widely, due to different structures of the industry in different countries.

While energy efficiency improvement options do exist in the pulping step, greater opportunities exist in the chemical recovery step. The most common pulping process in the United States is the Kraft pulping process. Black liquor is produced as a by-product. The chemicals are currently recovered in a recovery boiler, combusting the ligno-cellulosis. Because of the high water content, the efficiency of the recovery boiler is not very high, and the steam is used to generate electricity in a steam turbine and steam for the processes. Gasification of black liquor would allow use of the generated gas at a higher efficiency. This would make a Kraft pulp mill an electricity exporter (Nilsson et al., 1995).

In papermaking the pulp is diluted with water at a ratio of about 1:100. This pulp is screened and refined. The solution with the refined fibers (or stock) is fed into the paper machine, where the water is removed. In the paper machine, the paper is formed into a sheet, and water is removed by dispersing over a wire screen. At the end of the forming section, 80 percent of the water has been removed. The rest of the water is removed in the pressing and drying sections. While only a small amount of water is removed in the drying section, most energy is used there. Hence, those using such energy efficiency opportunities try to reduce the water content by increasing the water removal by pressing. In a long nip press, the pressing area is enlarged. The larger pressing area results in extra water removal. New technologies are under development aiming to increase the drying efficiency considerably. One technology—impulse drying—uses a heated roll, pressing out most of the water in the sheet; this may reduce the steam consumption of the paper machine by 60 to 80 percent.

Energy Efficiency Measure	*Typical Energy Savings (%)*	*Payback Estimate (years)*
Distribution System		
Reducing Steam Leaks	3-5%	
Insulating Steam Pipes	5-10%	0.3-1.7 year
Condensate Return	10-20%	<1 year
Process Integration & Heat Recovery	5-40%	2-
System Operation and Maintenance		
Water Treatment	10-12%	
Load Control	3-5%	
Decentralization Steam Supply	<40%	<4 years
Hot Standby		
Boilers		
Boiler Tune-Up	1-2%	
Combustion Air Preheating	<12%	<5 years
Boiler Feed Preheating	2-10%	<4 years
New Low-NOx Boiler Type	>5%	n.a.
Monitoring and Control	1-4%	<3 years

Table 2.
Energy Efficiency Measures and Estimated Improvement Potentials for Steam Boilers.

The pulp and paper industry uses approximately 6 to 8 EJ globally. Because energy consumption and intensity depend on the amount of wood pulped, the type of pulp produced, and the paper grades produced, there is a great range in energy intensities among industrialized countries of the world. In Europe energy use for papermaking varied between 16 GJ per metric ton and to 30 GJ per metric ton of paper in 1989. The Netherlands used the least energy per metric ton of paper, largely because most of the pulp was imported. Countries such as Sweden and the United States have much higher energy intensities due to the larger amount of pulp produced. Sweden and other net exporters of pulp also tend to show a higher energy intensity. Energy intensity is also influenced by the efficiency of the processes used. Many studies have shown considerable potentials for energy efficiency improvement with current technologies (Worrell et al., 1994; Nilsson et al., 1995; Farla et al., 1997), such as heat recovery and improved pressing technologies.

Cross-Cutting: Steam Production and Use

Besides the energy-intensive industries, many smaller and less energy-intensive, or light, industries exist. Light industries can include food processing, metal engineering, or electronics industries. In light industries energy is generally a small portion of the total production costs. There is a wide variety of processes used within these industries. Generally a large fraction of energy is used in space heating and cooling, in motors (e.g., fans and compressed air), and in boilers. Industrial boilers are used to produce steam or to heat water for space and process heating and for the generation of mechanical power and electricity. In some cases these boilers will have a dual function, such as the cogeneration of steam and electricity. The largest uses of industrial boilers by capacity are in paper, chemical, food production, and petroleum industry processes. Steam generated in the boiler may be used throughout a plant or a site. Total installed boiler capacity (not for cogeneration) in the United States is estimated at nearly 880 million megawatts. Total energy consumption for boilers in the United States is estimated at 9.9 EJ.

A systems approach may substantially reduce the steam needs, reduce emissions of air pollutants and greenhouse gases, and reduce operating costs of the facility. A systems approach assessing options throughout the steam system that incorporates a variety of measures and technologies is needed (Zeitz, 1997), and can help to find low-cost options. Improved efficiency of steam use reduces steam needs and may reduce the capital layout for expansion, reducing emissions and permitting procedures at the same time. Table 2 summarizes various options to reduce losses in the steam distribution and to improve system operation and the boiler itself. In specific cases, the steam boiler can be replaced almost totally by a heat pump (or mechanical vapor recompression) to generate low-pressure steam. This replaces the fuel use for steam generation by electricity. Emission reductions will depend on the type and efficiency of power generation.

Another option to reduce energy use for the steam system is cogeneration of heat and power (CHP) based on gas-turbine technology as a way to substantially reduce the primary energy needs for steam making. Low- and medium-pressure steam can be generated in a waste heat boiler using the flue gases of a gas turbine. Classic cogeneration systems are based on the use of a steam boiler and a back-pressure turbine. These systems have relatively low efficiency compared to a gas turbine system. Steam-turbine systems generally have a power-to-heat ratio between 0.15 (40 kWh/GJ) and 0.23 (60 kWh/GJ) (Nilsson et al., 1995). The power-to-heat ratio depends on the specific energy balance of plant as well as energy costs. A cogeneration plant is most often optimized to the steam load of the plant, exporting excess electricity to the grid. The costs of installing a steam turbine system strongly depend on the capacity of the installation. Gas-turbine-based cogeneration plants are relatively cheap. In many places (e.g., The Netherlands and Scandinavia) gas turbine cogeneration systems are standard in paper mills. The power-to-heat ratio is generally higher than for steam turbine systems. Aero-derivative gas turbines may have a power-to-heat ratio of 70 to 80 kWh/GJ . Aeroderivative turbines are available at low capacities, but specific costs of gas turbines sharply decrease with larger capacities.

POTENTIAL FOR ENERGY EFFICIENCY IMPROVEMENT

Much of the potential for improvement in technical energy efficiencies in industrial processes depends on how closely such processes have approached their thermodynamic limit. There are two types of energy efficiency measures: (1) more efficient use in existing equipment through improved operation, maintenance or retrofit of equipment and (2) use of more efficient new equipment by introducing more efficient processes and systems at the point of capital turnover or expansion of production. More efficient practices and new technologies exist for all industrial sectors. Table 2 outlines some examples of energy efficiency improvement techniques and practices.

A large number of energy-efficient technologies are available (see Table 3) in the steel industry, including continuous casting, energy recovery, and increased recycling. Large technical potentials ranging from 25 to 50 percent exist in most countries. New technologies are under development (e.g., smelt reduction and near net shape casting) that will reduce energy consumption as well as environmental pollution and capital costs. A few bulk chemicals such as ammonia and ethylene represent the bulk of energy use in this subsector. Potentials for energy savings in ammoniamaking are estimated to be up to 35 percent in Europe and between 20 percent and 30 percent in Southeast Asia.

Iron and Steel
Heat recovery for steam generation, pre-heating combustion air, and high efficiency burners
Adjustable speed drives, heat recovery coke oven gases, and dry coke quenching
Efficient hot blast stove operation, waste heat recovery for hot blast stove, top gas power recovery turbines, direct coal injection
Recovery BOF-gas, heat recovery of sensible heat BOF-gas, closed BOF-gas-system, optimized oxygen production, increase scrap use, efficient tundish preheating
UHP-process, Oxy-fuel injection for EAF plants, and scrap preheating
Heat recovery (steam generation), recovery of inert gases, efficient ladle preheating
Use of continuous casting, 'Hot connection' or direct rolling, recuperative burners
Heat recovery, efficient burners annealing and pickling line, continuous annealing operation
Chemicals
Process management and thermal integration (e.g. optimization of steam networks, heat cascading, low and high temperature heat recovery, heat transformers), mechanical vapor recompression
New compressor types
New catalysts
Adjustable speed drives
Selective steam cracking, membranes
High temperature cogeneration and heat pumps
Autothermal reforming
Petroleum Refining
Reflux overhead vapor recompression, staged crude pre-heat, mechanical vacuum pumps
Fluid coking to gasification, turbine power recovery train at the FCC, hydraulic turbine power recovery, membrane hydrogen purification, unit to hydrocracker recycle loop
Improved catalysts (reforming), and hydraulic turbine power recovery
Process management and integration
Pulp and Paper
Continuous digester, displacement heating/batch digesters, chemi-mechanical pulping
Black liquor gasification/gasturbine cogeneration
Oxygen predelignification, oxygen bleaching, displacement bleaching
Tampella recovery system, falling film black liquid evaporation, lime kiln modifications
Long nip press, impulse drying, and other advanced paper machines
Improved boiler design/operation (cogeneration), and distributed control systems
Cement
Improved grinding media and linings, roller mills, high-efficiency classifiers, wet process slurry
Dewatering with filter presses
Multi-stage preheating, pre-calciners, kiln combustion system improvements, enhancement of internal heat transfer in kiln, kiln shell loss reduction, optimize heat transfer in clinker cooler, use of waste fuels
Blended cements, cogeneration
Modified ball mill configuration, particle size distribution control, improved grinding media and linings, high-pressure roller press for clinker pre-grinding, high-efficiency classifiers, roller mills

Table 3.
Efficiency Improvement Measures in Energy Intensive Industry
SOURCE: Worrell, Levine, et al., 1997.

Energy savings in petroleum refining are possible through improved process integration, cogeneration, energy recovery, and improved catalysts. Compared to state-of-the-art technology, the savings in industrialized countries are estimated to be 15 to 20 percnet, and higher for developing countries. Large potentials for energy savings exist in nearly all process stages of pulp and paper production (e.g., improved dewatering technologies, energy and waste heat recovery, and new pulping technologies). Technical potentials are estimated at up to 40 percent, with higher long-term potentials (see above). Energy savings in cement production are possible through increased use of additives (replacing the energy-intensive clinker), use of dry process, and use of a large number of energy efficiency measures (such as reducing heat losses and use of waste as fuel). Energy savings potentials of up to 50 percent do exist in the cement industry in many countries through efficiency improvement and the use of wastes such as blast furnace slags and fly ash in cementmaking.

In the United States various studies have assessed the potential for energy efficiency improvement in industry. One study has assessed the technologies for various sectors and found potential economic energy savings of 7 to 13 percent over the business-as-usual trends (Brown et al., 1998) between 1990 and 2010. Technologies like the ones described above (see Table 2) are important in achieving these potentials.

However, barriers may partially block the uptake of those technologies. Barriers to efficiency improvement can include unwillingness to invest, lack of available and accessible information, economic disincentives, and organizational barriers. The degree to which a barrier limits efficiency improvement is strongly dependent on the situation of the actor (e.g., small companies, large industries). A range of policy instruments is available, and innovative approaches or combinations have been tried in some countries. Successful policy can contain regulations (e.g., product standards) and guidelines, economic instruments and incentives, voluntary agreements and actions, information, education and training, and research, development and demonstration policies. Successful polices with proven track records in several sectors include technology development, and utility/government programs and partnerships. Improved international cooperation to develop policy instruments and technologies to meet developing country needs will be necessary, especially in light of the large anticipated growth of the manufacturing industry in this region.

SUMMARY

Manufacturing industry is a large energy user in almost all countries. About half of industrial energy use is in specific processes in the energy-intensive industries. On the other hand, various general energy conversion technologies and end uses can also be distinguished, such as steam production, motive power, and lighting. Opportunities and potentials exist for energy savings through energy efficiency improvement in all sectors and countries. Technology development, and policies aimed at dissemination and implementation of these technologies, can help to realize the potential benefits. Technologies do not now, nor will they in the foreseeable future, provide a limitation on continuing energy efficiency improvements.

MARKET IMPERFECTIONS

Modern economic theory provides a succinct description of the conditions under which the price system produces optimal outcomes in an idealized “laissez-faire” economy of perfectly competitive markets. This is the “First Welfare Theorem”; any competitive equilibrium is “Pareto optimal” (i.e., no agent in the economy can have his or her well-being increased except at the expense of another agent). Against this benchmark, the theory describes conditions under which policy interventions can, in principle, improve upon the performance of the unregulated market system. The possibility of such improvement arises from the existence of market “failures” or “imperfections,” which are factors in or features of particular markets that cause private decision-making to produce less-than-optimal economic outcomes.

Historically, the key imperfection in energy markets was thought to be “economies of scale,” or “declining average costs,” in electric power generation. This means simply that this was the kind of industry where a single firm’s costs of producing power would fall as its output was increased. Under this condition, unregulated market equilibrium with more than one competing firm would not result in economic efficiency, specifically the provision of power at minimum cost. Instead, power generation was a “natural monopoly”—a single firm could produce at lowest cost (in a given geographic area). This feature of power generation was the motivation for the U.S. system of privately owned, publicly regulated power companies, granted an exclusive license within a given service area with rates set by regulators. In the past several decades, however, technological change in electric power generation has resulted in a loss of economies of scale sufficient to motivate the deregulation or "restructuring" of this industry into a competitive form.

Currently, a different feature of energy markets having to do with the use of fossil fuels in energy production is recognized as entailing market failure. Among the assumptions required for the efficiency of competitive markets are that all commodities be both "rival" and "excludable." A rival commodity is one whose use by one precludes its use by another, while an excludable commodity is one whose production and consumption imposes no "side effects" on anyone not party to direct transactions involving the commodity. The market failures now most commonly ascribed to energy markets arise from the nonrivalry and nonexcludability of certain byproducts of energy consumption and production: so-called "environmental externalities," or side effects that have deleterious effects on health or welfare. Key examples are carbon monoxide emissions from vehicles, sulfur dioxide emissions from electric power generation, and emissions from power generation and from the use of fossil fuels. The creation of these by-products creates costs that are not reflected in market prices for energy products, so that in the absence of regulation or some other policy intervention there are no incentives to control them.

Sulfur dioxide emissions resulting from fossil fuel can have negative effects on urban air quality and create acid rain that harms aquatic life. These emissions are nonexcludable in that there is no private action that a particular individual can take to avoid this impact, and they are nonrival in that their effect on any one individual does not preclude or offset their effect on any other.

Another, more controversial, idea is that there may be market imperfections underlying the "energy-efficiency gap," the long-recognized apparent under-investment by consumers and firms in energy-efficient technology. Beginning in the 1970s, energy analysts used the term "market barrier" to refer to any of the various possible reasons for such underinvestment. Since then, there has been some effort to distinguish those "barriers" that constitute market imperfections. Although no consensus has emerged, there is general agreement that the energy-efficiency gap may arise in part from informational problems involved in private investment decisions. It is now widely recognized that the nonrivalry of information can result in market imperfections. To the extent that informational problems impeding optimal energy-efficiency investments are pervasive, the efficiency gap may be seen as another important example of an energy-related market imperfections.

POLICY RESPONSES

U.S. environmental regulations have for the most part tried to mitigate health and welfare effects from pollution through technological control strategies such as requiring installation of pollution reduction equipment. There has been a gradual increase of interest, however, in analyzing and attempting to correct environmental externalities within the paradigm of market failures or imperfections. In this paradigm, in the presence of market failures the government can under idealized assumptions reallocate resources to make some consumers better off while making none worse off—a "Pareto improvement." However, the recognition that in practice there will always be both winners and losers from a given policy led to the development of a less ambitious notion of the goals of policy. Thus, the focus of cost-benefit analysis is to determine how market failures justify policies in which some are better off, and these winners could in principle compensate the losers and still come out ahead. This is the "compensation principle."

We often think that solving the problem of environmental externalities means eliminating them altogether, but the cost-benefit approach applies a different criterion: emissions should be held to an optimal level, which is less than the unregulated level but in most cases not zero. The threshold is that the marginal damage from emissions should be equated to the marginal cost of abatement. This, in turn, naturally suggests the economic means of controlling emissions: the government should impose taxes or charges on them so that this marginal condition holds. This policy mechanism has been studied extensively as a way of reducing carbon emissions in an effort to mitigate global climate change. An alternative approach is for the government to issue permits to emitters that restrict the overall quantity of emissions; these permits would then be traded among emitters so that, overall, the cost of abatement would be minimized.

MARKET TRANSFORMATION

The term "market transformation" first appeared in the literature in the early 1990s. The term emerged more as an abstraction than a concrete program strategy or model. Market transformation provides a vision of the ultimate objective of strategic interventions—markets that yield energy-efficient outcomes automatically as the result of normal market forces. Market transformation can be viewed as a catalyst for change—a means of intervening in imperfect markets to effect long-term changes to improve market performance with respect to energy efficiency.

While there is not a single, precise definition of market transformation in professional practice, the following definition captures the essential elements:

> Market transformation is a strategic intervention to achieve a lasting, significant share of energy-efficient products and services in targeted markets. Market transformation is essentially synonymous with marketing strategy as used in the private business world. A key distinction is that market transformation is motivated by the social objectives of improving the performance of markets to yield greater energy efficiency. And like marketing strategies in the private sector, it often requires ongoing measures to achieve and sustain desired market outcomes. For example, market transformation will occur in the U.S. clothes washer market when energy-efficient washers (often horizontal axis machines that use about one-third the energy and water of old vertical-axis, agitator machines) become the norm as they already are in Europe. After introduction of new machines in the market, ongoing marketing and related support may be required to sustain a significant market share.

The overall goal of market transformation is to increase the share of energy-efficient products and services through fundamental, enduring changes in targeted markets. This goal also serves to improve the economy and reduce negative social and environmental effects that result from energy use. Intervention is needed because of market imperfections that do not allow the market on its own to provide an optimum level of energy-efficiency goods and services. In most cases intervention requires an evolving mix of strategies and implementation measures over an extended period.

Jay Joseph and Don Gardner collect an old refrigerator after delivering a new one. In 1993, the Sacramento Municipal Utility District paid customers $100 for their old refrigerator plus an additional $100 rebate to buy an energy efficient model. (Corbis-Bettmann)

Market transformation as a strategy to improve market performance has become more important as most energy utility markets deregulate and restructure. Restructuring is resulting in more competition and reliance on market mechanisms in energy markets that have been highly regulated. Utility energy efficiency programs of the 1980s and 1990s, called demand-side management (DSM) programs, are being abandoned and market transformation is being introduced to fill the void. However, the roots of market transformation lie within the regulated energy industries.

The goal of most DSM programs has been relatively narrow: to reduce energy and power demand to avoid investments in new power plants or transmission and distribution systems. DSM was used within the context of integrated resource planning to yield the lowest cost of energy services by avoiding more costly construction and operation of supply-side power plants. DSM was considered a resource comparable and substitutable for supply-side resources (hence the name—integrated resource planning). Individual utilities have typically implemented DSM for their own customers, as ordered by public utility commissions or other regulatory bodies. All utility customers generally have shared the costs for DSM programs because regulators mandated such programs and consequently provided cost-recovery mechanisms for utilities.

Integrated resource planning and demand-side management have declined in the wake of the movement to restructure and deregulate energy markets. DSM has evolved to be more market-based, as program designers sought lasting change, and utilities reduced program costs and shifted some of the remaining costs to the direct beneficiaries of DSM programs.

As DSM evolved, program managers realized that their efforts could have much greater impact if they went beyond the service territories of single utilities to encompass regional and national markets. While not termed "market transformation," there were several early initiatives that took this approach, including the Manufactured Housing Acquisition Program in the Pacific Northwest and the Power Smart Program, which originated in British Columbia and was later adopted elsewhere. These and other state, regional, national and even international collaborations, with multiple parties contributing funds and expertise, have tried to change building practices, introduce new products and change market shares. Collaborations, such as the Consortium for Energy Efficiency (CEE) in the United States, have been making larger changes in the markets for target technologies. Examples include promoting super-efficient refrigerators, clothes washers, and motors. More broadly, the Energy Star Program of the United States Environmental Protection Agency (EPA) and Department of Energy (DOE) is an example of a market transformation effort that spans numerous household and commercial appliances and applications—from home computers and air-conditioners to energy ratings of commercial buildings. Energy Star is a labeling program that identifies the most energy-efficient technologies within a given appliance or application category.

Market transformation initiatives typically require collaboration among a diverse set of stakeholders, including manufacturers, retailers, utilities, research and development (R&D) organizations, government, and public-interest efficiency advocates. In recent years the need for coordination and collaboration among such a diverse set of actors to achieve consensus has led to the development of specific U.S. regional market transformation organizations, including the Northwest Energy Efficiency Alliance (NEEA), the Northeast Energy Efficiency Partnerships, Inc. (NEEP), and the Midwest Energy Efficiency Alliance (MEEA).

These organizations vary significantly in their structure, funding and operation. However, their overall approach to market transformation is similar. Market transformation typically includes the following steps (not necessarily in sequence):

- Identify needs through market analysis and research—the markets where opportunities exist to increase market share of products and services that respond to customer needs and deliver superior energy-efficient performance.
- Identify market participants (manufacturers, retailers, consumers) and stakeholders (such as consumer advocacy groups, trade organizations, and government).
- Form collaboratives and define roles among key market participants and stakeholders to lead and manage the market transformation initiative.
- Establish funding to cover costs of the initiative (program costs).
- Define program goals for target products or services within the chosen market.
- Establish market baselines against which intervention(s) will be evaluated.
- Design strategies and measures for the initiative, including a transition strategy that may be an exit or continued intervention such as advertising and education.
- Implement measures.
- Track market performance and evaluate results of the initiative.
- Continue, modify or end initiative as indicated by monitoring and evaluation results.

Implementation of market transformation programs requires adoption of coordinated measures targeted to various market participants over a fairly long period. The duration of market transformation programs depends on numerous factors, including the complexity of the market; customer response; support of manufacturers, distributors and retailers; and time required for manufacturers to change manufacturing operations. Experience with past DSM programs and early market transformation programs suggests that periods of five to ten years or more are needed to transform energy efficiency markets.

Typical measures used with market transformation programs may include the following:

- marketing, such as media advertisements, point-of-purchase displays, utility bill stuffers and other promotions

- labeling (a key example is the Energy Star program established and operated by the U.S. EPA and DOE)
- consumer education
- professional training (e.g., sales associates, skilled tradespeople, contractors, manufacturers)
- research and development in support of program needs
- codes and standards (to codify energy-efficient technologies by establishing minimum performance standards)
- consumer rebates or other incentives to increase consumer acceptance
- manufacturer and retailer incentives
- technology procurement (specifying required performance of technologies and aggregating customers to create sufficient demand for suppliers to respond to performance requirements)
- other types of bulk purchasing or buyer aggregation to create market pull
- design competitions based on desired performance.

Market transformation collaborations involve multiple parties—each with different motivations and objectives. The target markets are typically broad in geographic scope (regional and national markets). These two factors alone pose major challenges for market transformation programs. The complexity and dynamic nature of markets pose a different set of challenges. While the challenges of market transformation are many and complex, the advantages of market transformation versus traditional DSM intervention are substantial. Market transformation focuses on systemic, complementary measures for market improvement, whereas DSM programs typically were isolated efforts that addressed much narrower symptoms of market imperfections. For this reason, market transformation is growing rapidly as a dominant model for publicly and privately supported energy-efficiency programs.

MASS TRANSIT

Mass transit is a transportation service available to the public for trips generally within metropolitan areas. As with all transportation services, an energy source is a critical input in the production of mass transit trips. Almost all of this energy consumption is derived from burning fossil fuels, a process that emits pollutants affecting human health, visibility, vegetation, and climate change. Transit service is increasingly being scrutinized for its pollutant emissions. Mass transit facilitates travel within densely developed, large urban areas. Because of the existence of mass transit, more intense development within an urban area can occur. Higher-density land use may enable reduced energy consumption when considering the settlement area as a whole.

FORMS OF MASS TRANSIT

The term “mass transit” generally refers to passenger vehicles that are common carriers in urban areas, as distinct from intercity travel. The terms “public transit” or simply “transit” also are frequently used. The major types of public transit are bus (rubber-tired vehicles), rail (running on tracks), and ferryboat. Within each type there are several subcategories.

Motor Bus

A rubber-tired, self-propelled transit vehicle using an internal combustion engine for power. Most use direct-ignition (diesel) engines, but gaso-

line, propane, natural gas, and other fuels are used as well. Buses are available in varying sizes and capacities, varying from 10 passengers to 150 or more passengers, including articulated and biarticulated vehicles. They can be designed for city service (fewer seats, more doors and standing room) or long-distance express service (often with no standees permitted). Buses can operate on most streets open to traffic, including expressways, and also can be operated on exclusive rights-of-way such as high-occupancy-vehicle (HOV) expressway lanes, bus lanes on city streets, or busways with on-line stations.

Electric Bus

When powered by an electric motor, generally taking power from overhead wires ("catenaries") such a vehicle is called an electric trolleybus or a trackless trolley. An electric bus taking power from current in the ground has been developed by Ansaldo-Breda. Battery-powered buses also have been developed, although all of these have been smaller than standard-size buses. In the late 1990s, "hybrid" electric-internal-combustion buses were placed in service. These vehicles have a smaller than normal internal-combustion engine, which continually recharges a battery pack. The batteries power an electric motor, which provides supplementary power when needed. Fuel cells, which can be thought of as chemical batteries, also are used on an experimental basis to power transit buses.

Streetcar or Tram

The streetcar or tram, powered by electricity from overhead catenaries and running on rails on city streets, was the backbone of mass transit service from 1890 until the widespread deployment of the diesel bus in the early post-World War II period. In general, the only streetcar lines in North America that survived the transition to the bus were those in high-demand corridors, or those operating in their own right-of-way, such as a roadway median, tunnel, or subway. Since the 1970s, there has been increasing deployment of new streetcar service, now referred to as light rail transit (LRT). These services tend to use larger, articulated vehicles and frequently operate partly on exclusive rights-of-way such as disused rail corridors or expressway medians.

Rail Rapid Transit

Also known as metro, subway, elevated, underground, or heavy rail, this higher-capacity rail service is distinguished by its use of trained vehicles (several

cars attached together) and third-rail electric power (a live connection at grade). Because of its unprotected power source, rail rapid transit cannot be operated on city streets, and runs in elevated or underground rights-of-way. Unlike suburban rail, rail rapid transit service generally operates within cities and on a frequent schedule. Some of the new rail rapid transit systems, such as BART in San Francisco, have a metropolitan scope and distant stop spacing, and thus are similar to suburban rail.

Suburban Rail

Also known as commuter rail, this type of service generally provides long-distance—50 km (31 mi.) or more—routes to the far reaches of a metropolitan area using railroad rights-of-way. These operations use either diesel or electric power. Service is primarily oriented toward commuters from suburbs to central city locations and is concentrated in the peak commuting hours. Express bus operations also provide similar services, without the need for a separate right-of-way.

Ferryboat

In metropolitan areas adjacent to bodies of water, ferries can be used as mass transit—that is, providing frequent service useful for local travel. Geography limits ferryboat use to a select group of cities. Twenty-one cities in the United States and its territories have transit ferryboat service. Another example is Vancouver's SeaBus, which provides very frequent shuttle service between the center city and North Vancouver.

Table 1 shows the frequency distribution of U.S. mass transit service supplied (vehicle distance operated) and service consumed (passenger boardings) by transit mode in 1997. The official U.S. transit statistics also include the "demand response" mode. This type of transit consists of minibuses or vans operating by request, rather than on fixed routes, and typically available only to a portion of the public, such as elderly or disabled people. As shown in Table 1, demand response accounts for 12 percent of service operated but only 1 percent of boardings. Buses accounts for the majority of both service supplied and service consumed. Removing the few largest rail systems from the totals would reveal even greater significance of the bus mode.

IMPACT OF MASS TRANSIT ON ENERGY CONSUMPTION

The potential of mass transit to provide transportation services with low energy consumption relies on the high capacity of transit vehicles, since these vehicles have higher energy consumption per vehicle distance traveled compared to private motorized vehicles or nonmotorized modes. Therefore the occupancy rate of transit service is a key factor in determining its energy efficiency. This rate can be measured by the ratio of person distance traveled to vehicle distance traveled.

The energy efficiency of transit per passenger distance traveled depends both on its usage rate (person travel per vehicle travel) and its fuel efficiency (fuel consumption per vehicle travel). The transit vehicles with the greatest potential for energy efficiency gains

Table 3.
Average Energy Intensity per Passenger Mile for Various U.S. Passenger Modes, 1970–1997.
SOURCE: Davis, 1999.

may not be those that can carry the most people per vehicle. Rather, the greatest potential gains can be had by matching vehicle capacity to travel demand. In fact, a high-capacity mode that is little used can increase energy consumption relative to the passenger automobile. On the other hand, a minibus with ten passengers may represent a significant reduction in energy use compared to the case of those ten passengers traveling by car.

The data in Table 2 dramatically illustrate the difference between vehicle fuel intensity and passenger fuel intensity from 1970 to 1977. (Fuel intensity, fuel use per distance traveled, is the inverse of fuel efficiency.) In 1970, the transit bus mode in the United States used 50 percent less energy per passenger mile than the automobile mode (passenger cars, not including light trucks). By 1997, transit buses used 19 percent *more* energy on average per passenger mile. How did this happen? The fuel efficiency of transit buses declined by 20 percent, while fuel efficiency improved by 37 percent for passenger cars. Occupancy declined in both cases, but twice as much for transit buses. The net result was a significant reduction in fuel use per passenger mile for cars despite declining occupancy, and an increase in fuel intensity for transit buses.

The evolution of transit bus compared to transit rail energy intensity in the United States from 1970 to 1997 is shown in Table 3. Transit bus and rail had similar energy intensities in 1970, but by 1997, energy use per passenger mile had increased by 33 percent for transit rail and by 75 percent for transit buses. This increase is yet more significant given that energy intensity for passenger cars declined 26 percent over the same period and given that intercity rail and intercity bus operations also showed energy intensity reductions of 33 percent and 17 percent, respectively.

In 1997, the intercity bus was the least energy-intense of the modes shown in Table 3. Its energy intensity per passenger mile was one-fifth of transit bus energy intensity. The vehicles used for the two operations are similar, although operating conditions are different. Intercity buses operate mostly on expressways, and transit buses mostly on local streets. Still, the fact that transit bus energy intensity increased 75 percent while intercity bus energy intensity decreased 17 percent suggests that changes in operating patterns, rather than changes in technology, accounted for much of the difference in energy use.

In the United States in 1997, transit accounted for a small fraction of transportation energy consumption, largely because it played such a small role in the total travel market, representing only 1.8 percent of trips. Transit accounted for only 0.7 percent of transportation energy consumption (bus 0.4%, rail 0.2%, and suburban rail 0.1%).

Transit represents an increase in energy use compared to walking or bicycling. For countries with a significant amount of nonmotorized transport, increasing transit use may mean increasing energy use. However, the increased energy consumption may be associated with significant improvements in urban passenger transport, which can produce large economic benefits. It is generally easier for transit modes to compete successfully with nonmotorized modes than with the private automobile for new passengers. But as demand for higher-speed travel increases, those customers may switch to private motorized vehicles.

COMPARISON OF MASS TRANSIT MODES

In the largest metropolitan regions, such as in Tokyo, New York, London, and Moscow, the huge demand for transit makes rail transit both indispensable and energy-efficient. But because transit energy efficiency is so dependent on matching supply with demand, the greater flexibility of the bus mode may have an advantage in this aspect. Bus service characteristics can be easily altered as to time of service, location of service, and size of vehicle used. For rail transit, not much change is possible in the short run.

The rail modes require a significant investment of both fiscal resources and energy in infrastructure,

Year	Diesel	Gasoline	Alternative Fuels						Total

including track, power supply, right-of-way, stations, and structures. This investment can produce a higher quality of service, but it commits the urban area to use of the rail mode and its relatively large vehicles.

The bus mode can use a broader range of vehicle sizes and does not require any separate infrastructure. Where right-of-way is shared with other vehicles, much of the energy used in producing the facilities may have been expended without consideration of use by mass transit. Where there is a need for exclusive bus infrastructure to bypass congested areas, busways can be constructed to improve service.

It is common outside of Europe and North America for bus service to be provided by private operators. The higher service efficiencies often achieved by private transit providers can translate into greater energy efficiency. While contracting out of transit service is possible for rail, it has been more common for bus operations.

Why has the load factor for transit decreased? Transit demand has declined due to higher incomes, higher automobile ownership, and a decrease in the share of jobs and population living in areas that are strong transit markets. At the same time, transit supply has increased, spurred by the growth of government subsidies for transit operation and capital investment. The long-standing problem of intense peaking of transit demand means that large vehicles are needed for only a few hours during the day, only to run nearly empty during off-peak hours. Transit agencies in the United States have been generally reluctant to use smaller vehicles. Privatized transit operations outside of London, England, were quick to adopt minibuses. Transit operation in the United States has largely become regionalized, with providers' operating areas spreading out over vast territories. Because all taxpayers in the region are typically required to contribute to transit via designated sales, property, or motor fuel taxes, transit agencies feel a political obligation to provide at least a minimum amount of service in all parts of the region, no matter how weak the transit demand.

Most urban rail service is electric-powered and most urban bus service is diesel-powered, although diesel rail and electric bus operations do exist, as noted above. The efficiency and environmental impacts of electricity depend greatly on the source of electric power. Although electric vehicles produce no tailpipe emissions, generation of electricity can produce significant emissions that can travel long distances. For example, coal-powered electricity plants produce particulate emissions that travel halfway across North America. Urban buses also can be powered by a variety of alternative fuels.

NEW TECHNOLOGIES

Applications of engineering and computer technology have the potential for reducing fuel use, greenhouse gas emissions, and toxic emissions from mass transit. They also may help in increasing transit load factors. Technology that enables greater operating efficiency of transit also has the potential to reduce fuel consumption per passenger distance traveled. The introduction of electronic fare cards in New York City prompted the development of new fare policies, including free transfer from bus to rail. The result was a 36 percent increase in bus use between 1997 and 1999. With only a 9 percent increase in bus service during the same period, the fuel efficiency of transit increased dramatically.

Traffic signal preemption and other technologies that seek to speed transit can have a similar effect. Faster bus travel means less fuel consumption per vehicle distance traveled. However, faster transit service increases demand for transit, potentially increasing the transit load factor.

The “conventional” fuels used for transit applications include gasoline, diesel fuel, and electricity. Alternatives to these fuels have been sought to reduce energy consumption, pollutant emissions, greenhouse gas emissions, and use of imported fuels. The conventional fuels for internal-combustion engines are the most energy-dense fuels: petroleum and diesel fuel.

Alternative fuels often are handicapped by the need to develop an alternative fueling infrastructure. Most transit fleets have their own fueling stations, so they are prime candidates for early introduction of new fuels. And transit agencies have experimented with many different fuels. Alcohol-fueled engines proved unreliable for heavy-vehicle applications. Los Angeles found that methanol and ethanol corroded bus engines, scrapped some of the vehicles, and converted the remainder to diesel in 1998-1999. The most popular alternative fuel has been compressed natural gas (CNG). This fuel offers lower pollutant emissions than diesel, but at a higher total cost than diesel. In addition to requiring new vehicles with natural-gas-powered engines and storage areas for fuel cylinders, using CNG requires an investment in new fueling and compression facilities and modifications to depots and maintenance facilities. Considering fueling, inspection, and maintenance, operating costs typically are higher for CNG than for comparable diesel vehicles.

Between 1992 and 1998, alternative fuels increased from less than 1 percent to more than 5 percent of total mass transit fossil fuel consumption in the United States (see Table 4). The share of alternative fuel consumption that was CNG increased from 19 percent to 72 percent over the same period.

One promising new technology is the hybrid electric vehicle, which combines an internal-combustion engine and an electric motor powered by batteries. The engine recharges the batteries, and the electric motor provides additional power during acceleration. These vehicles do not have the severe range and capacity limitations of battery-powered electric vehicles and do not have long refueling (recharging) times. Hybrids equipped with regenerative braking are well suited for city bus routes requiring extensive stop-and-go driving.

Ambient particulate matter (soot) has been linked to increased mortality. Diesel engines are high emitters of particulates. Particulate is also formed in the atmosphere from other pollutants, including those emitted by gasoline engines. As the public has become more aware of this problem, diesel engines have become much cleaner. By adding emissions control devices and electronic controls and by modifying engine designs, a large reduction in the emissions of particulate matter and nitrous oxides (precursors to both soot and smog) has already been achieved. In 2000, the U.S. Environmental Protection Agency proposed new regulations requiring very-low-sulfur diesel fuel and further large reductions in particulate and nitrous oxide emissions. Low-sulfur fuel reduces sulfate particulate emissions and also enables the introduction of emissions control devices that would be damaged by high-sulfur fuel. These regulations require diesel vehicles that have an emissions profile similar to today’s CNG buses.

In the longer term, more exotic technologies, such as fuel cells powered by hydrogen, may be feasible. These technologies are far from being economically feasible, but rapid progress is being made. However, as conventional vehicles become cleaner, the relative emissions-reduction benefits from alternative fuels declines.

LAND USE AND SOCIAL AND POLITICAL FACTORS

Matching the supply of transit service to its demand is the primary determinant of the energy efficiency of transit. The demand for transit depends on income levels and land use. As average income rises, so does the value of travel time, and therefore the cost of time spent traveling. Higher incomes also make automobile use more obtainable.

Land use is the other key determinant of transit use. Public transit requires a concentration of trips in the same time and place. A concentration of residential and commercial land use, such as that typically

A conductor on the number five train at Grand Central Terminal in New York on the eve of a possible strike by the subway and bus workers, December 1999. (Corbis Corporation)

found in cities, is necessary to generate significant transit demand. Concentrated land use has another, perhaps more important effect. To function efficiently, the private automobile must be provided with a significant amount of space for both storage and movement. In many cities there is insufficient space for the automobile, making automobile travel expensive. The largest costs of urban automobile travel are storage (parking) costs and travel time costs, due to traffic congestion. Under these circumstances, mass transit modes can compete effectively. They provide travelers with similar or lower total travel time (including time spent walking to and waiting for transit vehicles), and the avoided cost of parking may be several times greater than the cost of the transit fare.

However, most North American urban development since 1945 has been designed around the space needs of the automobile. A generous quantity of off-street parking is required for all new residential and commercial development. Streets are designed to be wide enough to accommodate free-flowing traffic, even in peak periods. Expressways have been constructed to connect all parts of the metropolitan region. The result has been the development of urban areas that are convenient for motoring. The same set of changes also has made them inhospitable to any mode of daily transport other than driving. The low population density of residential development makes postwar neighborhoods difficult to serve by public transit. More important, the prevalence in North America of widely scattered office parks with ample free parking has ensured that transit cannot compete for trips to those destinations, since driving is inexpensive and transit is either not available or takes up to twice as long.

Cities that were large (1 million or more) before 1920 have cores with a large concentration of jobs, expensive parking, and a large transit share of trips. The New York metropolitan area is the premier example, accounting for nearly 40 percent of all U.S. transit trips. Although newer areas have been able to increase transit ridership, none has transit shares approaching what is still common in the older large cities.

Per capita transportation energy consumption in a city such as New York is much lower than the U.S. average as a result of much lower car use. Although high-quality public transit service is one explanation for this result, parking costs, bridge and tunnel tolls, and the convenience of walking are equally important. Public transit is vital for the transportation needs of New York City residents. But many of the trips that residents of the typical U.S. metropolitan area take by auto are taken by New Yorkers on foot, or not at all. It is the lower number of auto trips, rather than a one-for-one substitution of transit trips for auto trips, that has a large impact on reducing energy use. Transit service in New York City is well used, making it energy-efficient despite the slow speed of surface transit travel.

In the United States, outside of the core areas of older major cities, transit has become the transport of last resort. There is a substantial social stigma attached to using transit, due to the low income levels of transit patrons in most U.S. cities. Transit customers also sometimes fear their vulnerability to crime, especially while waiting at bus stops.

INTERMODAL TRAVEL

Many transit trips involve transfers between transit vehicles. All else being equal, passengers would prefer not to transfer. However, the mode of access to transit is of interest. The vast majority of transit customers walk to transit and then walk again to their final destination. It is difficult to develop high transit demand in an urban environment that is not conducive to walking.

Park and Ride

A recent trend is the development of park and ride areas for transit passengers to drive to transit. These facilities help make transit accessible to a wide geographic area. Because emissions control devices are ineffective when cold, the auto trip to the transit station may produce nearly as many pollutants as a direct trip to the final destination. Further, park and ride lots occupy a lot of space, making transit stations unfriendly to pedestrians and reducing the opportunities for station-area real estate development. Finally, those driving to transit must still pay the full costs of automobile ownership. In fact, the only reason they are likely to take transit is if the cost of station-area parking and transit fare is less than the parking cost at the final destination. This explains why park and ride areas are most successful on transit lines serving urban cores with high parking costs. Most workers in North America, however, pay nothing out of pocket for parking at work.

Bicycling and Transit

Bicycling to transit is another solution for providing access. With no fossil fuel consumption and no pollution, bicycling to transit is attractive from an environmental point of view. Personal fitness is a major motivation for many bicyclists. Public health authorities concerned about physical inactivity have started to promote bicycling. Bicycle access to train stations is very popular in Japan and the Netherlands and some places in Germany. Since bicyclists can travel faster than local transit on some routes, the bike and ride option is most attractive for accessing express services such as suburban rail or express bus. Bike stations that provide bike storage, rental, and repair services and changing facilities adjacent to transit stations have been developed in three California cities.

Permitting bicyclists to take bicycles aboard transit vehicles allows them to use the bicycle for the trip to their final destination as well. Although many transit agencies are reluctant to make room for bicycles during crowded peak hours, railcars designed with bicycle storage have been deployed in Europe and North America. In the 1990s, hundreds of buses in North America were equipped with bicycle-carrying racks.

Despite the energy, emissions, and public health benefits of combining bicycle use with transit, few people in North America take advantage of this combination. Many urban roads are designed for high-speed operation and have narrow lanes. These designs often scare bicyclists from using the roads, a fear sometimes reinforced by motorists and police who do not believe that bicyclists have a right to use roads. Secure, sheltered bicycle storage at transit stations is rare, and therefore the threat of bicycle vandalism and theft deters others from using bicycling as an access mode to mass transit.

MATERIALS

Energy and materials were developed together in early civilizations, beyond the use of fire for cooling and heating. In the courtyard of the stepped pyramid at Sakahra, built near Cairo, Egypt, in about 2600 B.C.E., there are a series of carved relief panels in stone, showing that the ancient Egyptians had mastered the smelting and working of metals with heat energy (fire), as well as many other technical skills. Glass melting was discovered at least 10,000 years ago, and fired ceramics (pottery) even much earlier.

Solid materials are essential to the production and transmission of energy; in the next section gives examples of materials used in these processes. The article then focuses on the large energy requirements needed to produce the metals, ceramics, glasses, and electronic materials (silicon and germanium) that our technological civilization demands, and finishes with an overview of the environmental problems encountered in trying to satisfy this vast demand for materials.

MATERIALS IN AUTOMOBILES AND TRUCKS

Advances in materials science have been a leading factor contributing to improvements in vehicle fuel economy and performance since the 1973 oil embargo. Better tire materials have reduced rolling resistance, better materials for moving parts have reduced friction, and most importantly lighter body parts have reduced the overall weight of vehicles.

The average 1993 model American car weighed about 3,200 pounds (1,450 kg) and delivered 28 miles per gallon of fuel (171 km/liter), representing a 19 percent reduction in weight and a 44 percent reduction in fuel consumption as compared to the average 1975 model. This reduction was achieved by substituting polymers for interior metallic trim, aluminum engines for cast iron, and careful design attention to weight factors. Weight reduction and improved engine design contributed greatly to better fuel economy. There is further potential for weight reduction through increased substitution of polymer matrix composites, aluminum, and ceramics for metals in vehicles.

Metal	Form or Process	Energy 10^{12} J/kg
Iron	Steel	28
Bismuth	Bulk	30
Lead	Ingot	31
Thallium	Sponge	36
Zinc	Electrolytic	70
Sodium	Bulk	107
Copper	Refined Bar	128
Cobalt	Electrolytic	144

Beryllium	Cast	6100
Gallium	Electrolytic	13,500
Gold	Bars	68,400

Table 1.
Energy Required to Produce Purified Metals

MATERIALS IN ENERGY PRODUCTION, TRANSMISSION, AND STORAGE

Metals are of overwhelming importance in these applications. Steel, which is iron containing carbon and many different metallic additions, is still the most used metal. Aluminum is increasingly used in many applications because of its light weight and resistance to chemical attack. Copper is required for transmission lines, wiring, and generators because of its high electrical conductivity. There are many specialized uses of other metals: manganese, vanadium, and molybdenum as alloying elements to improve strength and chemical durability of steel; uranium and plutonium in nuclear reactors; silver in electrical contacts; and tungsten as filaments in lamps.

Ceramics, including concrete, are useful especially in structures, reactors, as refractories in combustion of fuels, and as nuclear fuel. Porcelain insulators on transmission lines are an example of a specialized application of ceramics.

Electronic materials are needed for computers and control devices; purified silicon is the basic material for these applications. In addition silica glass (SiO_2) is an insulator, aluminum an electrical conductor, and polymers are reactive materials for patterning in these devices. Control of every step of energy production and transmission is now completely dependent on electronics.

ENERGY USE: REFERENCES AND METHODS

The energy use data in the tables come from three Battelle-Columbus reports and an article by H. H. Kellogg on "Energy Considerations in Metals Production in the Encyclopedia of Materials Science and Engineering." The Battelle-Columbus reports have detailed descriptions of the processing of all the materials listed in the tables, with methods from mining through separation to purification, and cost estimates at each processing step. There is a remarkable amount of valuable information on each material in these reports. The section on metals also relied heavily on the article by Kellogg.

The estimates for energy use can be separated into the following components:

$$\text{energy use} = F + E + S - B$$

where F is the heating values of fuels used, E is the fuel equivalent of electrical energy (from the U.S. average fuel equivalent of $11.1(10)^6$ joules per kilowatt hour), S is the fuel equivalent of supplies and chemical reagents consumed in the processing, and B is the fuel equivalent of by products and surplus steam. The units of energy use are given in joules per kilogram of final material produced in the tables; the conversion to English units is: divide J/kg by 1.16 to get Btu/ton (British thermal units per 2,000 pounds).

The energy equivalent of one barrel (159 liters) of crude petroleum is about $6.6(10)^9$ joules. Table 1 shows that the production of a metric ton (1,000 kg or 2,200 pounds) of steel requires about four barrels of oil; a ton of aluminum requires about forty barrels

Metal	*Energy 10^{12} J/kg*
Manganese	58
Chromium	71
Silicon	89
Niobium	220
Vanadium	570

Energy to Produce Metal for Alloying with Iron (Ferrometals)

of oil, and a ton of gold more than ten thousand barrels of oil. Table 2 shows the energy needed to produce metals for alloying with iron to produce steel.

ENERGY FOR MINING

The amount of energy required for mining the ores and minerals needed to make materials depends on their depth in the ground, and processing and separation methods. Ore and minerals lying near the surface need only be excavated by shovel or dredge, and thus require low energy expenditure (10^{11} J/kg). Fine grinding (0.1 mm) requires up to $3(10)^{11}$ J/kg. Loading, elevation out of a mine, and transporting the ore can require up to $5(10)^{11}$ J/kg.

If the ore consists of separate grains containing the desired material, it can be separated from undesired minerals by physical methods such as flotation, sedimentation, or magnetic separation. For metals this step can lead to 80 to 95 percent concentration of the value of the ore. Ceramic raw materials such as sand and clay can often be found pure enough in nature so that no concentration is needed.

If the desired material is not in separate grains, chemical treatment of the ore is required for metals, and for purification of ceramics.

ENERGY USE FOR PROCESSING OF METALS

Table 1 shows estimated values of energy to produce a kilogram of reasonably pure metals, or for metal useful for practical applications. The range of a factor of more than 2,000 between steel and gold depends on the concentration in ore, the chemical processing needed, and amount of technology development for the particular metal. Steel production has been developed during about three millennia, and iron ore is highly concentrated and can be reacted directly to steel alloys. Gold is widely dispersed in low concentrations, and requires intensive chemical treatment of ores.

Metal	*Consumption in millions of kilograms*	*Fraction as scrap*
Iron and steel	97	0.35
Aluminum	4.0	0.34
Copper	2.9	0.45
Lead	1.1	0.55
Zinc	0.95	0.29
Nickel	0.13	0.27
Platinum group	0.10	0.12
Gold	0.087	0.57
Magnesium	0.08	0.09
Titanium	0.036	0.34
Silver	0.033	0.72

Table 3.
Total Consumption of Certain Metals in the United States in 1981

Table 3 shows the total consumption of some metals in the United States.

If the metallic compound in the ore can be selectively leached by acid or base without dissolving much of the remaining ore, then the energy requirement is only about 10^{12} J/kg. Examples are leaching of oxide ores of copper, zinc, or uranium with sulfuric acid.

Much more energy is needed if the entire rock matrix must be chemically dissolved to free the metallic compounds. Examples are the separation of aluminum oxide (Al_2O_3) from bauxite ore by dissolution by strong base at elevated temperature and pressure (Bayer process), with an energy requirement of about $8(10)^{12}$ J/kg, and smelting of nickel ores by heating to produce a molten nickel-iron alloy and oxide slag, with energy up to $(10)^{13}$ J/kg needed. These high energy requirements result from the fuels needed to heat furnaces or reactors to the high temperatures of these chemical reactions, and for the energy equivalent to make the chemical reagents employed, such as acids, bases and iron alloys.

The grade of metallic ore is the percentage of metal (native and chemically combined) in the ore. For example, high grade iron ore can contain up to 65 percent iron, whereas usual gold ores contain less than 0.001 percent gold. The weight of ore that must be processed is inversely proportional to the grade of the ore. For example, about $7(10)^{13}$ J/kg are required for mining and concentration of hard rock ore containing 0.6 percent to copper, and $4(10)^{16}$ J/kg are needed to mine and concentrate a gold ore containing 0.001 percent gold. Thus, the grade of ore is a major factor in energy consumption.

High grade ores are used first, and are already substantially depleted for most metals. With time one might expect the energy use in Table 1 to increase. Improved technology can offset this increase somewhat; belt conveyors in mines and computer control of grinding are examples. Ordinary rocks contain small quantities (parts per million by weight) of many different metals, and have been suggested as a source for rare metals and those with depleted ores. For example, many rocks contain about 0.01 percent copper; it would require about one thousand times the energy to recover copper from these ores as from presently-available ores (Table 1). The large energy demand precludes the use of these rocks for producing copper, because of the low price of copper. Gold, however, is more valuable, and would justify a larger energy input.

In the concentrated ores most metals are in chemical compounds, as oxides or sulfides. Reducing these compounds to the metallic state in the final stage in producing metal can be accomplished by chemical processes or electrolysis. Two examples of chemical reduction are

Copper sulfide

$$CuS + O_2 = Cu + SO_2 \tag{1}$$

Steel blast furnace

$$2Fe_2O_3 + 4C + O_2 = 4Fe + 4CO_2 + \text{heat} \tag{2}$$

where $2Fe_2O_3$ is hematite coke ore. Because the oxides and sulfides of many metals are stable, their chemical reduction is difficult, and they are reduced to metal by electrolysis (electrowinning); examples are zinc, aluminum, and magnesium.

The electrolytic processing of concentrated ore to form the metal depends on the specific chemical properties of the metallic compound. To produce aluminum about 2 to 6 percent of purified aluminum oxide is dissolved in cryolite (sodium alumino-fluoride, Na_3AlF_6) at about 960°C. The reduction of the alumina occurs at a carbon (graphite) anode:

$$2Al_2O_3 + 3C = 4Al + 3\,CO_2 \tag{3}$$

Magnesium is reduced from a mixture of magnesium, calcium, and sodium chlorides. Electrolysis from aqueous solution is also possible: zinc, copper, and manganese dissolved as sulfates in water can be reduced electrolytically from aqueous solution.

Process energies are found by subtracting energies for mining and concentrating from the values in Table 3. The free energies of formation of the metal oxides are a measure of the total (theoretical) energy required to reduce the metal from the oxide. The ratio of the actual process energy to the free energy of formation is a rough measure of the efficiency of the reduction process. The free energies of formation are a measure of the chemical stabilities of the oxides; stable oxides such as aluminum, magnesium, and titanium intrinsically require more energy for reduction than from less stable oxides (or sulfides) of copper, lead, and nickel.

The most efficient processes in Table 1 are for steel and aluminum, mainly because these metals are produced in large amounts, and much technological development has been lavished on them. Magnesium and titanium require chloride intermediates, decreasing their efficiencies of production; lead, copper, and nickel require extra processing to remove unwanted impurities. Sulfide ores produce sulfur dioxide (SO_2), a pollutant, which must be removed from smokestack gases. For example, in copper production the removal of SO_2 and its conversion to sulfuric acid adds up to $8(10)^{12}$ J/kg of additional process energy consumption. In aluminum production disposal of waste cryolite must be controlled because of possible fluoride contamination.

As global warming develops, the formation of large quantities of carbon dioxide (see Equations 1 and 3) may become a problem in metals production. There is no simple or inexpensive way to reduce these emissions. Switching to electrolysis processing of steel, or a different electrode reaction for aluminum, would involve unacceptably large energy use and cost. Chemical absorption of carbon dioxide may be necessary in a wide variety of chemical and energy-producing processes, at enormous cost.

The scale of production also influences efficiency. Small-scale batch processing for metals such as titanium, tungsten, and zirconium leads to higher energy use and costs.

RECYCLING OF METALS

Reuse of waste metals generated from metal fabrication and from discarded products (scrap) can save large amounts of energy, particularly for metals that have high energy use in production, such as aluminum. The low fractions of energy used to produce metals from scrap for aluminum, certain sources of copper, and nickel show the value of recycling these metals.

The purity of the scrap mainly determines the fraction of energy needed to produce metal from it, and the value of recycling. Clean copper scrap need only be remelted and cast to form recycled copper; if the copper is contaminated with organic materials and other metals, more complex separation processes are needed that are similar to production from ores. It is easier to remelt the steel of a car driven in Arizona compared to one rusted by the road salt in snowy areas. Scrap that is produced as a by-product of metal processing can be easily recycled, and it can be collected from relatively few locations. There has been a strong effort to educate both householders and industrial users to separate scrap and return it to waste collectors, leading to a supply of reasonably separated scrap.

Despite the efforts of many communities to encourage recycling, there is still a large amount of metal that is not recycled. Only an estimated 30 percent of aluminum is recycled, as compared with up to 50 percent for precious metals. Landfills contain large amounts of metals, especially large use metals (Table 3) such as iron, aluminum, and copper, and more metals continue to accumulate in landfills. As the cost of disposal increases and ores of metals such as copper become of lower grade, it may be economically feasible to “mine” landfills for metals. Development of new technologies for treatment and separation of waste materials is needed to make this mining economical.

ENERGY USE IN PRODUCING CERAMICS

Traditionally ceramic raw materials have been dug out of the ground and used with little or no treatment or purification. Sand, fireclay, talc, and gypsum are examples. The energy expenditure for producing these materials is therefore small. Some of these materials can be found naturally in high purity. Silica sands (SiO_2) with less than 100 ppm (parts per million by weight) of impurities are known, and some clay deposits are nearly pure kaolin. Minerals such as feldspar, kyanite, and kaolinite (clay) can be purified by washing or solution treatments at near ambient temperatures, with low energy expenditure.

Many ceramic products require firing at high temperatures, and the fuels required to reach and sustain these temperatures are major factors in the energy consumed to make these products. Portland cement is made by firing a mixture of compounds, mainly carbonates, sulfates, and silicates to form the desired calcium silicate products. The firing is done in a rotary furnace or kiln, so that a fraction of the raw materials become liquid. As the resultant calcium silicates cool, they go through a large volume change that causes the cement particles to break into smaller sizes.

Concrete is made from a mixture of about equal parts of sand, gravel, and cement, plus some added water to give a mixture that flows. The low energy expenditures to make these raw materials mean that concrete is a material that requires very low energy; the only additional energy is a small amount for transport and for mixing the constituents. Concrete requires about one-third the energy expenditure for steel, and one thirtieth that for aluminum (Table 1). In Western Europe concrete has replaced metals and wood in many applications, because forests are depleted and energy costs are higher than in the United States. Examples are in building; American homes still use a wood frame, but in Western Europe almost all homes are made from concrete or stone. Electrical transmission poles in the United States are made of wood or aluminum, and in most of the rest of the world these poles are made of concrete because of their lower energy requirements. Considerable energy savings could occur by substituting concrete for metals in a variety of applications. Concrete has excellent compressive strength but is weak in tension or bending. By reinforcing concrete with steel bars the concrete building or structure has good strength in bending and tension as well as compression.

Other applications of ceramics require clay, either raw or purified, sand, and feldspar. Brick, porcelain, and white wares are made from these raw materials; the main expenditure in making these products is in firing the mixtures of powders to a dense solid. Ordinary brick made from fire-clay requires a small amount of energy; even refractory brick for high temperatures and chemical durability, made partly from purified oxides such as alumina or chrome ore, requires only about the same energy to make as an equivalent weight of steel.

Glass for containers is made continuously in a large tank or furnace. Raw materials (sand, soda-ash, limestone) are fed in at one end of a gas-fired furnace. The molten glass slowly passes through the furnace at high temperature (1,200°C-1,300°C) to homogenize it and remove bubbles. At the exit end the molten glass is fed into special molds in two stages to make containers of desired sizes and shapes. Flat glass (windows) is also made in a continuous furnace; a glass layer leaving the furnace is spread onto a bath of molten tin (float glass) to provide smooth surfaces. Lamp bulbs are made from a continuous furnace; a ribbon of glass is fed to blowers that blow the bulbs into a mold (ribbon machine). All these processes are continuous with large furnaces for melting, and so are energy efficient, using about $20(10)^{12}$ J/kg, a factor more the ten lower than the energy required to make an equivalent weight of aluminum. Nevertheless, aluminum containers have replaced glass for many purposes, because aluminum is easier to handle, and harder to break. Polymer (plastic) containers are also popular because of low cost, chemical durability, and ease of handling. As energy costs increase, aluminum containers will become less attractive than glass; the raw material (petroleum) for polymers may also become more expensive, leading to a return of glass as the primary container material.

For many specialized uses glass is made in small batches, so the energy costs are much higher than for the continuous furnaces. Special processes, such as for drawing fibers, casting optical components, and making laser glass, require highly purified or controlled raw materials, leading to much higher energy requirements than for continuously made glass.

Many ceramic applications are high value and small volume, so energy expenditure is high. Ferroelectric magnets, electronic substrates, electro-optics, abrasives such as silicon carbide and diamond, are examples. Diamond is found naturally, and made synthetically by the General Electric Company at high pressure and temperature. Synthetic diamonds for abrasives require less energy to make than the value in Table 4; nevertheless, the market is carefully divided between natural and synthetic diamonds.

Large quantities of uranium oxide are required for nuclear reactor fuel. The uranium ore must be carefully purified and processed to desired shapes, causing high energy expenditure.

Single crystals of synthetic quartz are made by crystallization from aqueous solution at temperatures and pressures well above ambient. The crystallization is slow and carefully controlled, so energy costs are high.

The energies for producing some gases are listed in Table 5 for comparison with those for other materials.

RECYCLING OF CERAMICS

Bulk ceramics such as building materials, porcelain, and concrete are not recycled, because of the low energy required to make them and the difficulty of collecting, transporting, and reforming them into useful shapes. Some glass is recycled in the form of "cullet," which is waste glass. The amount of cullet in a glass furnace is rigidly controlled, because the final product of the furnace must have just the right viscosity for the automatic machinery (container mold, tin bath, or ribbon machine) that forms the glass. Glass manufacturers are unwilling to build tanks to accept waste glass, because its variable composition leads to uncontrollable variations in the viscosity of the glass. Viscosities of silicate glasses are highly sensitive to impurities, especially water and alkali (sodium and potassium) compounds.

ELECTRONIC MATERIALS

Silicon wafers are the basis for electronic circuits. The silicon must be highly purified, then grown as a single crystal containing a small amount (a few parts per million) of additions to give either negative carriers (electrons from phosphorous or arsenic) or positive carriers (holes, from boron or aluminum). These processes require temperatures above the melting point of silicon (1,414°C) and careful control of several processing steps. The energy expenditure for making silicon for wafers (chips) is about the same as that for germanium, given in Table 4. The energy of about $2{,}500(10)^{12}$ J/kg is greater than that required to make such a valuable metal as silver, or zirconium, which is strongly bonded in compounds, because of the highly complex processing and high purity required for the semiconductors. Subsequent processing of silicon wafers to form devices on the wafers for practical use is highly specialized, carefully controlled, and expensive in cost and energy.

Material	*Form or process*	*Energy 10^{12} J/kg*
Sulfur	Frasch	2.2
Antimony	Bulk	7
Graphite (carbon)	Refined, bulk	40
Tellurium	Bulk	96
Phosphorous	Bulk elemental	200
Selenium	Bulk solid	340
Iodine	Solid	620
Germanium	Semiconductor grade	2500
Diamond	Natural	830,000

Chlorine	21
Ammonia	45

Table 5.
Energy to Produce Commercial Gases

ENVIRONMENTAL CONCERNS

There is great interest in the more energy efficient production of materials to reduce costs and environmental damage. The products of materials production receiving the greatest attention are sulfur dioxide, fluorides, and carbon dioxide. The production of energy from fossil fuels, especially coal and oil, leads to production of sulfur dioxide, which causes much damage locally and at long distances. It leads to respiratory problems and damage to plants, especially trees, and can acidify soils and lakes, damaging them for growing plants and animals. Sulfur dioxide can be scrubbed from flue glass at considerable expense, but much of it is still discharged into the atmosphere. Sulfur dioxide is a by-product in much of the materials production discussed here; sulfide ores (copper) when oxidized produce sulfur dioxide (Equation 2), and some raw materials for cement contain sulfates.

Fluorides are used in many materials processes, and can poison the environment when they are discarded. Examples are cryolite (sodium aluminofluoride, Na_3AlF_6) used to dissolve aluminum oxides for electrolysis, and hydrofluoric acid (HF) used in etching lamp bulbs and semi-conducting circuits. Today lamp bulbs are etched much less than they used to be to reduce fluoride disposal; not much has been done to reduce the amount of cryolite for aluminum production.

Some heavy metals and semi-metals are quite toxic (chromium, lead, and antimony) and expensive care is needed to prevent them from being dispersed in the environment. Lead in gasoline and paint has been almost completely eliminated; its use in storage batteries has resisted efforts to find a suitable substitute.

The discharge of carbon dioxide from combustion of fuels from vehicles, and from processes such as steelmaking, cement production, and much other materials production has increased the concentration of carbon dioxide in the atmosphere. Some computer models demonstrate that this increase is responsible for an increase in the mean temperature of the surface of the Earth, and there are numerous predictions of further temperature increases as more carbon dioxide is discharged into the atmosphere. There are other claims that this result is not proven. Reduction of carbon dioxide emissions is highly difficult and expensive. If the connection between carbon dioxide emissions and global warming is proven more conclusively and a carbon dioxide reduction plan is instituted, materials industries will feel a great impact because they consume about 20 percent of all industrial energy.

Reduction of overall energy use is one solution to the above problems. It requires money, technical advances, political power, and courage; some reduction has been achieved, but much more is needed to reduce emissions of gases. One solution being advanced is use of processes to produce energy that do not emit gases. Hydropower has been exploited about as fully as possible, and supplies only a small fraction of total energy needs. Other sources such as wind and solar power are still much too expensive.

One energy source that first appeared to be highly attractive was nuclear power. The problem with nuclear power is that some costs were hidden in its initial development. Especially pernicious is the disposal of uranium oxide fuel after it has become depleted. It can be reprocessed, but at considerable expense, and the product plutonium can be used for weapons. In the United States the plan is to bury depleted uranium from reactors, but many persons are not convinced that burial is safe. Much work has been done on encapsulation of radioactive waste in glass; the problem of reactor waste remains.

SUMMARY

The energy required to produce materials varies widely, gold requires more than two thousand times the energy to produce the same weight of steel, and diamonds two hundred thousand times the energy required to make ordinary brick. Factors in energy use are the quality (concentration) of ore, the complexity of processing, and the technological development of processing.

Some recycling of metals occurs; much more is possible, and substitution of materials requiring less energy for those requiring more has much potential.

Reduction of environmental pollution requires lower energy use and new technology to decrease emission of gases such as sulfur dioxide and carbon dioxide, and to prevent toxic fluoride, heavy metal, and radioactive wastes from discharging into the environment.

MATTER AND ENERGY

The entire observable universe, of which the Earth is a very tiny part, contains matter in the form of stars, planets, and other objects scattered in space, such as particles of dust, molecules, protons, and electrons. In addition to containing matter, space also is filled with energy, part of it in the form of microwave radiation.

INERTIA, MASS, AND ACCELERATION

Matter itself has energy, called “rest energy.” What distinguishes matter-energy from other forms of energy is that all matter has inertia and is subject to the force of gravity when at rest as well as when in motion. Inertia measures the resistance of an object to being accelerated by a force, and the inertia of an object at rest is proportional to its mass.

According to a law of physics first formulated by Isaac Newton and later modified by Einstein in his general theory or relativity, any object with mass can be accelerated by applying a force to it. Physicists use the term “acceleration” not only to describe the speeding up or slowing down of an object but also for changing its direction. A car going around a curve at constant speed is accelerating because its direction changes.

If you flick a small plastic ball on a table top with your finger, thereby exerting a small force on the ball, you will see it move rapidly from its resting position. But if you do the same with a steel ball of the same size, the same flick of the finger (the same force) will produce noticeably less motion. The steel ball has greater mass and therefore greater resistance to being accelerated. The ratio of the accelerations of two objects experiencing the same force is equal to the ratio of their masses.

The basic unit of mass is the kilogram, which is the mass of a standard platinum cylinder located in the city of Paris. A kilogram has a weight of 2.2 pounds. The basic unit of energy is the joule, which is equal to the kinetic energy that a one-kilogram object has when it is moving at a speed of 1.41 meters per second or the amount of potential energy the object has when lifted to a height of 0.102 meters.

PROPERTIES OF MATTER

Matter on earth commonly takes the form of solids, liquids, or gases, but may also be in the form of plasmas, which are "ionized" gases, that is, gases in which some of the atoms of the gas have lost one or more of their electrons. These electrons move within the plasma.

Gases, liquids, and solids have different physical properties. A gas fills its container, so that if a certain amount of gas is transferred from a small container into a large one, the gas will expand to fill the new container. If there is a hole in the top of a container filled with gas, the gas will escape. A liquid keeps the same volume when transferred from one container to another, but takes the shape of the new container. On Earth, a liquid has a flat, horizontal surface, If there is a hole in its container below that surface, the liquid will spill out. A solid keeps both its shape and its volume when transferred from one container to another.

Solids, liquids, and gases all change their volumes when the temperature is changed. All gases and nearly all solids and liquids tend to expand when their temperature is raised. When heat is applied to a solid, its temperature normally goes up, but at a certain temperature it can change its state (phase) to a liquid while the temperature remains constant. Similarly, as heat is applied to a liquid, its temperature normally rises until a certain temperature, when it changes its state to a gas. On still further heating, the gas will expand if the container has a movable piston to let it expand; otherwise, the pressure of the gas will increase. Eventually, if enough heat is applied, the gas can become partially ionized, that is, it can turn into a plasma.

The sun is a partially ionized gas or plasma. It has no container to hold it together. Instead, the enormous gravitational forces in the sun do the job. Even on Earth, the atmosphere (a gas) does not escape to outer space because of gravity. On the surface of the moon, gravity is only one-sixth as strong as on the surface of the earth. This is not strong enough to hold gases on the moon, so the moon has no atmosphere.

According to Albert Einstein's theory of relativity, no object with mass can travel as fast as the speed of light in empty space (in vacuum). So another definition of matter is anything that is subject to gravity and is either at rest or traveling slower than the speed of light in vacuum. The speed of light in vacuum, denoted by the special symbol c, is a constant speed (186,000 miles per second, or 300,000 kilometers per second) and is the speed in vacuum of any quantum (packet) of energy that has no mass. (At this speed, light can travel seven times around the world in a little under a second.) Light, and anything else that travels at the speed of light in a vacuum, is not considered to be matter. However, all things that travel at the speed of light, including light itself, possess kinetic energy.

The theory of quantum mechanics says light has some properties of a wave (for example, a wavelength), but its energy is concentrated in little packets called photons. These quanta, or particles of light, do not have mass and always travel at the speed of light in vacuum. Light travels slower in a material medium (such as glass) than in a vacuum because the photons get absorbed and reemitted by the atoms of the medium, thereby slowing down the progress of the light wave.

Is the universe matter dominated or energy dominated? The very early universe was "energy dominated" in the sense that only a small fraction of the energy of the universe at that time was in the form of the rest energy of matter and antimatter. Much of the energy of the universe was in the form of electromagnetic radiation. It is not known whether the universe originally had an excess of matter over antimatter or whether the excess of matter developed as time went on. Most cosmologists favor the idea that reactions in the early universe led to the excess of matter, but the mechanism is not known. As the universe expanded it cooled, until, about 300,000 years after the Big Bang, the quanta of radiation (photons) no longer had enough energy to create electrons and positrons. As the universe continued to expand, the radiation cooled still further, until today all that is left of it is the microwave background radiation at a temperature of 2.7 K. The amount of energy in the background radiation plus all the light energy from stars is only a tiny fraction of the rest energy of matter. Therefore, today, the visible universe appears to be matter dominated. However, it is an open question whether other, as yet unseen, forms of energy exist that would make the universe energy dominated.

Forces, such as the gravitational force, are transmitted by means of quantities that scientists call "fields." All matter is influenced by forces carried by gravitational fields. Electrically charged particles are influenced by forces carried by electromagnetic fields. The gravitational and electromagnetic fields are not matter, but they have energy.

As far as is known, ordinary matter is made of tiny building blocks called elementary particles. For example, an atom is made up of a nucleus surrounded by one or more electrons. As far as scientists have been able to determine, the electrons are elementary particles, not made of anything simpler. However, an atomic nucleus is not elementary, but is a composite particle made up of simpler particles called protons and neutrons. (The lightest nucleus is the nucleus of ordinary hydrogen, which consists of only a single proton.) Today, physicists believe that even protons and neutrons are not elementary but are composite particles made up of still simpler building blocks called quarks.

At the present time, quarks are believed to be elementary particles. All the particles in an atom, whether elementary or not, are particles of matter and possess mass. Electrons, protons, and neutrons can also exist outside of atoms.

In addition to ordinary matter, scientists have evidence for the existence in the universe of "dark matter." Some of the dark matter is ordinary matter, such as dust in outer space and planets going around other stars. Astronomers cannot see ordinary dark matter because any light coming from such matter is too faint to be observed in telescopes. However, most of the dark matter in the universe is believed not to be ordinary matter. At the present time it is not known what this mysterious dark matter is, or what it is made of. Scientists know that this dark matter exists because it exerts a gravitational force on stars (which are made of ordinary matter), causing the stars to move faster than they otherwise would. According to present estimates, there is perhaps five times as much dark matter in the universe as ordinary matter.

GRAVITY

Gravity is a force that acts not only on matter but on anything, such as light, that possesses energy. A gravitational force cannot speed up light or slow it down, but it can accelerate light by changing its direction. Light from stars directly behind the sun can be seen on earth during an eclipse of the sun because the sun's gravity bends some starlight around it. An observation of this effect was first made in 1919 during a solar eclipse, and the amount of bending observed was in agreement with the predictions of general relativity.

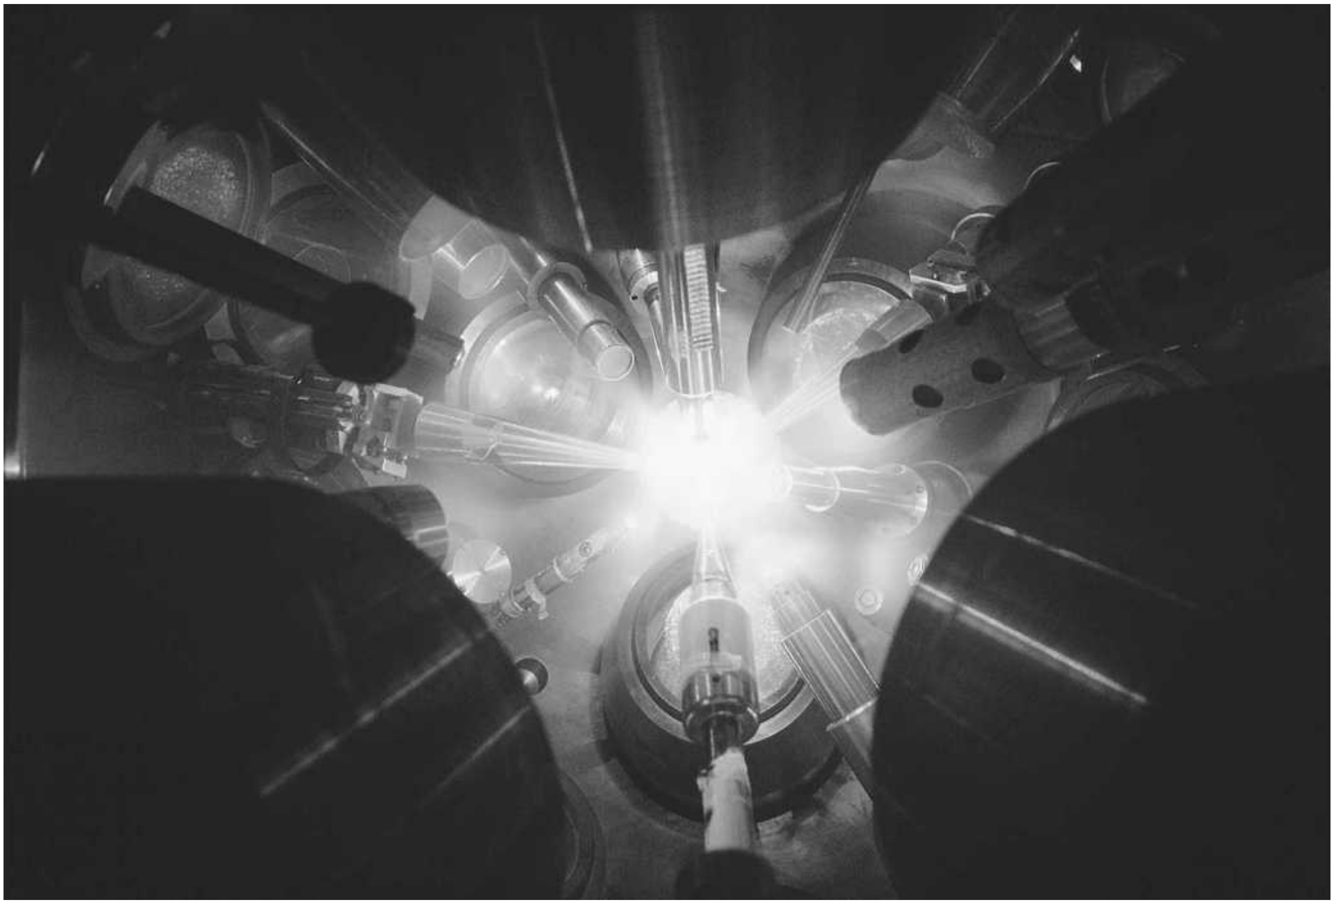
Gravity can also give energy to light or take energy away from light. If light from a laser is directed down from the top of a building to the ground, the light will gain a small amount of energy by "falling" in the gravitational field. Scientists can measure this slight energy gain as an increase in the frequency (decrease in the wavelength) of the light. Conversely, if the laser light shines upward, the light loses energy, and its frequency slightly decreases.

According to the theory of relativity, all matter has a kind of energy, called rest energy, denoted by the symbol E. If an object at rest has a mass denoted by m, its rest energy E is given by Einstein's famous formula $E = mc^2$. Because the speed of light c is such a large number, a small amount of matter contains a large amount of rest energy.

It has been noted that a one-kilogram object moving at 1.41 meters per second has a kinetic energy of 1 joule. The rest energy of the object is 90 million billion times as great. In fact, the rest energy of ordinary objects is so large that some people dream of unlocking that energy and converting it into more useful forms of energy, such as kinetic energy and heat. The laws of physics do allow matter to be converted into energy and energy into matter. However, at present, no way is known to convert the rest energy of matter entirely into energy except by "annihilation" in a collision with a form of matter known as antimatter.

PROPERTIES OF ANTIMATTER

Earth and the sun, and, as far as is known, the stars and planets in the rest of the visible universe, are made of ordinary matter. However, according to a theory first proposed by Paul Dirac in 1928, for every kind of particle of ordinary matter that exists in nature, there can exist an antiparticle made of antimatter. Some antiparticles have been discovered: for example, the antiparticle of the electron, called the positron, was discovered in 1932 in cosmic rays falling on earth and have also been created in experiments performed in the laboratory. Antimatter is very simi-



Lasers are focused on a small pellet of fuel. This is an attempt to create a nuclear fusion reaction for the purpose of producing energy. (Corbis-Bettmann)

lar in some of its properties to ordinary matter, while other properties are quite different. For example, an electron is a particle of ordinary matter with negative electric charge. However, although the positron has a mass equal to that of an electron, it has positive electric charge. The mysterious dark matter of the universe is not the antimatter of ordinary matter.

According to general relativity, both matter and antimatter are attracted by gravitational forces. However, as yet no experiment has succeeded in showing that antimatter falls under Earth's gravity. The reason is that only small particles of antimatter, such as antiprotons, antineutrons, and positrons, have been created in the laboratory. The electric and magnetic forces acting on these particles are much stronger than the gravitational forces and mask the effects of gravity.

The most spectacular difference between a particle and an antiparticle is that, as the result of a collision, the particle and antiparticle can both annihilate into pure energy. For example, if an electron and a positron collide, they may destroy each other (annihilate) into radiation. This is an example in which the rest energy of matter and antimatter is converted entirely into another form of energy. Conversely, under some conditions the kinetic energy of rapidly moving particles can be converted into new particles of matter, usually together with particles of antimatter. Because antimatter is rare in the universe, nobody has to worry about our earth colliding with enough antimatter to annihilate the earth, although some particles on earth are annihilated by antiparticles from outer space.

It is because of the rarity of antimatter that we cannot use annihilation of matter as a source of kinetic energy, heat, light, and other forms of energy. Of course, scientists can create antimatter, but they have to supply the energy to create it. When the created antimatter annihilates, the scientists get back only the energy that they put in. It is actually much worse than that, because creation of antimatter is a very inefficient process, and most of the input energy is wasted. Furthermore, it is very difficult to store antimatter. It cannot be stored in any container made of matter, as it will annihilate with the walls of the container. Antimatter has to be contained by electromagnetic forces in a vacuum.

CONVERTING MATTER TO ENERGY

Although it is impractical to convert the rest energy of matter entirely into other forms of energy, nevertheless, a small fraction of rest energy is converted in chemical and nuclear reactions. For example, if hydrogen is burned in oxygen (a chemical reaction), the product is water plus heat and light. A scientist can describe this process by saying that burning converts chemical energy into heat and light. However, the process can be looked at in another way. If careful measurements are made, it is found that the mass of the water is slightly less than the sum of the masses of the original hydrogen and oxygen. So it can also be said that "the burning process" converts a small amount of rest energy of the hydrogen and oxygen into heat and light.

Normally, electrons in an atom are "bound" in the atom by the attractive electrical forces between the electrons and the atomic nucleus. A certain amount of energy must be applied to an atom to release an electron from the atom, thereby ionizing it. This amount of energy is called the "binding energy" of the electron in the atom. The binding energy of the electrons in hydrogen and oxygen is slightly different from the binding energy of the same electrons when the oxygen and hydrogen are combined in water. A change in binding energy causes a change in rest energy of the same amount. This difference in binding energy (or rest energy) is the source of the heat and light when hydrogen is burned.

Just as electrons are bound in atoms, so are protons and neutrons bound in atomic nuclei, but the binding energy of the protons and neutrons is far greater. Consequently, changes in the binding energy in nuclei are a much greater source of heat and light than changes in the binding energy of electrons. More than a million times as much matter can be converted into energy in a nuclear reaction as in a chemical reaction, and even in such a nuclear reaction only about 0.1 percent of the matter is converted into energy.

Most of the energy of the sun comes from changes in binding energy when hydrogen is converted into helium in nuclear reactions. When very light nuclei, such as hydrogen nuclei, are combined to produce nuclei having less total mass than the very light nuclei, energy is released. The process is called "nuclear fusion." The energy released in the sun in nuclear fusion is what causes the sun to shine.

When very heavy nuclei, such as those of uranium and plutonium, are split into lighter nuclei having less total mass than the very heavy nuclei, energy is released. The process is called "nuclear fission." In either nuclear fission or nuclear fusion, much of the converted rest energy emerges as kinetic energy, heat, and light.

The explosion of an atom bomb (a uranium or a plutonium bomb) and the operation of a nuclear reactor are cases of energy released in nuclear fission, the first in a very fast process and the second in a slower, controlled way. In a nuclear reactor, a small fraction of the rest energy of the uranium or plutonium is converted into heat. The heat is then used to turn water into steam, which drives a turbine attached to an electric generator in order to generate electricity (electrical energy). In a hydrogen bomb, most of the energy released comes from nuclear fusion. Scientists have tried for almost fifty years to build a fusion reactor. Although scientists have been able to generate a small amount of heat by controlled fusion, they have not succeeded in generating large amounts of heat from controlled fusion in a profitable way.

MAXWELL, JAMES CLERK (1831-1879)

James Clerk Maxwell is the one theoretical physicist between Isaac Newton and Albert Einstein of a stature comparable to theirs. Maxwell's contributions to science ranged over many areas, of which the two greatest were his creation of the electromagnetic theory of light, and his work on molecular physics, gas theory, and statistical mechanics. He entered the scientific scene in the early 1850s, immediately after the principle of conservation of energy had been established. Its impact is seen everywhere in his work.

A descendant of a distinguished Scottish family, the Clerks of Penicuik, and, by an illegitimate line, of the ninth Lord Maxwell, he was born in Edinburgh but lived much of his life at his estate in Galloway in southwest Scotland, where he inherited 2,000 acres of rich farmland. From the ages of ten to nineteen he was educated in Edinburgh, entering the University of Edinburgh in 1847. At nineteen he went on to Cambridge University to take the rigorously severe mathematical *tripos*, from which he graduated in 1854 second in order of merit. He became Fellow of Trinity College in the following year and then, in 1856, at twenty-five, was appointed professor of natural philosophy at Marischal College, Aberdeen. In 1858 he married Katherine Mary Dewar, daughter of the principal. Though lacking any prior scientific training, she became an enthusiast in experimental research and worked closely with Maxwell on several experiments, first in color vision and then in physics. They had no children.

In 1860 Maxwell became a professor at King's College, London, where he served for five years. He retired from professorial life in 1866, at the age of thirty-five, to spend six years writing his famous *Treatise on Electricity and Magnetism* (1873). During the same time he also produced his small but important *Theory of Heat* (1871). In 1871 he was appointed Cavendish Professor of Experimental Physics at Cambridge and was responsible for designing and setting up the Cavendish Laboratory. Maxwell died of abdominal cancer in 1879 at age forty-eight.

ELECTROMAGNETIC THEORY

When Maxwell began studying electricity and magnetism in 1854, the field was in a state of confusion. The laws of electric and magnetic force had been established by Charles Augustin de Coulomb in the 1780s, and impressive mathematical structures had been built on them. However, the triumph was unsettled by Hans Christian Oersted's discovery in 1820 of electromagnetism—a peculiar twisting action exerted by an electric current on a magnet. This departure from Newtonian attractions and repulsions met two contrasting reactions. André Marie Ampère sought to reinterpret Oersted's force as a disguised form of attraction. Michael Faraday treated it as primary and related it geometrically to properties of lines of magnetic and electric force.

It is wrong to see Maxwell's achievement as one of merely translating Faraday's ideas into precise mathematical language. Though he once described Faraday as "the nucleus of everything electric since 1830," two other men, William Thomson (Lord Kelvin) and Wilhelm Weber, were equally influential.

From Faraday Maxwell gained a way of thinking; from Thomson, the first mathematizations of Faraday's ideas and several groundbreaking connections to the concept of energy; from Weber, the remarkable insight that the ratio of the two kinds of force, electrostatic and electromagnetic, somehow involves a velocity.

Between 1855 and 1868 Maxwell devoted great effort (five substantial papers) to clearing up the confusions in electromagnetism. The outcome was the dramatic discovery that light is an electromagnetic phenomenon, and the prediction—twenty-seven years before they were detected by Heinrich Hertz—of radio waves. Crucial was Maxwell's devising in 1861 of a speculative "ether" transmitting Faraday's lines of magnetic force. To his astonishment he found that this ether would transmit waves. Using some measurements by Weber and Friedrich Kohlrausch, Maxwell then calculated their velocity and found, to his even greater astonishment, that it was just equal to the velocity of light. Thus the great discovery was made and thus began the great intellectual metamorphosis, shaped by Maxwell and Einstein, in which the velocity of light was transformed from an isolated quantity into a universal fundamental constant influencing every part of physics.

The essence of Maxwell's later development of his theory was in the electromagnetic equations and the idea that electric and magnetic energies, instead of being located on charged bodies, are disseminated through space. That he could so quickly discard his ether model was closely related to the new doctrines of energy. Rather than attempt to explain light or electromagnetism in terms of a mechanism, Maxwell demonstrated that one set of unexplained equations describes both. Philosophically, the theory became a theory of relations. In this line of thought, Maxwell was strongly influenced by his mentor at Edinburgh, Sir William Hamilton, who held that all human knowledge is of relations rather than absolutes.

Maxwell's *Treatise on Electricity and Magnetism* (1873) covered every branch of the science and was a source of ideas and discoveries for fifty years to come.

GASES, MOLECULES, AND STATISTICS

In 1859 Maxwell, who had just completed a famous essay on the structure of the rings of Saturn, chanced to read a paper by Rudolph Clausius on gas theory. Maxwell had proved that the rings had to be composed of large numbers of independent bodies constantly colliding with each other. Clausius, expanding on earlier work by James Prescott Joule and August Karl Krönig, proposed that in a gas the rapidly moving molecules are constantly colliding. His interest at once aroused, Maxwell in a few months had written the first of several papers that created the modern kinetic theory of gases.

Maxwell's and Clausius's innovations were of two kinds, mathematical and physical. Mathematically, the key to dealing with large numbers of molecules was statistics, used not as a means of processing scientific data but as a fundamental explanatory idea. Clausius recognized that molecules must travel a certain average distance between collisions—the mean free path—but restrictively assumed that they all have the same speed. Maxwell transformed the discussion by introducing his velocity distribution function, giving the proportion of molecules traveling with a particular speed. Armed with this mathematical weapon, he could attack many previously intractable physical phenomena. He obtained theoretical formulas for viscosity, diffusion, and heat conduction in gases that then could be compared with experimental data. One startling consequence was that the viscosity of a gas should be independent of its pressure. When this was confirmed in independent experiments by Oskar Emil Meyer and by Maxwell and his wife, it added tremendous credibility to the theory.

The work on gas theory had many extensions. In 1865 Johann Josef Loschmidt used estimates of the mean free path to make the first generally accepted estimate of atomic diameters. In later papers Maxwell, Ludwig Boltzmann, and Josiah Willard Gibbs extended the mathematics beyond gas theory to a new generalized science of statistical mechanics. When joined to quantum mechanics, this became the foundation of much of modern theoretical condensed matter physics.

Through his famous "demon" Maxwell addressed one mystery of energy physics: the relation between the first law of thermodynamics, which states that energy as a whole is conserved, and the second law, which states that mechanical energy will be gradually dissipated. Maxwell was the first person to realize and forcefully argue that the second law is a statistical rather than a dynamical truth. Following this clue, Boltzmann in 1872 found the exact formal expression relating entropy to probability. Their work, together with earlier reflections by Kelvin, framed a discussion of irreversibility in physics, embracing even the nature of time, that has continued to this day.

Julius Robert Mayer. (Library of Congress)

MAYER, JULIUS ROBERT (1814–1878)

In the early nineteenth century many scientists had glimmerings of the conservation-of-energy principle. The three most important among these were the Frenchman Marc Séguin, the American-born, well-travelled soldier of fortune Benjamin Thompson, and the chief engineer of the city of Copenhagen, Ludwig Colding.

The three men whose work later in the nineteenth century was crucial in bringing clarity to this principle were two Germans, the physician Julius Robert Mayer and the great polymath Hermann von Helmholtz, and the British amateur scientist James Joule. In a lecture delivered by Helmholtz on February 7, 1854, in Königsberg on "The Interaction of Natural Forces," he referred to Mayer as "the founder" in 1842 of the principle of conservation of energy and acknowledged Mayer's priority in this discovery over Colding (1843), Joule (1843), and Helmholtz himself (1847). Rudolf Clausius agreed with Helmholtz and put Mayer in touch with the British physicist John Tyndall, who quickly became Mayer's English champion in his long-drawn-out priority dispute with Joule and his British supporters, William Thomson (Lord Kelvin) and George G. Stokes.

MAYER'S LIFE AND CONTRIBUTIONS TO SCIENCE

Julius Robert Von Mayer was born in 1814 in Heilbronn, a small town on the Neckar river, halfway between Heidelberg and Stuttgart. Interested in science as a youth, he decided on a career in medicine, and in 1832 began his medical studies at the University of Tübingen. After completing his studies there in 1838, he received his M.D. degree.

In February 1840, Mayer embarked for a year as physician on a freighter carrying cargo to Jakarta in the East Indies, just south of the equator. In Jakarta he noticed that sailors' venous blood was a much brighter red than he had observed in patients back in Germany. He surmised that this change was due to the hot climate and the reduced oxidation needed to preserve normal body temperature. This stimulated him to thinking more generally about how heat affects human metabolism. This interest in heat, work, and what is now called energy became the passion of Mayer's life.

Mayer returned to Heilbronn in 1841, began his medical practice, and eventually became chief surgeon of the town. In his free time he did some experiments and struggled with difficult, abstract concepts in an attempt to understand the nature of energy. He knew so little physics from his one semester of the subject at Tübingen that many of the papers he submitted for publication were rejected as incompetent by the important scientific journals of the day. He was forced to publish most of his writings at his own expense, and so their circulation was confined primarily to Heilbronn residents.

The first published results of Mayer's work appeared in the March 1842 issue of *Liebig's Annalen der Chemie und Pharmacie* in an article entitled "Remarks on the Forces of Inanimate Nature." It contained a great deal of philosophy and some inaccurate science, and yet buried among these distracting elements was the essence of the conservation-of-energy principle. Perhaps more important to scientists, the article contained the first quantitative attempt to determine the relationship of the "calorie" (a unit of heat) to what is now called the "joule" (a unit of energy).

Mayer's calculations were based on his conviction that there is a definite quantitative relationship between the height from which a mass falls to the ground and the heat generated when it strikes the ground. Here he was stating his conviction that energy is conserved in this process if heat is considered a form of energy. He calculated the ratio of the joule to the calorie, and found that it was equal to 3.59 J/cal, which differs considerably from today's accepted value of 4.18 J/cal. His whole approach to the problem was correct, however, and his numerical result was certainly of the right order-of-magnitude, but he had used inaccurate values for some constants needed in his calculation.

Few details of his research were given in Mayer's 1842 paper, but in 1845 he published (at his own expense) his most original and comprehensive paper, "Organic Motion and Its Relation to Metabolism," in which he gave full details of his earlier work. In 1848 he also published, again privately, "Contributions to Celestial Dynamics," in which he made the interesting conjecture that the source of the energy radiated by the sun was its constant bombardment by high-energy meteors.

Mayer had married in 1842, and for the first few years his marriage was a very happy one, but then his life began to fall apart. Between May 1845 and August 1848 three of his children died. A nasty priority controversy with Joule became public when their claims were read and discussed by the Academy of Science in Paris. Mayer was upset that his writings on energy conservation were not more widely read, and that they often were not appreciated by the few scientists who did read them. And, as the final blow, he was accused by local scientists of being more a mad philosopher than a competent scientist.

Finally on May 28, 1850, in a fit of despair, Mayer threw himself out of his bedroom window to the street thirty feet below, but escaped without serious injury. He spent three years in mental hospitals and did little scientific work of value after his release in 1853, although he was able to return to limited service as a physician in Heilbronn.

Physicists around the world gradually came to appreciate Mayer's scientific work, but by this time they were unsure whether he was still alive and, if so, what his mental condition was. In his later years he finally reaped some fruit from his scientific labors. In 1859 he received an honorary doctorate from the University of Tübingen. This was followed in 1871 by his reception of the Copley Medal from the Royal Society of London, and then the Prix Poncelet from the Paris Academy of Sciences. It is unknown how appreciative Mayer was of this belated notoriety when he died of tuberculosis in 1878.

MECHANICAL TRANSMISSION OF ENERGY

Mechanical devices are used to magnify the applied force (mechanical advantage), to magnify the distance moved, or to change the direction of the applied force. They of course cannot decrease the amount of work (force × distance) necessary to do a job; they only make it more convenient to do it. In many cases, without a machine, the job would be impossible.

There is generally considered to be five distinct simple machines: lever, wedge, wheel and axle, pulley, and screw. The transmission of energy by these simple machines is so basic that people use them with little understanding of the physical principles involved. Most learn their use intuitively, through experience, and consider their application just plain common sense.

THE BASICS

The history of the origin of simple machines is largely conjectural, but there also exists documentation of the ancient Egyptians using simple machines to build pyramids nearly 5,000 years ago. An inscription in a 4,000-year-old tomb tells of 2,000 men pulling a statue estimated at 132 tons into place. The mass of the 2,000 men would be about the same as the mass of the statue, and it would probably take that many because they moved it on sledges without wheels.

The use of simple machines has sometimes been taken as a definition of what separates humans from animals; however, some primates have been observed fashioning probes out of sticks to pry out or to reach food. One of the most powerful images depicting the use of tools as defining humanity is the opening scene in the movie *2001*. An ape has discovered the club and is bashing some bones. One of the bones flies upward and in slow motion morphs into a spaceship. The club or the hammer is such a basic tool that it does not even make it into the classical listing of the five simple machines. However, it is also a mechanical device that multiplies force and transmits energy.

In the transmission of energy by these simple machines, the conservation law always applies: The work input equals the work output. When work is done *by* a system, energy is transferred out of it; and when work is done *on* a system, energy is transferred into it. When two objects interact by way of a machine (e.g. a lever), the work out of one object equals the work into the other. The work done by a person forcing one end of a lever downward equals the work done lifting a load at the other end as the lever moves upward. In any practical situation, the frictional forces resisting motion will always increase the amount of force (and work) required to do a job.

The amount of work done on an object is determined by the force exerted on it multiplied by the distance it moves in the direction of the force. Therefore the key to figuring out how much the force is magnified by a simple machine is to compare distances moved. For example, if the end of a lever under a stone weighing 2,000 newtons moves upward 1 meter, the amount of work done lifting the stone is 1 meter × 2,000 newtons = 2,000 joules. An equal amount of work must be done by a person on the other end of the lever. If that end of the lever is pushed downward 2 meters, then the person needs to apply a force of only 1,000 newtons to do the same amount of work (2,000 joules) and lift the 2,000 newton stone.

In brief, the mechanical advantage of a lever or any machine equals the ratio of the distance the applied force moves to the distance the load moves.

THE LEVER

The lever is such a part of everyday activity that its application usually requires no conscious thought: the pop top on a soda can, a doorknob, a wrench, pliers, a fishing pole, a faucet with a handle that lifts, a wheelbarrow, fingernail clippers, and so on. The crank and winch used to pull a heavy boat out of the water up onto a trailer can be thought of as a lever in circular form.

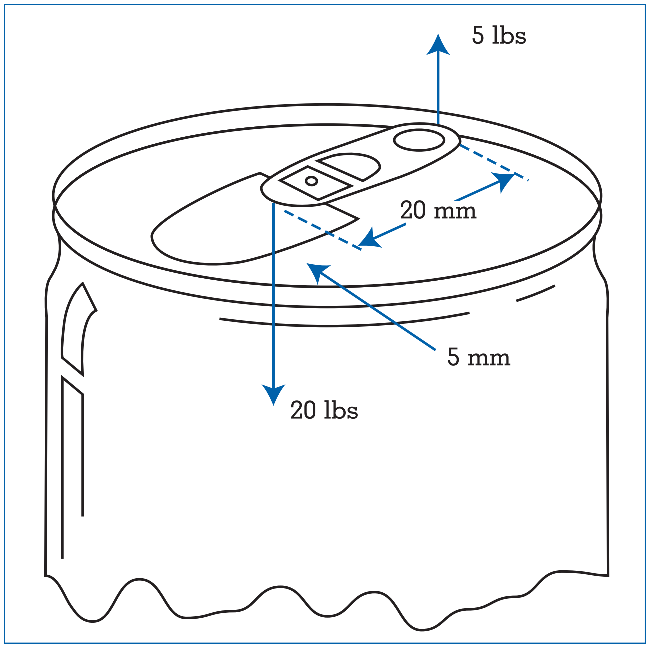

Figure 1.
Standard design of a can with a pop top.

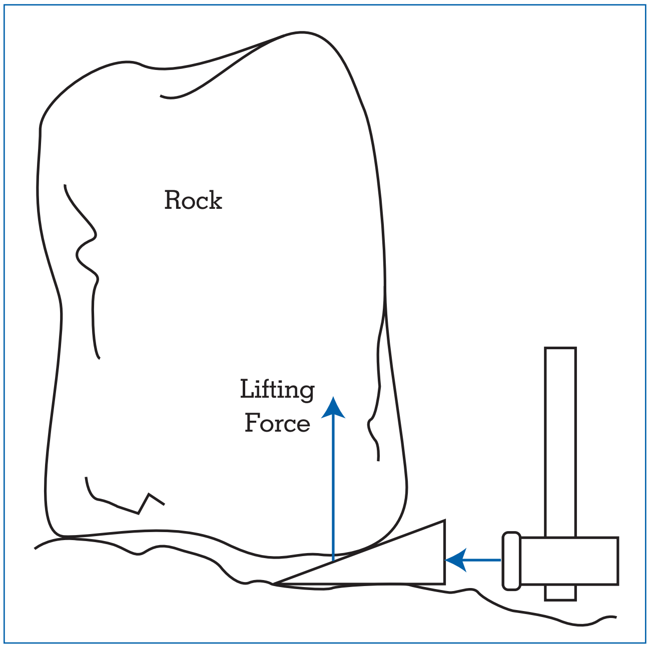

Figure 2.
Forces involved in the use of a wedge and hammer.

Basically, a lever is a solid object with an axis about which it rotates (fulcrum). As the lever rotates about its fulcrum, a point on the lever farther from the fulcrum moves a greater distance. The conservation of energy applied to the lever results in the fact that the output force times its distance from the fulcrum equals the input force times its distance from the fulcrum. A little experience lifting heavy loads with a lever soon teaches one that to maximize the output force, the load should be placed as close to the fulcrum as possible and the input force as far from the fulcrum as possible. To dramatize the nearly infinite possibility of the lever to magnify force, Archimedes said that if he had a lever long enough and somewhere to stand, he could move Earth.

As an illustration of the lever, consider the current design of the pop top on a popular brand of cola (Figure 1). The built-in opener is a piece of aluminum 25 mm long, made rigid by crimping its edges. The fulcrum is 5 mm from the end which presses into the top of the can to "pop" it open. This leaves 20 mm from the fulcrum to the end, which the user lifts up on with a force of about 5 pounds to open the can. (Since ratios of quantities are involved, there is no problem with mixing English and metric units.) The ratio of distances is 20 mm/5 mm = 4, which means that the opener presses into the top of the can with a force of 4 × 5 pounds = 20 pounds. If the built-in opener is missing, it is necessary to open the can by pressing a small object such as a key into the top with a force of 20 pounds. It is not impossible but it is awkward, and a slip could be messy.

THE WEDGE, THE INCLINED PLANE, AND THE SCREW

These three simple machines change the direction of the applied force as well as magnify it. Each one's operation can be understood by nearly the same physical principles.

A wedge is fairly easy to understand. One side of a heavy rock can be lifted a small amount by pounding a wedge under it, as illustrated in Figure 2. If friction is neglected, the force pushing the wedge under the rock is magnified by the ratio of the distance the wedge moves to the amount the rock is lifted. This follows from requiring the work done by the driving force to equal the work done in lifting the rock. This magnification is the ratio of the length of the wedge to its width, and is obviously greater the smaller the angle of the wedge. The friction force of the wedge against the rock decreases the available lifting force, but it is to

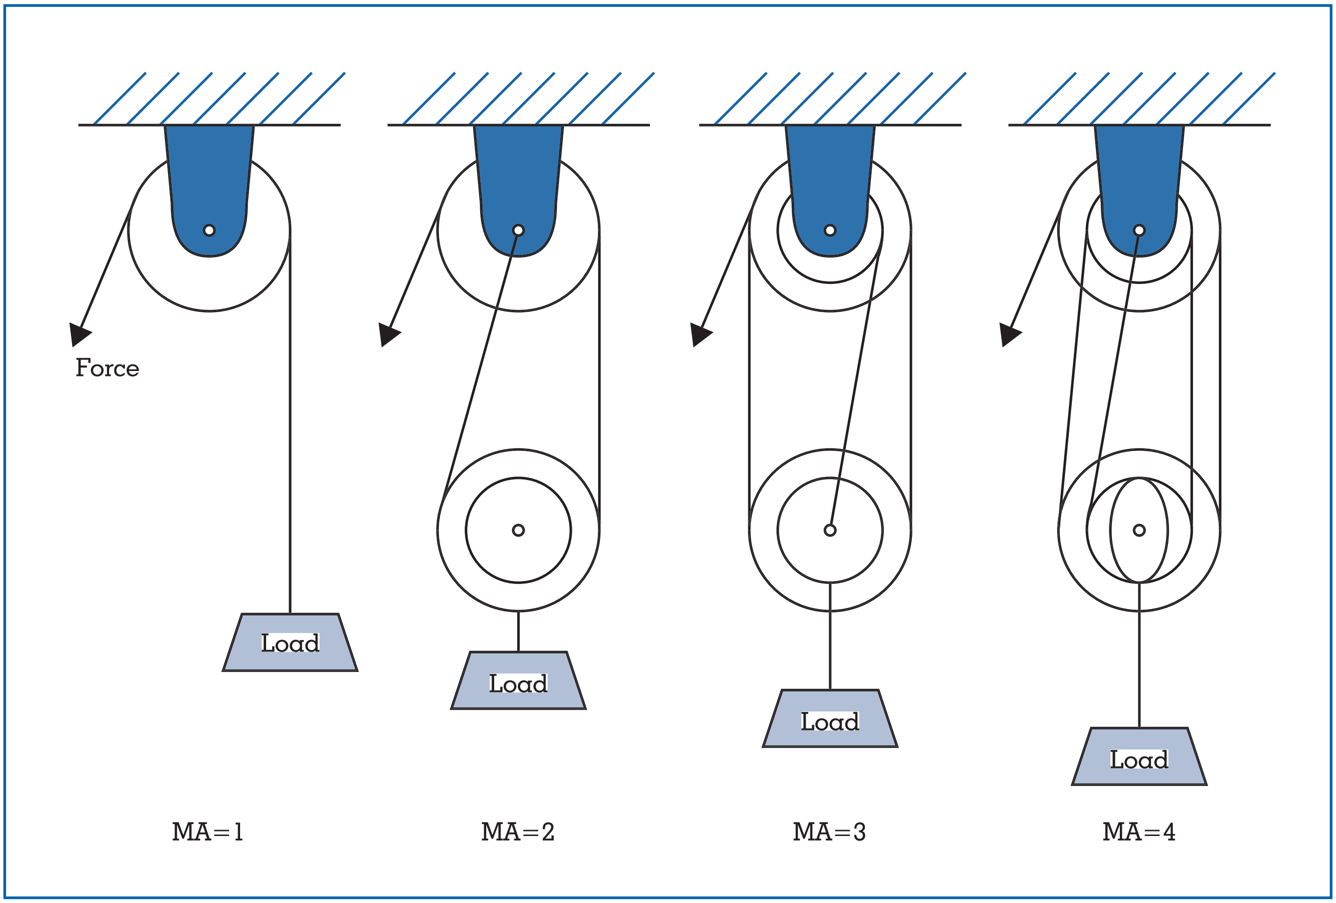

Figure 3.
Pulley systems with varying mechanical advantages.

some extent an advantage. It holds the wedge in place even when no driving force is applied. A wedge is usually used in combination with a hammer.

The hammer itself is an important simple machine used to magnify force. The ape in *2001* was shown inventing the hammer or the club. The user applies a force on the hammer through a relatively large distance, giving it kinetic energy. The hammer comes into contact with an object, compressing it or moving it some short distance. The average delivered force depends on how much compression or motion of the object there is and on whether the hammer rebounds off the object. The mechanical advantage is approximately the ratio of the distance the hammer moves to the distance the wedge, for instance, moves. A person might apply a relatively small force to a hammer for a 1-meter swing. If it drives the wedge 1 millimeter, then the mechanical advantage is 1,000. No wonder that striking a wedge with a hammer can lift an object weighing several tons.

The inclined plane is stationary, and the load to be lifted is moved; whereas it is the other way around for the wedge. The force is magnified by the ratio of the distance the load is pushed to the height through which it is lifted. Again friction will increase the amount of force that has to be applied. If the coefficient of friction is large enough (at least as great as the tangent of the angle of incline), then the load will not slip back down the incline when the pushing force is released. For most materials (coefficient of friction greater than, 0.6 say), an angle less than 30 degrees will keep the load from slipping back on its own. This allows the pushers to take a break to regain their strength before finishing the job. Or they can push the load up the incline a little at a time by lunging at it. In this way they play the role of the hammer relative to the wedge as they collide with the heavy load.

The screw is an inclined plane that is conveniently wrapped around a circular cylinder. The incline of the screw is in the form of a helix similar to a spiral staircase. The mechanical advantage is the ratio of the distance the driving force moves in a circle as it rotates the screw to the distance the load is lifted. A screwdriver with a large handle will provide a larger mechanical advantage, as will a screw with threads closer together. By using a screw jack with a long enough handle, a person can easily lift an automobile or a house. Again, friction conveniently keeps the screw from backing up on its own so that the user can just leave the jack supporting the load, assured that the jack will stay in place.

THE PULLEY

A fixed pulley is a device for changing the direction of an applied force. A common form is a mounted wheel with a rim around which a rope passes. In a very primitive form it could be a vine looped over a tree branch. A pull downward on the rope (vine) results in lifting a load on the other end. Neglecting friction, the mechanical advantage of the single fixed pulley is 1; the load moves the same distance as the applied force.

A combination of fixed and movable pulleys can achieve larger mechanical advantages. The diagrams in Figure 3 show systems of pulleys with mechanical advantages of up to 4. The mechanical advantage is always the ratio of the distance the applied force moves to the distance the load moves. Another, and perhaps easier, way to determine the mechanical advantage of a system of pulleys is to count the number of rope segments that support the load. That number is the mechanical advantage.

Friction is a very important factor in the actual mechanical advantage of a system of pulleys because the frictional losses are compounded each time the rope passes over a pulley. For a typical coefficient of friction of 0.03 (greased shaft with no ball bearings), the system with a theoretical mechanical advantage of 4 would be decreased by friction to an actual mechanical advantage of about 3.5. The largest mechanical advantage that could be obtained with pulleys having a coefficient of friction of 0.03 is about 16 no matter how many pulleys are used. A coefficient of friction of more than 0.333 (such as a vine over a tree branch) results in an actual mechanical advantage of less than 1 for any system of pulleys.

The friction coefficient of 0.03 used above is so low due to the advantage of a wheel on an axle. The friction force at the axle of the pulley wheel is overcome by a smaller force applied at the rim in accord with the principle of the lever.

The friction forces in a pulley system will never hold the load by themselves, but the effort required can be quite small. In the case of a block and tackle used to lift an engine out of an automobile, the weight of the chain hanging from the last pulley may be enough to keep the engine in place. By wrapping a rope once around a post, a cowboy can hold a raging bull in check.

GEARS

Gears are used almost entirely in rotary motion applications, and as such it is easier to discuss the mechanical advantage as a multiplication of torque rather than as a multiplication of force. The work involved in rotary motion is torque times angle; whereas for the linear motion discussed above, it is force times distance.

Torque arises when a force is applied so that it tends to rotate an object about an axis. The force must have a component at right angles to the axis and at some distance from the axis. The torque produced is the product of the force component and its perpendicular distance from the axis. The units of torque turn out to be the same as the units of energy: force × distance. However, torque is not energy. An angle is the ratio of two lengths (arc length/radius for the angle in radians) and has no units; thus the work in rotary motion (the product of torque and angle) has the appropriate units for work.

Upon comparing the work input with the work output for a gear system similar to the one shown in Figure 4, the mechanical advantage is found from the ratio of the angles turned by the respective shafts as the gears engage. This ratio in turn is equal to the ratio of the numbers of teeth on each gear. For example, if a gear (pinion) with 10 teeth drives a gear with 40 teeth, the mechanical advantage is 4—that is, the torque imparted to the large gear is 4 times the torque input by the small gear. There is a commensurate speed reduction; the large gear will rotate once for each four revolutions of the small gear.

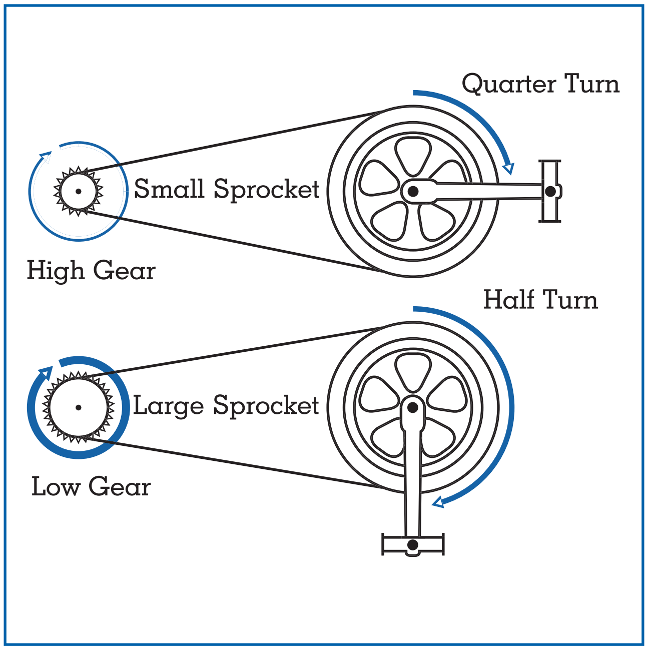

Figure 4.
Gear set with a 12/24 ratio.

Gears may be used to increase the available torque, as in most applications of electric or internal- combustion engines, or to increase the amount of motion, as in a bicycle.

In an automobile, except for the highest gear, the transmission reduces the rotation rate of the drive shaft relative to the engine speed. The differential gears further reduce the rate of rotation. For a typical automobile cruising at 60 mph, the engine runs at about 2,000 rpm while the wheels turn at about 800 rpm giving a mechanical advantage of 2,000/800 = 2.5.

For a typical 21-speed bicycle, on the other hand, the lowest gear ratio is 1.0 and the highest is nearly 3.5. In the highest gear the wheels rotate 3.5 times for each rotation of the pedals. The torque with which the rear wheel propels the bicycle is less than the torque exerted on the pedals by a factor of 3.5. The propulsion force is further reduced by the fact that the radius of the pedals is less than the radius of the rear wheel. The advantage of a bicycle is basically that the wheels move faster than the pedals, coupled with the fact that it takes very little force to overcome the rolling friction of the wheels on a hard, smooth surface. This allows the rider to move faster than a pedestrian using the same energy. However, there is no advantage in force even in the lowest gear. To climb a really steep incline with a bicycle, it is better to get off and walk. From a standing start the greatest acceleration is achieved by pushing the bicycle.

BELTS AND CHAINS

Another function of the transmission of energy by mechanical means is to transfer the motion of a rotating shaft to another shaft at a distant location. A historical application was to get the rotation of a waterwheel coupled to a mill located safely away from the stream in order to grind grain. Another was to drive several rotating machines in a factory from a single large steam engine. Before the invention of the electric generator and the electric motor this type of problem was solved by the use of belts. Today it would be ridiculous to use belts in this way. Think how complicated it would be to connect the power company's spinning steam turbine to a refrigerator in a home by means of belts. Electricity makes it easy. The power is distributed electrically through relatively small wires to drive individual small electric motors.

Today belts are used in automobiles to drive auxiliary devices such as air conditioning, power brakes, power steering, the alternator, and the cooling fluid pump. Belts also can be found in household appliances such as vacuum sweepers, on lathes in machine shops, or inside copying machines.

A belt drive is an inexpensive solution for transmitting mechanical energy over short distances. Compared with machining precision gears, fashioning two pulleys to be linked by a belt is not technologically demanding. The mechanical advantage is the ratio of the diameter of the pulley on the load to the pulley on the driver. The length of the belt makes no difference. By adjusting the sizes of the two pulleys, the mechanical advantage can be conveniently changed. Also, one twist in the belt will reverse the direction of rotation. One disadvantage of a belt is that the amount of torque it can deliver is limited to the product of three factors: the coefficient of friction between the belt and the pulley, the force producing tension in the belt, and the radius of the load pulley.

A V-belt greatly increases the deliverable torque, since the wedging of the belt in the sheave groove increases the force of contact between the surfaces (N) far above the tension force (P). The driving action takes place through the sides of the belt rather than the bottom, which normally is not in contact with the sheave at all. This is yet another example of the application of the wedge as a force multiplier.

For a situation where large torques are involved, such as a bicycle drive, a chain linkage is superior to a belt. A person putting all his or her weight on a pedal probably would make most belt systems slip. Another advantage of a chain over a belt is that a chain is more efficient, mainly because it does not require any ambient tension. The return side of a chain drive has only enough tension to support itself. Furthermore, the chain links are equipped with rollers, which can rotate as they contact the teeth, reducing the frictional forces and wear.

The mechanical advantage of a chain linkage can be calculated by counting the teeth on the load sprocket and the drive sprocket. The output torque is found by multiplying the input torque by the ratio of the number of load teeth to the number of drive teeth. A chain drive is also compact compared to a belt. Imagine trying to arrange 21 speeds on a bicycle derailleur using belts.

A serious disavantage of belts and chains for transmitting energy is that they can be quite dangerous. Whereas the low torque of a bicycle chain rarely results in bad injuries when trouser cuffs or shoestrings get caught in the chain, high-torque industrial and agricultural machinery (such as mechannical reapers with numerous belts and chain drives) is another matter. They have caused many grave inuries and loss of limbs because of the tremendous torque that engines and motors transmit to belts and chains. Therefore, as a safety measure, almost all new equipment comes equipped with guards to prevent accidental injuries either from broken belts and chains whipping out with tremendous force, or the careless actions of workers.

MEITNER, LISE
(1878–1968)

In a 1959 lecture at Bryn Mawr College in Pennsylvania, Lise Meitner reflected that "Life need not be easy, provided that it is not empty." Life was not easy for any Jewish woman scientist in Germany in the first half of the twentieth century, and Meitner certainly had her own experience in mind when she made this statement.

Lise Meitner grew up in the Vienna of Emperor Franz-Josef and horsedrawn trolley cars. She was born there in 1878 into a well-to-do Jewish family and decided at an early age that she wanted to be a scientist like Madame Curie. (Later Albert Einstein would call her "the German Madame Curie.") In 1901, she entered the University of Vienna. There, where serious women students were considered odd, she was treated rudely by many of her fellow students. In 1905 she was only the second woman in the university's history to receive a Ph.D. in science.

In 1907, she went to Berlin to study under Max Planck, promising her devoted parents that she would return to Vienna in six months at the most. She stayed in Berlin for thirty-one years. In Berlin, Meitner met Otto Hahn, a professor of chemistry, and took an unpaid position assisting Hahn with his research on the chemistry of radioactive substances. At that time women were not allowed to work in the Chemical Institute, and she had to set up her laboratory in a carpenter's workshop outside the Institute.

While continuing work with Hahn at the new Kaiser Wilhelm Institute for Chemistry in Berlin-Dahlem, beginning in 1912 Meitner served as assistant to Max Planck at the Institute for Theoretical Physics at the University of Berlin, and in 1918 was appointed head of the physics department at the Kaiser-Wilhelm Institute.

Lise Meitner. (Library of Congress)

MEITNER'S CONTRIBUTIONS TO NUCLEAR ENERGY

In their years together Hahn and Meitner did significant research on beta- and gamma-ray spectra. They discovered the new element protoactinium-91 and, at Meitner's suggestion, took up, and made great progress with, work on neutron bombardment of nuclei that Enrico Fermi had commenced in Rome. In 1938, this research was suspended when Adolph Hitler annexed Austria and Meitner had to flee Germany.

Based on the strong recommendations of her German physics colleagues, Meitner received a research position in the Stockholm laboratory of Manne Siegbahn, the Swedish physicist who had received the 1924 Nobel Prize in Physics for his precision measurements on X-ray spectra. Siegbahn provided laboratory space for Meitner, but no suitable equipment for her to continue the research she had started in Berlin, and little encouragement for her work.

Meitner was left very much to herself in the Stockholm Physics Institute, which had little research in progress when she arrived in 1938. Meitner's stipend from the Nobel Foundation was a pittance, and she was forced to do without many of the little comforts she had grown used to in Berlin. It was a difficult time for her, relieved only by regular letters from Hahn containing news of what had once been their joint research effort.

At the end of 1938, Hahn sent her a description of his experiments on the interaction of neutrons with uranium. He and a young chemist, Fritz Strassman, had determined that one of the reaction products was clearly barium. Meitner was so excited about this that she showed Hahn's letter to her nephew, physicist Otto Frisch. Their discussions on the topic gave birth to the idea of nuclear fission.

Frisch then demonstrated in his laboratory the tremendous release of energy accompanying fission, and a short paper by Meitner and Frisch in the British journal *Nature* in 1939 revealed the momentous concept of nuclear fission to the scientific world. It provided a new source of energy for the Earth, while at the same time introducing the possibility of a new weapon capable of unbelievable destructive power.

The step from nuclear fission to a nuclear chain reaction and the atomic bomb was, in principle, quite straightforward. In practice, however, it consumed more time and money than was ever foreseen. Although it was her basic insight that eventually led to the fission bomb dropped on Hiroshima, Meitner refused to work on the bomb and, for humanitarian reasons, hoped that it would not work.

When the question of the award of a Nobel Prize in Physics for the discovery of nuclear fission arose at the end of World War II, it was complicated by the fact that both Hahn and Strassmann were chemists. Another complication was that the Nobel Prize Committee had always considered radioactivity and radioactive atoms the responsibility of their chemistry committee—despite the fact that the discovery of fission had been interdisciplinary from beginning to end. The Swedish Academy of Science was divided on whether the Chemistry Prize should be given jointly to Hahn and Meitner, or to Hahn alone. Finally they decided by a close vote to give the 1945 chemistry prize solely to Otto Hahn.

The physics prize was still in question, and many nominators were strong in their support of Meitner as the recipient. She had continued to correspond with Hahn and advise him from afar on experiments to be performed in Berlin, but when Hahn and Strassmann published their paper on barium as a reaction product of neutron bombardment of uranium, Meitner's name was not included as a coauthor. The Nobel Committee finally decided to award no physics prize for the discovery of nuclear fission in 1945, and gave the prize for that year to Wolfgang Pauli for his theoretical discovery of the Exclusion Principle.

After the war, although now famous, Meitner continued her research in Stockholm, interrupted only by trips to receive honorary degrees and other scientific accolades. She shared in the prestigious Enrico Fermi Prize awarded by the U.S. Atomic Energy Committee in 1966. She retired to Cambridge, England, in 1960, to be near her nephew, Otto Frisch, and died there in 1968 at the age of ninety. Like so many people all over the world during the Hitler period, Meitner's life had been far from easy, but no reasonable person would ever be tempted to call her life empty.

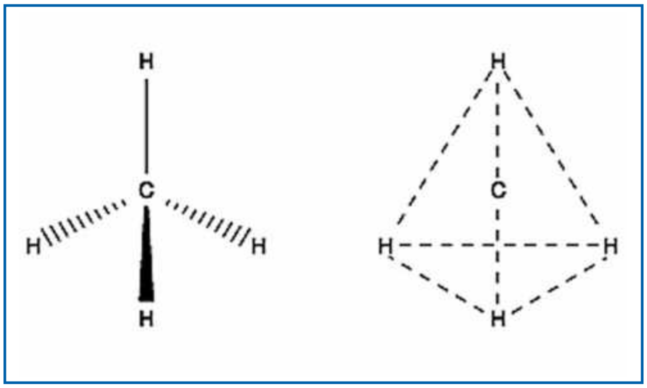
METHANE

The hydrocarbon methane (CH_4) is the major component of natural gas (around 90 percent) that is found in oil and gas wells throughout the world. Since the beginning of time, methane has also been produced by a number of biological sources—both natural and human—by the decomposition of organic material. From 1800 to 2000, atmospheric concentrations of methane, which are approximately 0.00017 percent, have grown around 150 percent. However, the patterns of methane emission is highly irregular and, for reasons yet unclear, the rate of increase slowed considerably from 1980 to 2000. The major natural releases of methane are from wetlands (marsh gas) and termites; the major human releases are from energy use, rice paddies, gaseous emissions from animals, human/animal wastes, landfills and biomass burning. Methane research is proceeding in two major directions: the energy course, looking for ways to make bioconversion of wastes to methane more economically attractive as an alternative fuel; and the environmental course, looking for ways to limit its release into the atmosphere since it is a much more potent greenhouse gas than carbon dioxide—a thermogenic effect four to six times that of carbon dioxide. The shared goal is finding ways to "harvest" for energy production much of the methane now being released into the atmosphere.



Molecular structure of methane. (Gale Group)

In the energy sector, many coal mines are looking at ways to put the methane produced as a result of the mining process to work instead of venting it into the atmosphere. The U.S. Environmental Protection Agency estimates that up to 40 percent of the methane that migrates to the atmosphere can be used for power generation (electricity and heat), injection into pipeline systems, methanol production, or onsite applications like coal drying. Besides methane sales revenue and greenhouse gas reductions, the removal of methane from coal seams could serve the vital function of decreasing the risk to workers of firedamp—methane-air mixtures igniting inadvertently.

A researcher checks a sealed poy of methane in Kajima Corp.'s newly developed system designed to break down organic waste. (Corbis-Bettmann)

Other energy sector concerns are methane emissions from unburned fuel, and from natural gas leaks at various stages of natural gas production, transmission and distribution. The curtailment of venting and flaring stranded gas (remotely located natural gas sources that are not economical to produce liquefied natural gas or methanol), and more efficient use of natural gas have significantly reduced atmospheric release. But growth in natural gas production and consumption may reverse this trend. Methane has the highest ratio of hydrogen to carbon of any fossil fuel (4:1), so switching to natural gas is increasingly seen as an attractive option for cleaner air and carbon dioxide reduction.

Unlike natural gas production, the biological production of methane is attractive from a sustainability perspective. Whereas the methane that sits in underground natural gas reservoirs is finite, the methane production from biological sources is potentially very large as well as renewable. Anaerobic bacteria digestion of organic materials, in the absence of air, can produce a biogas that is 60 to 70 percent methane (state-of-the-art systems have reported producing 95 percent pure methane), the rest being carbon dioxide and other trace gases. Burning this gas can provide energy for cooking and space heating, or electricity generation.

Bioconversion of manure-to-methane is accomplished with biogas devices called digesters: organic material fed into the digester tank is heated to increase the natural decomposition rate by microorganisms, and then a pipe carries the biogas to where it will be used. There is an outlet for digested residues that usually are used as fertilizer. Several demonstration projects are taking place that are showcasing the technology. The Mason Dixon Dairy located in Gettysburg, Pennsylvania, produces enough methane from cow manure to meet its power needs, with excess power sold to the local utility. However, wide-scale development is unlikely because the low margins characteristic of farming do not support the additional capital investment to build such an operation.

Landfill gas-to-energy is another promising way to reduce atmospheric release and provide inexpensive energy to local industry and communities. Boilers for steam heat, hot water and the generation of electricity can be designed to burn a blended fuel or fueled exclusively on landfill gas. Because large-scale landfill methane recovery projects are most economical when an industrial facility is located nearby, landfill gas-to-energy projects are few and can only provide a limited amount of energy.

Controlling methane release from wetland, rice paddies and gaseous emissions from animals is more problematic. The release from rice paddies and wet lands is slow, intermittent and takes place over a wide geographic area, and thus very difficult to control. Gaseous emissions from agricultural animals contribute to atmospheric accumulation of methane due to fermentative digestion that produces methane in the rumen (stomach). Although the rate of release is highly variable, affected by factors such as quantity and quality of feed, body weight, age and exercise, beef cattle and draught animals are suspected of contributing around 50 percent, dairy cows around 20 percent, and sheep around 10 percent. Higher quality feed standards, which increase the efficiency of nutrient use, are being recommended as a way to curtail these emissions.

Methane from renewable biological sources will never be a major energy resource, yet it can be a valuable addition to the energy supply mix. Nevertheless, whether methane comes from fossil fuel reservoirs or from bioconversions, it is certain to provide useful energy for many years to come.

METHANOL

Robert Boyle, an Irish chemist noted for his pioneering experiments on the properties of gases, discovered methanol (CH_3OH) in 1661. For many years methanol, known as wood alcohol, was produced by heating hardwoods such as maple, birch, and hickory to high temperatures in the absence of air. The most popular modern method of producing methanol, which is also the least costly, is from natural gas (methane) by the direct combination of carbon monoxide gas and hydrogen in the presence of a catalyst. Methanol also can be produced more expensively from oil, coal, and biomass.

Methanol accounted for less than one hundredth of one percent of total transportation fuel consumption in 1999. However, it is a high-octane, clean-burning liquid fuel that has been an important component of rocket fuel, and has been the fuel of choice for Indianapolis-500 race cars since 1965. Internal combustion engine vehicles can operate on methanol alone, but M85 (85% methanol and 15% unleaded gasoline), with an octane rating of 102, is a more common automotive fuel since it requires less dramatic vehicle modifications.

Automobiles that are designed to run on methanol need a few modifications to become flexible fuel vehicles (vehicles that run on either gasoline or methanol). First, for the fuel tank, fuel lines and fuel-injection equipment, the vehicle needs noncorrosive materials such as stainless steel and high-fluorine elastomers. Second, since methanol is a lower energy density fuel, fuel injectors must be larger to provide greater volumes of fuel, and vehicles must be equipped with larger fuel tanks to achieve a range comparable to a gasoline vehicle. Third, a fuel sensor that detects fuel composition is needed to relay information to the on-board computer. And finally, the lower volatility and higher heat vaporization of methanol requires a special starting system for convenient cold weather start-ups.

By 1996, California had about 13,000 cars and 500 buses and trucks running on methanol, which was more methanol vehicles than the rest of the United States combined. The driving force for methanol vehicle growth was stringent California emission regulations designed to improve air quality. Since methanol vehicles cost only marginally more than gasoline-only vehicles, and the combustion of M85 produces less smog-forming and toxic air pollutants than comparable gasoline-powered vehicle—around 30 percent of the non-methane hydrocarbons (HC), 20 percent of carbon monoxide (CO), and 10 percent of the nitrous oxide (NO_x) of conventional gasoline engines—fuel-flexible methanol vehicles were seen as a very cost-effective means of improving air quality. However, the near-term future for methanol vehicles looks bleak. Los Angeles had to scrap its methanol transit fleet in the late 1990s because of the corrosive effect of the fuel on the heavy-duty diesel engines. The oil companies also responded to the methanol threat by developing much cleaner-burning reformulated gasoline. Combined with the tremendous advances in vehicle technology, such as improved fuel injection, advanced computer controls, variable valve timing, and electrically heated catalysts, some standard model year 2000

THE UNTAPPED METHANE RESERVES: HYDRATES

Since methane is almost always a byproduct of organic decay, it is not surprising that vast potential reserves of methane have been found trapped in ocean floor sediments. Methane forms continually by tiny bacteria breaking down the remains of sea life. In the early 1970s it was discovered that this methane can dissolve under the enormous pressure and cold temperatures found at the ocean bottom. It becomes locked in a cage of water molecules to form a methane hydrate (methane weakly combined chemically with water). This "stored" methane is a resource often extending hundreds of meters down from the sea floor.

Some petroleum geologists believe that there may be more methane trapped in hydrates than what is associated with natural gas reserves. However, as an energy source, there is considerable uncertainty whether this methane can ever be recovered safely, economically, and with minimal environmental impact. The Russians have experimented with the use of antifreeze to break down hydrates at some onshore locations in Siberia. But perhaps a more promising approach would be to pipe warm surface water to the bottom to melt the hydrates, with a collector positioned to convey the gas to the surface. Another approach might be to free methane by somehow reducing the pressure on the methane hydrates.

Regardless of the "harvesting" method, before these vast methane hydrate reserves can become a viable energy source, ways must be found to minimize the impact to the ocean floor and ocean-bottom ecosystems, and to limit the amount of methane escaping into the atmosphere.

gasoline-powered automobiles not only can meet the California Air Resource Board's Ultra Low Emission Vehicle standards (HC: 0.040, CO: 1.7, NO_x: 0.040 grams/mile), but also the proposed Super Ultra Low Emission Vehicle standards (HC: 0.02, CO: 1.0, NO_x: 0.010 grams/mile).

In the rest of the United States, the primary use of methanol is as a chemical feedstock and in the synthesis of methyl-t-butyl ether (MTBE), the most widely used gasoline additive that boosts octane and reduces the level of emissions. To reduce carbon monoxide emissions, the Clean Air Act of 1992 designated thirty-nine areas in the United States where gasoline sold from November through February must contain 2.7 percent oxygen. MTBE, with an octane rating of 116, is the primary oxygenate additive. Oil companies favored MTBE over ethanol, which has an octane rating of 108, since gasoline formulated with MTBE runs more smoothly with less knock because of its higher boiling point, and MTBE does not vaporize out of the gas tank as quickly as ethanol. The downside for MTBE, however, is that it adds five to ten cents a gallon to the cost of gasoline and reduces gas mileage by around 10 percent. There have also been concerns about the toxicity of any spilled MTBE that may get into the water supply.

As a fuel, none of the four ways of producing methanol can compete with petroleum at its 1999–2000 price of $15 to $30 a barrel. The per-barrel price of oil would have to surpass $40 for methanol made from natural gas to become a competitive alternative, over $50 if the methanol was produced from coal, and close to $70 if it was made from wood. Although methanol is a cleaner burning fuel than gasoline and diesel fuel, when produced from natural gas, it generates more carbon dioxide emissions (which is suspected of contributing to global warming) than diesel fuel.

Although methanol's future is bleak as a fuel for internal combustion engines, its future is much brighter for fuel cell vehicles. Fuel cell vehicles run on hydrogen, yet due to hydrogen's low energy density, it is expensive to transport and store. Thus, auto makers are looking at ways to extract hydrogen from methanol through a device called a steam reformer. Steam reformers combine methanol with steam and heat to produce hydrogen, carbon dioxide and trace amounts of carbon monoxide (that must be removed by an oxidation reactor downstream of the reformer):

$$CH_3OH + H_2O \rightarrow XO_2 + 3H_2$$

By 1999, General Motors, Daimler-Chrysler, Toyota, and Nissan all had demonstration fuel cell vehicles operating on methanol, with plans to start introducing vehicles into the market by 2005. Auto makers have shown a preference for methanol over gasoline primarily because of the likelihood of the sulfur content in gasoline poisoning some of the catalysts used in the fuel cell.

Nevertheless, methanol still faces a major technological hurdle: the endothermic (requires heat) nature of the methanol steam reformer. Heat must come from an additional reactor to burn some of the fuel or exhaust gases from the fuel cell stack. It also takes time to reach operating temperature, which may be an unacceptable compromise for potential auto buyers accustomed to start-and-go vehicles. Additionally, if methanol for fuel cell vehicles began to capture a significant share of the transportation fuel market, it would require major investments in infrastructure. Gasoline and methanol cannot share the same distribution system since methanol can be highly corrosive and presents a greater fire hazard. And since methanol is much more toxic than gasoline, colorless and nearly odorless, greater precautions are needed to lower the risk of groundwater contamination from leaking storage tanks.

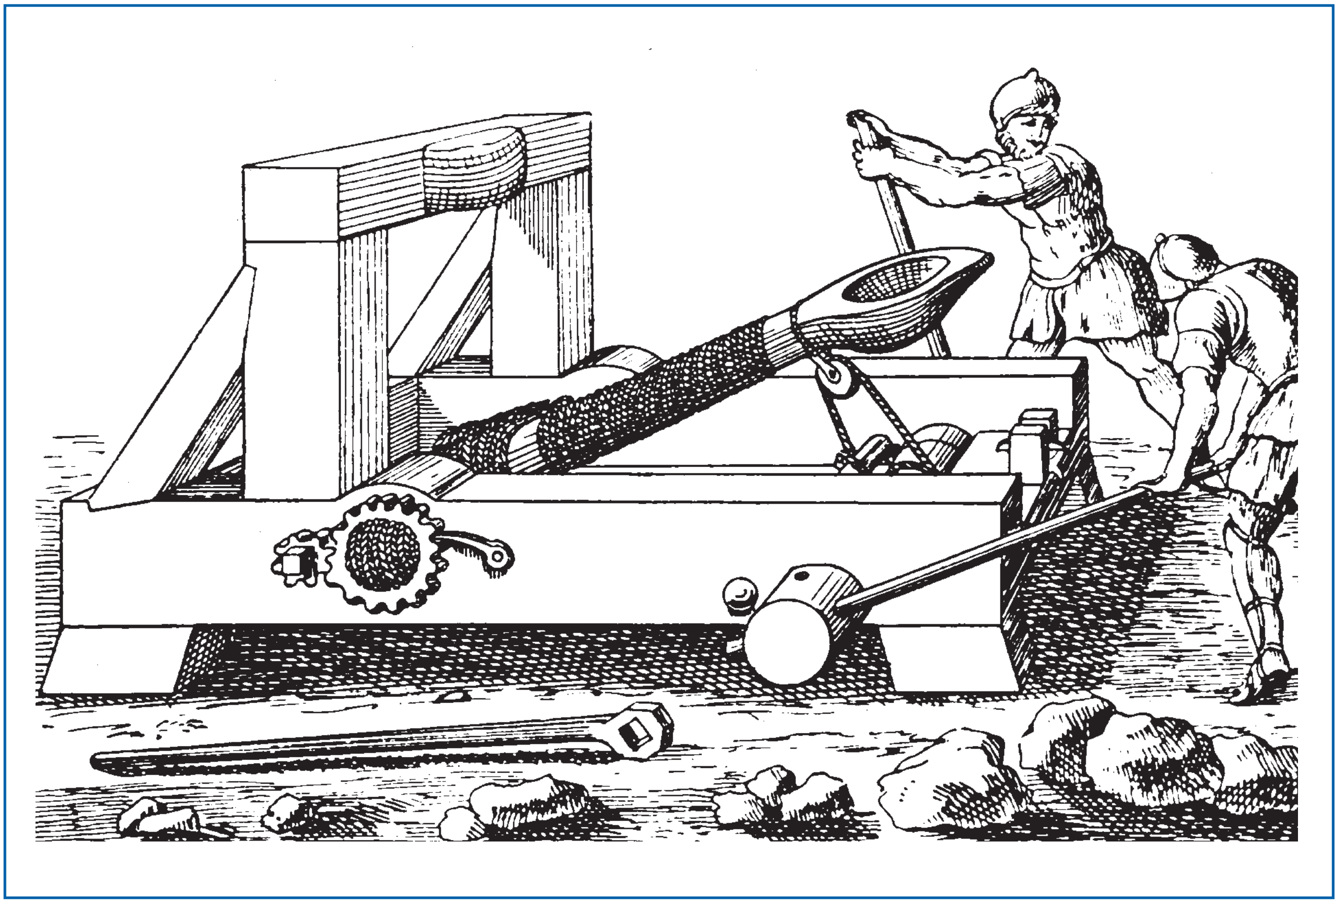
MILITARY ENERGY USE, HISTORICAL ASPECTS

According to historian Vaclav Smil, the destructive energy of military weapons has increased by sixteen orders of magnitude over the past five thousand years. The exploitation of inanimate energy sources has also resulted in the increased technical specialization of men-at-arms, with corresponding changes in the relationships between industry, the state, and military forces. Conquests were once limited by the availability of food for the pillaging troops; naval exploits were at the mercy of the winds, tides, and aggregate human energy of rowing crews. The discovery and subsequent harnessing of ever more efficient sources of energy unshackled the militaries of the Western world, but forced soldiers, sailors, and civilians to reexamine and redefine the place of the military in larger society. By the late nineteenth century, Western militaries were highly industrialized and bureaucratized institutions with intricate divisions of labor. Scientific enterprises, the purview of lone investigators and small collectives of enthusiasts before the nineteenth century, increasingly came under the direct control of state authorities.

ANCIENT HISTORY

Organized military aggression was limited to the use of human muscle power for thousands of years. Warfare was a matter of close-quarters combat, much of it hand-to-hand, and the energy expended in this activity was limited to the physical endurance of the participants. Personal kinetic energy weapons—slings, bows, and crossbows—increased slightly the fighting range of the combatants, but again the energy expended to kill others was limited to the strength of the warrior. The use of the horse as a combat mount increased the destructive energy available to the military, as cavalry were used to bear down on unprotected footsoldiers, although special weapons such as the pike, or architectural protections such as obstructions or fort walls, could limit the impact of the mass of the charging horse and rider.

Siege ballistic weapons, the largest of the early kinetic energy weapons, were developed and deployed to counter the protective walls and other stubborn defenses of cities and fortifications. The most dramatic early example of this kind of device was the catapult, invented in 399 B.C.E. in the siege workshops organized by Dionysus I of Syracuse. The early catapult used mechanical elastic energy to hurl projectiles and smash high fortification walls or disrupt formations of men. Although the catapult did not significantly extend the destructive range of the attacker, this device did allow for the use of projec-



Early example of a catapult. A simple lever is turned into a potent long-distance weapon. (Corbis Corporation)

tiles of ever greater mass, with a corresponding increase in the destructive kinetic energy applied to an opponent. Other offensive devices employed by Dionysus included the battering ram and siege tower, elements of the so-called "offensive-defensive inventive cycle," a kind of arms race that pitted fortress and city defenders throughout Europe and East Asia against marauding attackers. Although the application of kinetic energy to fortress walls could influence the course of a siege, the availability of biomass energy (food) for the consumption of attackers or defenders often determined the ultimate outcome of these stalemates that were so common in European and Near Eastern warfare before the fifteenth century.

The immediate availability of biomass energy, in the form of forage and food, placed serious constraints on military operations before 1850. Feudal political arrangements in Europe and Asia facilitated the growth of large armies capable of protracted warfare, but only at great human and monetary expense. The long-standing constraints on marching range and military strength were gradually addressed as emerging national governments created more effective systems of taxation and resource allocation to support military forces. Logistics, a system of energy distribution for the benefit of military forces, developed into a kind of science as emerging states recruited large standing armies and engaged in open warfare against other organized political groups. Although troops relied heavily on local food supplies (often with disastrous consequences for the local civilian population, as was the case during the Thirty Years' War in Central Europe from 1618 to 1648), the growth of logistics support institutions in the centuries that followed relieved some of the energy-demand burden from non combatants. The presence of logisticians, either civilian contractors or soldiers consigned to a support role, precipitated wider military reforms and the changing role of the army and navy in society at large.

Harnessing the energies of explosive materials, first in the form of gunpowder, produced a revolution in warfare, albeit a very slow one. Explosive powders were commonplace in Asia before the fifteenth century, although dynastic China did not use this material in an effective military capacity. Early hand-cannons, sometimes made of leather-wrapped iron cylinders, were little more than launch tubes for unrefined (and inaccurate) projectiles. The military firearm evolved slowly, beginning with the invention in the fifteenth century of the matchlock (or arquebus), followed by the invention of the German wheel-lock in 1515. The flintlock, subject to various mechanical improvements until the weapon was eclipsed in the nineteenth century by the breech-loading rifle, was a standard infantry arm by the close of the eighteenth century.

With subsequent improvements of these weapons, the explosive energy released by the combustion of gunpowder was harnessed to yield longer projectile ranges with more accuracy. State interest in firearms technology led to government sponsorship of scientific research into aspects of chemistry and ballistics in an effort to better understand the mechanics of explosive energy. The alignment of guilds and other productive tradesmen with military institutions in the sixteenth century foreshadowed a restructuring of the relationship between armies and industry in the years to come.

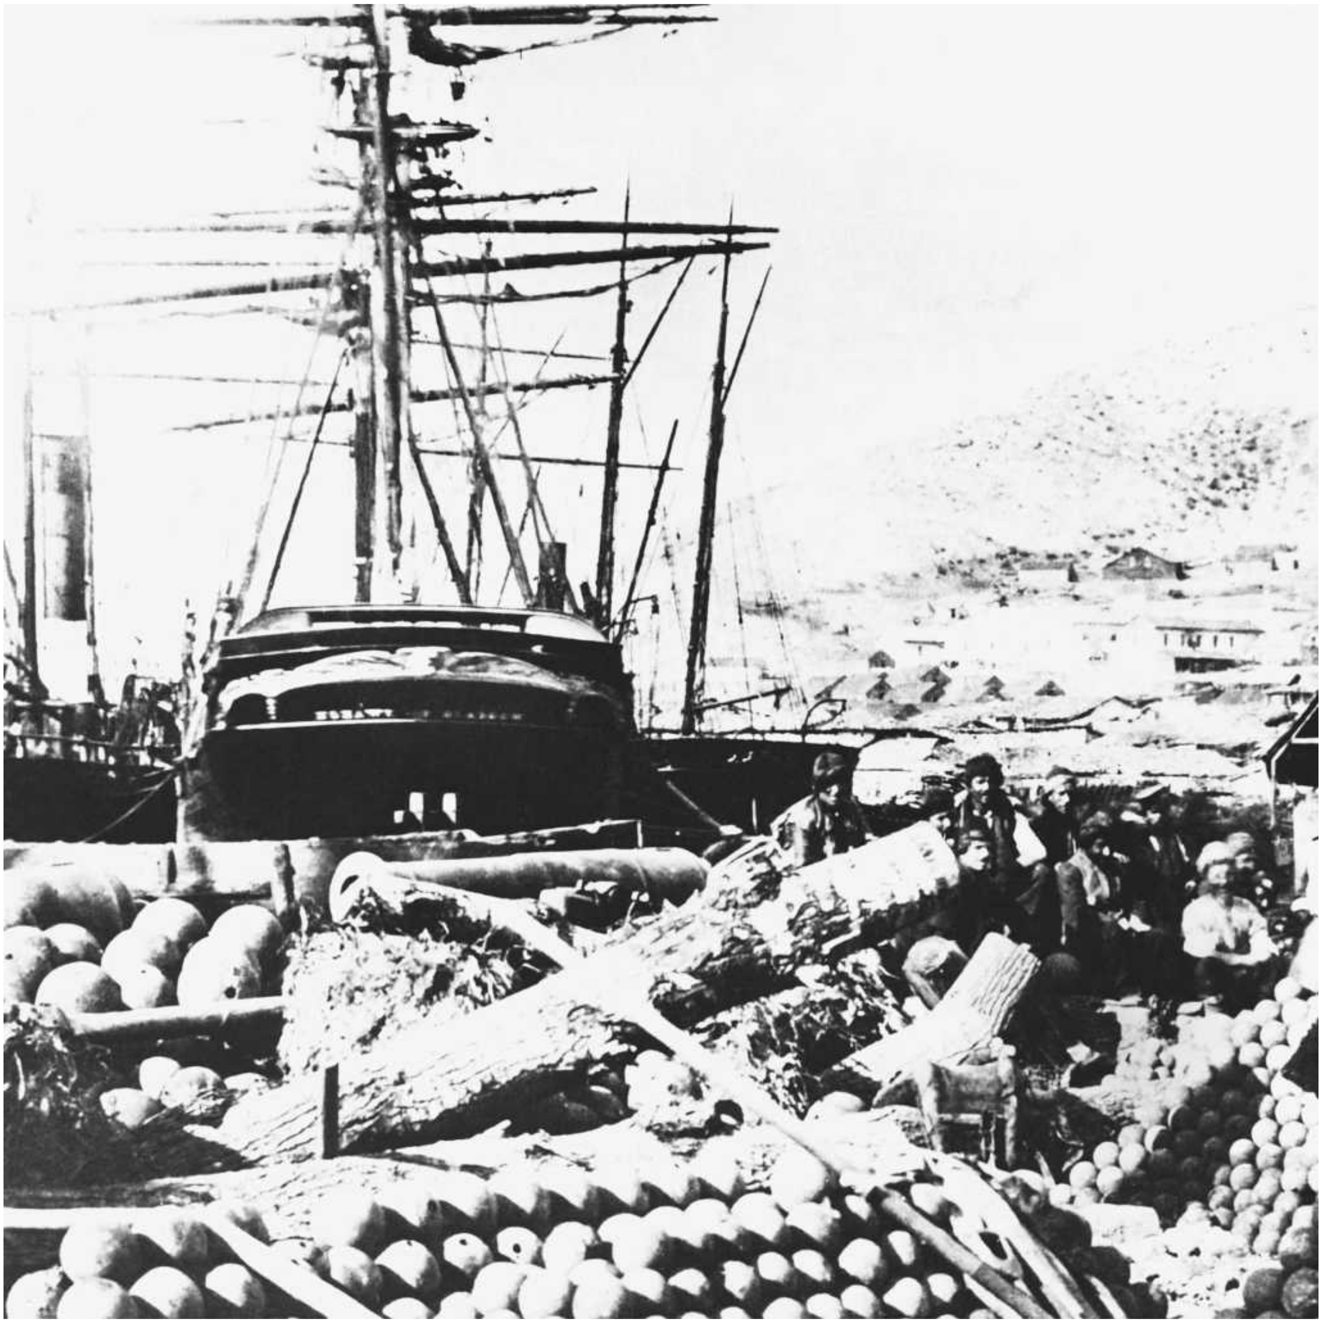
Gunpowder technologies heightened the competition between defense and offense, and raised the stakes for sovereign polities. Vauban, a French military engineer in the employ of Louis XIV, devised an innovative fortification system to respond to the threat of new siege techniques developed since 1400. Among these new threats was the increasing power of portable artillery and, more ominously, an improved form of "sapping," a process of undermining the walls of a fortification with explosives deposited by tunneling enemies. In the 1490s, the first portable siege guns were deployed as part of a larger military expedition organized by Charles VIII; within a century, small cannons could be found in the arsenals of every European power, as well as various kingdoms in India and Asia. Vauban's geometric fortifications were designed to maximize the firepower of the defenders with ramparts that would effect devastating cross-fires on any enemy bold enough to approach the high walls. The importance of specialists, such as miners, to the military endeavor stratified armies and increased the costs of warfare, but the effectiveness of new destructive energies made this kind of investment worthwhile.

THE AGE OF STEAM

One of the hallmarks of the industrial revolution, the steam engine, had important military uses. After nearly two centuries of labor-augmenting industrial use, steam power matured into a viable energy source for military applications in the nineteenth century. The same rails that were used to transport goods between the rural border regions and the urban centers of the Western world were also used for the rapid transportation of troops. In India, the "famine and security" lines built with the assistance of the British government in the late nineteenth century linked provincial territories with the administrative centers where military forces were housed. These rail lines were used to move food and other vital supplies to impoverished areas for relief of the population, or to move troops to quell civil unrest. Railroads proved to be important military assets during the American Civil War (1861–1865) and the Wars of German Unification (1864–1871); the rails served as arteries of support for the combatants. The rapid mobilization of troops in 1914, which eventually led to the horrors of stalemate on the Western Front, was facilitated by the efficiency of Western European railroads.

Guncotton (nitrocellulose) and nitroglycerine, substances that exponentially increased the explosive energy available to mankind, were developed in 1840. In 1867 Alfred Nobel found that nitroglycerine liquid could safely be absorbed in a clay-like substance called kieselguhr. This solid and relatively safe form of explosive became known as dynamite. In 1875, Nobel mixed nitroglycerine liquid with collodion cotton to make an explosive gelatin with both mining and military applications. These early forms of high explosive were refined into more powerful and destructive substances, including French Poudre B (1884) and ballistite (1888). By the 1880s, nitroglycerine (in various forms) and other nitrated organic compounds were important components of munitions manufacturing in Europe and the United States.

The development of high-energy explosives in the nineteenth century corresponded to a period of great



The war of 1854–1856 was fought mainly in the Crimean peninsula between Russia on the one hand and Great Britain, France and Turkey. Shown are cannonballs used during the war. (Corbis-Bettmann)

innovation in artillery design and manufacturing, as more powerful and longer-range guns were introduced into the arsenals of the West. The ranges of these weapons increased from about two kilometers in the 1850s to more than thirty kilometers in the 1890s. The production of the steel and powder necessary for the deployment of these weapons required a tremendous amount of energy, most of it derived from fossil fuels.

The expansion of the colonial empires between 1870–1900 involved the deployment of troops and military hardware to the far reaches of the world, and placed enormous energy demands on the economies of the imperial powers. The so-called tools of empire—steamships, the railroads, and canals—were energy-intensive projects with important military uses. The first oceangoing steam-powered naval vessels were commissioned in the 1850s, and were quickly demonstrated as important military tools. During the Crimean War, the British government nationalized a fleet of private steamships to transport men and supplies to the Ottoman Empire, an arrangement made possible by a special "militarization" clause inserted in the charter agreements between the British government and commercial shipping companies. Private and military fleets grew substantially in the decades that followed; during the period from 1870 to 1910, steam vessels became increasingly more energy-efficient and powerful. Around 1880, the triple-expansion steam engine was invented, followed by the introduction of the quadruple-expansion steam engine in the 1890s. These innovations made warships more fuel efficient with longer cruising ranges. This also meant that remote colonial possessions became more strategically important as coal refueling stations for modern naval forces.

The harnessing of electrical energy had a profound effect on the conduct of military operations. Perhaps most importantly electricity revolutionized communications, with consequences for the conduct of military affairs. The British telegraph network of the late nineteenth century connected the vast reaches of the empire to London, and other imperial powers were often beholden to the British system for news and diplomatic correspondence. In 1901, the first trans-Atlantic "wireless" communications system was demonstrated by Guglielmo Marconi, who promptly approached representatives of the American, British, and Italian navies with the hope of selling his invention. Wire-based telegraph and telephone systems, as well as the "wireless" radio, were adopted by the world's armed forces between 1900 and 1914. The defeat of a Russian expeditionary force in Eastern Asia at the hands of the Japanese army (1904–1905) was widely attributed to the latter's decisive use of the telephone and telegraph to coordinate the movement of troops and the distribution of supplies. The availability and proper application of inanimate energy, it seemed, was vital for the correct distribution of biomass during protracted campaigns, a necessary condition for victory.

Despite the obvious implications that new and more efficient inanimate energy resources held for the world's armies and navies, it was some time before military planners began to consider the importance of energy resources and infrastructure. In 1830 revolutionaries in Paris attempted to paralyze the state government by plunging the city into darkness by attacking the gasworks, the principle distribution center for the gas supply that fed the city's street lamps. The growing popularity of central electric plants in the United States and Europe around 1900 raised questions about the vulnerability and strategic importance of these facilities. By 1914, electric power plants, which supplied crucial power to the war industries, were being protected from sabotage by militiamen and professional soldiers. When called upon, military forces were deployed to disrupt the activities of striking coal miners and others who threatened economic stability or national security. In other instances, military forces were sent abroad to protect energy resources from the predations of other states.

OIL AND THE INTERNAL COMBUSTION ENGINE

Large-scale crude oil exploitation began in the late nineteenth century. Internal combustion engines, which make use of the heat and kinetic energy of controlled explosions in a combustion chamber, were developed at approximately the same time. The pioneers in this field were Nikolaus Otto and Gottleib Daimler. These devices were rapidly adapted to military purposes. Small internal-combustion motors were used to drive dynamos to provide electric power to fortifications in Europe and the United States before the outbreak of World War I. Several armies experimented with automobile transportation before 1914. The growing demand for fossil fuels in the early decades of the twentieth century was exacerbated by the modernizing armies that slowly introduced mechanization into their orders of battle. The traditional companions of the soldier, the horse and mule, were slowly replaced by the armored car and the truck in the early twentieth century.

Internal combustion and electricity wrought a number of changes in naval architecture. Electric power was introduced on warships in the 1880s, allowing for the construction of larger ships, with better light and ventilation, deeper decks, improved artillery fire control, and improved efficiency in han-

British pilots on the Western Front swoop down on a German formation during actual combat in World War I. (Corbis Corporation)

dling ammunition and steering the ever-larger gun turrets. Highly energy-efficient oil-burning turbine engines were introduced on naval vessels about 1900. In 1906, the British navy commissioned the Dreadnaught, widely hailed as a revolutionary warship design, powered by turbine engines, equipped with heavy steel plate armor, and fitted with powerful long-range cannons. Twentieth-century battleships dwarfed the steam-powered vessels of the previous century in terms of displacement and destructive power.

Various schemes of powered flight were finally realized at Kitty Hawk, North Carolina, in 1903 when the Wright brothers successfully demonstrated a self-propelling flying machine. The Wright brother's plane was a breakthrough because of its lightweight aluminum internal combustion engine. Within a few years, strategic planners were speculating about the military importance of the airplane, although there was some debate as to whether the machines would ever pose a threat to static fortifications or field armies. Aircraft were used by the belligerents during World War I, ordered to perform reconnaissance and harassing work. Improvements in engine design, metallurgical science, and aerodynamic theory resulted in net increases in the energy efficiency of aircraft. By the mid-1930s, both airships and airplanes could perform a range of military functions, serving as interceptors, bombers, transports, and reconnaissance craft.

MILITARY ENERGY USE IN THE TWENTIETH CENTURY

The great demand for fossil fuels, a consequence of the rapid industrialization of emerging world powers in the early twentieth century, created political frictions between states vying for energy supplies. The United States, Britain, France, and Russia benefited from direct control of oil- and coal-producing territories, while Germany, Japan, and other modernizing nations were forced to import great quantities of precious energy. Historians have suggested that Japanese expansionism in the 1930s was an expression of energy insecurity; regardless of the causes, Japanese aggression in the Pacific, culminating with the attack on Pearl Harbor, Hawaii, on December 7, 1941, resulted in a protracted war, during which an unprecedented amount of energy was consumed by the combatants. The importance of energy resources, especially fossil fuels, affected the military strategies of all involved. German campaigns in North Africa were planned with the intention of liberating the Suez Canal from British control and permitting the Nazis access to Middle Eastern oil supplies. Allied bombing raids on Ploetsi, Romania, struck the oilfields of that region, a move designed to deny the Germans and Italians access to that energy. The German army's drive to seize the Caspian oilfields in 1941, an operation that compromised the effectiveness of the siege of Stalingrad, was an attempt to secure energy resources for the war effort. The Japanese invasion of Dutch Indonesia was undertaken to obtain the precious oil reserves found among the islands of the archipelago.

World War II was ultimately a contest between economies, and victories were a direct result of effective resource mobilization. The atomic bombs dropped on Hiroshima and Nagasaki in August 1945 released a tremendous amount of energy in the form of heat and radiation; the development of that weapon required a substantial economic and energy investment. After 1945, states went about building up strategic reserves of important natural resources; renewed national environmental and conservation efforts began with concerns about security. In some instances, the interests of the state, the military, and industry aligned, resulting in the execution of energy policies designed to protect the stability and security of the state. In the 1960s, for example, France undertook an aggressive nuclear energy development program in response to the agitations of the domestic coal-mining unions; it was feared that the miners had developed close ties with the French Communist Party. Civil nuclear power was the crossover manifestation of a technology originally developed for military purposes, but adapted for civilian use. Fuel cells and other high-yield, portable power-generation devices, developed in the mid-twentieth century and designed for use in space or other hostile and isolated environments, have both civilian and military applications.

The availability of ever-more-efficient kinds of inanimate energy has made the coordination of men and machines easier. With more efficient and powerful forms of energy generation, the coordination of the movements of man and machines became more effective. Two hundred years ago, soldiers were dependent upon verbal and visual signals for direction; the effective use of electrical communications technologies has resulted in the increased scope and scale of military operations. Digital computer technology, developed in the latter half of the twentieth century, found a ready audience among military officers seeking to maximize their control over subordinates and improve the collection and distribution of intelligence information.

The improvement of human control over inanimate forms of energy, put to use to military ends, has improved the logistics and coordination aspects of armies and navies, and increased the overall destructive capacity of humanity. Energy-efficient propulsion systems have reduced the costs and increased the ranges of various forms of transportation, both military and civilian. For the military, energy is both a blessing and a vulnerability, requiring ever-more-specialized soldiers and more expensive equipment to remain effective in the face of competition from other modern military forces.

MOLECULAR ENERGY

The fusion reactions that power the stars are nuclear reactions, in which one type of atom is converted into another. The extremely high heat of our Sun provides energy so intense that when atoms collide, they may collide with enough force to allow their nuclei to fuse together, a process that in itself releases tremendous energy. At moderate temperatures, as on our temperate planet Earth, when two elements bump into each other, they do not ordinarily contain enough energy to fuse. However, under the right circumstances, they may bind together to form a new compound. What

Figure 1.
When the elements are arranged in order of atomic number, a remarkable repetition of chemical properties occurs. The periodic table arranges the elements so that those in any one vertical column possess similar properties.

holds the two elements together is called a chemical bond. The energy involved in forming a typical chemical bond is ten million times smaller than that involved in nuclear reactions. Yet it is chemical bonding that allows for the existence of the highly organized and complex collection of chemical entities found here on Earth, even for life itself.

ELECTRONIC STRUCTURE OF THE ATOM

An atom is composed of a nucleus, which contains two types of relatively massive particles: the positively charged proton and the neutral neutron. The nucleus is surrounded by very light, negatively charged electrons equal in number to the number of protons, so that the overall charge on the atom is neutral. The number of protons in an atom, its atomic number, defines it as a chemical element. There are 105 elements, each with a different number of protons in its nucleus, and hence a unique atomic number. For example, all atoms with six protons are by definition carbon; those with seventy-nine protons, gold. The electrons surround the nucleus in distinct spatial patterns and possess specific energies. These energies and spatial patterns define the element's chemical behavior. They are in large part responsible for determining which elements will react with each other to form molecules. When atoms come close enough for their outer electrons to interact, attractions among the atoms may occur that are strong enough to hold them together to form a chemical bond.

In the mid-seventeenth century, when accurate atomic weights for a large number of elements were

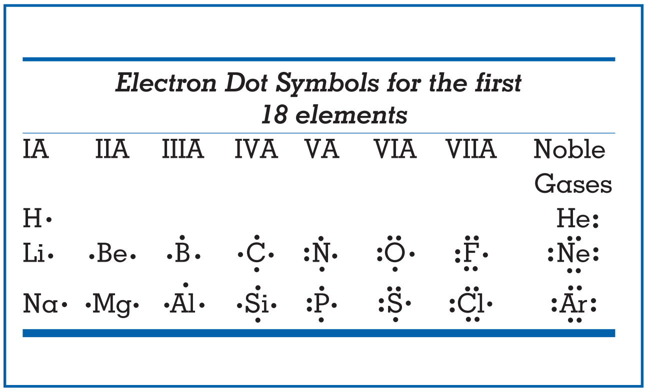

Figure 2.
Electron-dot symbols for the first eighteen elements. This scheme, invented in the early twentieth century by G. N. Lewis, provides a rough but useful tool for predicting the availability of an atom's valence electrons for chemical bonding.

becoming increasingly available, it was noted that there is a periodic recurrence of similar properties among the elements, both in terms of their characteristics as elements (are they, for example, metallic or nonmetallic?) and their behavior in chemical reactions (reactive or stable?). (See Figure 1.) Through the latter half of the nineteenth century natural philosophers amassed an ever-increasing collection of empirical rules, called "valence rules," to describe the formation of chemical bonds and to systematize the characterization, synthesis, and use of new compounds. The periodic table, developed in the mid-nineteenth century, provided a basis for predicting the nature of chemical bonds and the likely composition of a growing list of compounds. However, the approach was largely intuitive and descriptive. No underlying theoretical principle existed to explain chemical bonding.

In the early part of the twentieth century, G. N. Lewis observed that chemical bonding seemed to favor a state in which the atoms in stable compounds, by "sharing" electrons, achieved the stable electron distribution exhibited by the nonreactive noble gases, so-called because they are almost always found as pure elements in the gas state. He proposed that the electrons shared between two elements act as an electromagnetic "glue" to hold the two atoms together. The positive nuclei are attracted to the negative electrons; the electrons spend most of their time between the two nuclei, where the negative charge on the electrons screens the repulsive forces between the two nuclei. This attraction between positive and negative charges and the shielding of the positive nuclear charges by the electrons create a lower-energy state for the two atoms. The energy required to pull these two atoms apart again is called the bond energy. To pull apart a mole of H_2 molecules into two moles of H atoms requires 432 kJ of energy. Lewis's schemes for predicting bond formation among elements, the octet rule and electron-dot diagram, although incomplete, provided a strong predictive tool for describing covalent bonding and are still useful. (See Figure 2.)

The advent of quantum mechanics—developed over the first half of the twentieth century—provided the theoretical framework for our modem understanding of the chemical bond. This body of work predicates that light, ordinarily described in terms of electromagnetic waves, also can be understood as a collection of quanta. And, likewise, moving particles can possess wave-like properties. (This interchangeability is known as "wave-particle duality.") Infrared light quanta are similar in scale (and energy) to molecular bonds; the wavelengths of electrons in atoms and molecules are similar in scale (and energy) to the wavelengths of ultraviolet and visible light.

At the turn of the twentieth century, the planetary model for the atom, with electrons orbiting the nucleus, held sway, despite its fatal flaws: The laws of classical physics stipulate that the orbiting, charged electron should radiate energy and gradually spiral and crash into the nucleus. In 1913 Niels Bohr proposed discarding this classical notion and limiting the electron orbits to those having angular momenta that are integer multiples of Planck's constant h divided by 2π. Although not completely correct, Bohr's theory of the hydrogen atom paved the way for quantum mechanics and won him a revered place in science history.

In 1926, Austrian physicist Erwin Schrödinger made the next leap. He expanded the suggestion by Louis de Broglie (1924) that likened the wave behavior of the hydrogen electron, with its fixed energy values, to a guitar string. The string vibrates at a distinct frequency and has harmonics at wavelengths related to string length by integer numbers, indicating that the guitar string's vibrations are "quantized": The string can vibrate only at those frequencies characterized by integer numbers. To set up an analogous mathematical description of systems such as the electron in the hydrogen atom, Schrödinger described a nonclassical wave function that contains information on the whereabouts of an electron in an atom (or molecule). The wave function (actually, its square) tells us the *probability* of finding the electron at a given point in space. The probability distribution for an electron in a given energy level is known as an orbital.

We now know that electrons in atoms can hold only particular energies and that their probable whereabouts are described by Schrödinger's wave function. The energies and probable locations depend on integer numbers, or "quantum numbers." Quantum numbers describe the energy and geometry of the possible electronic states of an atom. These states, in turn, determine the chemical behavior of the elements—that is, how chemical bonds can form.

The periodicity of the elements derives from the rules dictating the manner in which electrons in atoms fill the energy levels. These levels can be roughly collected as a series of "shells," which one might think of as floors in a multistory building. Each floor, or shell, lies at a discrete energy; higher floors lie at higher energies. Quantum numbers dictate the number of orbitals in each shell. Each orbital can hold no more than two electrons. Electrons begin occupying the lowest-energy shell first; once a shell is filled, the additional electrons must go into the next, higher-energy shell. The most stable (i.e., the lowest-energy) configuration for an atom is to have completely filled electron shells. An atom with one or two vacancies in its highest shell is stabilized by the addition of one or two electrons. An atom with only one electron in its highest shell is stabilized by the release of that lone electron. Atoms interact to form chemical bonds by capturing, losing, or sharing electrons. The shared electrons hold groups of atoms together to form molecules of distinct geometry and character.

The ionization energy, electron affinity, and orbital occupancy determine the chemical behavior, or reactivity, of the elements. The uppermost (highest-energy) occupied orbitals are called the valence orbitals; the electrons occupying them are the valence electrons. An element's ionization energy, the energy required to remove an electron from a neutral atom, is related to its reactivity: A low ionization energy means that the valence electron is readily removed, and the element is likely to become involved in bonding with another atom by losing an electron to it. Electron affinity, the energy released upon capture of an electron by a neutral atom, is an important characteristic with respect to ionic bonding: The energy of an atom with high electron affinity is lowered as another electron approaches. If that approaching electron is attached to another atom, the two atoms can form a bond.

Electron Configurations for the First 20 Elements

Name	Atomic Number	Electron Structure

Table 1.
Bohr diagrams showing the electronic configurations for the first ten elements, along with representative bond formation.

Atoms are held together to form molecules either by the attraction between oppositely charged atoms (ionic bond) or by the sharing of electrons among positively charged atomic nuclei (covalent bond). In the language of quantum mechanics, a "bonding molecular orbital" is formed between the atoms in a molecule by the combination of atomic orbitals in a way that increases the likelihood of finding electrons between the nuclei. Both the attraction between opposite charges and the screening of repulsive forces between the positive nuclei by the negative electrons lower the overall energy of the system. The bonding

1. Electrons in an atom differ in energy depending on the orbital they occupy—that is, their average location in space relative to the nucleus.
2. Electrons closest to the nucleus have the lowest energy.
3. Electrons can obtain only certain discrete energy values in a stable atomic state.

molecular orbitals are lower in energy than the isolated atomic orbitals from which they arise.

BOND FORMATION BY THE FIRST TEN ATOMS

The "first floor" of the atom can hold only two electrons. When two hydrogen atoms, each with one electron, come together, each nucleus is in effect "sharing" two electrons, and as far as each nucleus is concerned, its shell is filled. The helium atom already contains two electrons; its first floor is filled. That is why helium is unreactive. When two helium atoms collide, rather than stick together, they simply bounce apart. (See Table 1.)

The second shell can hold up to eight electrons. Lithium (Li), the first element in the second row of the periodic table, has atomic number 3. With three electrons, lithium's first shell is filled and its second shell has only one electron. Lithium is highly reactive and readily gives up its lone second-shell electron. In fact, all elements in the same column as lithium, called the alkali metals, have a single valence electron and share these properties. Because an alkali metal gives up its valence electron readily, the bonds formed between alkali metals and other elements are ionic: The electrons are not shared equally. In sodium chloride, NaCl, sodium carries a positive charge and chlorine a negative charge.

Electrons are not only charged, they also have a characteristic physicists call "spin." Pairing two electrons by spin, which has two possible values, "up" or "down," confers additional stability. Beryllium (Be, atomic number 4) has two spin-paired electrons in its second shell that are easily given up in chemical reactions. Beryllium shares this characteristic with other elements in column two, the alkaline earth metals. These atoms also generally form ionic bonds. Boron (B, atomic number 5) will readily give up three electrons.

Carbon (C, atomic number 6) is the most versatile of all elements and is found abundantly in compounds produced by living organisms. With four unpaired electrons, it can make as many as four covalent bonds to fill its outer shell to eight, producing extremely stable molecules. Carbon can form branched and cross-linked chains, and it can form especially stable double bonds and "aromatic" bonds (highly stable, delocalized bonds found in planar ring compounds, like benzene) that can absorb energy in the visible and ultraviolet range of the electromagnetic spectrum.

Nitrogen (N, atomic number 7) has five outer electrons, two of which are paired. It therefore has three electrons to share in chemical bonds. Oxygen (O, atomic number 8), with six outer electrons, has two paired and two single electrons. Oxygen combines readily with other elements to gain two electrons to fill its outer shell, in a process called oxidation. Reactions between oxygen and carbon are especially favorable. (Carbon-oxygen compounds, particularly carbon dioxide, CO_2, are stabilized to a very low energy.)

Fluorine (F, atomic number 9) has seven outer electrons, one unpaired. Because it needs to obtain only one electron to fill its outer shell and gain stability, it is highly reactive. Neon (Ne, atomic number 10), on the other hand, has a filled outer shell. Like helium and its other column mates, the noble gases, neon does not readily react with any element.

ENERGY AND CHEMICAL CHANGE

In chemical reactions, when the atomic configurations of molecules are changed, matter is neither created nor destroyed (Law of Conservation of Matter). The identity and number of atoms remain unchanged. When methane gas (CH_4) is burned, its atoms don't disappear; they combine with oxygen (O_2) in the air and are transformed into carbon dioxide (CO_2) and water vapor (H_2O):

$$CH_4 + 2\,O_2 \rightarrow CO_2 + 2\,H_2O + \text{heat}$$

Likewise, in chemical change, energy is neither created nor destroyed (Law of Conservation of Energy). When charcoal is burned the potential energy stored in the carbon-carbon bonds is released as heat. Although in this reaction the *forms* of matter and energy are changed, both are ultimately conserved; the number of atoms and the amount of energy in the universe remain unchanged.

Energy is the capacity to do work. Potential energy is the energy possessed by an object as a result of its position. Heat, another form of energy, ran be thought of in molecular terms as frictional losses of the uncoordinated motion of molecules.

In a heat-producing (exothermic) reaction the molecular energy of the products is lower than that of the reactants. In the combustion of methane, the energy stored in the bonds of the molecules CO_2 plus two molecules of H_2O is less than that in CH_4 plus two molecules of O_2. If the molecular energy of the products is greater than that of the products (an endothermic reaction), energy (often in the form of heat) must be added for the reaction to occur.

Oxidation reactions release energy because oxidized compounds have lower energy than the reduced compounds from which they were formed. This energy difference derives from the strong "greediness" of oxygen for electrons. Oxygen has a high electronegativity, the attraction of an atom for an electron in chemical bonding. The electronegativities of carbon and hydrogen are roughly the same. Similarly, in the oxygen molecule, the two oxygen atoms share their bonding electrons equally. In carbon dioxide, however, oxygen, which is more highly electronegative than carbon, holds its electrons much more tightly than carbon. The same is true for the other product molecule: water. It is a more stable (lower-energy) situation for the electrons to be held closer to the nucleus of the highly electronegative atom, oxygen, than it is for the electrons to be shared between atoms (carbon and hydrogen) that are less electronegative. Oxygen "wants" the electrons, while carbon and hydrogen are somewhat more "ambivalent" about holding on to them.

SPONTANEITY AND RANDOMNESS

Like a ball at the top of an incline, chemical reactions seem to have a tendency to naturally "roll downhill" from a state of higher to a state of lower potential energy, with the potential energy converted to kinetic energy along the way (motion for the ball, heat for the chemical reaction). However, while most spontaneous chemical reactions are indeed exothermic, many spontaneously occurring chemical changes actually absorb heat, notably ordinary table salt dissolving in water.

In determining if chemical change will occur spontaneously, one must consider not only whether heat is released (the reaction rolls downhill energetically), but also whether it creates order or disorder. Both the lowering of energy and an increase in disorder are changes that tend to occur spontaneously. The measure of the randomness of a system, its "entropy," increases, for example, when a solid or liquid is converted to a gas, when a solid or a liquid is dissolved in solution, with increasing weakness between bonds, or with an increasing number of particles. Sodium chloride (table salt) dissolves spontaneously in water. Energy must be added to break the salt's crystalline bonds, but the increase in entropy (disorder) produced as hydrated sodium and chloride ions are freed from the ordered NaCl crystal into solution drives the reaction forward. The importance of entropy in determining whether a chemical reaction will proceed spontaneously increases as the temperature is increased. For example, ice is the lowest-potential energy state for water. However, at temperatures above 0°C entropy becomes a driving force for melting, and water goes from a low-entropy crystalline phase to a more disordered liquid phase in which the water molecules can move more freely.

OXIDATION AND REDUCTION

Reactions that involve the loss and gain of electrons are termed reduction-oxidation, or Aredox," reactions. The two processes of reduction (loss of an electron) and oxidation (gain of an electron) are complementary and always occur together: One substance's loss is another's gain. Reduced forms of matter—often fuels such as sugar, fat, gasoline, and charcoal—are high in potential energy. Oxidized forms, such as carbon dioxide and water, are low in potential energy.

The term "oxidation" derives from its original use to describe reactions involving combination with oxygen. The broader definition includes reactions in which an element or compound gains oxygen (in the combustion of methane, the carbon gains oxygen atoms and is thus "oxidized"), loses hydrogen, or loses electrons. The working definition for reduction includes reactions in which an element or a compound loses oxygen atoms, gains hydrogen atoms, or gains electrons. The oxidation of fuels—by engine, stove, or living organism—releases energy, often in the form of heat, that can be used to perform work. Green plants convert the light energy of the sun, by reducing carbon dioxide during photosynthesis, into potential energy stored in hydrocarbon bonds:

$$6\ C0_2 + 6\ H_2O + \text{solar energy} \rightarrow C_6H_{12}O_6(\text{glucose}) + 6\ O_2$$

Redox reactions occur in the reduction of ores (metal oxides) into pure metals and the corrosion (oxidation) of pure metals in the presence of oxygen and water. Rusting iron, $4Fe + 3O_2 + 6H_2O \rightarrow 4Fe(OH)_3$, is a good example of metal oxidation. Strong oxidizing agents can be used as antiseptics (hydrogen peroxide, H_2O_2) or bleaches (sodium hypochlorite, NaOCl).

A voltaic cell produces electrical energy through spontaneous redox chemical reactions. When zinc metal is placed in a solution of copper sulfate, an electron transfer takes place between the zinc metal and copper ions. The driving force for the reaction is the greater attraction of the copper ions for electrons:

$$Zn + Cu^{2+} \rightarrow Zn^{2+} + Cu + \text{energy}$$

To exploit the energy produced in this reaction, the "half reactions" are separated. The oxidation reaction is carried out at a zinc electrode ($Zn \rightarrow Zn^{2+} + 2$ electrons) and the reduction reaction is carried out at a copper electrode ($Cu^{2+} + 2$ electrons $\rightarrow$ Cu metal). Electrons flow through a metal wire from the oxidizing electrode (anode) to the reducing electrode (cathode), creating electric current that can be harnessed, for example, to light a tungsten bulb.

BIOENERGETICS

Biological systems ultimately rely on energy from the Sun to build complex, high-potential energy molecules used to store fuel (glucose), provide structure (collagen), transmit signals (hormones, neurotransmitters), or carry information (DNA). Plants harvest the Sun's energy directly through photosynthesis to produce glucose from carbon dioxide and water. Whether by means of a vegetarian, carnivorous, or omnivorous diet, animals, too, benefit from the Sun's energy, albeit less directly. Living organisms couple energy-releasing reactions to energetically unfavorable reactions in synthesizing complex compounds that are high in potential energy. The primary energy-producing reaction in living organisms (those that use oxygen) is the combustion of sugar:

$$C_6H_{12}O_6\ (\text{glucose}) + 6\ O_2\ (\text{oxygen gas}) \rightarrow 6\ CO_2\ (\text{carbon dioxide}) + 6\ H_2O + \text{energy}$$

Biological glucose combustion is coupled through a complex set of reactions to the synthesis of the energy-storing molecule adenosine triphosphate, ATP. This elaborate metabolic pathway ensures that much of the energy released, 686 kilocalories per mole of glucose, is stored in small parcels of useful energy in the phosphate bonds of ATP, while allowing as little energy as possible to be wasted as heat. Glucose metabolism can be broken down into three parts: glycolysis, the citric acid cycle, and the respiratory chain. In glycolysis, also known as anaerobic fermentation, glucose is broken down into pyruvic acid in about ten steps, none of which requires oxygen. Over the course of these steps a significant portion of the energy released is taken up by the formation of ATP or by the reduction of special molecular intermediaries, nicotinamide adenine dinucleotide, NAD^+, and flavin adenine dinucleotide, FAD:

$$NAD^+ + H_2O + 52.7\ \text{kcal/mole} \rightarrow NADH + H^+ + \tfrac{1}{2}\,O_2$$

$$FAD + H_2O + 36.2\ \text{kcal/mole} \rightarrow FADH_2 + \tfrac{1}{2}\,O_2$$

The citric acid cycle, a nine-step process, also diverts chemical energy to the production of ATP and the reduction of NAD^+ and FAD. In each step of the citric acid cycle (also known as the Krebs cycle) a glucose metabolite is oxidized while one of the carrier molecules, NAD^+ or FAD, is reduced. Enzymes, nature's chemical catalysts, do a remarkable job of coupling the oxidation and reduction reactions so that energy is transferred with great efficiency.

The reduced carrier molecules NADH and $FADH_2$ are recycled in the respiratory chain. The reoxidation of these intermediaries releases additional energy for use in the production of more ATP:

$$NADH + H^+ + \tfrac{1}{2}\,O_2 \rightarrow NAD^+ + H_2O + 52.7\ \text{kcal/mole}$$

$$FADH_2 + \tfrac{1}{2}\,O_2 \rightarrow FAD + H_2O + 36.2\ \text{kcal/mole}$$

Photosynthesis uses many of the same enzyme-driven steps found in glucose metabolism, only in reverse. The stages of photosynthesis termed the "dark reactions" are fueled not by the Sun but by ATP and reduced nicotinamide adenine dinucleotide phosphate, NADPH. This series of reactions, which takes place in the chloroplasts of the plant cell, synthesizes glucose from carbon dioxide. In the "light reactions," solar energy trapped by chlorophyll molecules is used to produce the continuous supply of ATP and NADPH (NADH in bacteria) necessary to power the dark reactions. The light-harvesting apparatus is composed of chlorophylls and beta-carotene, aromatic molecules with molecular orbitals that are highly Adelocalized," meaning that they are spread over a major portion of these large molecules. These delocalized molecular orbitals have energy spacings that are similar in energy to light in the visible range: Chlorophyll-*a* absorbs violet light; chlorophyll-*b* absorbs blue and, to a lesser extent, red; and the carotenes are long, antenna-like molecules that harvest light at wavelengths not picked up by the chlorophylls, in the orange and yellow portion of the visible spectrum. Green light is not absorbed, but is reflected, giving green plants their characteristic color.

NANOTECHNOLOGIES

Nanotechnology is the technology of building things at a molecular scale, that is, where objects are measured in nanometers. Nanotechnology has the potential to improve both energy production technology, and the efficiency of end–use technology. Before this is possible, scientists must develop techniques to manipulate atoms and molecules well enough to build machines and structures. This means that the design of an object must specify each atom in the object, and all the chemical bonds between them. Such a design or object is called "atomically precise." In plants and animals, molecular biology has this capability, with certain substantial limitations. In the laboratory, atoms and molecules can be moved with the tip of a scanning probe, such as an STM (scanning tunneling microscope) or an AFM (atomic force microscope), but with other limitations. Other approaches include manipulation with electron beams, light waves ("optical tweezers"), and deposition in thin films (sputtering, molecular beam epitaxy).

HISTORY

In the 1950s, biologists (notably Francis Crick and James Watson) discovered the molecular basis for information coding in DNA and established that the workings of cells were molecular machines with understandable structure and function. Mathematician John von Neuman developed a mathematical theory of self-reproducing machines based on the biological theories.

In the 1960s, physicists such as Richard Feynman and Carver Mead showed that the speed and power efficiency of machines can improve with decreasing scale, particularly for solid-state electronics. A trend toward miniaturization in electronics was accelerated by the space program. Biologists began to decipher the genetic code.

In the 1970s, computers on a chip (microprocessors) appeared. Electron microscopes neared molecular resolution. By the end of the decade, transistors could be made the size of a human cell (10 microns).

In the 1980s, biologists began manipulating ("recombining") DNA–they could now read and write information at the molecular scale. Physicists (notably Gerd Binnig and Heinrich Rohrer) invented "scanning probe microscopes" able to image individual atoms. Technologists (notably William Trimmer) began to build "micromachines" using techniques from microelectronics. Futurists (notably Eric Drexler) began describing nanomachines and using the term "nanotechnology." At the end of the decade, transistors could be made the size of a bacterium (1 micron).

In the 1990s, nanotechnology emerged as a distinct field, with its own journals, conferences, and funding programs. MIT conferred the first Ph.D. in nanotechnology (to Drexler). Micromechanics became a burgeoning commercial field. Although most of the activity was still nanoscience as opposed to nanoengineering, the explosion of computational power made designing and simulating molecular machines feasible. Drugs and industrial catalysts were routinely designed and simulated in this fashion. Genetically modified organisms were commercial technology. Nanotechnologists (notably Nadrian Seeman) built controllable, albeit very rudimentary, molecular machines. By the end of the decade, commercial electronics had one-tenth micron (100 nanometer) transistors, but switching with single molecules had been done in laboratories.

ENERGY

As the field of nanotechnology matures, the ability to manipulate atoms and molecules will develop into the ability to build machines that do so. This will revolutionize the generation, storage, transmission, and use of energy. For example, a major source of energy is the oxidation of fossil fuels. If the fuel is burned, the energy is thermalized, and must be recovered by a heat engine. The laws of thermodynamics together with engineering constraints give this process a poor efficiency, typically 30 to 50 percent. Efficiency is even worse for small (e.g., handheld) engines. Nanotechnology gives us the prospect of a different approach. Molecules of oxygen and fuel could be positioned rigidly and moved mechanically through the oxidation process, so that it becomes reversible (both practically and in the technical thermodynamic sense). This would raise the efficiency to near 100 percent, even in small engines.

Reversing the process yields an efficient method of energy storage. The process inputs combustion products such as carbon dioxide and water, and energy in the form of electricity or shaft power, and outputs oxygen and fuel (typically hydrogen or hydrocarbons).

Reversible fuel oxidation is as yet not well understood, and can be considered a major goal of nanotechnology in the energy area. Other forms of reversible conversion, such as shaft power to electricity and vice versa (generators and motors), are better understood and there are existing designs awaiting only construction capability. When of reversible oxidation becomes a reality, nanotechnology will enable the construction of heat engines that are small, powerful, clean, and as efficient as thermodynamics permits. One early application that is the subject of research is storage of hydrogen as a fuel.

The understanding of the electronic properties of nanostructures is one of the most rapidly advancing areas in science. This has two major implications: first, it will lead to the construction of nanocircuitry and nanocomputers that will use considerably less power than current computers while being faster and smaller; and second, it will lead to increasing efficiency and decreasing cost of photovoltaic power conversion (“solar energy”).

ATOMIC IMAGING AND MANIPULATION

A scanning-probe microscope consists of a sharply pointed object, preferably so sharp that its tip is a single atom, mounted on a block of piezoelectric material such as a quartz crystal. A voltage is applied to the block, which warps in response. This warping can be controlled to atomic dimensions, allowing the tip to be steered across a molecular sample. The proximity of the tip to atoms of the sample can be sensed by various means, allowing a computer to build up a picture of the sample by scanning the tip across it. Kinds of scanning probe microscope include STM (scanning tunneling microscope) in which a current tunneling from the sample to the probe is measured, the AFM (atomic force microscope) in which the probe presses on the sample and the resulting force is measured, near-field optics in which the probe is an optical funnel focusing or detecting photons with much greater precision than their free-space behavior would allow, and many others.

Scanning probes can also be used to manipulate atoms and molecules individually, placing the tip in contact with the subject atom and pushing or pulling (atoms stick to the tip by virtue of the van der Waals force).

COMPUTATIONAL NANOTECHNOLOGY

Computer-aided design (CAD) and simulation of molecular structures is a rapidly advancing and widely applicable field. Molecules can be designed with molecular CAD programs; early programs allowed the user to specify the type and place of each atom or of substructures (“moieties”) from a library. Research in molecular CAD is now focusing on the automation of parts of the process, following in the footsteps of a similar development in design software for digital electronics (e.g., for microprocessors).

Simulation of molecules can be done at the quantum mechanical level, as is necessary to determine the electronic properties of molecules, to analyze covalent bonds or simulate bond formation and breaking. However, quantum mechanical simulation is extremely computationally intensive and is too time-consuming for all but the smallest molecular systems.

A more practical approach for larger systems is molecular dynamics. In this method, the properties of bonds are determined through a combination of quantum-mechanical simulation and physical experiments, and stored in a database called a (semi-empirical) force field. Then a classical (non-quantum) simulation is done where bonds are modeled as spring-like interactions. Molecular dynamics simulations are appropriate for studies involving the properties of molecules as physical structures and shapes (including "docking" and the catalytic properties of biomolecules in solution, and the structural properties and energy dissipation mechanisms of nanomachine parts in operation).

EARLY COMMERCIAL NANOTECHNOLOGY

Commercial nanotechnology in the 1990s was limited by the lack of a general synthetic capability. It characterized by a plethora of techniques for building nanostructures, including a number of methods based on gas-phase nucleation (e.g., laser pyrolysis, sputtering), methods from synthetic chemistry, including dendrimers and fullerenes, and methods from molecular biology, including DNA synthesis and the use of DNA as a structural material, and protein engineering. In general, the limitations on DNA/protein methods are in the ability to design and predict structures, where the limitations on the other methods are on their physical synthetic capabilities.

Methods capable of detailed atomic manipulation were confined in the 1990s to the laboratory, since they were generally incapable of producing commercially useful amounts of product. There are a few exceptions to this, in applications where a few carefully constructed molecules can be useful, such as chemical sensors, laboratory equipment, and so forth.

THE FUTURE OF NANOTECHNOLOGY

The field of nanotechnology is advancing rapidly, so it is not practical or useful to make short-term predictions about its specific form and capabilities. At most it can be noted that one of the most rapidly advancing subfields is nanoelectronics (sometimes referred to as "molectronics," for molecular electronics).

For longer-term projections, a common practice is to compare the field with others that are advancing as rapidly. Computers, both hardware and software, and biotechnology are cases in point. Both fields bear on nanotechnology and contribute to its advance. In computers, the watershed capability was the stored-program von Neumann architecture. In nanotechnology, it is expected to be another von Neumann design, the self-reproducing system. In practical terms, this simply means that nanomachines need to be capable of making parts for nanomachines, just as a conventional machine shop is capable of making parts for its own machines. Once this is achieved, it will be possible to build commercial quantities of product with atomic precison, and in particular, to have commercial quantities of product that consists of working nanomachines.

NATIONAL ENERGY LABORATORIES

The Department of Energy operates seventeen major national laboratories and thirteen minor facilities in the United States that carry out energy research and development, basic science, and defense weapons work. The combined budgets for these laboratories exceed $6 billion annually, with a scientific and technical staff of more than thirty-thousand.

Each of these laboratories is a government-owned/contractor-operated facility selected from industry, academia, and university consortia. As of 1999, the most prominent civilian contractor was Lockheed Martin, the operator of Oak Ridge and Sandia, and the major academic institution was the University of California, administrator of Los Alamos, Lawrence Berkeley, and Lawrence Livermore.

ATOMIC ENERGY COMMISSION YEARS

The origins of the national laboratory network can be traced back to the late 1940s and the beginning of the atomic age. At the end of World War II, the scientific community, particularly the staffs from the Manhattan Project laboratories, lobbied Congress for civilian control of atomic power. Toward this end, the federal government transferred authority from the Army to the newly established Atomic Energy

Commission in 1946. Atomic research and development, both for defense and peaceful use, was to be solely in the hands of the Atomic Energy Commission. Its mission was to "assure the common defense and security," and to "improve the public welfare, increasing the standard of living, strengthening free competition, in private enterprise, and promoting world peace."

After the Russians achieved the first detonation of a nuclear device in 1949, there was a great fear of falling behind in the nuclear weapons race, setting in motion an all-out effort to develop a thermonuclear device. Prominent scientists like Edward Teller and Ernest O. Lawrence were instrumental in establishing the Lawrence Livermore Laboratory to join Los Alamos as a major weapon design laboratories. This strong nuclear science emphasis made the 1950s and 1960s an era of great advances in civilian nuclear energy as well as nuclear weapons and nuclear propulsion for the military. Nuclear weapons not only became more powerful, but more tactical and versatile, including a variety of designs for short, intermediate, and long-range missiles.

The laboratories at Argonne and Oak Ridge were busy designing nuclear reactors in the 1960s. Once the electric utility companies saw that nuclear power could compete with fossil fuel plants on purely economic grounds, more than one hundred reactors were being designed or under construction by the mid-1960s. But confronted by safety and environmental concerns, the nuclear juggernaut started to run into trouble shortly before the energy crisis of 1973—ironically at a time when the need for alternatives to oil and natural gas was greatest.

With so much of the work at the laboratories involving the design of nuclear reactors, the future of many of the laboratories, particularly Argonne and Oak Ridge, looked bleak. But the energy crisis brought plenty of new energy research and development funding to all the laboratories. It also gave many of the laboratories an opportunity to diversify beyond nuclear energy.

DEPARTMENT OF ENERGY YEARS

When the Department of Energy (DOE) was established in 1977, along with its many missions, it was granted authority over a coveted prize: oversight of all the laboratories and research facilities from the predecessor agencies. These included the Bureau of Mines research laboratories at Bartlesville, Morgantown, Pittsburgh, and Laramie from the Federal Energy Administration, and the National Laboratories that were managed by the Atomic Energy Commission (1947–1974) and the Energy Research and Development Administration (1974–1977).

By the late 1990s the number and the size of the laboratories had grown tremendously. From 1977–1997, the federal government's investment in the laboratories was in excess of $100 billion, in seventeen major laboratories and thirteen minor laboratories.

Since the end of the Cold War, the focus of all the laboratories has moved beyond weapons, accelerators, and energy-related research to encompass almost every imaginable field of basic and applied science. Most of the laboratories are increasingly being pushed by Congress to create partnerships with industrial firms to commercialize laboratory-developed technology in the hope that it will improve the overall competitiveness of the U.S. economy.

AMES LABORATORY

To accompany the physics program of the Manhattan Project, Frank H. Spedding, an expert in the chemistry of rare Earth metals, agreed to set up a chemical research and development program in 1942. The Ames Project went on to develop new and far less expensive methods for both melting and casting uranium metal. Based on this successful work, in 1947 the Atomic Energy Commission established Ames Laboratory to produce high-purity uranium metal in large quantities for atomic energy. Although still heavily involved in material research, the research scope expanded considerably through the years to include engineering, environmental, mathematical, and physical sciences.

ARGONNE NATIONAL LABORATORY

The Atomic Energy Commission designated Argonne National Laboratory as the first national laboratory on July 1, 1946. Argonne was the lead laboratory for nuclear reactors, instrumental in designing and building the first nuclear powered submarine, the *USS Nautilus* in 1954, and the first nuclear reactor that completely powered the town of Arco, Idaho, in 1955.

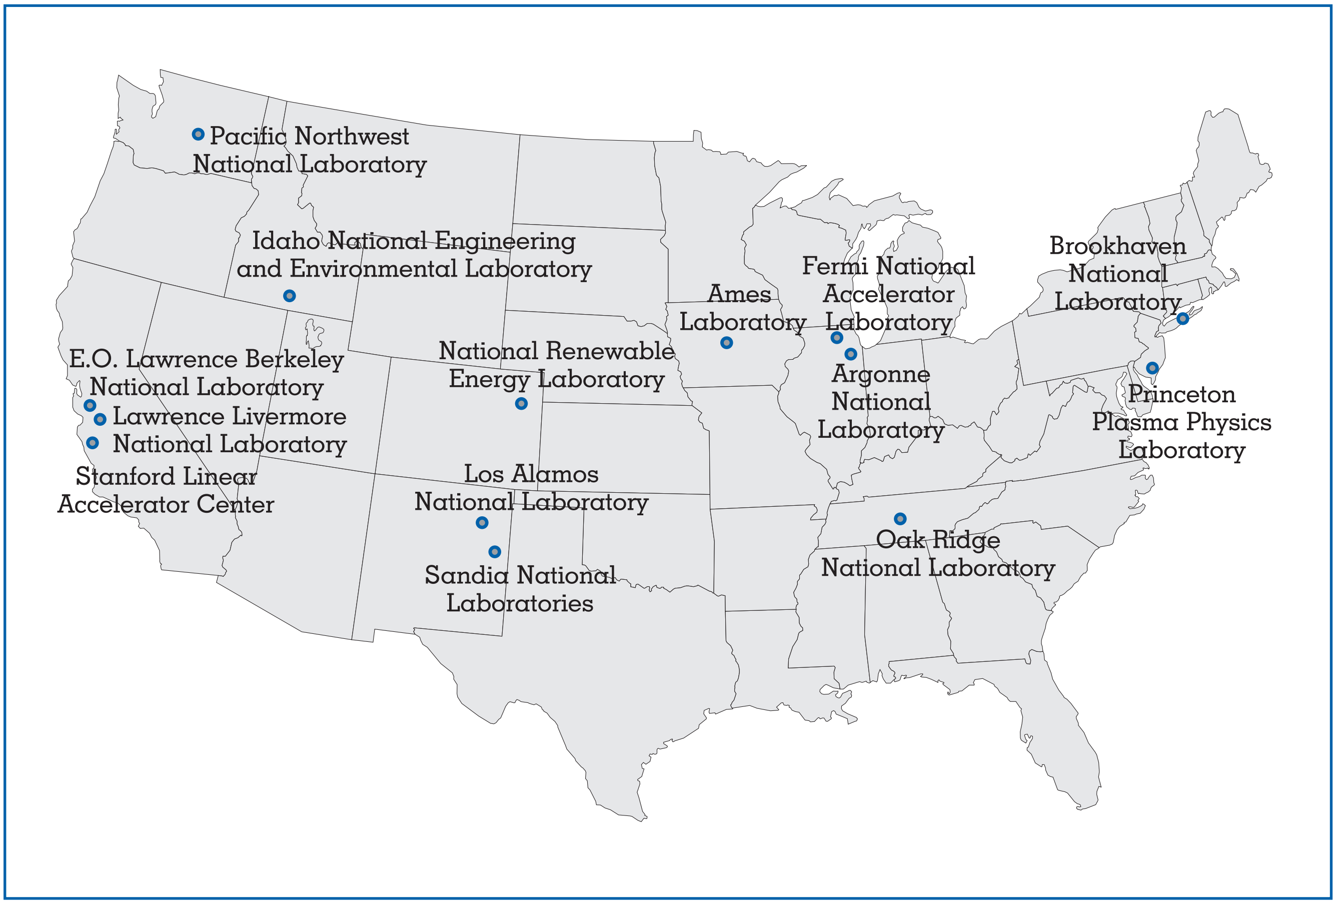

Figure 1.
Locations of the major U.S. National Energy Laboratories.
SOURCE: U.S. Department of Energy website <http://www.doe.gov/people/labsmap.htm>.

Through the 1960s and 1970s, Argonne scientists continued to design and build nuclear reactors, but as nuclear power became engulfed in controversy, federal support dwindled. In response, Argonne began to emphasize other areas such as batteries, magnetohydrodynamics, solar, and fusion in 1977. From the early 1980s through the late 1990s, Argonne continued its diversification, encompassing fields such as materials, medical research, and transportation fuels.

BROOKHAVEN NATIONAL LABORATORY (BNL)

BNL was also founded in 1947 by the Atomic Energy Agency. The management contract was awarded to the nonprofit educational consortium called Associated Universities Inc. with the goal being to create a regional laboratory with the advanced facilities too costly for Universities to build and maintain. Initially BNL concentrated on developing small nuclear reactors for peaceful scientific exploration, and also was one of the pioneers in nuclear medicine. The scope of the laboratory has evolved in the late 1990s beyond the basic sciences to include areas such as environmental research and energy technology.

FERMI NATIONAL ACCELERATOR LABORATORY (FERMILAB)

Fermilab, where groundbreaking for its first linear accelerator began in December 1968, is the premier high energy physics facility in the world. Its mission is to advance the understanding of the fundamental nature of matter and energy. Universities Research Association Inc., a consortium of eighty-six research

Aerial view of the world's largest particle accelerator, located at the Fermi National Accelerator Laboratory in Batavia, Illinois. (Corbis-Bettmann)

universities, operates the laboratory for the DOE. Fermilab is home to the Tevatron, the most advanced accelerator in the world, that can accelerate particles at 0.950 TeV. Huge amounts of electricity, typically running anywhere from $10 to $20 million a year, are needed to power the laboratory and conduct experiments. The future role of Fermilab was uncertain when the Superconducting Super Collider was approved by President Reagan in January 1987. But because federal budgetary problems led to the termination of SSC funding in 1993, it guaranteed the role of Fermilab as the foremost experimental particle research facility in the United States for many years to come.

IDAHO NATIONAL ENGINEERING LABORATORY (INEL)

INEL's origins were as one of the satellite facilities for the Manhattan Project in the 1940s. Since the early 1950s, INEL has developed and operated fifty-two nuclear reactors for the commercial power and national security sectors. INEL has diversified through the years, but the areas of concentration continue to be energy, environmental management (methods for characterizing, treating, and storing radioactive and hazardous waste), and national security. As with the other major laboratories, INEL is committed to the transfer of technology to the private sector.

LAWRENCE BERKELEY LABORATORY (LBNL)

The roots of the LBNL can be traced back to the 1920s, and the pursuit of the secrets of the nucleus. Ernest O. Lawrence, built the first large cyclotron (a particle accelerator) on the Berkeley campus of the University of California in 1931. Unlike most the other labs, LBNL's beginnings depended on the support of philanthropists who saw the promise in Lawrence's work. Seeking private sector support, an onerous chore in good times, was all the more difficult for Lawrence because of the Depression. Nevertheless, by the late 1930s Lawrence had raised enough money to plan his 184-inch diameter cyclotron. It was too big to build on campus, so he moved his Radiation Laboratory to the hill above the campus. After World War II Lawrence and Brobeck built the 7 billion electron volt proton accelerator (called the Bevatron), specifically designed to produce antiprotons, which it did in l955. But with no more flat land in the Berkeley hills, the lead for more powerful accelerators passed to SLAC (Stanford Linear Accelerator Center), the Fermilab, and to CERN.

As the lead in high-energy accelerators passed to Fermi Laboratory in the 1950s, LBNL moved beyond high energy physics to become a collection of interdisciplinary groups working in many diverse fields. By 1977, because of the energy crisis, the focus continued to change with the addition of two new divisions, one for Energy and Environment and another for Earth Sciences, which included geothermal energy and the disposal of nuclear wastes. By the late 1990s these two divisions together had grown to account for about one quarter of the laboratory's budget.

LAWRENCE LIVERMORE NATIONAL LABORATORY (LLNL)

In an attempt to develop the hydrogen bomb before the Russians, a second weapons laboratory, Lawrence Livermore, was established in July 1952 to handle the additional work that would be necessary to stay ahead of the Russian nuclear weapons program. The administrator chosen was the University of California. For the next forty-five years, this LLNL was a formidable competitor to Los Alamos in the development of nuclear weapons. But much like most of the other major national laboratories, its focus also shifted away from nuclear weapons to basic science to fields like magnetic and laser fusion energy, non-nuclear energy, biomedicine, and environmental science. By the late 1990s, half of the laboratory's budget was nondefense related as the shift away from nuclear weapons continued.

LOS ALAMOS NATIONAL LABORATORY (LANL)

In 1943, under the direction of J. Robert Oppenheimer, the Los Alamos National Laboratory, referred to as Project Y at the time, was the site chosen to develop the technology and build the bombs that were instrumental in ending World War II. Managed since its beginning by the University of California, the laboratory's original mission to design, develop, and test nuclear weapons has broadened and evolved through the years. During the Cold War, from the 1950s to the 1980s, the work primarily involved nuclear weapons and the Strategic Defense Initiative. But as the Cold War ended, programs in energy, nuclear safeguards, biomedical science, environmental protection and cleanup, material science, and other basic science programs were added and enhanced. National security remains at the core of LANLs mission, yet the laboratory continues to try to diversify toward more basic science research, and the development and commercialization of emerging technologies.

NATIONAL RENEWABLE ENERGY LABORATORY (NREL)

In the belief that solar energy was a key to energy independence, the Solar Energy Research Institute (SERI) was established in 1977. Meanwhile Rockwell International, the operator of the nearby Rocky Flats Plant, was awarded a federal grant to build and test many different small wind turbines in various configurations. SERI and Rocky Flats wind energy programs were merged in 1984 and transferred to SERI. Both programs prospered in the late 1970s because of very generous federal appropriations, but after federal funding for solar energy research declined in the 1980s, SERI, renamed the National Renewable Energy Laboratory in 1991, was forced to expand its mission well beyond photovoltaics, solar industrial technologies, solar thermal electric, and wind energy to a greater emphasis on biomass electricity, biofuels, and geothermal power. In a renewed effort to transfer more technology for commercialization, Battelle Memorial Institute and Bechtel Corp. began managing the laboratory in collaboration with Midwest Research Institute, the original administrator, in November 1998.

OAK RIDGE NATIONAL LABORATORY (ORNL)

Ground breaking for the "Clinton Laboratories," what Oak Ridge was originally called, occurred in February 1943. Whereas the Manhattan Project at Los Alamos served as the center of weapons design, ORNL devised the techniques to produce and purify the large quantities of fissionable uranium and plutonium. ORNL was a natural choice due to the abundant hydroelectric power that the Tennessee Valley Authority could provide. During the war, the lab was managed by DuPont and the University of Chicago, but in December 1947 the Atomic Energy Commission chose Union Carbide, whose tenure lasted until 1984. Argonne was designated the lead laboratory for reactor design, so ORNL concentrated on isotope production and radiochemical separations, biological research, and specialized reactors for the Navy and Air Force. The promise of electricity "too cheap to meter" in the 1950s and 1960s led to a renewed nuclear reactor emphasis. But as the energy crisis erupted and the promise of nuclear power faded in the 1970s, ORNL diversified into other areas such as energy conservation, synthetic fuels, and solar power. The diversification continued into the 1980s and 1990s with an expansion of environmental research, and an international outreach as ORNL scientists began advising developing countries on ways to secure the energy needed for economic growth.

PACIFIC NORTHWEST LABORATORY (PNL)

Battelle Memorial Institute took over management of what was then called Hanford Laboratories in 1965, and the research facility was separated from Hanford site operations (the Hanford site is where much of the weapons grade plutonium was manufactured from the 1940s to the late 1980s) and renamed the Pacific Northwest Laboratory. PNL is a unique multiprogram laboratory in that part of the facilities are Battelle Memorial Institute (established by the estate of Gordon Battelle, a wealthy industrialist, in 1929) facilities, and part are DOE facilities. When Battelle took over management, they invested $50 million in private research facilities adjacent to the government laboratory.

At first PNL focused on nuclear technology and the environmental and health effects of radiation, but through the years expanded its mission to cover nearly every field of basic science to solve problems in the areas of environment, energy, and national security. Environmental issues and cleanup still encompass two-thirds of PNL work in the 1990s, but PNL has strengthened its role in regional electric power issues as well.

PRINCETON PLASMA PHYSICS LABORATORY (PPPL)

In 1951 Professor Lyman Spitzer, Jr., conceived of an idea of plasma being confined in a figure-eight-shaped tube by an externally generated magnetic field. Called the "stellarator," the Atomic Energy Commission decided to fund it, which established Princton University's controlled fusion effort. Magnetic fusion research was declassified in 1958 so that all nations could collaborate. The PPPL has managed to secure the lion's share of federal plasma and fusion research funding from the 1960s through the 1990s, and with it developed the Tokamak Fusion Test Reactor, that operated at PPPL from 1982 to 1997. Early in the next millenium, an advanced fusion device—the National Spherical Torus Experiment—will begin operation. Although much of the promise of fusion has been unfulfilled to date, some of the knowledge gained in fusion research has found applications in other areas such as materials science, chemistry, and manufacturing.

SANDIA NATIONAL LABORATORIES (SNL)

Sandia National Laboratories began as an ordinance design, testing, and assembly facility in 1945 as part of what is now Los Alamos National Laboratory. AT&T began managing the laboratory on November 1, 1949, and continued to do so until 1993 when the Martin Marietta Corp., now Lockheed Martin, took over. The primary mission of the laboratory was to provide engineering design for all non-nuclear components of the nation's nuclear weapons, but by the late 1990s the laboratory's mission had expanded to include all defense systems, energy security, environmental challenges, and national technological challenges facing industry.

STANFORD LINEAR ACCELERATOR CENTER (SLAC)

The Stanford Linear Accelerator Center, administered by Stanford University, was founded in 1962 as a center for experimental particle physics, but it took until 1966 for its first linear accelerator to be completed. The Stanford Synchrotron Radiation Laboratory, built a decade later, became part of SLAC in 1992. Unlike many of other national laboratories that greatly expanded their mission through the years, SLAC always remained a national basic energy research laboratory.

THE FUTURE OF THE LABORATORIES

The most valuable attribute of the laboratories is the vast human and physical resources that can be called upon to solve national problems of great complexity and scope. However, without a national problem or crisis on the horizon, as was the case in the 1990s, the vast funding needed to maintain this national resource comes into question. And since the laboratories are all funded almost exclusively by federal dollars, the ultimate customer is the U.S. taxpayer, a taxpayer who asks: What have I received for my investment? What can I hope for in the future?

In considering the future course of the laboratories, and the involvement of the federal government, there are two important realities to consider. (1) The number of laboratories and their funding has always increased. (2) No national laboratory has ever been closed. There is a good reason for both realities. The laboratories are located in so many different congressional districts that, much like military bases, finding the political will to close any of the laboratories would prove extremely difficult. Moreover, all the major laboratories have also diversified into many different areas of scientific research to further ensure greater and more stable funding. When there was talk about closing one of the defense laboratories as a “peace dividend” following the breakup of the Soviet Union in the early 1990s, Congress approved more funding, not less.

Critics contend that the laboratories are bureaucratically bloated and inefficient, citing numerous independent reports and audits over the last few decades warning that DOE ownership and operation does not work well. Bureaucracy has made it difficult for the laboratories to generate and carry out a viable mission. And following the Chinese spy scandal of 1999, the DOE has also been widely faulted for a failure to ensure the proper security at its weapons labs.

Some critics recommend that the weapons laboratories (Los Alamos, Sandia, Lawrence Livermore) come under the control of the Department of Defense, and that ownership of the other laboratories be sold to the highest bidder, or turned over to the administrator now running the laboratory. The new owner can then contract with public and private entities in the free market, or shut down the laboratories. They contend that this is the best way for the laboratories to create a vision with value and effectively carry out a mission.

Of course, much of the vision and mission problems of the laboratories can be traced back to funding. Federal funding strongly influences activities of the laboratories. Although much of the $5.0 billion allocated each year for basic science and energy research and development is steered toward the laboratories, the projects supported are decided more for political reasons rather than sound economic and scientific ones. This results in the majority of research dollars flowing toward marginal ideas, which is not the fault of the laboratories, yet the laboratories are held accountable for the dismal record of picking winners and losers that were, in reality, ill-conceived political and bureaucratic decisions. Take electricity generation. The winner—the fuel of choice—turned out to be the fuel that the DOE did not feature in its research and development portfolio: natural gas. Of the $60 billion (in 1996 dollars) spent from 1978 through 1996, only 1 percent ($787 million) went to natural gas, while 99 percent was spent on conservation ($13.3 billion), civilian nuclear ($20.1 billion), coal ($13.3 billion), solar ($5.1 billion), geothermal ($1.8 billion), wind ($900 million), other renewables ($2.8 billion), oil ($1.4 billion), and hydroelectric ($193 million).

Proponents of the laboratories counter that, despite these shortcomings, the laboratories serve a vital mission of undertaking the high risk and expensive investments that the private sector would never agree to invest in. Although natural gas research and development was minimal, DOE support accelerated technological advances on natural gas-fired turbines. Much of the research and development at the laboratories has provided a net social benefit to the nation and economy, work such as safe nuclear reactors and the development of sophisticated defense weapons.

The laboratories undertook the high risk and expensive investments that helped improve the efficiency of current technologies on both the consumption and production end. To lessen dangerous emissions at U.S. coal power plants, the laboratories helped develop better burning systems (e.g., pressurized fluidized bed system), and better scrubber systems. They have also participated in partnerships that have been responsible for a number of fuel cell technology breakthroughs. On the consumption side, the laboratories have helped to develop energy use standards for appliances that have significantly helped lower the nation's overall energy consumption.

Another area of success has been in applied materials research. Because of the integral nature of materials to advances in energy production and consumption, the laboratories have developed a number of toughened ceramics. When used as a replacement for steel, they will improve the energy performance characteristics of high-temperature applications for components of combined-cycle power plants and vehicle engines.

Proponents also point to the fact that thirty-one scientists associated with the laboratories have won Nobel prizes, and that the laboratories have received more "R&D 100" awards (award given annually to technology innovations that hold a strong prospect for commercial success) than any other institution.

NATURAL GAS, CONSUMPTION OF

Natural gas is a mixture of naturally-occurring methane (CH_4) with other hydrocarbons and inert gases. The 2.3 trillion cubic meters (Tcm) or 81 trillion cubic feet (Tcf) of gas marketed and consumed globally in 1997 accounted for about 24 percent of the world's primary energy, ranking third among fuels after petroleum liquids (40%) and coal (25%).

The modern natural-gas industry has its origins in the nineteenth century as urban "gas works" that distributed synthesis gas (a mixture of carbon monoxide, hydrogen and carbon dioxide made by the incomplete combustion of coal, oil, or organic wastes in the presence of steam). Gas works illuminated London streets even before 1800, and subsequently

Gas lit lamps in use around 1911. (Library of Congress)

provided lighting, cooking, water- and space-heating for homes, businesses and public buildings. By the late nineteenth century, gas light was common in the central districts of cities and larger towns throughout North America and Western Europe, and even in such places as Buenos Aires, Cairo, St. Petersburg, Shanghai, and Sydney.

Between the World Wars, consumption in North America switched rapidly from synthesis gas to natural gas which, lacking carbon monoxide, was nontoxic and contained three to four times as much energy as synthetic gas per unit of volume. This shift resulted from the advent of thin-walled, seamless welded steel pipe and leak-proof pipe couplings, which permitted highly compressed vapors to be transmitted safely and efficiently over long distances, together with the discovery and production of large volumes of methane as an initially unwelcome byproduct of crude oil. By 1940, almost every major American gas had become a local distribution company engaged in the resale to retail customers of natural gas purchased mostly from oil companies. In western and central Europe, a similar transition from synthesis gas to natural gas waited until the last third of the twentieth century, when pipelines were laid from natural-gas fields in the North Sea, North Africa, and Western Siberia.

In North America, the local distribution companies that distribute and sell gas to retail customers tend to be distinct from both gas producers and the operators of long-line gas-transmission pipelines, although common ownership of businesses in two or three sectors is not uncommon. Gas distributors are generally treated as public utilities, whose retail prices and other terms of service are regulated by state or provincial authorities. Prior to the 1980s, distribution utilities held a legal monopoly on both the physical delivery and the sales of gas within their local service areas. Recently, however, there has been a trend among state/provincial regulators to unbundle gas

sales from supposedly naturally monopolistic transport functions of distributors, and to permit competition among gas marketers for retail sales, particularly to industrial and commercial customers.

GAS USE BY COUNTRY

Reliance on natural gas as a primary fuel varies widely among different national economies from the 1999 global average of 25 percent. In absolute quantity of gas consumed (see Figure 1), the United States is the largest single consumer, with natural gas accounting for 25 percent of its total energy consumption. The share of natural gas in total primary energy consumption in the European Union was similar to that of the United States, 23 percent, but varied from a high of 41 percent in the Netherlands, through 34 percent in Italy, 22 percent in Germany, 13 percent in France, to less than 2 percent in Sweden.

The number-two gas-consuming country, Russia, used about the same volume of gas per capita as the United States in 1999 but depended on gas for more than half (54%) of its total energy. It is worth noting that although the Russian Federation was the world's biggest gas producer, and international exporter, the entire eastern third of the country—Eastern Siberia and the Russian Far East, roughly from Krasnoyarsk to Vladivostok and Magadan—consumed less than five percent of its primary energy in the form of natural gas.

Figure 2 shows no systematic correlation between a country's dependence on natural gas and its degree of industrialization or per capita; GDP. Variation in relative dependence on gas was even wider among the less-developed and emerging economies outside of Europe and North America, from a high of 82 percent in Uzbekistan, 70 percent in Bangladesh and Algeria, and 50 percent in Argentina, to only 8 percent in India, 3 percent in China, and none at all in several African and Latin American countries.

NATURAL-GAS CONSUMPTION PATTERNS

In addition to widely differing degrees of dependence on natural gas, different regional economies exhibit dramatically contrasting consumption patterns for the gas that they do consume. Strong distinctions are evident, for example, between the diversified and finely-tuned natural-gas markets of high-income, high-latitude countries in Europe and America; the high-volume but relatively undifferentiated gas industry of Russia and other former Soviet republics; and the specialized liquified natural gas-based gas-consuming sectors of Japan, South Korea, and Taiwan.

North America and the European Union.

Figures 3 and 4 contrast the gas-consuming patterns of the world's two largest economies, the United States and Japan. The uses of gas tend to be the most diverse in high-latitude areas, where seasons are distinct and winters are cold, and in regions such as North America and the European Union, where economies are generally sophisticated. In these areas, a dense network of transmission and distribution pipelines makes gas directly available to a numerically large and finely differentiated population of potential residential, commercial, and industrial customers. There, the sales for residential, commercial, and institutional space heating peak in the winter months when the market value of gas is highest. "In contrast, peak demand for gas to generate electricity in combustion turbines and combined-cycle plants occurs in the summer, driven by power requirements for air-conditioning. Together, these climate-sensitive, seasonal components of gas demand constitute its most valuable portions, generating more than 60 percent of total sales revenue."

More than 60 percent of natural gas physically consumed in the course of a year is nevertheless attributable to purchases at lower, interruptible prices by industrial boiler-fuel users and electrical generators that are capable of substituting natural gas in off-peak months, when gas is available at prices competitive with those of "black fuels" (coal and heavy fuel oil). In addition to these relatively low-value, price-sensitive industrial gas uses is a wide range of intermediate-value demand categories for natural gas, such as in process and feedstock use.

In such diverse and sophisticated gas-using economies, security of supply and the efficient employment of producing assets depend upon an extensive network of pipelines that interconnect regions with diverse climates and diverse consumption patterns: winter-peaking and summer-peaking; demand that is climate-sensitive, business cycle-sensitive, and price-sensitive; customers who place a high premium on continuity of supply, and those who are relatively insensitive to risk of interruption. These parties depend to a different degree, and place

different values on the access these lines give them to a large and widely distributed system of underground and other gas-storage facilities. The dispatch and allocation of producing, transmission, and storage capacity within the large and diverse population of producing assets and end-users is coordinated by a highly differentiated system of first-sale and wholesale, cash and forward prices for the gas commodity, and for auxiliary services.

Former Soviet Union

Russia, Ukraine, and other entities of the former Soviet Union [FSU] depend even more heavily on natural gas for their primary energy than do the high-income market economies of North America and the European Union. Moreover, their structure of gas demand differs considerably from that of Europe and America, along with the physical and institutional infrastructure of their energy sectors. Because of severe winters, space-heating and domestic water heating doubtless account for an even greater share of total gas consumption than in the West. Rigorous comparison is not possible, because space- and water-heating by means of gas is seldom served or metered separately for individual homes or flats, offices, or small enterprises. Most dwellings and workplaces do use gas or another primary fuel such as coal for space- and water-heating, but only indirectly through steam or hot water cogenerated at steam-electric stations or generated in stand-alone gas-fired district heat plants. District heat produced in this manner is typically distributed to apartment blocks and office towers through elevated and insulated ducts.

Gas for process and feedstock use, and industrial heat for metallurgy, smelting, and materials drying, and other manufacturing applications in the FSU is often delivered directly to the gas-using enterprise, but neither price nor any general system of end-use priorities is systematically used to dispatch or allocate transmission capacity seasonally or among competing domestic shippers, or gas deliverability among competing domestic users. Thus far, the prevailing strategy for accommodating supply and demand in these areas has been to strive to provide sufficient field deliverability and transmission capacity to accommodate the unconstrained aggregate demand of all connected customers, without causing pipeline pressure to collapse.

Japan, South Korea, and Taiwan

The natural-gas industries of Japan, Korea and Taiwan are based almost entirely on gas imported by tanker as liquified natural gas (LNG). These insular and peninsular economies produce almost no domestic natural gas, and until recent efforts to develop production on the Russian island of Sakhalin immediately north of Japan, import of natural gas by pipeline from nearby has not seemed a realistic alternative. In 1999, LNG imports provided about 12 percent of Japan's primary energy, 9 percent of South Korea's, and 6 percent of Taiwan's. In turn, these three countries together accounted for 79 percent of the world's international movements of LNG.

LNG imports to East Asia from Alaska, Southeast Asia, and the Middle East have generally been targeted to specific base-load electrical generating stations built adjacent to the receiving terminals. To minimize delivered costs per unit of fuel, the entire chain of physical facilities from the producing field, through the liquefaction plant at tidewater in the exporting country, the tankers and import terminals, to the receiving customers are tightly coordinated as to capacity and scheduling. The corresponding chain of commercial transactions is composed almost entirely of long-term "take-or-pay" contracts—which oblige the purchaser to pay for the full contracted volume, even if that volume is not or *can* not be taken—for fixed rates of delivery from specific physical sources to specific end-use facilities.

Japan is the world's second largest economy and the fifth greatest consumer of natural gas, behind the United Kingdom and Germany and ahead of Ukraine and Canada. It nevertheless lacks a network of transmission and distribution pipelines capable of delivering gas to diverse and dispersed customers, or reallocating it among them in response to shifting seasonal or business demand. As a result, delivered gas prices to households and industry (other than for base-load power generation) are nearly the highest in the world. Not surprisingly, consumption of natural gas in the residential, commercial, and industrial sectors, and for peak-load electric generation, is exceptionally small.

In the 1990s, Japan's smaller insular and peninsular neighbors, Taiwan and South Korea, began to create integrated national gas-distribution systems that joined previously separate LNG terminals and the potential markets between them. This strategy, particularly in Korea, is consciously directed at creating a more competitive bulk market for gas and expanding the use of gas for space-heating, electricity peaking supply, and industrial fuel.

COMMERCIALIZATION STRATEGIES FOR "STRANDED GAS"

Natural gas is frequently found in association with crude oil, in the search for crude oil, or fortuitously at great distances from developed gas markets or from existing gas-transmission infrastructure-providing access to such markets. In the first half of the twentieth century, carbon black—high-quality soot used as colorant in printing inks and as an additive to rubber in tires—was a leading "scavenger industry" for stranded gas in North America. Later in the century, manufacture of fertilizer, particularly ammonia and urea, created a major part of the early demand for gas along the U.S. Gulf Coast, in Alaska's Cook Inlet basin and in China. The oil industry has recently devoted great effort to promoting gas-to-liquids (GTM) conversion systems to make stranded gas into motor gasoline or diesel fuel. Several GTM technologies are firmly proved, but thus far appropriate market conditions for their commercial application have been hard to find. All of these initiatives are seeking opportunities to convert abundant, low-cost gas into a higher-valued commodity that is liquid or solid at ambient temperatures, and thus can be moved in "normal" tankers, barges or railcars, rather than requiring costly transcontinental pipelines or cryogenic (super-cooled) transport systems. Other notable applications for stranded gas are the local generation of electricity for local consumption and, particularly in the Middle East and North Africa, desalinization of seawater.

INTERFUEL SUBSTITUTION AND COMPETITION

The broad variance in the amount of energy consumed as natural gas, and the diverse mixes of consumption patterns in different countries, illustrate important characteristics of energy supply and demand generally:

- Neither gas nor any other primary fuel or energy source is technically or economically indispensable to

modern civilization. Society's energy "needs" are for heat, light, motive power, information media, and small hydrocarbon building blocks for construction of larger organic-chemical molecules. Primary energy in one form of another is the world's most abundant resource and, in the aggregate and at any human scale, inexhaustible. Economical means are already well established, rapidly proliferating, and improving to transform liquid, solid, or gaseous fuels (and "non-fossil" energy forms) one into another, or into electricity.
- Commercially exploitable natural gas is distributed unevenly in the earth's crust, but is everywhere in relentless competition with other fuels and energy forms over practically all of its actual and potential uses. A substantial share of existing fuel-consuming equipment, mostly in industry or used to generate electricity, has installed dual or multi-fuel capacity. Considering (1) those additional facilities that could economically be retrofitted to use another fuel or energy source, (2) facilities that are nearing the end of their economic lives and subject to replacement by alternatively powered installations, and (3) imminent investment decisions regarding new producer and consumer durables, at least half of the world's energy use is attended by active, near-term interfuel competition.

With appropriate changes in intake, burner, and exhaust hardware, natural gas is readily substitutable for liquid petroleum, coal, and other fuels in almost every stationary (i.e., non-transport) application. Common stationary uses include space heating and cooling, electrical generation, metallurgy, pulp and paper manufacture, petroleum refining, materials drying, and food processing. Natural gas in compressed form or as LNG does indeed serve as transport fuel in motor vehicles, ships, and railway locomotives, and can be adapted even for aircraft, but such mobil employments are less common. Methane and the havier hydrocarbon components of natural gas- ethane and propane-also compete with naphtha, gas oil, and synthesis gas from coal as a feedstock for making the fertilizers ammonia and urea, and "primary petrochemicals" such as ethylene, propylene, methanol, vinyl chloride and acetonitrile. These primary petrochemicals serve as building blocks for further processing into plastics, solvents, pharmaceuticals and other intermediate chemical products.

TRENDS IN GAS CONSUMPTION

Because of the greater difficulty and expense of storing or transporting fuel in gaseous form, markets have historically tended to treat natural gas as less valuable than liquid petroleum products per unit of heating value. However, at the turn of the twenty-first century, world consumption of natural gas is increasing at nearly twice the rate of increase for total primary energy for two reasons: emissions and efficiency.

Natural gas will continue to be substituted for oil and coal as primary energy source in order to reduce emissions of noxious combustion products: particulates (soot), unburned hydrocarbons, dioxins, sulfur and nitrogen oxides (sources of acid rain and snow), and toxic carbon monoxide, as well as carbon dioxide, which is believed to be the chief "greenhouse gas" responsible for global warming. Policy implemented to curtail carbon emissions based on the perceived threat could dramatically accelerate the switch to natural gas.

Natural gas also has an efficiency advantage in electricity generation. The economic and operational superiority of gas-fired combustion turbines and combined-cycle machines (and prospectively, the superiority of gas-powered fuel cells) relative to coal- and nuclear-powered steam turbines made the combination of natural gas and natural gas turbines the supply favorite of most electric utilities in the 1990s.

NATURAL GAS, PROCESSING AND CONVERSION OF

Natural gas is an important energy source consisting mainly of methane gas. It is usually found commingled with deposits of crude oil and also in standalone deposits where the gas has migrated to, leaving the associated petroleum in some other location. Methane is also produced by decaying vegetation (swamp gas) in some coal mines and in land fills, but these sources generally are not suitable for commercial use.

When natural gas comes out of the ground (see Figure 1), it typically consists of 75 to 95 percent methane, with small quantities of ethane, propane, and butane. It may also contain water vapor, carbon dioxide, nitrogen, oxygen, and sulfurous gases such as hydrogen sulfide. Unlike petroleum, which needs to be separated and refined into a variety of fuels and petrochemical products, the nature and general purity of natural gas makes processing far less complex. Most natural gas from the wellhead needs little processing. Nonhydrocarbons are removed from the contaminated alkanes (hydrocarbons containing only single carbon-carbon bonds) by absorption. The heavier hydrocarbons tend to liquefy at the high operating pressures needed for natural gas pipelining. If the natural gas is to be liquefied (LNG), the hydrocarbons are separated by absorption or low temperature distillation.

Before entering the pipeline, the gas is also adjusted in the field to achieve a uniform heating value of 1,000 Btu (British thermal units) per cubic foot. And for safety, because natural gas is odorless and colorless, an odorant is added to provide a distinctive and disagreeable smell that is easy to recognize.

CONVERSIONS

The clean-burning nature of natural gas has for many years made it the fuel of choice for heating and cooking. If its energy content per cubic meter were comparable to liquid fuels like such as diesel and gasoline, it would be ideal as a transportation fuel as well. However, the void is wide. Whereas gasoline and diesel deliver 110,000 to 120,000 Btu per gallon, an equivalent volume of natural gas delivers only about 134 Btu per gallon. Thus, there is great interest in finding ways to efficiently compress or liquefy natural gas so that the same low-emission benefits found in the residential, industrial, and electricity generation markets serviced by pipelines can also be enjoyed by areas without pipeline service and by the transportation sector.

Once water vapor, sulfur, and heavy hydrocarbons are removed, natural gas can be compressed or liquefied. As a transportation fuel, the high methane content gives natural gas its high octane rating (120–130) and clean burning characteristics, resulting in the dual benefit of high engine performance and low pollution. There are no sulfur or particulate (smoke) emissions. Currently, there are two types of natural gas vehicles: exclusively natural gas and bifuel. The latter operate on natural gas or either diesel or gasoline, and the fuel can usually be changed with the flip of a switch.

Compression or conversion for greater use in the transportation market is promising for two reasons: First, natural gas is usually cheaper than liquid fuel and, second, there exist large quantities of stranded gas—remotely located natural gas sources that are not economical to use because tanker or pipeline transportation costs can be over four times as much as for crude oil. Often this gas is recompressed and injected back into the oil-producing zones to help maintain reservoir pressure and optimal crude oil flow to the wellhead. In some cases this gas is wasted by being flared, but this practice is increasingly frowned upon. The demand for cleaner-burning transportation fuels, and the advances in gas turbines that have dramatically improved the efficiency of natural gas powered electricity generation have renewed interest in developing ways to compress or liquefy this gas to lower its shipping cost. Liquefaction can mean cooling the natural gas until it condenses at –187°C (at atmospheric pressure) or converting it chemically to a suitable liquid fuel. Both of these schemes entail considerable energy costs.

Some environmentalists have also touted natural gas as a way station on the road to a hydrogen fuel (carbon dioxide-free) economy. As seen in Table 1, per unit of energy released, natural gas generates about 23 percent less carbon dioxide than gasoline and about 30 percent less than heavy fuel oil. This is helpful in reducing greenhouse emissions, but the other excellent properties of natural gas are even

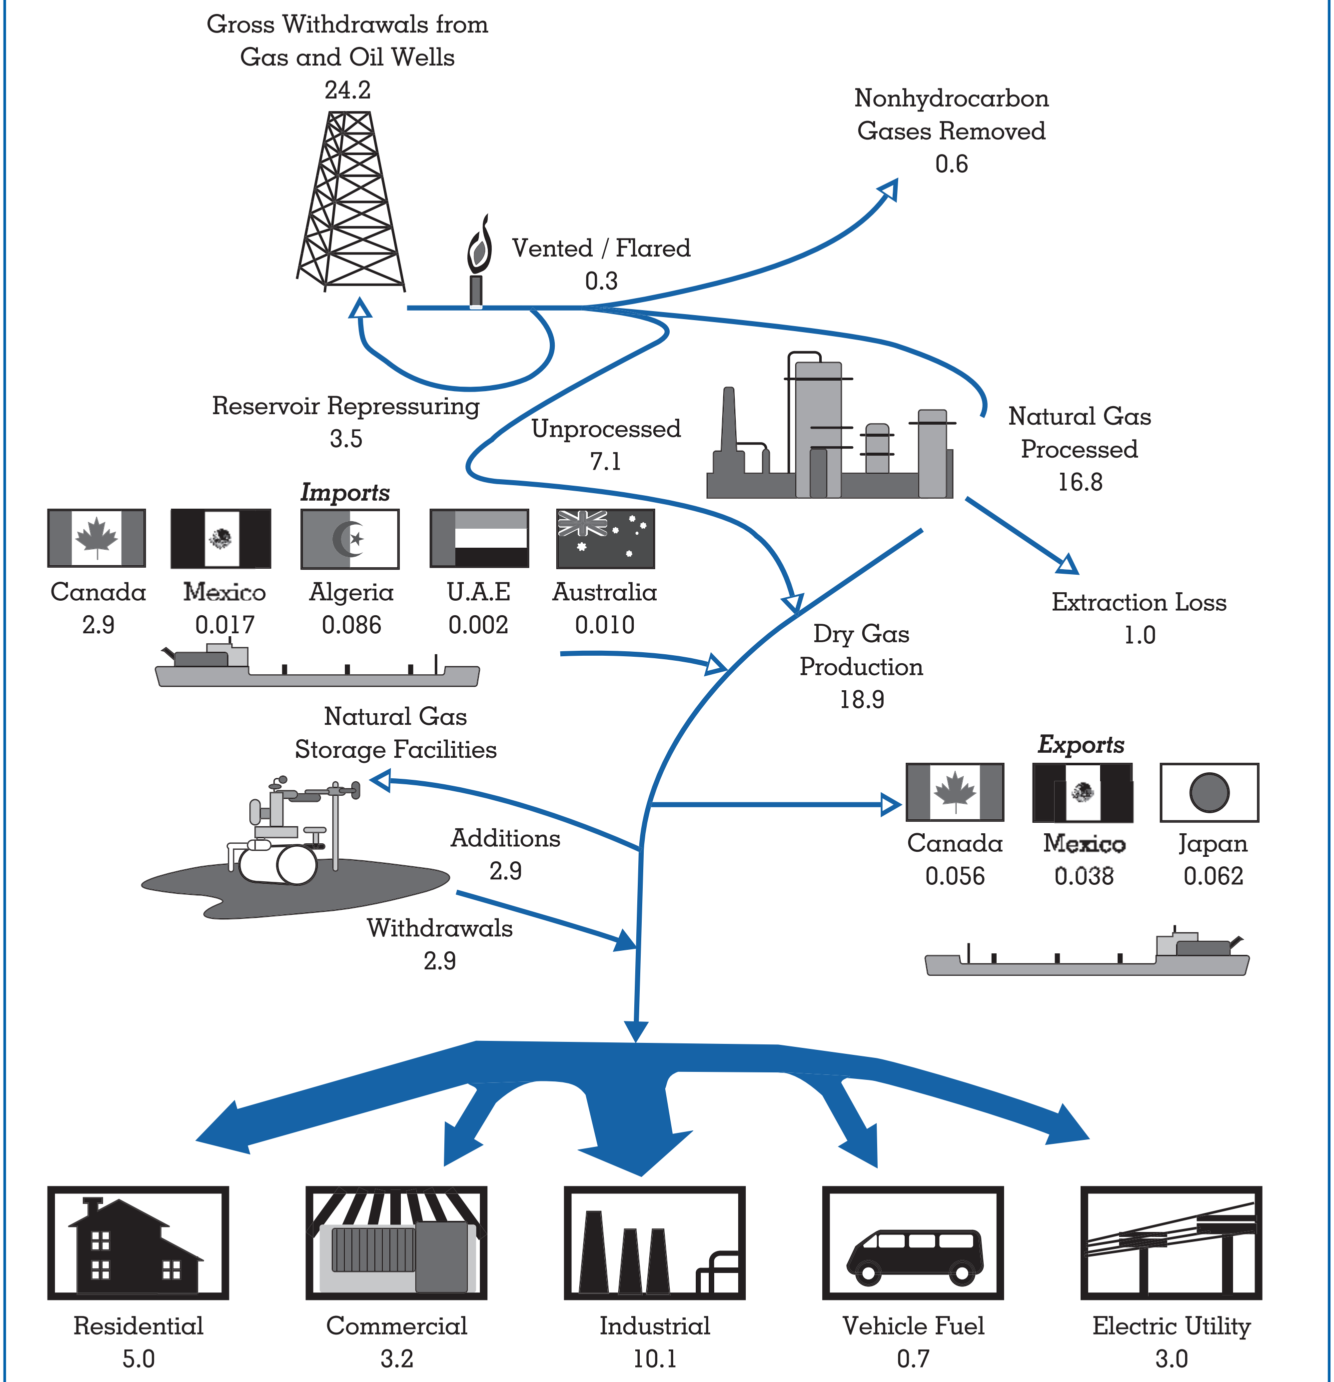

Figure 1.
Natural gas supply and disposition in the United States in trillions of cubic feet.

Grams CO_2 evolved per kilocalorie	0.00	0.207	0.250	0.270	0.254

Table 1.
Fuel Combustion Properties

more important from the standpoint of economic efficiency. However, if the natural gas has to be converted chemically to methanol, the high-octane, clean-burning advantage is maintained, but the carbon dioxide advantage is lost.

As seen in Table 1, on a weight basis, hydrogen has the highest heat of combustion of all fuels. Hydrocarbons are less than half as energetic, the lighter, more hydrogen-rich molecules having somewhat higher heating values than the heavier, more carbonaceous fuels. However, on a volumetric basis, the heavier fuels win out, as their higher density (specific gravity) more than off-sets the difference in heat of combustion per unit weight.

COMPRESSED NATURAL GAS

Table 2 compares the heating value of 20-gal tanks of natural gas at different pressures. Pipelines deliver natural gas at a relatively low pressure of 60 pounds per square inch (psi). A 20-gallon vehicular tank filled at this pressure would provide only about 11,000 Btu versus about 2.4 million Btu for a diesel fuel tank of the same size. Thus, the gas must be compressed and stored in a welded bottle-like tank at 3,000 to 3,600 psi to provide any reasonable range. A 20-gallon 3,000 psi tank will provide about 20 percent of the diesel heating value, so to begin to approach the range of gasoline or diesel vehicles, some of the newer vehicles offer advanced tanks capable of holding gas compressed to 5,000 psi.

Although the heating value of a 20-gal 3,000 psi tank of natural gas is only 20 percent of the same volume of diesel fuel, the mileage range comparison will likely be better than the volumetric ratios because the natural gas engines can achieve higher performance.

There are two ways of refueling compressed natural gas (CNG): time-fill or fast-fill. For a time-fill compressor, it is necessary to develop a pressure only slightly greater than the vehicle storage pressure—the gas flows from greater pressure to less pressure. Time-fill compressor stations can require a couple of hours to refuel, which is a major inconvenience for most motorists. However, it is the best choice for many fleets that can be refueled overnight with one fill-post for each vehicle to be refueled.

Public stations are of the fast-fill type, typically to satisfy the desire of customers to refuel quickly. The biggest problem for fast-fill operations is the lack of space and high cost. Large capacity high pressure storage is needed to fast-fill vehicles because the larger and greater the pressure, the faster the fill-up.

All CNG ground storage, vehicle storage and refueling equipment must meet stringent industry and government safety standards for both normal operation and crashes. The controls include monitors of critical pressures and temperatures from the pipeline to the storage tank, and the flow of gas from ground storage to vehicle storage. Once the compressor reaches discharge pressure (fill-up complete), a control then automatically turns off the compressor. CNG is then delivered to the engines as low pressure vapor (ounces to 300 psi). Since natural gas cylinders are much thicker and stronger than gasoline or diesel tanks, the safety record of natural gas vehicles is equal or better than conventionally fueled vehicles.

Almost all the major car, bus, and truck manufacturers have developed compressed natural gas engines and vehicles. These manufacturers have been able to offer better performance (due to higher octane) and far lower emissions of nitrogen oxides, carbon monoxide, particulate matter, and carbon dioxide to the atmosphere. In 1998, Honda introduced the cleanest internal combustion engine vehicle ever commercially produced: the natural gas Civic GX with emissions at one-tenth the state of California's Ultra Low Emission Vehicle standard. Primarily due to the high octane of natural gas, Honda achieved these results without sacrificing performance.

Despite the environmental benefits of natural gas vehicles, large numbers of compressed natural gas stations need to be built or compressed natural gas will never be more than a niche fuel servicing large fleets of buses, cabs, and delivery trucks that can be fueled at a central location. Nonroad short-range vehicles such as forklifts, backhoes, street sweepers, and airport ground support equipment are also ideally suited for natural gas use.

The high mileage, local routes, and regular returns to a central refueling point make local transit buses an ideal application for CNG vehicles. Another option for local driving and commuting is home refueling. For around $2,500, a system can be plumbed directly into a home's natural gas supply for refueling in the garage or driveway. Though the benefit of home refueling is a tremendous benefit for the majority of drivers, the CNG disadvantages of shorter range, slower refueling, and few refueling stations far outweigh its advantages. American car buyers want the mobility to go anywhere at any time. Whereas most gasoline cars and trucks can go 250 miles or more on a tank of fuel, natural gas vehicles typically can go about half that distance. Consumers are reluctant to switch to a CNG vehicle that requires refueling twice as often with so few refueling options.

The industry has developed higher compression tanks to expand the range, and more fast-fill stations are becoming available, yet the prospects of the majority of service stations adding compressed natural gas refueling anytime in the near future are bleak. The oil companies, which control most of the service stations and over 60 percent of America's natural gas reserves, are not eager to make the massive infrastructure investment to cannibalize the billions of dollars they have tied up in refineries, pipelines, and service stations designed to deliver gasoline and diesel fuel. However, though not willing to lead, they are certain to follow. If consumers purchase the vehicles, the oil companies will naturally invest in the infrastructure. Supply will follow demand. Moreover, if it turns out that fuel cell vehicles that run on hydrogen are the future, compressed natural gas vehicles could be the logical bridge between petroleum and hydrogen because hydrogen is also a compressed gas. The same infrastructure can deliver both.

Pressure	*Million BTUs*
Ambient (14.7 psi)	0.00267
60 psi	0.01009
3000 psi	0.546
5000 psi	0.910
diesel oil	2.4

Table 2.
Energy in a 20-Gallon Tank of Natural Gas (in million BTUs)

More stringent clean-air regulations and enforcement was the primary reason for natural gas vehicle growth in the 1990s, and is highly likely to play a part in future growth. According to the Natural Gas Vehicle Coalition, more than 20 percent of all new orders for transit buses were for natural gas-fueled vehicles in 1998. These new vehicles require a significant capital investment, yet often justify this higher initial investment by reducing air pollutants, lower maintenance costs, and offering fuel savings of about 30 percent compared to gasoline and diesel.

LIQUEFIED NATURAL GAS

Natural gas is liquefied by cooling it to its liquid state (approximately –260°F), at either the wellhead, central facility, or on-site. Since liquefaction reduces its volume by a factor of about 600, it becomes economical to ship by tanker.

To remain a liquid at a reasonably low pressure, liquefied natural gas (LNG) must be maintained at below at least –117°F. Insulated storage tanks alone cannot maintain these very cold temperatures. LNG is stored at its boiling point to take advantage of "autorefrigeration." Just as the temperature of water does not rise above its boiling point (212°F) with increased heat (it is cooled by evaporation), LNG is kept near its boiling point if kept at a constant pressure. As long as LNG vapor boil off is allowed to leave the storage tank, the temperature will remain constant. The pressure and temperature in the tank will rise when the vapor is not drawn off.

During the liquefaction process, usually much of the oxygen, carbon dioxide, sulfur compounds and water are removed so that liquefied natural gas (LNG) is nearly 100 percent methane. LNG takes up one-six-hundredth the volume of natural gas, with a density less than half that of water.

Although LNG is as safe or safer than gasoline and diesel fuel, and emits less harmful emissions when burned, it has three major drawbacks: It is expensive to produce, requires a larger and heavier fuel tank (about 1.5 gallons of LNG per gallon of gasoline and 1.7 gallons per gallon of diesel to achieve the same range), and is not the best fuel for vehicles used rarely or intermittently because of vapor boil-off over time. The best applications for LNG are heavy-duty vehicles (trucks and buses) that are heavily used, and vehicles that can store larger fuel tanks, or are not inconvenienced by need for more frequent refueling.

LNG tanks use low pressure (less than 5 psi), yet need double-wall construction so that insulation between the walls keeps the LNG cool. For the large tanks, a cylindrical design with a domed roof is used, but for smaller quantities (70,000 gallons or less), storage is in horizontal or vertical vacuum-jacketed tanks at pressures any where from less than 5 psi to over 250 psi.

Because much of the world lacks the natural gas resources and transportation pipelines of the United States, remote natural gas must be liquefied and transported by ship. Gas-rich countries want to capture stranded gas by liquefying and shipping it to gas-poor regions as LNG. The gas-poor countries enter into contracts so that a long-term supply is available to warrant the investment in the electricity-generating infrastructure. The overall investment is enormous, not only in the liquefaction plant, but in the refrigerated tankers and the regasification plant at the delivery site.

Sometimes LNG is the only option in regions and countries where political issues constrain pipeline development.

Shipments of LNG began in the early 1960s and continued to expand so that by 1995 there were over 65 ships transporting almost 68 million tons of LNG, with each equipped with a specialized refrigeration system to keep LNG cool enough to stay in its liquefied state. Transportation was estimated to reach 107 million tons by 2,000, with the major exporters being Malaysia, Abu Dhabi, and Qatar, and the major importers being Japan, Korea, and Europe. Since OPEC production quotas limit petroleum production, which by extension limits revenue, LNG has also developed into an attractive export commodity for OPEC countries since current production agreements do not extend to natural gas. Several major projects to expand LNG trade went to contract in the late 1990s. New LNG processing facilities have been built or are under construction in Oman, Qatar, Nigeria, and Trinidad, with Japan, South Korea, Taiwan, and Thailand being the largest customers committing to purchase output from the new facilities.

There has never been an LNG tanker accident; yet, with growing shipments, there is growing concern about a tanker accident since an explosion and fire occurring in a crowded harbor could be disastrous. However, while an LNG tanker may contain the energy equivalent of several Hiroshima atomic bombs, the damage would hardly be comparable because the LNG energy cannot be released quickly. For a detonation, LNG must first be mixed with air in the correct flammability ratio, and near a tank rupture the mix would probably be too rich to explode. Further, the liberation rate of LNG as a gas would be determined by the heat transfer rate to the boiling liquid. Thus, any accident would likely be a large deflagration, not a horrific explosion.

CHEMICAL CONVERSIONS

As an alternate to LNG, natural gas can be chemically converted to methanol, chemical feedstocks (such as ethylene), gasoline, or diesel fuel. Most processes start with the conversion of methane to synthesis gas, a mixture of carbon monoxide and hydrogen. This can be done partial oxidation, an exothermic reaction:

$$CH_4 + 0.5\ O_2 \rightarrow CO + 2\ H_2$$

or by steam reforming, an endothermic reaction:

$$CH_4 + H_2O \rightarrow CO + 3\ H_2$$

Shortly after World War I, Badische Anilin patented the catalytic conversion of synthesis gas to methanol, and Fischer and Tropsch (F-T) announced a rival process in which an iron catalyst converted synthesis gas into a mixture of oxygenated hydrocarbons. Later,

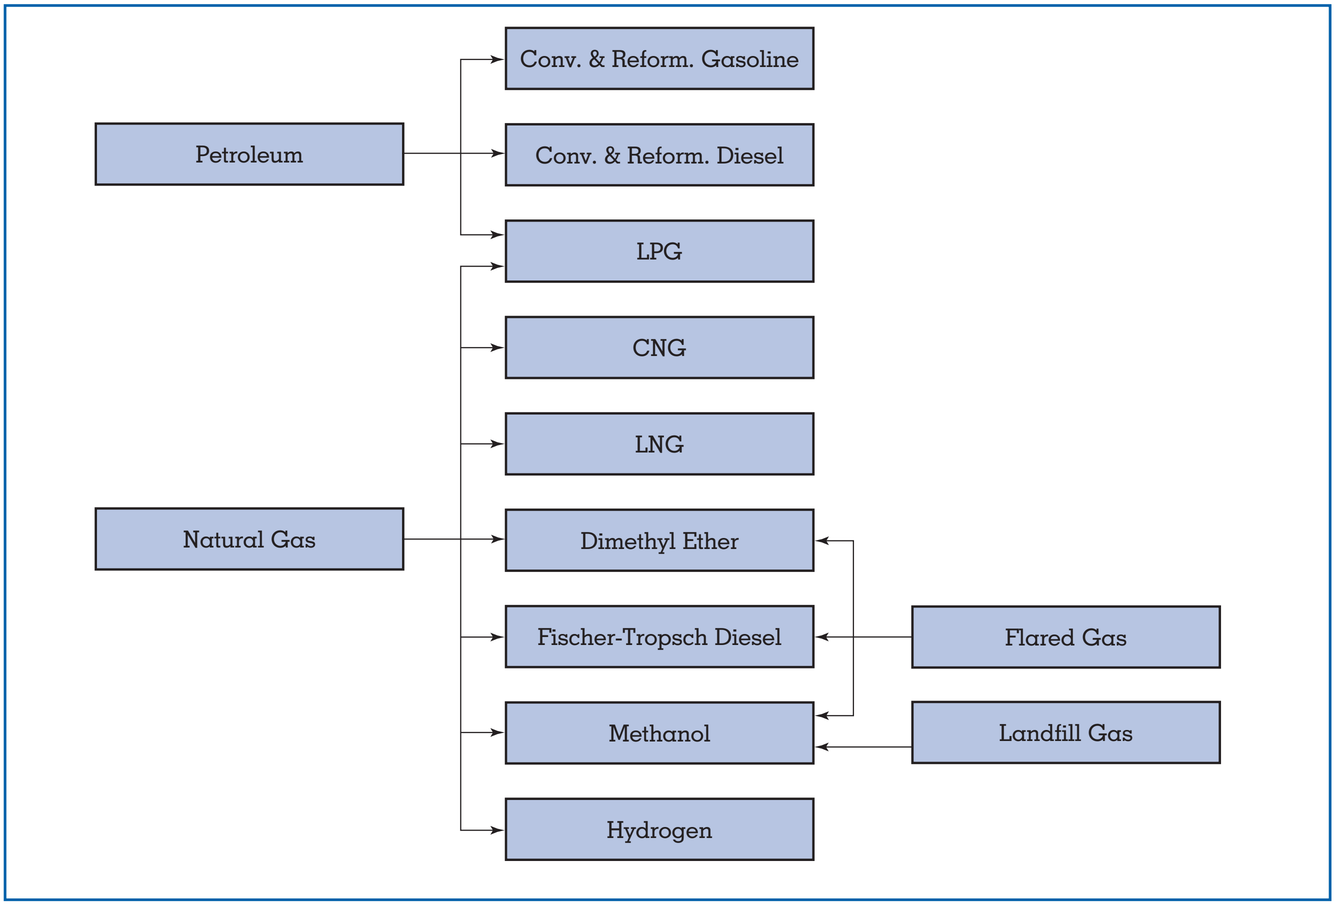

Figure 2.
Alternative fuels derived from natural gas.

improved F-T catalysts produced a liquid resembling a very paraffinic (waxy) crude oil.

Most of the early commercialization used coal as the synthesis gas feed-stock. Use of stranded natural gas feed to a F-T refinery was finally innovated by Shell-Mitsubishi in a small, 10,000 bbl per day refinery in Sarawak, Malaysia in 1993. F-T liquids are refined in the usual manner to produce gasoline and diesel fuel/kerosene of very high quality.

Similarly, a natural gas-to-methanol-to-gasoline process was finally developed by Mobil as a result of the 1973 oil crisis. Methanol is transformed into gasoline range hydrocarbons using proprietary Mobil synthetic zeolite catalysts. This process was commercialized at a small New Zealand refinery in the 1980s. Methanol is also the feedstock of choice in the production of the oxygenated additives needed to produce today's cleaner-burning gasoline blends.

While several other processes have been developed to convert natural gas to liquid fuels (GTL), these technologies are generally uneconomical composed to using the crude oil feedstocks. About one-third of the energy in natural gas is lost in converting it into liquid fuels, so highly distressed gas prices or government subsidies are needed for GTL to be competitive.

Fischer-Tropsch Diesel

One of the most promising GTL fuels is Fischer-Tropsch diesel. Fischer-Tropsch diesel offers lower emissions without compromising fuel efficiency, creating distribution problems (new infrastructure), or requiring a greater investment in equipment for fuel storage and refueling. Depending on the price premium for GTL, the Fischer-Tropsch diesel can be used as a fuel or blended with traditional diesel that is not compliant with Federal or California standards. Used alone, GTL diesel reduces hydrocarbons by over 20 percent, carbon monoxide over 35 percent, nitrous oxide about 5 percent, and particulates around 30 percent. Although GTL diesel is more expensive than traditional diesel fuel, it seems to be a promising short-term solution for the fuel industry to meet the California heavy-duty diesel engine standard that goes into effect in 2004. ARCO, Exxon, Chevron, and Texaco are all in the process of developing pilot plants.

The major advantage of Fischer Tropsch diesel, compared to natural gas, lies in its liquid nature. It does not need special infrastructure and compression like CNG does, and unlike LNG, once converted, it is a liquid fuel that can be treated like any other liquid fuel. However, because the GTL process is more complex than traditional refining, it requires low-cost natural gas priced at less than $1 per million BTUs to remain cost-competitive. Without stranded gas, sources sold at a large discount compared to crude oil, GTL diesel would be considerably more expensive than traditionally refined diesel fuel.

Hydrogen

Many transportation experts feel that hydrogen is the fuel of the future. It has a high energy content and many environmental advantages. However, before hydrogen becomes an economical alternative fuel, ways to produce hydrogen on a large scale will need to be developed. Conversion from natural gas is widely viewed as a promising option for two reasons: Hydrogen-rich natural gas can be converted more cleanly than coal, and natural gas requires less energy input than a conversion from water.

NATURAL GAS AS A FUEL ADDITIVE

Many GTL-derived fuels are being considered for blending with gasoline and diesel to achieve emission reductions of particulate matter (PM), carbon monoxide (CO), nitrogen compounds (NOx) and nonmethane hydrocarbons (NMHC). The most promising fuels converted from natural gas are methanol and ethers such as dimethyl ether (DME) and methyl-t-butyl ether (MTBE).

Like LNG, the natural gas-to-methanol fuel market relies on stranded gas as feedstock. The advantages of conversion to methanol is that it requires far less specialized infrastructure than LNG since the final product is a 110-octane liquid that ships in regular tanks, and does not need regasification. And because of a plentiful natural gas supply in the United States, methanol derived from natural gas as a fuel additive is a promising future market. Methanol has neither the environmental problems of methyl-t-butyl ether (MTBE), nor the evaporating qualities of ethanol.

NATURAL GAS, TRANSPORTATION, DISTRIBUTION, AND STORAGE OF

Transportation of natural gas across state lines from production to consuming areas is a function of interstate pipeline companies. The modern U.S. natural gas industry also includes natural gas exploration and production companies, intrastate pipelines, local distribution companies (LDCs), end-users and, the most recent addition to the industry, marketers.

HISTORICAL BACKGROUND

Transportation of natural gas through pipelines began in the United States in the early part of the nineteenth century. One of the first known uses occurred in 1821 with the building of a system of metallic lead pipes to transport natural gas from a nearby shallow well to commercial establishments in Fredonia, New York. Gas lights—burning gas made from coal—illuminated the streets of Baltimore beginning in 1816.

By 1900, natural gas had been discovered in seventeen states, mostly as a byproduct of oil exploration. Lacking a viable long-distance transportation system to move it to market, however, natural gas, until the 1920s, was used mainly for lighting city streets or was vented into the air when found with oil.

Today, the natural gas industry—responsible for locating, producing, transporting and distributing gas to end-users—is a major contributor to the U.S. economy, employing more than 170,000 workers nationwide. And the fuel, in addition to being used in a variety of commercial and industrial applications—including one of the fastest growing markets, the generation of electricity—is the primary source of energy for space heating in more than fifty million American homes and provides some 25 percent of all the energy consumed in the United States.

This is largely due to the discovery and development of major natural gas fields in the U.S. Southwest, mid-continent, on- and offshore areas of the Gulf of Mexico and Canada—and the development of safe and efficient interstate natural gas transmission pipelines to transport natural gas to markets across the country. Some 77 percent of the natural gas consumers use is produced domestically.

NATURAL GAS PRODUCTION

The first step in the movement of natural gas from production areas to consumers (see Figure 1) begins at the wellhead. Most natural gas wells require pumping to bring the natural gas to the surface. From there, small-diameter gathering lines, connected to clusters or a series of natural gas wells, carry the gas to pipelines or to facilities where it is processed to remove valuable hydrocarbon liquids such as ethane, propane, butane, iso-butane or natural gasoline. Prior to entering the pipeline transmission system, and during actual transmission, the natural gas stream also may undergo processing to remove water vapor, solids and other elements that may interfere with efficient transportation of the fuel.

NATURAL GAS TRANSPORTATION

Natural gas pipelines are generally defined as intrastate, those transporting gas to markets within state boundaries, or interstate, those crossing state lines. Natural gas from Canada, a growing source of natural gas consumed in the United States, also enters the U.S. through interconnections with interstate pipelines.

Today, a network of more than 300,000 miles of interstate natural gas pipelines serves markets across the U.S. Construction of this network began in the 1920s, but large-scale expansion was limited by the technology of the day, the Great Depression and, finally, World War II.

Following War II, advancing technology in steelmaking and the manufacture of pipe, along with increased energy demand, led to rapid growth of the nation's natural gas transportation network. Today, large-diameter, high-quality steel pipe, normally ranging from twenty to forty-two inches in diameter, is constructed at pipe mills, generally in twenty and forty-foot "joints" (sections). Transported by truck or train to construction sites, the joints are welded together and buried in trenches to form the long-distance pipelines necessary to transport natural gas from production basins to distribution and other customers across the nation.

Compressor stations, generally located fifty to sixty miles apart along interstate pipelines, house reciprocating or gas turbine engines that drive compressors to propel the gas through the pipeline. The compressor engines, usually powered by a small portion of the natural gas flowing through the pipelines, compress the gas to an average of 700 to 950 pounds per square inch. In the very early years of the natural gas transmission industry, sections of pipe made of iron or steel were bolted together, often resulting in the loss of major amounts of gas in transit. The advent of modern technology, welded pipe seams, and pipeline protection and monitoring programs have reduced the amount of lost and unaccounted for gas during interstate transportation to negligble quantities, generally a fraction of one percent of all the gas transported.

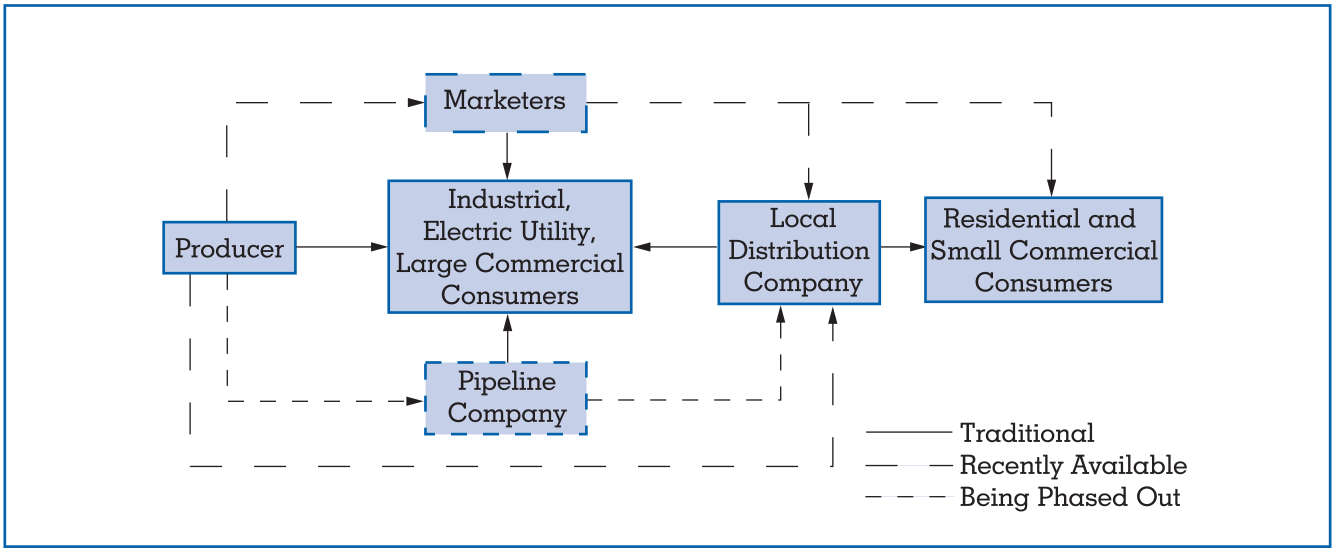

Figure 1.
Transaction paths for natural gas purchases.

BALANCING SUPPLY AND DEMAND

Because of their role as the link between producing and market areas, interstate natural gas pipelines play a crucial role in balancing supply and demand. To do so, the interstate pipelines continually monitor pipeline performance. These companies rely heavily on computers to gather, analyze and retain information on the performance of their pipelines, and to control the flow of gas in remote sections of the line.

Interstate pipelines also use computer simulation programs to calculate pipeline capacity, pressures, horsepower, fuel and other physical characteristics and properties of their systems. Using this information and incorporating variables such as ambient temperatures, facility outages, and changes in market patterns, transmission companies can run daily studies to determine how much natural gas their systems will deliver under expected operating conditions.

Another tool the interstates use to maintain their pipelines is a device known as an intelligent “pig.” Propelled through the pipeline with the gas stream, these devices, taking thousands of measurements with electronic sensors that can be analyzed later by computers, can inspect pipeline interior walls for corrosion or other defects and remove accumulated debris from a section of pipeline. Pipelines also use state-of-the-art coating and cathodic protection to battle corrosion.

Advancing technology has had an impact on the interstate pipeline industry in other ways. Interstate pipeline shippers now have access to electronic bulletin boards (EBBs) which are developed and maintained by the pipelines and can be accessed by users to purchase transportation services, check on billing, determine status of pipeline utilization, arrange for the storage of gas transported through a pipeline and gain other information that allows the pipeline’s capacity to be used efficiently.

NATURAL GAS STORAGE

Underground storage fields play a key role in smoothing the peaks and valleys of natural gas supply and demand. Natural gas transported by pipeline, for instance, can be injected into storage fields near market areas during periods of low demand in the summer and withdrawn during periods of high demand in the winter, thus reducing the need to build additional pipeline capacity to meet high demand periods and allowing pipelines designed to operate at high load factors to run at efficient levels all year. Storage can also be used to prevent flaring of gas and other waste when production exceeds market demand.

Recent uses for natural gas storage include: utilizing storage to provide transportation balancing services, to take advantage of variations in prices, to maintain wellhead production and to meet new sales commitments by marketers.

A crane moves soil next to sections of 42-inch pipes to be used for a gas pipeline. (Corbis-Bettmann)

The three basic types of underground storage facilities for natural gas are depleted oil and gas formations, salt caverns, and aquifer formations. Depleted oil and gas formations, the most commonly used storage sites, are generally classified as seasonal supply reservoirs, where gas is injected in summer and withdrawn in winter. Salt caverns, the large majority of which are located in the Gulf Coast region, are well-suited to storing gas and provide very high withdrawal and injection rates compared with their working gas capacity (the amount of natural gas inventory that can be withdrawn to meet customer needs). Aquifer formations, water-only reservoirs conditioned to hold natural gas, are generally classified as seasonal supply reservoirs and are generally more expensive to develop and maintain than depleted oil or gas reservoirs.

NATURAL GAS DISTRIBUTION

The final link in the physical transportation of natural gas is distribution, the delivery of natural gas by local distribution customers (LDCs) to local consumers. LDCs deliver gas to consumers from storage or from wellheads accessed by pipelines.

Metering gas as it enters their systems, LDCs lower it to pressures suitable for their customers and add the familiar odor that identifies natural gas, otherwise odorless, to the consumer.

For most of the twentieth century, LDCs, either investor owned or municipally owned, have had exclusive rights or franchises to distribute gas in specified geographic areas. Regardless of ownership, LDCs are regulated, either by state public utility/service commissions or local government agencies, to assure adequate gas supply, dependable service and reasonable prices for consumers.

Today, distribution of natural gas involves some 1,200 LDCs that deliver natural gas to more than 160 million American consumers in all fifty states.

RESTRUCTURING OF THE NATURAL GAS INDUSTRY

Government, recognizing the need to provide dependable service at reasonable prices, has been involved with the gas industry since the mid-1800s. Local regulation gave way to state regulation as the issues surrounding exploration, production, transportation, and distribution became increasingly complex. As improved technology allowed pipeline's to carry large volumes of natural gas over great distances, the federal government increasingly became involved in regulation of this segment of the industry.

The first major federal regulatory event affecting natural gas pipelines was the Natural Gas Act of 1938, which gave the Federal Power Commission jurisdiction to regulate three areas: (1) pipeline sales of gas purchased from producers and resold to local distribution companies in interstate commerce; (2) transportation in interstate commerce; and (3) the facilities used for such sales and such transportation.

The second major federal regulatory event was a Supreme Court decision in 1954 which resulted in the imposition of wellhead price regulation of gas sold in interstate commerce.

Until the 1970s, however, the structure of the industry remained relatively constant. Gas producers explored for and produced natural gas and sold it to pipeline companies. The pipeline companies transported the gas across the country and, for the most part, sold it to local distribution companies, who then sold the gas to end users. The price producers sought for their gas from interstate pipelines was regulated by the federal government, as was the price interstate pipelines imposed on gas sold to LDCs. State or local government agencies in turn regulated the price charged by LDCs to end users.

In 1978, the structure of the industry began a period of dramatic change. Following a severe winter and an energy crisis that closed schools, businesses, and industries—and threw more than a million people out of work, Congress passed the National Energy Act (NGPA) and the Public Utility Regulatory Act. This legislation, assuming the nation was running out of natural gas, said that gas could no longer be used for "low-priority" uses and that national policy should promote conservation and shift demand to alternative fuels. The NGPA, to provide producers with incentives for exploration and development of new supplies of gas, called for phased and gradual deregulation of the price of newly discovered gas.

In the early to mid-1980s, retail gas prices began to rise as the more expensive "new" gas constituted an increasing percentage of the pipelines' average cost of gas. This drove consumer prices above the level that would exist in a competitive market, and demand for natural gas was subsequently reduced as large industrial customers switched to other fuels. Also reducing demand were the Fuel Use Act, which prohibited the use of natural gas as a boiler fuel, increased conservation by residential and commercial customers, warmer-than-normal winters, and an economic recession.

In 1985, the Federal Energy Regulatory Commission (FERC) began a series of regulatory actions designed to improve the competitiveness of the natural gas market and give the customers of interstate pipeline companies more service options and thus allow ultimate consumers to benefit from deregulation of wellhead prices.

By 1993, the structure of the interstate pipeline industry had undergone dramatic changes. The interstates, which once had acted as both transporters and merchants of natural gas, "bundling" the sale and transmission of gas into one service, were required to separate these services and give pipeline customers the opportunity to contract for only those services they needed.

With "unbundling," interstates no longer own the gas transported on their pipeline systems. They simply transport it for third parties who range from LDCs to natural gas marketers. (Emerging in the 1980s in response to the deregulation of prices, marketers serve as intermediaries between gas buyers and all other segments of the industry.) And buyers of natural gas can now negotiate price and contract terms with different gas suppliers while contracting separately with the interstates for transportation, storage and other services.

Restructuring has also affected LDCs. Many LDCs, for example, given increasing flexibility by regulators, now allow large volume customers to select the most cost-effective and efficient mix of supply, transportation, storage, and other services.

PRICING OF NATURAL GAS

Several factors determine the ultimate price consumers pay for natural gas. They include

Pipeline Transportation Pricing: The Federal Energy Regulatory Commission (FERC) regulates the rates, terms and conditions of service provided by interstate natural gas pipelines. The FERC, with the issuance of its "restructuring" rule, Order 636, in April 1992, set a policy goal to separate the transportation of gas from the sale of gas and to put all natural gas suppliers and gas purchasers on equal footing. Before restructuring, as described earlier, the interstates bought gas from producers and sold it to LDCs and other end users. The rates they charged were "bundled" and included charges for a variety of services including supply, storage, and transportation. Now the interstates must provide all transportation services on an equal basis, whether the gas being transported is purchased from the pipeline, a pipeline marketer or another gas supplier.

Wellhead Pricing: With passage of the Natural Gas Wellhead Decontrol Act of 1989, all remaining wellhead price controls on natural gas were lifted. As a result, federally mandated natural gas wellhead prices no longer exist. With this, the competitive marketplace has become the most important factor affecting natural gas wellhead prices, along with weather, demand, pricing of competitive fuels and competition for supplies.

The Spot Market: This segment of the natural gas market consists of transactions of a short duration that can be rearranged quickly if gas prices change. The spot market developed in the early and mid-1980s, when there was a substantial supply of gas and long-term supply contracts fell into disfavor. Spot market prices fluctuate depending on availability of supply. Most LDCs do not rely exclusively on spot-market transactions, depending on time of year. In the event of unexpected demand surges, however, LDCs and other customers may be forced to purchase spot market gas.

Futures Prices: Natural gas futures contracts began trading on April 3, 1990, on the New York Mercantile Exchange (NYMEX). Sabine Pipe Line Company's Henry Hub near Erath, Louisiana, is the delivery site for these contracts. Henry Hub consists of an interconnection of seven interstate pipelines, two interstates and one gathering system. These interconnections allow natural gas to move from major production areas to major consumption areas. The transportation of natural gas to and from Henry Hub is contracted separately by the seller and buyer, respectively.

Price Indexing: Some gas prices, by contractual agreement, reflect changes in the spot, futures or other markets, such as heating oil. Price indexing is often used to reflect that the parties to the contract believe the price to be paid is related in some way to the particular index used.

Residential Pricing: Residential natural gas rates are for natural gas service and for the gas commodity. The price of the gas commodity comprises about one-third of the total price a residential customer pays, on average. The remainder of the bill includes amounts for transmission and distribution of gas, system maintenance, safety and inspection programs, customer service, metering, billing and other costs.

THE FUTURE OF THE NATURAL GAS INDUSTRY

Additional Regulatory Change

The natural gas industry, undergoing fundamental changes in recent years, continues to face additional change. Current issues include discussion about lifting the federally-set caps on pipeline pricing for certain services and letting the market determine pricing on these services, as well as a number of new pipelines proposed to import significant new volumes of Canadian gas into the United States.

On the state level, several pilot programs now allow customers to choose gas suppliers other than their LDCs.

Supply Outlook

Debate continues over just how much natural gas remains in North America. Part of this debate centers on the definition of gas reserves—the amount of gas in a given area that is recoverable and gas resource, the total amount of gas in the ground. Gas production to date, as might be expected, has most commonly been from easy-to-produce conventional sources, such as the mid-continent or the highly permeable sands of the Gulf Coast.

A considerable amount of gas is located in areas of lower permeability or where the geology is poorly understood, making it more difficult to earn a profit using current technology and production methods. New technology may open these sources to future development and production.

Additionally, new supplies of natural gas from Canada and Alaska could significantly increase available supply, along with imports of Mexican gas and the potential for liquefied natural gas from overseas.

Demand Outlook

Demand for natural gas, in all markets—residential, commercial, and industrial—is projected to grow into the foreseeable future, particularly in the electric power generation market and the industrial sector. Total natural gas use in the United States is projected to grow from 20.1 quadrillion British thermal units in 1992 to 26.1 by 2010, an average growth rate of 1.6 percent per year.

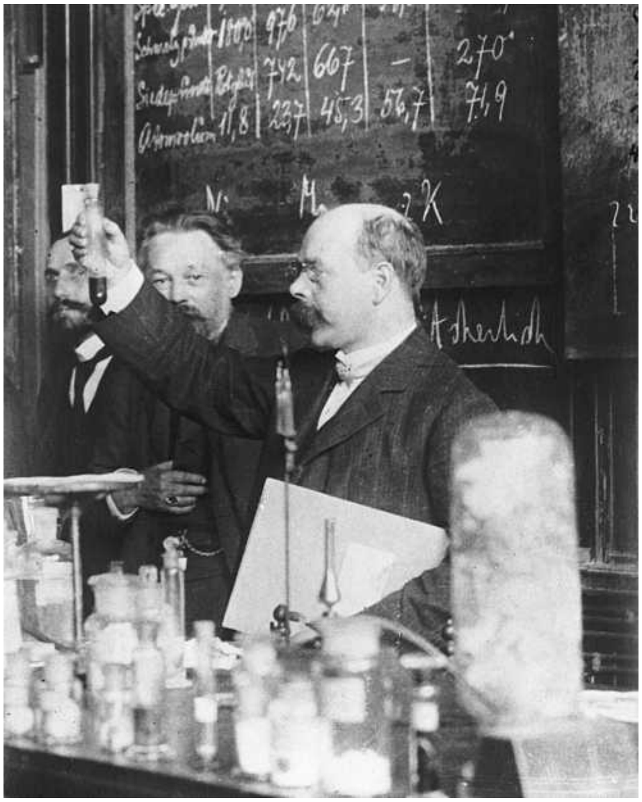
NERNST, WALTHER HERMANN (1864–1941)

Walther Hermann Nernst was born in Briesen on June 25, 1864, into a prominent Prussian family. The line of his ancestors can be traced back to the era of the first Prussian king in the seventeenth century. His most famous ancestor is Hermann Nernst, who received an award for conveying the news to the king's family about the Germans victory against Napoleon in the Battle of Waterloo. Nernst lost his mother, Ottilie Nerger, very early. His father, Gustav Nernst, was a district judge. Nernst was a very impulsive person and known for his impatience. He died of a heart attack in his country house in Zibelle on November 18, 1941.

When Nernst attended secondary school, his chemistry teacher awakened in him a passion for chemistry. This left a deep impression on the young pupil, who started early to do his own chemistry experiments at home, in the cellar. Nernst often changed universities during his study of physics, as he wanted to take part in selected lectures by the most influential comtemporary scientists. First he visited the physics lectures of Heinrich Friedrich Weber in Zurich in 1883 and then he went to Berlin for a semester to take thermodynamics lessons from Hermann von Helmholtz, the most famous German physicist at that time. After another semester in Zurich, Nernst studied for the fourth semester in Graz, where Ludwig Boltzmann founded the statistical interpretation of thermodynamics. Nerst, finished his education there and started his Ph.D. program in collaboration with Albert von Ettinghausen, one of Boltzmann's students. Nerst, finished his Ph.D. requirements in Wurzburg in 1887 under the supervision of Friedrich Whilhelm Georg Kohlrausch, who entered a completely new physical field with his research on the ionic conductance of liquids. Nernst adopted Boltzmann's atomistic view (or mechanical picture) of natural phenomena and combined it with the energetic view that he became familiar with during his collaboration with Wilhelm Ostwald in



Walther Hermann Nernst in his laboratory. (Corbis-Bettmann)

Leipzig. It was due to Svante Arrhenius that Nernst became highly interested in the new topic of ionic theory that was established by Ostwald. Fascinated by this topic, Nernst habilitated in Leipzig in 1889 on the electromotive activity of ions. He incorporated into this work Arrhenius' theory of dissociation and Jacobus Henricus van't Hoff's osmotic theory of solutions. Two years later Nernst became an assistant professor in physical chemistry at the University of Gottingen. In 1905 he was offered an appointment as the successor of Hans Landolt and started his work at the University of Berlin. In the same year he discovered the third law of thermodynamics during the time he was lecturing on the thermodynamical treatment of chemical processes. Nernst worked in many fields of physical chemistry—for example the osmotic theory of galvanic elements, the law of distribution, equilibrium at high temperatures and high pressures, specific heats at high and low temperatures, calorimetry, IR radiation, chain reactions, electrochemistry, and photochemistry.

Of fundamental importance to Nernst's discovery of the Third Law of Thermodynamics is Nicholas Leonard Sadi Carnot's work in the middle of the nineteenth century establishing thermodynamics by combining the laws of motion with the concept of action. At the same time Helmholtz found that the principle of energy conservation is also valid for thermal energy and established together with Robert Julius Mayer and James Joule the first law of thermodynamics. A short time later Rudolf Clausius and Carnot introduced the concept of entropy and established the second law of thermodynamics. The chemical affinity—the extent to which a compound is reactive with a given reagent—was known of since attempts of alchemists to produce gold in the Middle Ages. The importance of the concept of chemical affinity was first recognized by van't Hoff. He showed that it was possible to measure the chemical affinity via free energy. Helmholtz and Josiah Gibbs independently established an exact mathematical relationship between the total energy (the energy content of a system) and the free energy (the capacity of a system to perform work). According to Marcellin Pierre Berthelot the total and the free energy should be the same during the electrochemical processes in the galvanic cells Nernst was investigating. Nernst's experiments showed that this statement was not exactly valid for moderate temperatures, and the deviation became larger as the temperature was increased. Therefore he assumed that both energies should be equal at zero value of temperature. Finally, he got the idea that the difference between these two energies asymptotically approaches zero as the absolute temperature approaches zero. This is the first formulation of the new law. Nernst was led to this law, which he and other scientists spent a long time investigating, while he was searching for mathematical criteria for the description of chemical equilibrium and the spontaneity of chemical reactions. That why some chemical reactions are spontaneous while others are not was already known a century before Nernst's own discovery. Since 1900 it was known that a thermodynamical calculation of the chemical equilibrium could not be performed using only the thermal data of the current thermodynamics because the integrated form of the Gibbs-Helmholtz Equation—which allowed calculation of the maximum yield of work during a thermodynamical process—contained an undetermined integration constant.

Nernst's contribution to the solution of this problem was to give this undetermined constant a new interpretation. This new interpretation, however, required an additional assumption for the description of the free energy exchange in the vicinity of the absolute zero value of temperature. He recognized that the work function for the state transition of a system could not be calculated by means of energy differences. Rather, derivatives of the energy and the free energy with respect to temperature were necessary. Furthermore, Nernst assumed that the entropy approaches a constant value provided the absolute temperature approaches zero.

After Nernst's publication of his *Heat Theorem* all resources of the Institute for Physical Chemistry at the University of Berlin were dedicated to its experiments. No experimental result was found to contradict Nernst's heat theorem. Its general validity, which was established by experiments in many subfields of physical chemistry, justified its inclusion among the laws of thermodynamics. This law was regarded by Arnold Sommerfeld as "the most ingenious extension the classical thermodynamics ever experienced in the twentieth century." Expressing Nernst's heat theorem in terms of entropy, this law means that the entropy difference between different states of a system tends to zero as the temperature reaches absolute zero. It can also be expressed as the law of unattainability of absolute zero temperature. Franz Eugen Simon provided Nernst's heat theorem a more elegant theoretical foundation and reformulated it by stating that the entropy differences disappear between all those states of a system that are in internal thermodynamic equilibrium. Very soon after he set forth the third law of thermodynamics, Nernst showed the importance of his discovery by calculating the chemical equilibrium using thermal data only. Nernst was awarded the Nobel Prize in chemistry in 1920 as recognition of his work in thermochemistry.

NEWCOMEN, THOMAS (1663–1729)

Fable or fame? Thomas Newcomen, like many inventors who preceded him in the steam revolution, has been clearly overshadowed in historical circles by the far more famous Scotsman, James Watt, who remains—incorrectly to some—known as the inventor of the steam engine. Watts engines arrived more than fifty years after Newcomen's successful mechanical works, and were considered improved versions of the Englishman's concepts. But this was precisely the basis of many inventors' successes, building upon their predecessors' efforts in the normal course of technological advancement. What is irrefutable is that both men, as well as others, can lay claim as pioneering "fathers" of the Industrial Revolution.

Newcomen came from the ranks of practical tradesmen, unlike many industrial inventors who tended to be noblemen, philosophers and royal protégés. The Newcomen family had had an impressive lineage and had held its manor from the twelfth century until misfortune dropped them into obscurity four centuries later. Yet, a work ethic was instilled by Newcomen's grandfather, who became a merchant venturer (owning several ships), a freeholder of Dartmouth, treasurer for his town, and a staunch Parliamentarian. Elias Newcomen, the father of Thomas, was also a freeholder and a merchant of Dartmouth, trading to distant areas with a ship that he had inherited.

It is reasonably certain that Thomas Newcomen was born in late January or early February 1663 in the family house in Dartmouth in Devon, England. He was schooled at home by the well-known nonconformist scholar, John Flavell, who played a key role in Newcomen's educational thinking. Although throughout his life Newcomen was proud of his common status as an ironmonger, some rivals attempted to credit his success to no more than good luck and chance. Many of his contemporaries doubted that he could be the sole author of so momentous an invention.

But going solo neither accurately summed up the style of Newcomen's inventiveness, nor his ability to learn from others and to work with them. In his teens, he served an apprenticeship before joining his partner, John Calley, in their shop at Dartmouth. By the time Newcomen began solving technical tin mining challenges at the beginning of the eighteenth century, he was already well established as an iron-monger, dealing in annual quantities as high as twenty-five tons per year. He apparently became acquainted with Thomas Savery, or at least his works, observing firsthand the pumping problems in the mines. He may also have read about earlier research on atmospheric pressure done by a Huguenot, Denis Papin, late in the seventeenth century.

Although Newcomen's predecessors may have had superior backgrounds and academic intelligence, his doubters possibly overlooked the practical advantages he and his partner brought to the research table. Through astute knowledge of every variety of metalwork in iron, brass, copper, tin, and lead, he and Calley possessed the right combination of commercial ability and highly practical and versatile craftsmanship. Historical data suggests that these categories may have been deficient among his forerunners in the matter of applying the principles of steam technology.

Yet, Newcomen's success came with great difficulty and frustration, taking ten years before achieving initial success at a South Staffordshire colliery (mine works) at Dudley Castle in 1712. He perfected a variation of Savery's work by creating a dramatic advance of an internal water injection system to cool the heated steam, creating a far more rapid and effective condensation and ensuing vacuum. There is some historical evidence that the arrival of this particular breakthrough came by fortunate accident, whereby an unintended leak may have led him to design his internal water-cooling system.

In another significant change, he connected one end of a large overhead rocking beam, or "great lever," to this piston. Realizing the risks of high pressure steam, he thus wisely relied on two basic forces to drive his engine—atmospheric pressure to plunge the piston down, and simple gravity to lift it back it up, through the weight of the counterbalancing rocker beam.

By modern standards, it was barely an engine at all, but it met the most important criteria of its time by dramatically meeting the challenge of pumping water from the mines, doing the equivalent work of twenty horses and forty men. The use of his excellent pumping engine spread throughout Europe, with over one hundred engines constructed within the life of the patent, which expired four years after his death on August 5, 1729, at the age of sixty-six. Well over fifteen hundred units were eventually built during the eighteenth century, despite their significant cost (over one thousand pounds), high consumption of fuel, and the requirement of an operating license.

The usefulness of Newcomen engines was both startling and unprecedented, with immediate impact benefiting the mining industry for the next century or more. The record for longevity for a Newcomen-type engine was probably set at the South Liberty colliery of the Ashton Vale Iron Company. It was built around 1750, and was still pumping from a depth of seven hundred feet it was until dismantled in 1900. Another remarkable example was at the Cannel Mine at Bardsley, where a Newcomen engine worked from 1760 to 1830, after which it rested in a derelict state for a full century. In 1930 it was acquired by Henry Ford and shipped to his museum in Dearborn, Michigan where it was restored and re-built.

While not nearly as sophisticated as later engines, the quantity of Newcomen engines built vastly exceeded the hundreds of Watt engines, with the more primitive types often used as substitutes for the newer, far more expensive versions.

NEWTON, ISAAC (1642–1727)

Isaac Newton was born at Woolsthorpe, near Grantham in Lincolnshire. He entered Cambridge University as a student in 1661. Although much is known of Newton's professional life, little is known about Newton's student life. He studied under Isaac Barrow, the Lucasian professor of mathematics. He was forced by the plague of 1665–1666 to return to Lincolnshire where, during the miraculous year of 1666, he forged the foundations for his considerable achievements in mathematics, optics, and dynamics.

After returning to Cambridge in 1667, Newton was elected Fellow of Trinity College. Two years later he succeeded Barrow as Lucasian Professor. In 1696 Newton moved to London. He served first as Warden and from 1699 to his death in 1727 as Master of the Royal Mint. He was elected a Fellow of the Royal Society of London in 1671, and the President of this society in 1703, a position he retained for the rest of his life. He also served two undistinguished terms as a Member of Parliament for the University of Cambridge (1689–1690 and 1701–1702). He was knighted in Cambridge in 1705.

In the period following the War of the Spanish Succession of 1714, Newton enjoyed a reputation as the most important natural philosopher of his day. His scientific output during the last twenty years of his life was restricted to the revision of his major works and in defending himself against his many critics. In his private life, he was modest, generous, and given to simple tastes; however was buried with great fanfare in Westminster Abbey.

In his scientific life, his behavior and demeanor were far different. Newton was hostile to any criticism and he was capable of ruthless behavior. The priority dispute with the German mathematician Gottfried Wilhelm Leibniz over the invention of the calculus is a case in point. In his capacity as President of the Royal Society, Newton appointed a committee of loyal Newtonians to investigate the matter. He then authored the committee's report, the infamous *Commercium Epistolicum* and submitted it as though it were an utterly impartial report in his own favor.

Newton has been regarded as the very exemplar of the modern scientist, employing a style of reasoning from "the phenomena of motions" that other scientific disciplines have attempted to emulate with limited success. However, his interests ranged far from mathematical physics. From 1669 to 1696 he pursued alchemy and chemistry with equal or greater passion. His knowledge of the Greek classics was profound. In his *The Chronology of Ancient Kingdoms Amended* (1728), he attempted to reconcile Jewish and pagan dates and to fix them absolutely from an astronomical argument about the earliest constellation figures devised by the Greeks. In *Observations upon the Prophecies of Daniel and the Apocalypse of St John* (1733), Newton also wrote on Judeo-Christian prophecy, sustained by the conviction that its decipherment was essential to the understanding of God.

Isaac Newton. (Archive Photos, Inc.)

As to his scientific output, Newton contributed to all extant branches of mathematics, but is renowned for his solutions to the problems in analytical geometry of drawing tangents to curves (differentiation) and defining areas bounded by curves (integration). Newton discovered that these problems were inverse to each other, and designed general methods of resolving problems of curvature—his "method of fluxions" (from the Latin meaning "flow") and "inverse method of fluxions." Fluxions were expressed algebraically, but

Newton made extensive use of analogous geometrical arguments. Late in life, Newton expressed a preference for the geometric style of the Classical Greeks, which he regarded as more rigorous.

During 1669, Newton worked out the details of his discovery of the decomposition of a ray of white light into rays of different colors by means of a prism. Newton's explanation of the theory of the rainbow followed from this discovery. These discoveries formed the subject matter of a series of lectures that he delivered as Lucasian Professor in the years 1669, 1670 and 1671. The results were communicated to the Royal Society in February 1672 and subsequently published in the *Philosophical Transactions.* Reactions to Newton's ideas were negative. The inability of the French physicist Edmé Mariotte to replicate Newton's prism experiments in 1681 entrenched the rejection of Newton's optical theory for a generation. Newton delayed the publication of his *Opticks* (published in 1704, revised in 1706), which was largely composed in 1692, until his critics were dead. The manuscript of his original lectures was printed in 1729 under the title *Lectiones Opticae.*

Through a curious set of circumstances, Newton failed to solve the problem of chromatic aberration, and so, he abandoned the attempt to construct a refracting telescope which should be achromatic, and instead designed a reflecting telescope, probably on the model of a small one that he had constructed in 1668. The form he used is known by his name today.

Newton's dynamics is presented in *Philosophiae Naturalis Principia Mathematica* (published in Latin in 1687, revised in 1713 and 1726, and translated into English in 1729). According to the famous story, on seeing an apple fall in his orchard sometime during 1665 or 1666, Newton conceived that the same force governed the motion of both the Moon and an apple. Newton calculated the force needed to hold the Moon in its orbit, as compared with the force pulling an object to the ground. He also calculated the centripetal force needed to hold a stone in a sling, and the relation between the length of a pendulum and the time of its swing.

These thoughts were put away until correspondence with Robert Hooke (1679–1680) redirected Newton to the problem of the path of a body subjected to a centrally directed force that varies as the inverse square of the distance. Newton calculated this path to be an ellipse, and so informed the astronomer Edmond Halley in August 1684. Halley's urgings prompted Newton to return to the problem raised by Hooke.

Facsimile of Newton's *Philosophiae Naturalis Principia Mathematica.* (Corbis Corporation)

The result of Newton's labor was *Principia,* which introduced a radically new style of reasoning in science, one that treated scientific problems as though they were exercises in pure mathematics. Newton's work enabled scientists to study forces of different sorts without any inhibiting considerations as to whether such forces can actually (or do actually) exist in nature.

Book I of *Principia* is organized around fundamental laws and axioms, erecting on this foundation the mathematics of orbital motion around centers of force. Gravitation is identified as the fundamental force controlling the motions of the celestial bodies. Newton did not advance an explanation for gravity itself, much to the disappointment of his critics. Its manner of action and its cause were matters that Newton worked hard to distance from the domain of mathematical physics. Further to this, the first half of this book is not entirely original, since it rests upon the achievements of René Descartes, Galileo, and Christian Huygens. Newton's genius shines, however, in the second half of the book where the problem of two bodies is reduced to an equivalent problem of one body attracted to a fixed center. It is here that we find the masterpiece of this book—Newton's treatment of the three-body problem. It is true that his formulation of the general laws of mechanics ruled out a solution to this problem, but Newton's approach inspired future generations of physicists.

Book II investigates the dynamical conditions of fluid motion. Book III displays the law of gravitation at work in the solar system. It is demonstrated from the revolutions of the six known planets, including Earth, and their satellites, though Newton could never quite perfect the difficult theory of the Moon's motion. It is also demonstrated from the motions of comets. The gravitational forces of the heavenly bodies are used to calculate their relative masses. The tidal ebb and flow and the precession of the equinoxes is explained in terms of the forces exerted by the Sun and Moon. These demonstrations are carried out with precise calculations.

Newton's work in dynamics was accepted at once in Britain, though it was strongly resisted on the Continent until 1740 or so when the last of his critics conceded that, while gravitation itself was inconceivable, Newton's arguments were incontestable. During the eighteenth century, Newton's dynamics was extended and perfected by others, but its basic character was unchanged. It was only in the late nineteenth century that Newton's dynamics began to reveal its limitations. Where Newton regarded the law of gravitation as a significant dynamical result, Albert Einstein argued that this law is a geometric result, on a par with Galileo's law of inertia. The movement of a planet around the sun, for example, is to be seen, not in terms of the action of gravity, but in terms of the curvature of space.

NITROGEN CYCLE

All life is dependent on nitrogen; nitrogen is a critical component of amino acids, protein, DNA, and RNA. While the atmosphere is 78 percent nitrogen, animals and plants cannot convert nitrogen directly from the atmosphere into a utilizable form. The nitrogen cycle is the process by which nitrogen from the atmosphere is converted to biological nitrogen compounds in plants and animals and then is returned to the atmosphere. The major steps in the nitrogen cycle are nitrogen fixation, nitrification, nitrogen assimilation, denitrification, and ammonification.

Nitrogen fixation is the conversion of nitrogen (N_2) in the atmosphere to nitrates (NO_3^-) and ammonia (NH_3). In nature, this is done primarily by microorganisms (bacteria and algae). The most important bacteria in this process are symbiotic bacteria that live on nodules on the roots of leguminous plants such as soybeans, peas, and alfalfa. The electricity in lightning also can cause a small amount of nitrogen to be fixed by directly combining nitrogen and oxygen. Nitrification is the process wherein ammonia is further converted to nitrates. Plants use nitrates to make proteins by nitrogen assimilation. Animals consume these plants for subsequent protein production. The cycle is completed by bacteria converting decaying plants, animals, and excretory products back into either atmospheric nitrogen (denitrification) or ammonia compounds (ammonification).

The natural supply of nitrogen available to plants from the nitrogen cycle is limited. To meet the growing demands for agriculture crops, nitrogen is added to soil in the form of fertilizers. An estimated one-third of the human population is fed as a result of the use of synthetic fertilizers.

To “fix” nitrogen in synthetic fertilizers requires hydrogen that is obtained by dissociation from water or from fossil-fuel hydrocarbons. Either way, this process is energy-intrusive. The situation is ominous to some scientists, since the supply of a fundamental world energy source—food—is dependent on nonrenewable energy sources that are being depleted. Although the addition of fertilizers is the largest human impact on the global nitrogen cycle, the burning of fossil fuels also accounts for an increase in the amount of fixed nitrogen in the atmosphere. Anthropomorphic activity is responsible for as much nitrogen fixation as that from natural sources.

There are environmental consequences to human influence on the nitrogen cycle. While the addition of nitrogen to the soil is required to feed the world population, it is estimated that 50 percent of the nitrogen added as fertilizers is washed off the soil and ends up in agricultural runoff. This can cause contamination of drinking water in agricultural areas. Excess fertilizers in waterways also can cause eutrophication, where excess nitrogen leads to events such as algae bloom, which robs other plants and animals of oxygen. Agricultural runoff has altered areas ranging from San Francisco Bay to the Baltic Sea to the Great Barrier Reef. In addition, excess nitrates in the soil can acidify the soil, causing loss of other soil nutrients.

Excess fertilizer and combustion processes also can increase nitrous oxide (N_2O) and nitrogen oxides (NO_X) in the atmosphere. Nitrous oxide is a powerful greenhouse gas, and nitrogen oxides lead to smog and acid rain. The production of fertilizers requires a great deal of energy. The use of fossil fuels to supply the thermal requirements for fertilizer production further increases emission of nitrogen compounds to the atmosphere.

NUCLEAR ENERGY, BASIC PROCESSES OF

Nuclear energy, sometimes referred to as atomic energy, originates in the atomic nucleus, which is the extremely dense core at the heart of an atom. A large

Nuclear Power Plant reactor building and cooling tower (left). (Field Mark Publications)

amount of energy can be released by nuclei in two different ways: fission, in which a very large nucleus is induced to break apart into two smaller ones, and fusion, in which two very small nuclei combine.

A great deal of energy is released when a large nucleus undergoes fission, but for most nuclei the fission process is not easy to initiate. There are very few nuclei—uranium-235 and plutonium-239, in particular—that are relatively easy to fission. At present, commercial nuclear reactors use fission of uranium-235 as the energy source. A uranium-235 nucleus can be induced to undergo fission through interactions with a slowly-moving neutron. The uranium nucleus absorbs the neutron, thus becoming a uranium-236 nucleus, which then breaks apart into two smaller nuclei called fission fragments. In addition, neutrons are also released, and these neutrons can then induce fission of other uranium nuclei in a chain reaction. Neutron-absorbing materials are located in the reactor core to ensure that the chain reaction proceeds at the proper pace. If too few neutrons are available for further fissions, then the reaction slows down or stops. If too many neutrons are available, then the reactor core can overheat.

The energy from nuclear fission is released mainly as kinetic energy of the new, smaller nuclei and neutrons that are produced. This kinetic energy is essentially heat, which is used to boil water to generate steam that turns turbines to drive electrical generators. In a nuclear power plant, the electrical generation area is essentially the same as in a plant that burns fossil fuels to boil the water.

Nuclear fission is also involved in nuclear weapons. To create a bomb, the concentration of the isotope uranium-235 must be increased to at least 85 percent from its natural concentration of only 0.7 percent. This increase of concentration is difficult and expensive. In a typical nuclear reactor the uranium-235 concentration in the fuel is only 3 to 4 percent, and hence a nuclear reactor cannot explode like a bomb. In a nuclear bomb the chain reaction is uncontrolled, and a large number of uranium nuclei undergo fission in a very short period of time, producing a nuclear explosion.

Generation of electricity by nuclear fission power reactors has many advantages. A primary advantage is that very little uranium fuel is required—only about two-hundred tons annually for a typical reactor. To generate the same amount of electricity, a coal-fired plant needs 3 million tons or 15,000 times as much coal. Another advantage is that nuclear power produces no air pollution such as nitrogen oxides and sulphur dioxide, both of which contribute to acid rain, and no greenhouse gases such as carbon dioxide and methane that contribute to global warming. Nuclear power also produces no ozone and no particulate matter in the air, and hence, in terms of air pollutants, a nuclear plant is much "cleaner" than a fossil-fuel electrical plant.

Nuclear reactors, however, do generate highly radioactive waste. This waste, which consists primarily of the fission fragments and their radioactive-decay products, must be stored for many years before its radioactivity decays to a reasonable level, and the safe long-term storage of this waste is a matter of great concern and debate. Fortunately, the volume of waste that is created is only about 20 cubic meters annually from a reactor, compared with 200,000 cubic meters of waste ash from a coal-fired plant. When nuclear weapons were tested in the atmosphere, the radioactive products from the nuclear explosions were released into the air and fell to Earth as radioactive fallout.

Another concern about nuclear power plants is their decommissioning. Nuclear reactors have useful lifetimes of about thirty years, after which they need to be shut down permanently. The remaining fuel, which is very radioactive, will have to be removed and stored for many decades. The entire reactor building structure has also been made somewhat radioactive, as well as all the pipes, valves, etc., in the plant. There are a number of options for dealing with this radioactive material, ranging from immediate dismantling of the plant (with some of the work probably done by robots) to using the normal reactor containment structure as a long-term storage facility. In the United States, the Nuclear Regulatory Commission has required that plant owners set aside sufficient funds for dismantling.

The greatest concern that most members of the general public have about nuclear energy is the possibility of a catastrophic accident such as occurred in 1986 at Chernobyl in the Ukraine. If reactors have been properly designed and the staff trained with safety in mind, then the chance of a major accident is very slight. The Chernobyl disaster was caused by a combination of poor reactor design and insufficient training of the reactor operators, who violated many of the operating procedures related to safety.

Nuclear *fusion* is the energy-producing process that occurs in the sun and other stars. Small nuclei such as those in hydrogen and helium fuse together to produce larger nuclei, releasing energy. Nuclear fusion is not yet commercially viable as an energy source, since extremely high temperatures are required to initiate fusion, and containment of the fusing nuclei at these temperatures is difficult. However, if nuclear fusion ever becomes a usable energy source, a typical fusion power reactor would require less than a ton of fuel annually.

It is often stated that nuclear fusion will produce no radioactive hazard, but this is not correct. The most likely fuels for a fusion reactor would be deuterium and radioactive tritium, which are isotopes of hydrogen. Tritium is a gas, and in the event of a leak it could easily be released into the surrounding environment. The fusion of deuterium and tritium produces neutrons, which would also make the reactor building itself somewhat radioactive. However, the radioactivity produced in a fusion reactor would be much shorter-lived than that from a fission reactor. Although the thermonuclear weapons (that use nuclear fusion), first developed in the 1950s provided the impetus for tremendous worldwide research into nuclear fusion, the science and technology required to control a fusion reaction and develop a commercial fusion reactor are probably still decades away.

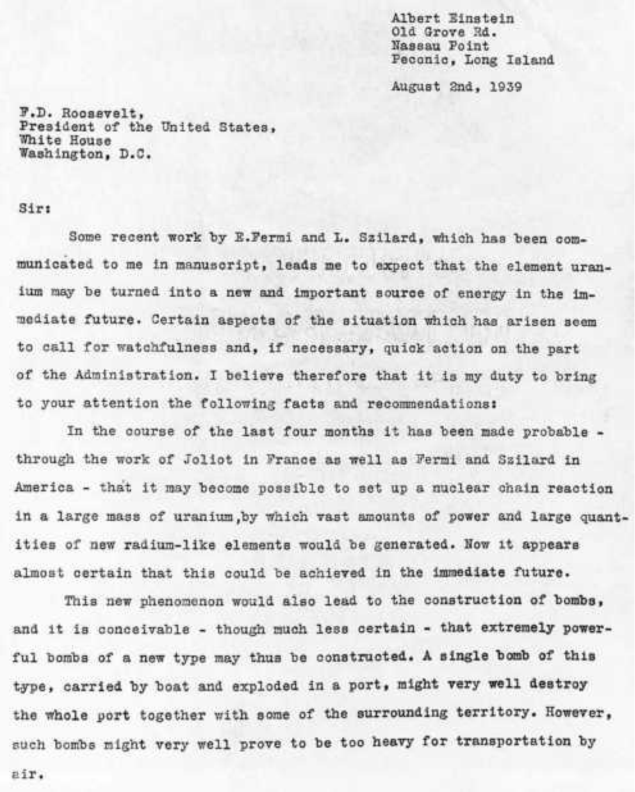
NUCLEAR ENERGY, HISTORICAL EVOLUTION OF THE USE OF

The history of nuclear energy is a story of technical prowess, global politics, unfulfilled visions, and cultural anxiety. The technology's evolution in the second half of the twentieth century progressed through several stages: theoretical development by physicists; military application as atomic weapons in World War II; commercialization by the electrical industry in several industrialized nations; proliferation (for military and non military uses) among less developed nations; crises spawned by power plant accidents, cost overruns, and public protests; and retrenchment and slowdown in the last few decades of the twentieth century. By far the most potent form of energy to be harnessed by humankind, nuclear power has not become the dominant form of energy because of the great economic costs and social risks associated with its use.

MILITARY ORIGINS

The concept of "atoms" dates back to the ancient Greeks, who speculated that the material world was comprised of tiny elemental particles, and for centuries thereafter alchemists attempted to unlock the secrets of the elements. But modern atomic science did not emerge until the turn of the twentieth century. In 1896 Henri Becquerel of France discovered radioactivity, and Albert Einstein calculated the mass-energy relationship ($E = mc^2$) in 1905. By the 1930s, scientists in several countries were making progress toward understanding nuclear reactions, including Ernest Rutherford and James Chadwick in Great Britain; Enrico Fermi in Italy; Niels Bohr in Denmark; and Ernest O. Lawrence in the United States. The key breakthrough came in December 1938, when German physicists Otto Hahn and Fritz Strassmann achieved the first controlled atomic fission, splitting atoms of uranium into lighter elements by bombarding them with neutrons, and releasing enormous amounts of energy in the process.

The news spread quickly, and became charged with implications as Hitler's Nazis began their march through Europe. Two days before the outbreak of World War II in Europe in 1939, Bohr and John Wheeler of Princeton published an academic paper on fission. Several leading physists fled Germany and Stalin's Soviet Union for the United States, including Hungarian refugee Leo Szilard. Fearful that the Nazis might build a powerful atomic bomb, Szilard and fellow Hungarian émigré Eugene Wigner convinced Einstein (then at Princeton University) to write President Roosevelt to warn of the possibilities of atomic weaponry and to suggest U.S. action.



Albert Einstein
Old Grove Rd.
Nassau Point
Peconic, Long Island

August 2nd, 1939

F.D. Roosevelt,
President of the United States,
White House
Washington, D.C.

Sir:

Some recent work by E.Fermi and L. Szilard, which has been communicated to me in manuscript, leads me to expect that the element uranium may be turned into a new and important source of energy in the immediate future. Certain aspects of the situation which has arisen seem to call for watchfulness and, if necessary, quick action on the part of the Administration. I believe therefore that it is my duty to bring to your attention the following facts and recommendations:

In the course of the last four months it has been made probable - through the work of Joliot in France as well as Fermi and Szilard in America - that it may become possible to set up a nuclear chain reaction in a large mass of uranium,by which vast amounts of power and large quantities of new radium-like elements would be generated. Now it appears almost certain that this could be achieved in the immediate future.

This new phenomenon would also lead to the construction of bombs, and it is conceivable - though much less certain - that extremely powerful bombs of a new type may thus be constructed. A single bomb of this type, carried by boat and exploded in a port, might very well destroy the whole port together with some of the surrounding territory. However, such bombs might very well prove to be too heavy for transportation by air.

The first page of a letter dated August 2, 1939, from Albert Einstein to President Franklin Delano Roosevelt. In the letter Einstein advises Roosevelt of the possibilities of nuclear research. (Corbis-Bettmann)

Einstein's letter (dated August 2, 1939) had little impact, however. What stirred the U.S. government into action were reports out of Great Britain in the early 1940s: one from German refugee physists Rudolf Peierls and Otto Frisch in 1940, which discussed the possibility of making a "super-bomb" from a uranium fission chain reaction; and a study from the top-secret British "MAUD committee" in 1941, which deemed a uranium bomb "practicable and likely to lead to decisive results in the war," and which urged the United States to make development of an atomic bomb its "highest priority."

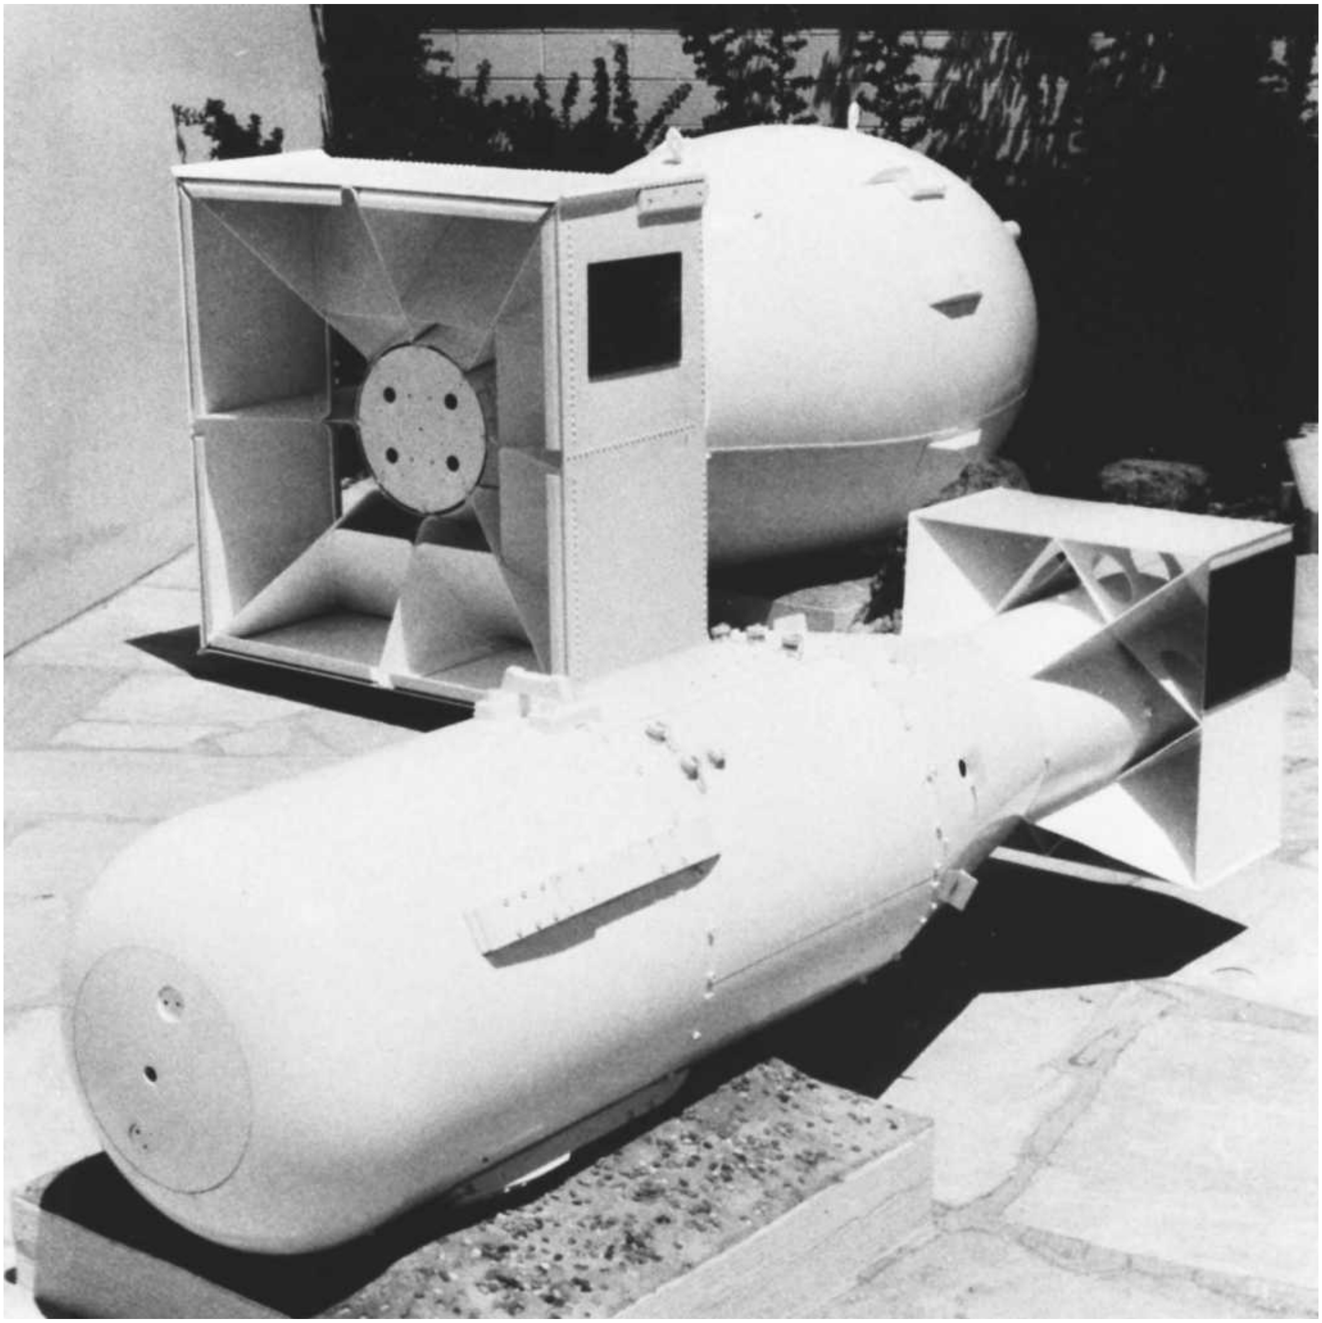
At the time, the scarcity of fissionable material—whether natural uranium or man-made plutonium—seemed the greatest barrier to atomic bomb production. Now determined to win the atomic bomb race, President Franklin Roosevelt approached Colonel (soon-to-be Brigidier General) Leslie Groves of the U.S. Army Corps of Engineers to head what was code-named the "Manhattan Engineer District" (later popularly known as the Manhattan Project), America's atomic bomb project. It was a massive, sprawling effort that ultimately encompassed several leading university laboratories, three giant manufacturing sites, tens of thousands of constructions workers, the world's best scientific talent, several major corporations, and some $2.2 billion of federal funds.

The project's two key scientific advisers were Vannevar Bush, an electrical engineer at head of the Office of Scientific Research and Development, and a former dean of the Massachusetts Institute of Technology; and James Conant, a chemist, chair of the National Defense Research Committee, and president of Harvard University. Groves also recruited Nobel laureate Arthur Compton to the project, who in turn recruited Wigner and Szilard as well as Nobel laureates Fermi and James Franck to his burgeoning research laboratory at the University of Chicago (code-named the "Metallurgical Laboratory"). Meanwhile, the army brought in Boston-based Stone & Webster as principal engineering contractor, and the giant Du Pont chemical firm, which had no experience in plutonium production but took on the work for costs plus $1. After Fermi—working in a racquetball court under the stands at the University of Chicago's Stagg Field—achieved the first self-sustaining nuclear reaction in December 1942, the Manhattan Project settled on water as a coolant and forged ahead with construction plans.

At Hanford, Washington, along the Columbia River, the project built three production piles (reactors) and four separation plants for separating plutonium from other elements. At Oak Ridge, Tennessee (near Knoxville), it built uranium-235 facilities utilizing three processes—thermal diffusion, gaseous diffusion, and electromagnetic separation; the latter, under the direction of Lawrence, proved to be the most successful. And at Los Alamos, New Mexico (near Santa Fe), the Manhattan Project in 1945 began building a facility for making both plutonium and uranium bombs under the direction of the brilliant Harvard- and Gottingen-educated physicist J. Robert Oppenheimer. Like the Chicago-based scientists before him, Oppenheimer and his researchers often clashed with Groves and the project engineers, who preferred to compartmentalize and control information about the project rather than exchange it freely among the scientists. At Los Alamos, Oppenheimer's approach prevailed.

Confident that the uranium bomb would detonate with a gun-type neutron device but less sure of the plutonium bomb's "implosion" detonation device (invented by physicist Seth Neddermeyer), the scientists tested a plutonium bomb—dubbed "Fat Man" in honor of Winston Churchill—at Alamogordo, New Mexico, on July 16, 1945. The awesome power of "Project Trinity" immediately inspired doubts and fears about a nuclear future, even among several Manhattan Project scientists. Szilard, Franck, and others urged the U.S. military to demonstrate the atomic bomb to the Japanese in an uninhabited area; but the momentum of the project, and political pressure for a rapid end to the war, were too great. On August 6, the U.S. B-29 bomber *Enola Gay* dropped a uranium atomic bomb ("Little Boy") that detonated over Hiroshima, Japan, at 8:15 A.M., killing an estimated 75,000 to 100,000 people instantly, and another 200,000 from radiation over the next five years. Three days later, the United States destroyed Nagasaki with a plutonium bomb, and the Japanese surrendered shortly thereafter. By building the largest government-business-university collaboration in its history, the United States had harnessed atomic energy and brought World War II to a rapid end.

Over the next several years, the atomic bomb helped usher in a new kind of geo political conflict: the Cold War. Rather than clashing with conventional weapons, the two postwar superpowers—the democratic United States and the Communist Soviet Union—relied increasingly on their growing arsenals of nuclear weapons to protect their spheres of influence and to deter encroachment with the threat of mutual destruction. Tensions in the early Cold War were heightened when the United States refused to share atomic bomb technology with its erstwhile ally the Soviet Union. When the USSR successfully tested its own atomic bomb in 1949, the "arms race" between the superpowers to achieve nuclear superiority was on. In October 1952 the United States tested its first hydrogen bomb, at Eniwetok Atoll in the Pacific. By fusing light forms of hydrogen to create helium—the reaction responsible for the Sun's energy—the "H-



Two atomic bombs named "Fat Man" and "Little Boy." The latter was used to destroy Hiroshima, Japan, during World War II. (Library of Congress)

bomb" exploded with 1,000 times the power (the equivalent of some 10 million tons of TNT) of its fission predecessor. The USSR had the H-bomb by 1953. The U.S. then began developing new, solid-fuel intercontinental ballistic missles (ICBMs) to deliver bomb warheads from the U.S. western plains deep into the Soviet Union.

The post–World War II generation was the first to live under the shadow of total and instantaneous annihilation, a reality that—coming on the heels of the holocaust and the massive military horrors of World War II—gave rise to a new nihilism among some philosophers and social thinkers. Psychologists began to probe the possible mental health consequences of life in the atomic age, although many concluded that nuclear apocalyse was too vast and horrible to comprehend. And, not surprisingly, the atomic bomb began to find its way into everyday life and popular culture, sometimes in bizarre and even lighthearted ways.

Communities began to refashion their civil defense procedures to accommodate the bomb. In the United States, this meant designating bomb shelters—usually in the basements of schools and other public buildings, but also involving construction of individual shelters beneath the yards of single-family homes in the nation's burgeoning postwar suburbs. Stocked with canned foods and other provisions, these underground chambers typically were small and spartan, although some realtors seized the opportunity to offer luxury models with modern conveniences. While never ubiquitous, individual bomb shelters nevertheless became normalized, as reflected in a 1959 *Life* magazine story about a newlywed couple who spent two weeks of "unbroken togetherness" honeymooning in their bomb shelter.

The atomic bomb also became a key subject in 1950s American film, particularly in the science fiction genre. While some films spun out scenarios about how the nuclear powers might accidentally bring on Armageddon—as in *Fail-Safe* and Stanley Kubrick's classic tragicomedy *Dr. Strangelove*—most focused on the insidious and little-understood effects of radiation on human and animal life. However implausible the premises of *The H-Man, Attack of the Crab Monsters, The Incredible Shrinking Man, Attack of the Fifty-Foot Woman,* and their ilk, such fantasies resonated with widespread anxieties about genetic damage from atomic fallout.

Although government officials attempted to educate the public and military personnel about atomic civil defense, in retrospect these efforts seem hopelessly naive if not intentionally misleading. Army training films advised soldiers to keep their mouths closed while observing atomic test blasts in order to not inhale radioactive flying dirt. Civil defense films used a friendly animated turtle to teach schoolchildren to "duck and cover" during a nuclear attack—that is, duck under their desks and cover their heads. Such measures, of course, would have offered pitiful protection to those in the blast zone.

Opinion polls showed that American anxiety about the atomic bomb ebbed and flowed in response to geopolitical events. Concerns ran high in the late 1940s in the wake of the atomic bombings of Japan (many wondered whether the weapon would be used in all military conflicts), and as the Soviet Union undertook a crash program in rocketry and atomic-bomb development. These fears cooled temporarily in the early 1950s, particularly after the death of Soviet dictator Joseph Stalin in 1953 raised hopes for U.S.-Soviet rapprochement. But ICBM development and a wave of H-bomb testing in the Pacific in 1954 stirred up renewed public fears about fallout, especially after milk in heartland cities such as Chicago was found to contain elevated levels of isotopes. The national heart rate spiked during the tense days of the Cuban Missile Crisis in 1962, then slowed after the United States and the Soviet Union signed the Partial Test-Ban Treaty in 1963. Whereas 64 percent of Americans identified the threat of nuclear war as their leading concern in 1959, only 16 percent put the same concern first in 1964.

"ATOMS FOR PEACE": THE ORIGINS OF THE NUCLEAR POWER INDUSTRY

The Atomic Energy Act of 1946 represented the interests of American scientists who wished to see nuclear energy developed for nonmilitary purposes. It called for the establishment of a five-member civilian Atomic Energy Commission (AEC), which could deliver weapons to the military only on presidential order. But the military tensions of the early Cold War delayed civilian nuclear power development until 1948, at which time 80 percent of the AEC's budget went to military ends. In 1951, U.S. civilian nuclear power development consisted of only a small experimental government (liquid metal) reactor in Idaho.

Through the efforts of Captain Hyman G. Rickover, a naval engineering officer, the U.S. Navy made rapid strides in nuclear ship and submarine development. Garnering support from Edward Teller and other key figures outside the navy, Rickover brought in Westinghouse, General Electric, and the Electric Boat Company to construct the *Nautilus,* the world's first nuclear submarine. First tested in 1955, the *Nautilus* ran faster and ten times farther without surfacing than conventional submarines. Nuclear-powered aircraft carriers and other surface ships followed, and by the 1960s U.S. nuclear submarines were equipped with solid-fuel nuclear missiles. In contrast, the U.S. merchant marine did not emphasize use of nuclear power. Its demonstration vessel, the *Savannah,* operated by the U.S. Marine

Corporation beginning in 1959, used a pressurized-water reactor instead of a boiling-water reactor, and required a heavy government operating subsidy.

In 1953 the AEC began planning a full-scale nuclear plant at Shippingport, Pennsylvania. The plant was to be owned and operated by Duquesne Light Company, managed by Rickover, and equipped with a version of the navy's pressurized-water reactor. But rapid U.S. nuclear power development came only in the wake of the new Atomic Energy Act of 1954, which permitted private power companies to own reactors and to patent nuclear innovations; and the Price-Anderson Act of 1957, which limited liability for individual companies to $560 million and gave government subsidies for liability insurance. The first American plants went on line in the early 1960s.

The USSR operated the first nuclear power plant supplying a national grid at Obninsk, south of Moscow in 1954. This modest (5,000 kW) plant was the opening wedge in an aggressive Soviet drive for nuclear energy as reflected in the Bolshevik slogan "Communism equals Soviet power plus electrification of the entire country." Two years later, the United Kingdom operated a full-scale commercial nuclear plant at Calder Hall, a facility designed to produce plutonium for defense with electricity as a by-product. France ran an experimental reactor, at Marcoule, that year, but began its commercial program with the 'Electricite' de France Chinon reactor in 1962. By 1965 the United Kingdom led in nuclear power output with 3.4 million kWh, followed by the United States (1.2 million kWh), the USSR (895,700 kWh); Italy (622,000 kWh); and five other nations producing at least 500,000 kwh each. Within a few years the United States took the lead in technology and total output, its pressurized-water and boiling-water reactors supplied by enriched fuel from Manhattan Project plants.

These were heady times for the nuclear industry. Well-informed experts predicted that electricity soon would become "too cheap to meter." At the 1964–1965 New York World's Fair, General Electric's "Progressland" exhibit featured "the wonders of atomic energy"; and the company's Medallion City claimed to produce fusion energy (using a 0.000006 second, 100 million flash). Fusion energy, said General Eelectric, was going to supply a billion years of electrical energy.

Nuclear power developed unevenly across the globe. In 1987 the United States operated 110 of the world's 418 nuclear plants, the USSR 57, France 49, the United Kingdom 38, Japan 37, Canada 19, and Sweden 12, while some regions—the Arab states, Africa (except South Africa), and most of Central America—had few or none. Although the United States produces a third of the world's electricity, it derives only 15 percent of it from nuclear energy.

In each country, the pattern of nuclear development reflected national technical and economic resources, politics, and culture. In France, for example, national economic planners ensured the rapid growth of nuclear energy by limiting citizen participation and by standardizing reactor design. The Federal Republic of Germany followed a style closer to the United States, and thus sustained greater political challenges by its environmentally sensitive Green Party.

In balancing development with social safety, the Soviet Union was a grim outlier. Recent research has revealed a series of Soviet nuclear accidents, many of them concealed from the outside world, beginning with a dramatic waste dump explosion in 1957 near Kyshtym in the Urals that spread more than 2 million Ci over 20,000 sq miles. The explosion of Unit 4 at Chernobyl, north of Kiev, on April 26, 1986, was the worst recorded nuclear accident in history. It happened when operators were testing a voltage-regulating scheme on turbogenerator 8 when coolant pumps were slowed. Vigorous boiling led to excess steam, slow absorption of neutrons, and increased heat in a "positive feedback" cycle that resulted in meltdown and explosion. By early May, airborne contamination completely covered Europe. Thirty-one people were killed, 200 suffered radiation sickness, hundreds of thousands of people were confined indoors or evacuated, foods that were suspected of being contaminated were banned, and scientists projected some 1,000 extra cancer deaths over the next fifty years. Perhaps most troubling, follow-up investigation faulted Soviet plant design as much as or more than operator error. Following the accident, public opinion shifted sharply against nuclear energy in Europe, but in the United States, the tide already had turned.

NUCLEAR POWER UNDER SIEGE

In the 1950s, widespread anxieties about the atomic bomb in the 1950s spurred few into action. One notable exception in the United States was the Greater St. Louis Committee for Nuclear Information, founded by biologist Barry Commoner and other scientists at Washington University in 1958. This watchdog group published *Nuclear Information* (renamed *Science and the Citizen*) in 1964. For the most part, however, citizens of the two superpowers and their satellites or allies saw nuclear weapons as a necessary tool in the global contest between democracy and communism. Indeed, for many, atomic supremacy was the most accurate measure of national prowess.

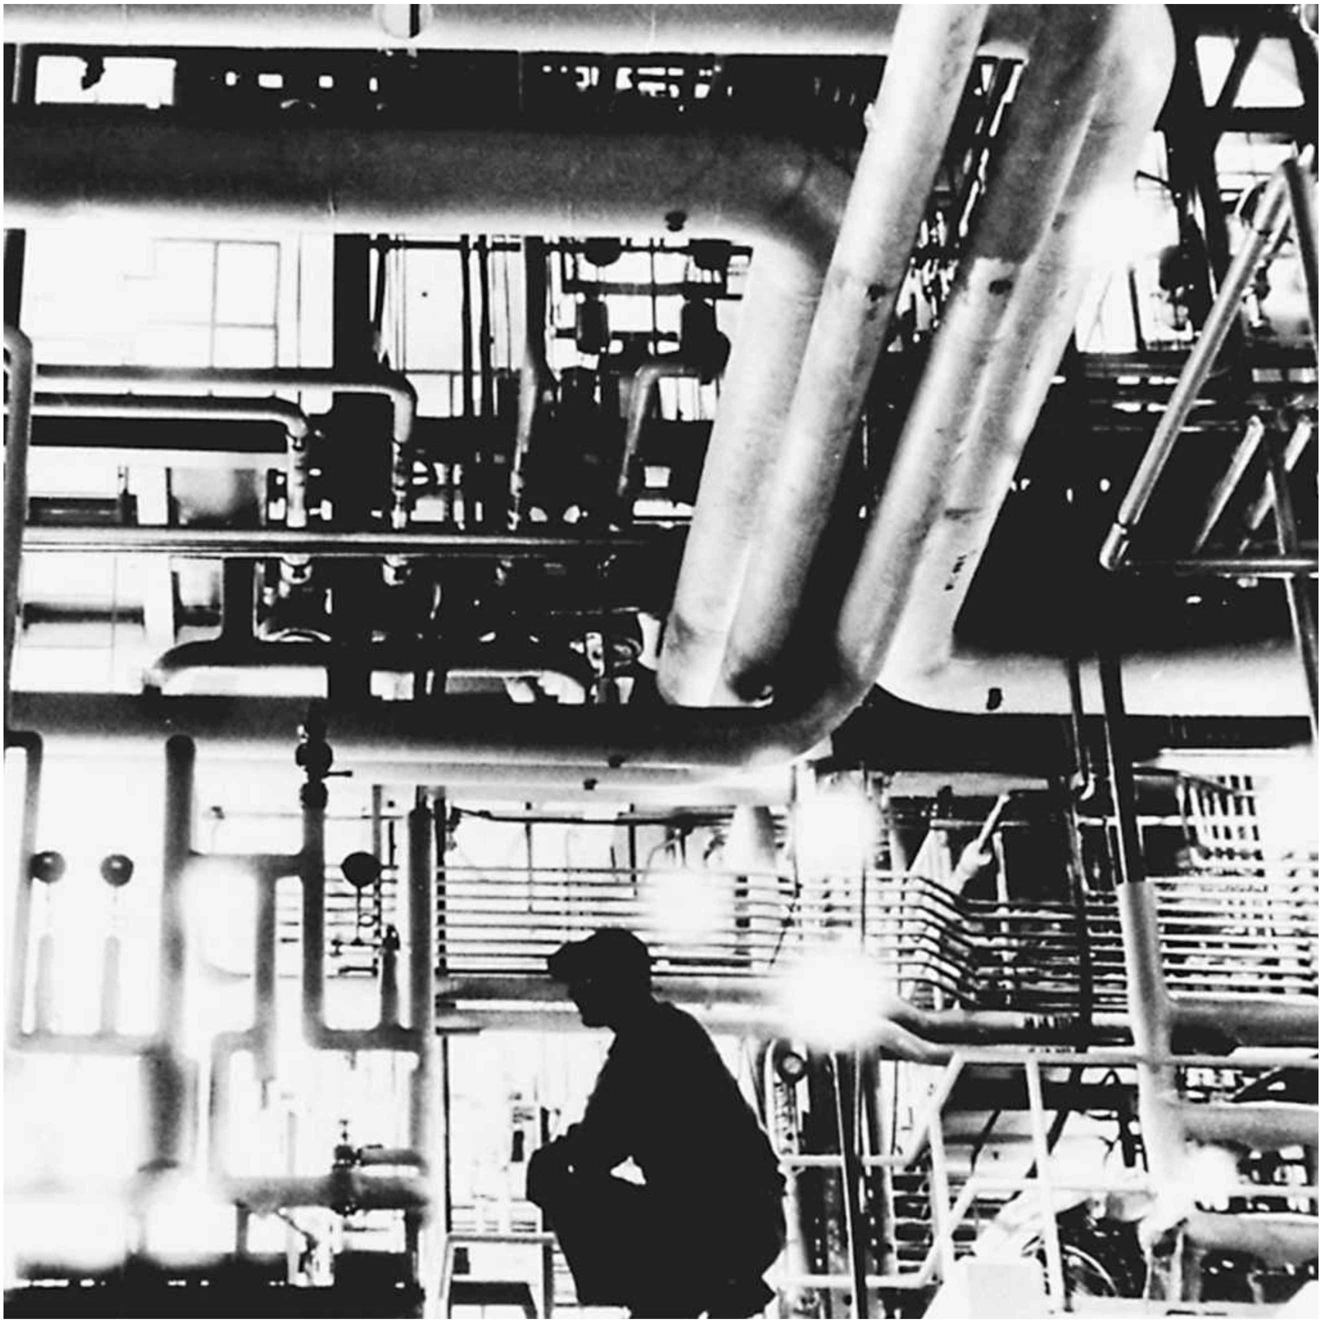
This changed dramatically in the 1960s and 1970s as antinuclear opinion switched from weapons to nuclear power and spread from activist groups into a large segment of the middle class. Antinuclear activism was strongest in the two nations with large nuclear power programs and the most open political systems—the United States and West Germany—although there were notable institutional and social differences between the two nations. And while antinuclear activism surely slowed the progress of nuclear power development in many countries, it was one of a cluster of economic, technological, political, and social forces constraining the industry.

Nuclear energy opponents initially targeted thermal pollution—the effect of nuclear power plants on local aquatic life by raising water temperature by several degrees. Attention soon shifted to the question of radioactive contamination of cooling water. When two scientists at Lawrence Livermore Laboratory in Berkeley, California—John Gofman and Arthur Tamplin—argued that the AEC acceptable level of 170 millirems per year would cause some 16,000 additional deaths (they later revised the figure to 74,000), an intense debate ensued that eventually led to a U.S. Senate committee and to a new standard of 25 millirems. Meanwhile, news of nuclear plant accidents in foreign countries reached the United States, which endured an accident of its own at Idaho Falls in 1961. New guidelines for remote nuclear plant citing followed, which resulted in scuttled plans for a Consolidated Edison plant in Queens, New York, and another in Los Angeles. Anti-nuclear activism was strongest in southern California, where protesters managed to stop the construction of a Pacific Gas & Electric plant at Bodega Bay in 1963 because it was near an earthquake fault.

The 1970s were hard times for the nuclear industry. The decade opened with the first Earth Day (April 22), which featured thousands of teaching events, many of them aimed at halting further nuclear power development, and ended with the accident at the Three-Mile Island nuclear plant in Pennsylvania. In between, the nuclear industry sustained increasingly sophisticated attacks from increasingly better organized opponents, such as the Environmental Defense Fund (1967); Ralph Nader's Critical Mass Project in Washington, D.C.; and the Union of Concerned Scientists, a consortium of nuclear scientists and engineers founded at MIT in 1971. In 1976, California passed a ballot initiative that halted nuclear plant construction until the federal government found a satisfactory way to dispose of radioactive wastes; while in New Hampshire the Clamshell Alliance was formed to oppose the construction of a nuclear plant at Seabrook, an effort that dragged on for years, involved tens of thousands of demonstrators, and helped force the plant's owner (Public Service Company of New Hampshire) to cancel plans for one of its two reactors and to declare bankruptcy in 1988—the first public utility to do so in American history.

In that case, protests caused delays that contributed to large cost overruns. But Seabrook was an exception; most nuclear utilities got into financial trouble with little help from protesters. Although oil prices rose dramatically in the 1970s—a spur to nuclear development—the "stagflation" of the times drove down demand for electricity from 7 percent to 2 percent per annum and drove up interest rates into the double digits. Between 1971 and 1978, nuclear capital costs rose 142 percent, making them more expensive to build per kilowatt-hour of capacity than new fossil fuel plants.

No case better illustrates the travails suffered by the nuclear power industry and its customers than the saga of the Washington Public Power Supply System (WPPSS). Thanks to abundant Columbia River hydropower, the Pacific Northwest enjoyed the nation's lowest electricity rates in the 1950s. By then the prime hydropower sites has been exploited, and demand for electricity continued to rise. In 1968 some one hundred utilities in the region, working through WPPSS, financed a ten-year, $7 billion Bonneville Power Administration plan to improve the region's hydropower and transmission and distribution assets as well as to build seven new thermal power plants, most of them nuclear. Construction costs skyrocketed, however; the second power plant (at Hanford, Washington), projected to cost $352 million in 1977, had consumed nearly $2 billion by 1980. Struggling to avoid bankruptcy, Bonneville boosted its wholesale rates 700 percent between 1979 and 1984. Irate ratepayers dubbed the project "WHOOPS."



Atomic electricity generating station in Shippingport, Louisiana. (Library of Congress)

Viewed in this context, the Three-Mile Island (TMI) accident was the *coup de grace* for an already foundering industry. In spite of the fact that the hydrogen gas bubble that accumulated in Reactor 2 did not explode, although some contaminated gas escaped; and that the commissions who investigated the accident faulted human error rather than equipment failure, TMI caused (as the *New York Times* put it) "a credibility meltdown" for the nuclear industry. (The release of a major motion picture with an eerily similar scenario, *The China Syndrome,* a few weeks before the real accident amplified the public relations crisis.) The TMI cleanup cost roughly $1 billion, less than a third covered by insurance. The Nuclear Regulatory Commission, a federal agency, began to enforce an informal moratorium on new plant licenses pending further investigation of TMI, and soon demanded expensive retrofitting for similar plants. But even without TMI, no new reactors have been ordered in the United States since 1978.

NUCLEAR ENERGY AND NUCLEAR DEFENSE FROM THE LATE 1970S TO THE PRESENT

As they did at the dawn of the atomic age, nuclear weapons have overshadowed nuclear energy for since the late 1970s. The shift began then, when the Carter administration switched its Soviet stance from détente to rearmament and ordered 200 new MX missiles. By then, the nonprofit organizations Union of Concerned Scientists—perhaps seeing civilian nuclear energy as moribund—shifted its attention to weapons. The Cambridge, Massachusetts–based Physicians for Social Responsibility, led by Helen Caldicott, began to publicize the horrors of nuclear war, garnered a large grant from the Rockefeller Foundation, and saw its membership surge from 500 in 1978 to 16,000 in 1980. At the same time, a movement favoring a moratorium on nuclear weapons began to take shape, with 1980 presidential hopefuls Governor Jerry Brown of California and Senator Edward Kennedy of Massachusetts joining the cause.

The election of Ronald Reagan to the White House in 1980 heightened nuclear tensions. Reagan dubbed the Soviet Union an "evil empire" and spoke of first-strike capabilities and strategies of limited nuclear war. Supporters of the 1981 Nuclear Weapons Freeze Campaign, in contrast, called for a verifiable treaty with the Soviet Union to halt nuclear proliferation. In 1983 Regan announced the extravagant Strategic Defense Initiative to shield the United States from nuclear attack using space-based missile interceptors and other yet-to-be-developed technologies. Endorsed by atomic bomb pioneer Edward Teller, the project was so expensive and technically speculative that it became popularly known as "Star Wars," after a Hollywood space fantasy. Although the president called it a purely defensive measure, many foreign-policy experts saw it as a form of destabilizing escalation. Others considered it a ploy to force the USSR into heavy military spending (to achieve parity with Star Wars) at a time when the Soviet empire was undergoing political and economic stress under the reformist regime of Mikhail Gorbachev.

The question of how much Star Wars may have contributed to the 1991 collapse of the Soviet Union continues to generate debate. But the breakup of the postwar nuclear superpower clearly ushered in a new era of nuclear quiescence. To be sure, the fate of the former Soviet Union's tens of thousands of warheads remains a vital concern, especially in light of the region's growing economic pressures. For example will unpaid military officers be tempted to sell nuclear weapons to well-funded terrorist groups? In the post-Soviet world, the threat of nuclear warfare no longer is seen as a matter of global annihilation bur rather as a risk in political hot-spots such as the Middle East, Korea, or—if Iraq's Saddam Hussein should acquire nuclear technology—the United States as a possible target. And dreams of a Star Wars-like defense live on; late in his final term, President Bill Clinton announced plans to consider the development of a nuclear defense system reminiscent of, though less elaborate than, the Reagan plan.

Although reactor-building continues steadily in France and Japan, and may take hold in parts of the less developed world, nuclear power will need a major technological breakthrough (or a fossil fuel energy crisis) to make a comeback in the United States and Germany. One possibility is the fusion reactor, which produces nuclear energy by combining two light elements (such as deuterium) into a single heavier one that weighs less than the sum of its parts, with the difference released in the form of energy. Fusion produces less radioactive waste than fission and faces no fuel constraints (deuterium is found in water). The problem is that scientists have not been able to combine light atoms through collusion—they bounce off each other—but rather do so by accelerating them with heat so intense it either consumes as much energy as the reaction produces, or (at much higher levels) it cannot be contained safely.

Since the earliest days of the atomic age, physicists and engineers have predicted the coming of practicable nuclear fusion within "ten years" or "a generation." History therefore offers many reasons to be skeptical about the promise of nuclear energy. At the same time, this unparalleled form of energy is not going to return to the Pandora's box pried open by the Manhattan Project more than a half century ago.

NUCLEAR FISSION

Nuclear fission is a process in which a heavy nucleus—usually one with a nucleon number of two hundred or more—separates into two nuclei. Usually the division liberates neutrons and electromagnetic radiation and releases a substantial amount of energy. The discovery of nuclear fission is credited to Otto Hahn and Fritz Strassman. In the process of bombarding uranium with neutrons in the late 1930s, they detected several nuclear products of significantly smaller mass than uranium, one of which was identified as ^{137}Ba. The theorectical underpinnings that exist to this day for nuclear fission were proposed by Lise Meitner and Otto Frisch. Shortly after Hahn and Strassman's discovery.

Some heavy nuclei will fission spontaneously. Others can be induced to fission through interaction with a neutron. In both spontaneous nuclear fission and induced nuclear fission the pool of neutrons and protons is conserved. For example, the nucleus ^{252}Cf (Californium) fissions spontaneously. The 98 protons and 154 neutrons in the nucleus of ^{252}Cf are reconfigured into other nuclei. Usually a few neutrons are released in the process. Pictorially, a typical spontaneous fission of ^{252}Cf producing two nuclei and three neutrons is shown in Figure 1.

The pictorial depiction of the spontaneous fission of ^{252}Cf can be summarized as an equation:

$$^{252}\mathrm{Cf} \rightarrow {}^{150}\mathrm{Ba} + {}^{99}\mathrm{Mo} + 3\mathrm{n} + \text{energy}$$

The nucleus ^{235}U (uranium) does not fission spontaneously, but it can be induced to fission through interaction with a neutron. Pictorially, a typical neutron-induced fission of ^{235}U producing two nuclei and three neutrons is depicted in Figure 2.

The pictorial depiction of the neutron-induced fission of ^{235}U can be summarized as an equation:

$$^{235}\mathrm{U} + \mathrm{n} \rightarrow {}^{144}\mathrm{Ba} + {}^{89}\mathrm{Kr} + 3\mathrm{n} + \text{energy}$$

Visually, nuclear fission is simply a rearrangement of neutrons and protons, and would seem to be possible for any nucleus. However, energy conservation principles limit significantly the number of possibilities for either spontaneous nuclear fission or induced nuclear fission. Total energy is conserved in a nuclear fission reaction as it is in all nuclear reactions. This means that the total energy before the fission equals the total energy of the fission products. For example, in the induced nuclear fission reaction discussed earlier, the combined energy of the neutron and ^{235}U nucleus equals the combined energy of the ^{144}Ba and ^{85}Kr nuclei and the three neutrons. The energy accounting includes kinetic energy as well as any potential energy associated with the nuclei and the neutrons. The energy associated with mass through the Einstein relation $E = mc^2$ is particularly relevant. The interaction of the neutron and the ^{235}U nucleus takes place when both are essentially at rest and, therefore, have negligible kinetic energy. Yet the reaction products—^{144}Ba, ^{85}Kr, and three neutrons—have significant kinetic energy. The kinetic energy of the products has its origin in the conversion of potential energy associated with the ^{235}U nucleus and the interacting neutron. The gain in kinetic energy is accompanied by a loss of mass in the interacting nuclei (neutron and ^{235}U nucleus). The kinetic energy of the reaction products (^{144}Ba, ^{85}Kr and 3 neutrons) is determined from $E = mc^2$, where m is the mass difference between the interacting nuclei and reaction products. The following example illustrates this principle. In atomic mass units the masses of the

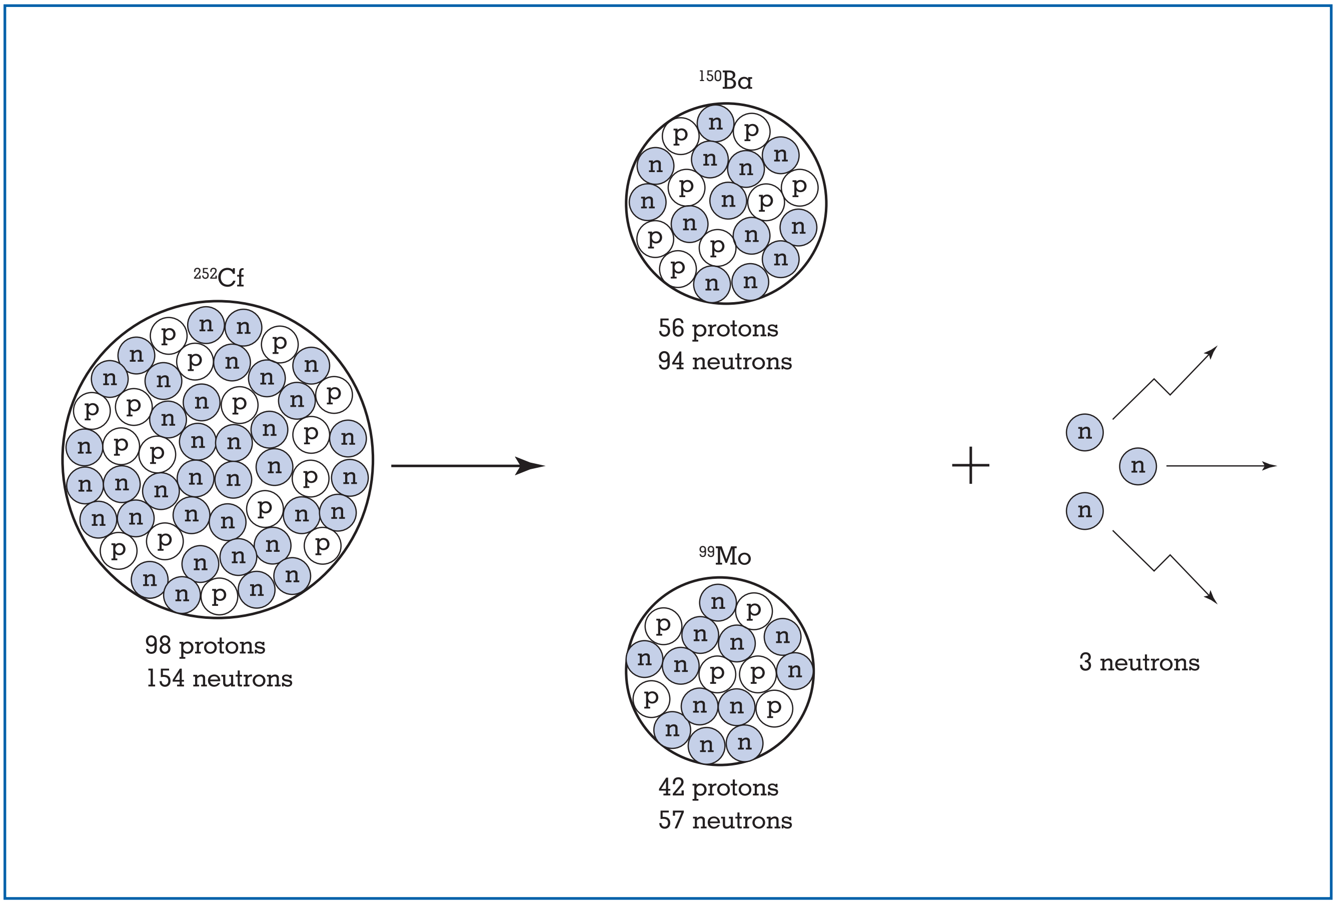

Figure 1.
Spontaneous fission process.

nuclei involved in the illustrative nuclear fission reaction are:

^{235}U	235.0439231 u	^{144}Ba	143.9229405 u
n	1.0086649 u	^{89}Kr	88.9176325 u
		3 n	3.0259947 u

Adding the left and the right columns yields 236.052588 u and 235.8665677 u, respectively. The reaction products have 0.1860 u less mass than the interacting nuclei. One atomic mass unit has an energy equivalent of 931.50 million electron volts (MeV). Therefore, 0.1860 u has an energy equivalent of 173.3 MeV. The energy acquired by the reaction products totals 173.3 MeV. This nuclear fission energy release is huge compared to that in a chemical reaction.

A typical chemical reaction such as that in burning a fossil fuel releases about 10 eV of energy. A release of 170 MeV in one nuclear fission reaction liberates the energy equivalent of 17 million chemical reactions in the burning of a fossil fuel.

A nuclear fission reaction will not occur unless the following occur: (1) the total mass of the reaction products is less than the total mass of the interacting nuclei, and (2) the sum of the neutrons and the sum of the protons in the interacting particles equals the sum of the neutrons and the sum of the protons in the products of the fission.

Any combination of reaction products consistent with these conservation principles is possible. For example, in the neutron-induced nuclear fission of ^{235}U it is possible to produce ^{140}Xe, ^{94}Sr, two neutrons, and 185 MeV of energy. The most likely reaction products are close in atomic number to xenon (Xe) and strontium (Sr), but the possibilities number in the hundreds.

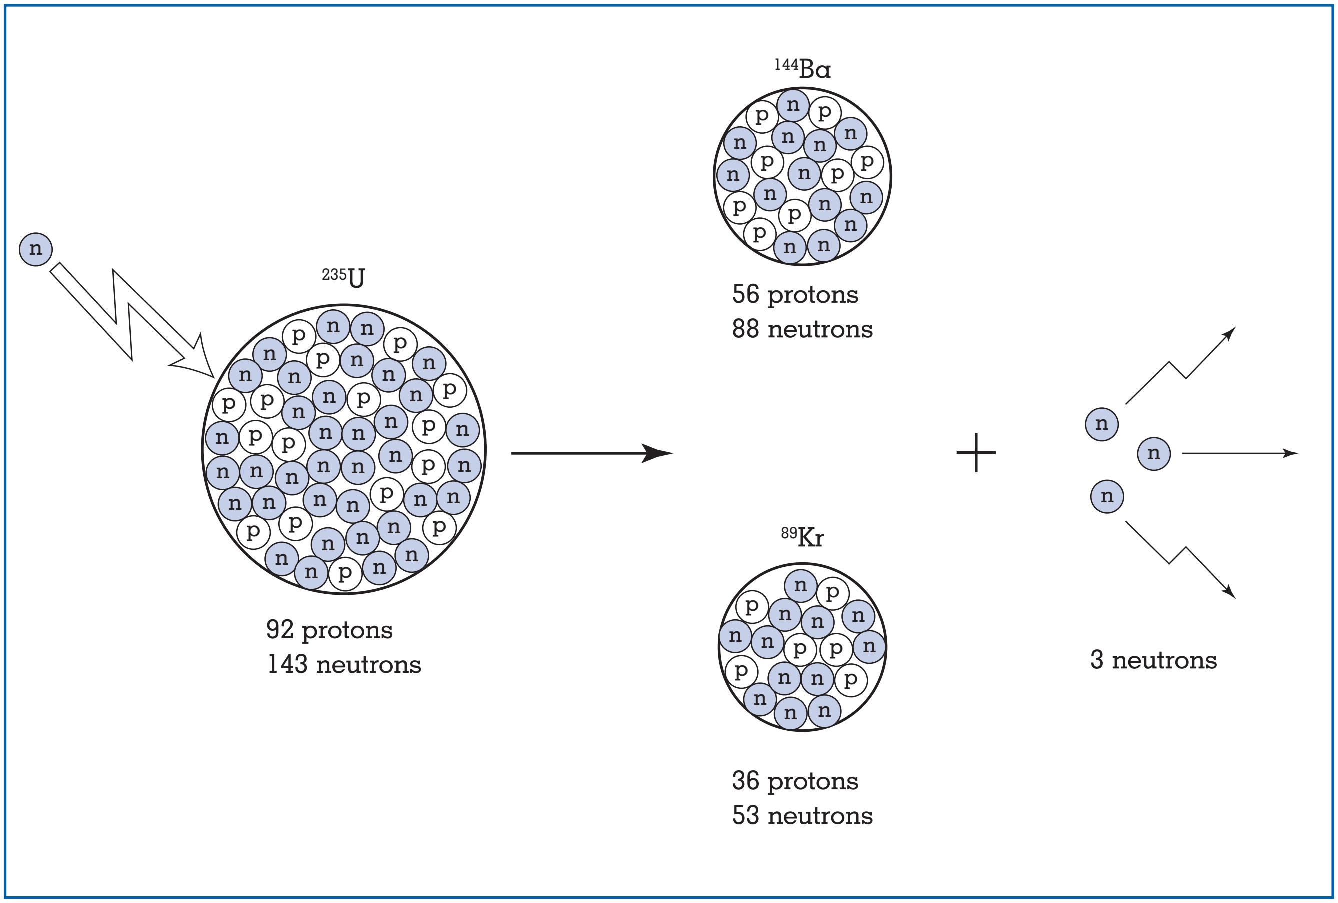

Figure 2.
Neutron-induced fission process.

Describing a neutron-induced nuclear fission reaction such as

$$^{235}\mathrm{U} + \mathrm{n} \rightarrow {}^{144}\mathrm{Ba} + {}^{89}\mathrm{Kr} + 3\mathrm{n} + \text{energy}$$

does not convey the likelihood of it actually happening. When a neutron encounters the ^{235}U nucleus, several nuclear events other than fission may occur. For example, the neutron may bounce off, changing the course of its path much like a marble bouncing off a bowling ball. Or the ^{235}U nucleus may capture the neutron and disintegrate in a way that does not involve nuclear fission. Whatever the event, there is only some chance that the event occurs when the neutron and the nucleus interact, and this probability depends strongly on the energy of the neutron. The fissioning of ^{235}U by a neutron is likely only for low-energy neutrons. Low in this sense means that the energy is of the order of the energy of a molecule in the air in a room.

A drop of water is a collection of molecules bound together by electric forces. Perturbing the drop in some way often causes the drop to separate into two smaller drops. A heavy nucleus such as ^{235}U has 92 protons and 143 neutrons and has features of a liquid drop that are useful for visualizing the dynamics of nuclear fission. The strong nuclear force that tends to bind the protons and the neutrons together competes with electric forces between protons that tend to cause the nucleus to break apart. Competition between these forces produces collective oscillations that are analogous to oscillations of a liquid drop. The energy added to the nucleus when it captures a neutron enhances the oscillations, and on some occasions the nucleus separates into two parts. The model is useful for visualizing the nuclear fission mechanism as well as for doing quantitative calculations involving the probability aspects of the process.

NUCLEAR FISSION CHAIN REACTION

A chain reaction results when some event triggers a sequence of identical events. A chain reaction on a crowded highway develops when a car runs into the rear of another car, the struck car collides with a car in front of it, and so on. An expanding chain reaction develops if a car hits two cars, each struck car moves on to strike two cars, and so on. A chain reaction is central to the operation of a nuclear fission reactor and a nuclear fission bomb. It begins with a neutron-inducing fission in a nucleus. Neutrons liberated in the fission in turn induce fission in other nuclei, and so on (see Figure 3). Each fission releases energy, and unless there is some purposeful control, the energy release proceeds uncontrolled. Controlled or uncontrolled, the chain reaction does not propagate unless (1) the fuel is properly arranged and (2) there is sufficient likelihood that a neutron induces fission.

This is tantamount to saying that a chain reaction of cars does not propagate unless (1) the cars are arranged properly and (2) there is a sufficient chance that a car will make other collisions.

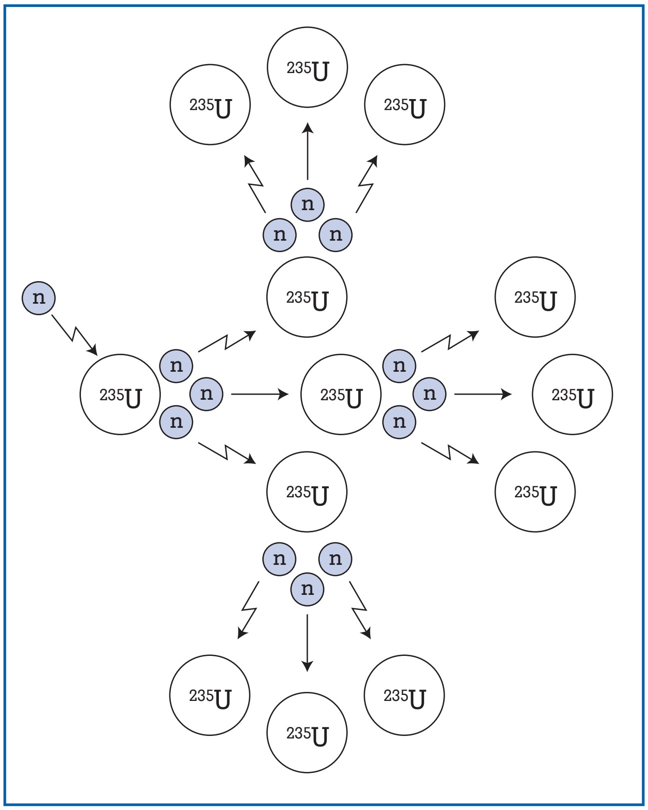

Figure 3.
A nuclear fission chain reaction.

NUCLEAR FUEL

Commercially, there are only two nuclear species that will function in a self-sustaining nuclear fission chain reaction; ^{235}U and ^{239}Pu (plutonium). Uranium occurs naturally in two predominant forms, ^{235}U and ^{238}U. The bulk, 99.3 percent, of natural uranium is ^{238}U. Even though ^{238}U differs from ^{235}U by having only three additional neutrons, the likelihood of neutron-induced fission of ^{238}U is so low that it cannot be used in a self-sustaining chain reaction. Thus the great bulk of natural uranium is not of a form that can be used in self-sustaining chain reactions. ^{239}Pu is not found naturally in appreciable amounts. Rather, ^{239}Pu is made through nuclear transmutations. The process begins by having ^{238}U capture a neutron to form ^{239}U. ^{239}U is unstable and undergoes radioactive decay, with the end product being ^{239}Pu.

NUCLEAR FISSION REACTOR PRINCIPLES

The fuel in a nuclear fission reactor is generally ^{235}U atoms arranged appropriately in a reactor vessel. Neutrons instigate fission of nuclei of ^{235}U atoms and liberate energy. The energy output may be controlled either by regulating the fuel and/or adjusting the neutron supply. Generally, the energy output is controlled by regulating the number of neutrons. Cylindrical control rods made of materials that readily absorb neutrons are moved up or down in strategically arranged spaces in the fuel assembly. Water circulating around the nuclear fuel removes heat produced by nuclear fission reactions and reduces moderates) the speed of neutrons liberated by fission. The main components of a nuclear fission reactor are shown in Figure 4.

Moderator

Neutrons produced in nuclear fission reactions are very energetic and are referred to as fast neutrons. To optimize the chain reaction, the speed of the reaction neutrons must be reduced. Water molecules surrounding the fuel help slow the neutrons through collisions with atoms. A proton is an optimum target for a neutron. Hydrogen atoms in water are a good source of protons because each water molecule has two hydrogen atoms and each atom has a single proton in its nucleus. A neutron produced in a nuclear fission reaction bounces around in a pool of water,

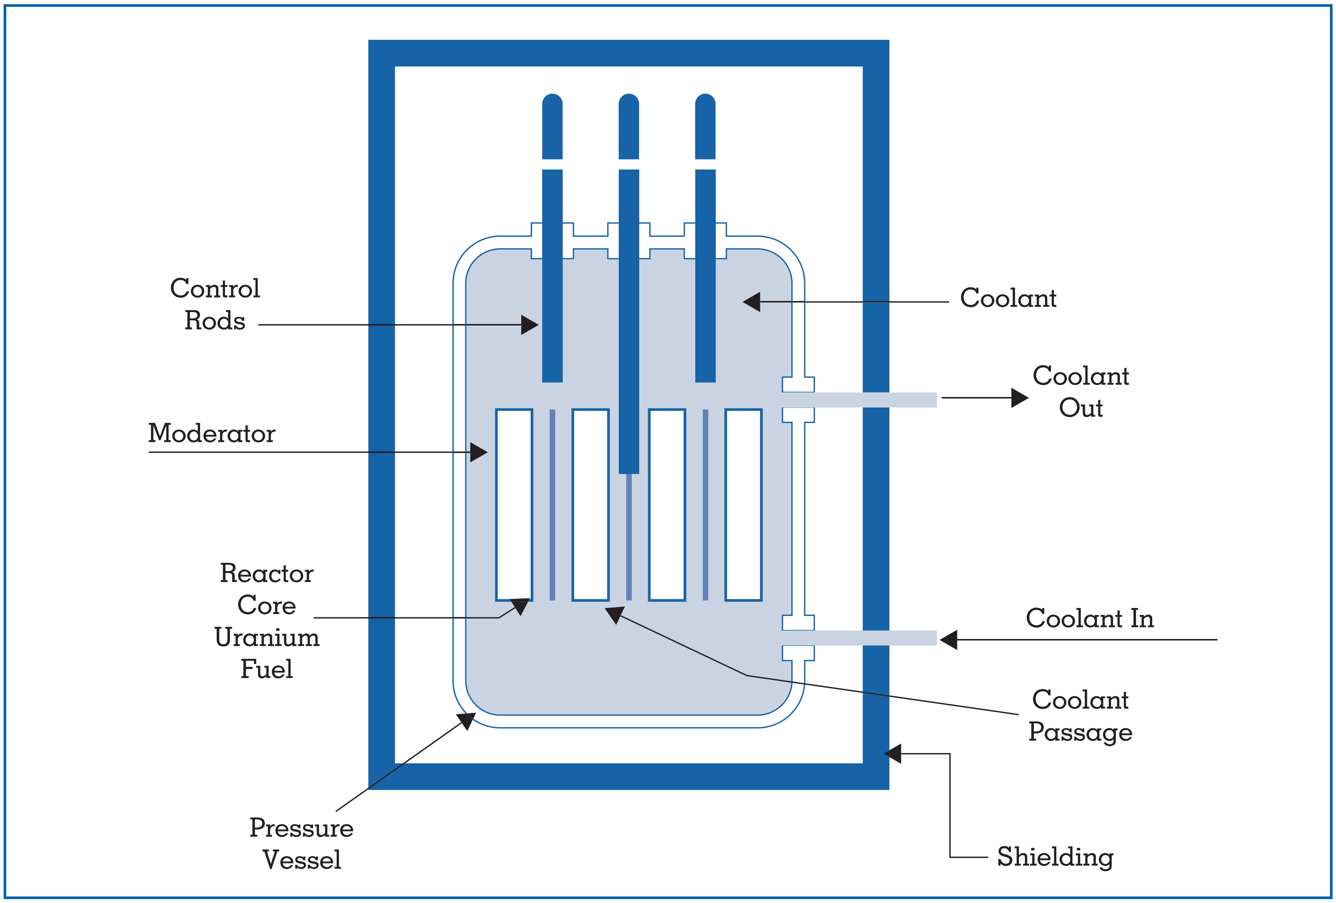

Figure 4.
Main components in a nuclear fission reactor.

losing energy with each collision with a proton. After its energy is reduced sufficiently, it may react with a ^{235}U nucleus to induce fission. Reducing the energy is referred to as moderation and the material used in the moderation is called a moderator. An object colliding head-on with a stationary object loses the greatest amount of kinetic energy when the masses of the two objects are the same. This is apparent when a billiard ball collides head-on with another billiard ball at rest. A hydrogen atom has roughly the same mass as a neutron. Accordingly, a neutron loses virtually all its kinetic energy in a head-on collision with a hydrogen atom. Because a water molecule (H_2O) has two hydrogen atoms, water is an efficient moderator for neutrons produced in nuclear fission reactions. Water is the moderator in nearly all reactors.

Control Rods

A nuclear chain reaction can be controlled by inserting materials within the fuel that deprive the fuel of neutrons. These materials are usually rod-shaped and are referred to as control rods. Control rods are made of materials that are more likely than the fuel to absorb neutrons. Boron and cadmium are favorite materials for control rods. To decrease the energy output, the control rods are inserted closer to the fuel. To increase the energy output, the control rods are pulled away from the fuel. Boric acid (H_3BO_3), a boron-containing liquid that strongly absorbs neutrons, is often included in the water moderator to provide further control of the energy output of the reactor.

Fuel

Uranium is a metal that is found naturally as a constituent of chemical compounds in minerals such as pitchblende. Uranium ore is mined much like coal: Open pits are used to mine shallow deposits, deeper deposits require shaft mining. Commercial ores yield 3 to 5 lb of uranium compounds per ton of ore. A material called yellow-cake is produced that is rich in the uranium compound U_3O_8. About 7 of every 1,000 uranium atoms in the yellow cake are of the variety ^{235}U.

Some nuclear fission reactors are designed to use natural uranium having 0.7 percent ^{235}U and 99.3 percent ^{238}U. CANDU reactors, manufactured in Canada, are examples. These reactors do not use ordinary water for the moderator. Most nuclear fission reactors use ordinary water for a moderator which requires that the fuel be about 3 percent ^{235}U and about 97 percent ^{238}U. Achieving this enrichment requires that the solid uranium compounds in the yellow cake be converted to gaseous uranium hexafluoride (UF_6). Following enrichment, gaseous UF_6 is converted to solid uranium oxide (UO_2) for fabrication of fuel elements for a nuclear reactor.

Uranium oxide fuel is formed into solid pellets about ⅜ in. in diameter and ½ in. long. Fuel pellets are stacked in tubes about 12 ft long. Neutrons must be able to penetrate the tube walls, called cladding, to interact with the uranium, and the walls must withstand the temperature required for heating water for a steam turbine. Stainless steel or a material called zircaloy is used for the cladding. Some 200 tubes are packed into a fuel bundle. About 175 appropriately arranged fuel bundles form the reactor core, where the energy is produced. A cylindrical steel vessel about 20 ft in diameter and about 40 ft high houses the core. Energy and neutrons are liberated from nuclear fission reactions within the fuel pellets. About 83 percent of the energy is in kinetic energy of the fission fragments. Fission fragments convert their kinetic energy to heat in the process of coming to rest in the fuel pellets. Heat is conducted from the pellets by water circulating around the fuel cladding. Water has two very important roles: conducting heat from the reactor core and moderating neutron speeds.

Energy Production

There are about 100 tons of uranium in the fuel bundles. With the control rods in their lowest position, there is no chain reaction, no energy produced, and no neutrons liberated from nuclear fission reactions. Energy production starts by raising the control rods and inserting a source of neutrons. Nuclear fission reactions begin producing energy and neutrons. Neutrons escape from the fuel elements into the water, where they lose speed and change direction with each collision with a proton. After losing sufficient speed, a neutron may reenter a fuel element and induce a ^{235}U nucleus to fission to help foster the chain reaction. If on the average one neutron from a nuclear fission reaction goes on to produce another nuclear fission reaction, the chain reaction is self-sustaining, and energy is produced at a steady rate. Raising the control rods allows more nuclear fission reactions and more energy production. Higher, but steady, energy production occurs at the new control rod position. Control of the chain reaction depends on

- the arrangement of the fuel elements
- the quality of the moderator
- the quantity of ^{235}U
- the neutron energy required for a high probability for inducing nuclear fission
- the material surrounding the reactor core that is used to minimize the escape of neutrons.

Although protons are very efficient neutron moderators, they also efficiently capture neutrons to form bound proton-neutron pairs called deuterons. Reactors using ordinary water for the moderator compensate for neutron capture by using fuel enriched to about 3 percent ^{235}U.

Usually atoms resulting from nuclear fission are radioactive. There are also radioactive atoms produced from neutron capture by both ^{235}U and ^{238}U. Both types of radioactive atoms remain in the nuclear fuel. It is these radioactive atoms that comprise the nuclear wastes that require disposal in an environmentally acceptable manner.

Boiling-Water Reactors and Pressurized-Water Reactors

Current light-water reactors have two basic designs. One is termed a boiling-water reactor (BWR), the other a pressurized-water reactor (PWR). The principles of the PWR design is illustrated in Figure 5. Water comes to a boil, producing steam inside the containment vessel of a boiling-water reactor. Water is kept under pressure and does not boil inside the containment vessel of a pressurized- water reactor. Steam for the turbine in a nuclear power plant using a pressurized water reactor comes from water brought to a boil in a steam generator garnering heat from water circulating around the reactor core. In a boiling- water reactor, steam is produced in the reactor vessel. In a pressurized-water reactor, steam comes from a system separated from the reactor vessel. Pressure and temperature in a boiling-water reactor are about 1,000 lb per sq in. and 545°F (285°C). These

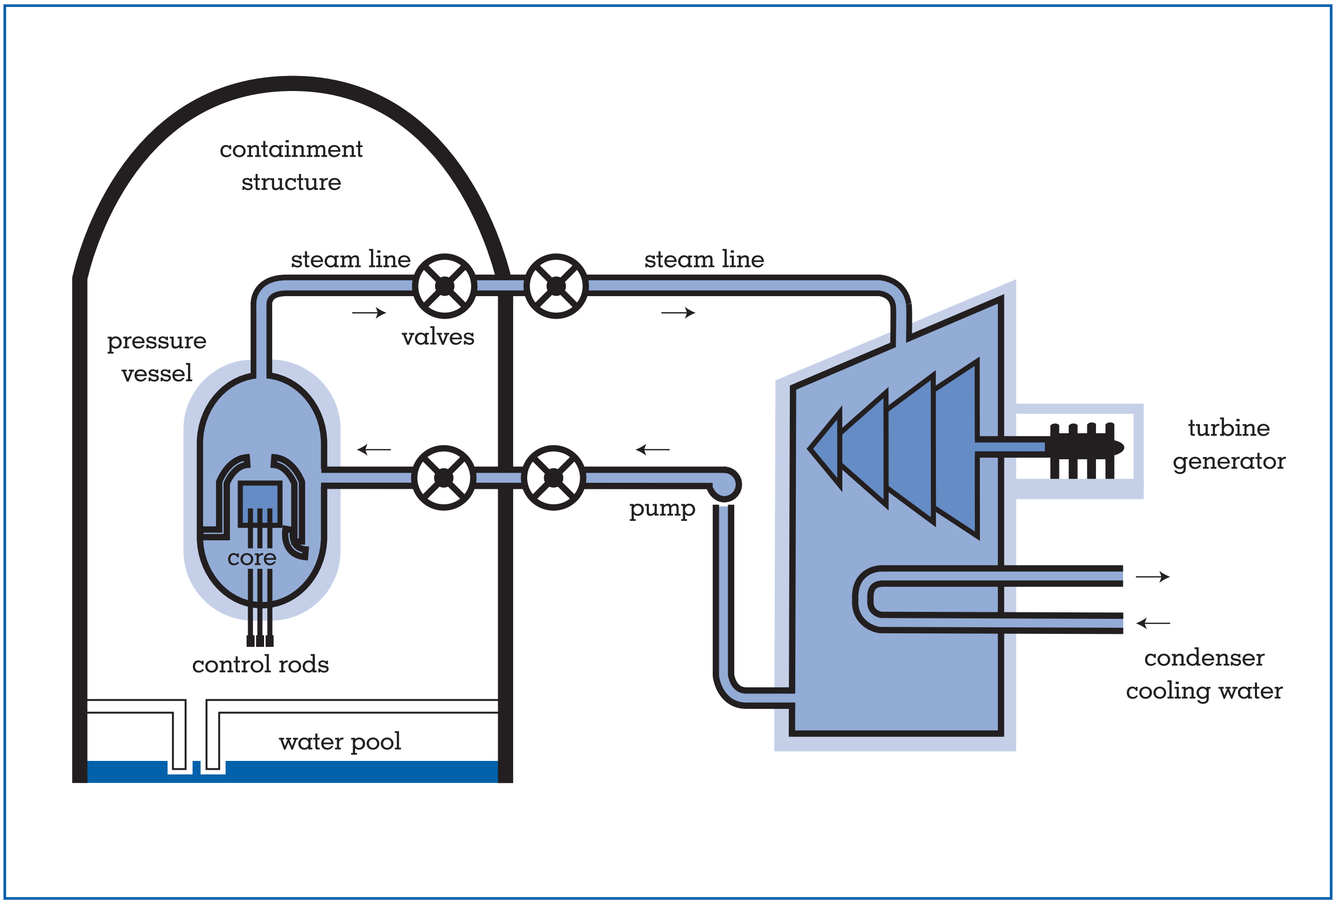

Figure 5.
The water-steam circuit in a pressurized water reactor.

numbers rise to about 2,250 lb per sq in. and 600°F (316°C) in a pressurized-water reactor. Roughly 70 percent of the reactors in the United States are of the PWR type. Essentially, the safety aspects of PWR and BWR reactors are equivalent.

At the beginning of the twenty-first century, 439 nuclear power reactors in 31 countries were generating 352 billion watts of electric power. More than 16 percent of the world's electricity was produced by these electric power plants. On average the power output of one of these plants is roughly 800 megawatts and is comparable to the power output of a large coal-burning electric power plant. Either one of these plants could supply the electricity needs of about a quarter of a million homes. The electric power outputs of solar and wind systems, for example, are usually factors of ten to a hundred times less than that of a large nuclear-fueled or coal-burning electric power plant.

REACTOR CONTROL

The products of nuclear fission reactions are radioactive and disintegrate according to their own time scales. Often disintegration leads to other radioactive products. A few of these secondary products emit neutrons that add to the pool of neutrons produced by nuclear fission. Very importantly, neutrons from nuclear fission occur before those from radioactive decay. The neutrons from nuclear fission are termed prompt. Those from radioactive decay are termed delayed. A nuclear bomb must function on only prompt neutrons and in so doing requires nearly 100 percent pure ^{235}U (or ^{239}Pu) fuel. Although reactor fuel is enriched above its natural 0.7 percent abundance, it is still some thirty times less concentrated than the fuel needed for bombs. A light-water nuclear reactor cannot achieve a self-sustaining condition using only prompt neutrons; delayed neutrons are needed as well. Control rods are slammed into position if a critical excursion from normal operation is sensed. The time involved in delayed neutron emission is crucial for success of the control operation.

A nuclear reactor and its auxiliaries involve a complex assembly of pumps, pipes, and valves for circulating water and steam. Minor malfunctions of the components are inevitable, and routine maintenance is inescapable. Distinct from the routine malfunctions is the possibility of loss of water in the main cooling of the reactor core. This bears the name "loss of cooling accident." Possible causes of such an accident include reactor operator errors, faulty construction, improper maintenance, natural disaster, and sabotage. A loss of cooling terminates the nuclear fission chain reaction because of the need for a moderator. However, radioactivity in the reactor core continues to produce heat at a level of 5 to 7 percent of its rated power. This percentage may seem low, but 5 percent of 3 billion watts of thermal power from normal operation amount to 150 million watts of thermal power that remains after the chain reaction stops. Many of the radioactive products are short-lived, and the power level drops accordingly. Still, there is sufficient heat to begin melting the core in about thirty seconds. Unless checked, this molten radioactive mass could melt its way through the bottom of the containment facilities. Emergency core-cooling systems must operate within this thirty-second time period. Although safety measures make the chance of an accident releasing radioactivity unlikely, it cannot be made zero.

THE NUCLEAR FISSION BREEDER REACTOR

Contemporary nuclear fission reactors are fueled with either ^{235}U or ^{239}Pu. In a nuclear fission reactor fueled with ^{235}U, some ^{238}U in the fuel is converted to ^{239}Pu through nuclear transmutations and becomes part of the fuel inventory. However, the reactor is not designed to optimize the production of ^{239}Pu. A nuclear breeder reactor is designed to both produce energy and convert ^{238}U to ^{239}Pu for fuel. The conversion process is termed breeding.

The fission of ^{235}U or ^{239}Pu liberates, on average, two to three neutrons. One neutron is required to sustain the nuclear fission chain reaction. In a nuclear breeder reactor, the extra neutrons are used to induce nuclear reactions that lead to the production of ^{239}Pu. The sequence begins by arranging for a neutron to be captured by a ^{238}U nucleus to form ^{239}U. ^{239}U is unstable and disintegrates producing a variety of neptunium, ^{239}Np. ^{239}Np is unstable and decays, forming ^{239}Pu. The breeding principle requires both fissionable fuel (^{235}U or ^{239}Pu) and a breeding material (^{238}U). Both resources are depleted as time passes.

The chance of inducing nuclear fission of ^{235}U is optimum for slow neutrons. Neutron capture by ^{238}U is significant only for energetic (or fast) neutrons. Accordingly, the nuclear fission reactions must be initiated by fast neutrons even though it is more difficult. Water cannot be used as a coolant, as in a light-water nuclear reactor, because of its moderating effect on neutrons. The alternative to water is usually liquid sodium. These reactors are termed liquid metal (for cooling) fast (for energetic neutrons) nuclear breeder reactors.

Nuclear Breeder Reactor Projects

An experimental nuclear breeder reactor has been operating at the Argonne National Laboratory near Idaho Falls, Idaho, since 1963. However, widespread commercial utilization of nuclear breeder reactors has not materialized. A commercial nuclear breeder reactor electric power plant was built in Monroe County, Michigan, in 1963, but was permanently terminated in 1966 after a blockage in a sodium cooling line produced a partial meltdown of its core. Plans were announced in February 1972 for a major nuclear fission breeder electric power plant to be built on the Clinch River in eastern Tennessee and planned for completion in 1980, but the project ultimately was not funded by the U.S. Congress. France and Japan have constructed major nuclear breeder reactor electric power plants, but at the turn of the century all had been closed. Reprocessing nuclear fuel to recover ^{239}Pu is necessity in nuclear fission breeder technology. This is a major stumbling block because of concerns for proliferation of ^{239}Pu for making nuclear bombs.

NUCLEAR FISSION FUEL

A nuclear power plant generates electricity in a manner similar to a fossil fuel plant. The fundamental difference is the source of heat to create the steam that turns the turbine-generator. A fossil plant relies on the combustion of natural resources (coal, oil) to create steam. A nuclear reactor creates steam with the heat produced from a controlled chain reaction of nuclear fission (the splitting of atoms).

Uranium is used as the primary source of nuclear energy in a nuclear reactor, although one-third to one-half of the power will be produced from plutonium before the power plant is refueled. Plutonium is created during the uranium fission cycle, and after being created will also fission, contributing heat to make steam in the nuclear power plant. These two nuclear fuels are discussed separately in order to explore their similarities and differences. Mixed oxide fuel, a combination of uranium and recovered plutonium, also has limited application in nuclear fuel, and will be briefly discussed.

URANIUM

Uranium (symbol: U; atomic number: 92) is the heaviest element to occur naturally on Earth. The most commonly occurring natural isotope of uranium, U-238, accounts for approximately 99.3 percent of the world's uranium. The isotope U-235, the second most abundant naturally occurring isotope, accounts for another 0.7 percent. A third isotope, U-234, also occurs naturally, but accounts for less than 0.01 percent of the total naturally occurring uranium. The isotope U-234 is actually a product of radioactive decay of U-238.

Nuclear power is now the only substantial use for uranium. But before uranium can be used in a nuclear reactor, it must undergo several processes. After uranium is mined from geological mineral deposits, it is purified and converted into uranium hexafluoride (UF_6). The UF_6 is next enriched, increasing the concentration of U-235 by separating out UF_6 made with U-238 atoms. The enriched UF_6 is then converted into uranium dioxide (UO_2), and pressed into fuel pellets for use in the nuclear reactor.

Uranium Mining and Milling

Uranium is found in most rock, in a concentration of two to four parts per million (ppm). Substantially greater average concentrations can be found in mineral deposits, as high as 10,000 ppm, or 10 percent. Most uranium deposits suitable for mining, however, contain an average of less than 1 percent uranium. Uranium is a metal, and thus its acquisition is not unlike the mining of any other metallic ore. Although uranium is found nearly everywhere on the earth, Canada leads the world in uranium production, mostly due to its heavy financial investment in uranium exploration, and to a few sizable deposits in the Saskatchewan territory. Table 1 depicts the total world uranium production in 1997.

Although the nucleus of the uranium atom is relatively stable, it is radioactive, and will remain that way for many years. The half-life of U-238 is over 4.5 billion years; the half-life of U-235 is over 700 million years. (Half-life refers to the amount of time it takes for one half of the radioactive material to undergo radioactive decay, turning into a more stable atom.) Because of uranium radiation, and to a lesser extent other radioactive elements such as radium and radon, uranium mineral deposits emit a finite quantity of radiation that require precautions to protect workers at the mining site. Gamma radiation is the

most prevalent, followed by beta and alpha radiation. Because airborne particulates can be ingested or inhaled, thus subjecting workers to internal doses of radiation, the most important step taken to protect mine workers is to minimize the amount of airborne particulate matter. In areas where airborne particulate is of great concern, the uranium ore can be wetted to prevent releasing dust to the air. In areas of even greater risk, workers can be outfitted with respiratory equipment. Radon gas is also emitted from uranium, but proper ventilation provides sufficient dilution of the gas so that workers are not affected.

In general, there are three methods available to mine uranium deposits: open-pit, underground, and in-situ leaching. Open-pit mining is used when the uranium deposit is relatively shallow. Underground mining is used when the deposit is relatively deep. But for underground mining to be cost-effective, the deposit must be relatively high-grade and abundant with uranium. For both of these mining methods, the uranium ore is crushed and ground into a fine powder, releasing the uranium from the material surrounding it in the mineral deposit. Next, the crushed uranium is leached from the ore with a solution designed to dissolve only the uranium. After the uranium is dissolved, the solution is separated. The uranium-rich liquid is run off into a collection facility, and the solid waste product is left behind. Note that this waste product, referred to as tailings, can be highly radioactive, and can accumulate in substantial quantity. Since the uranium is often found in deposits with other elements having substantially shorter half-lives, these short-lived isotopes are left behind in a concentrated waste mass. The waste water is evaporated from the sludge, and the remaining metals and minerals are stored, often in an open pit at the mill site, for the life of the facility.

A less environmentally invasive method of obtaining the uranium is through a process called in-situ leaching (ISL). Rather than crush the uranium mineral deposit in order to expose the uranium and then dissolve it, the dissolving solution is pumped directly into the uranium deposit. This way, the dissolved uranium solution is obtained without disturbing the minerals surrounding the uranium in the ore, and all of the waste solids are left behind. This assumes the mineral deposit is able to facilitate the leaching process. Uranium deposits must be permeable, like those found in sand and sandstone, to utilize ISL in order for the dissolving solution to pass easily into the deposit to extract the ore. Between 10 and 15 percent of the world uranium supply is mined via in-situ leaching.

Regardless of the method used to obtain the uranium—open pit, underground, or in-situ leaching—the result is a uranium-rich solution. The uranium is recovered from the solution through ion exchange or solvent extraction, and concentrated into a fine precipitate. The uranium-free solution can then be returned to the mine to extract more uranium. The uranium in the precipitate is a blend of uranium dioxide (UO_2) and uranium trioxide (UO_3), combined in a general uranium oxide (U_3O_8). The precipitate is usually dried, forming a yellow cake of uranium, simply called "yellow cake." This concentrated uranium is typically 70 to 90 percent uranium. In order to use the yellow cake as a nuclear fuel, the uranium must go through a process of conversion.

Uranium Conversion

Since the uranium from the milling process is still in an unusable form, the yellow cake is broken down once again. The uranium trioxide is reduced to uranium dioxide at very high temperatures. Refining of the product also takes place. Now the uranium product consists almost entirely of UO_2.

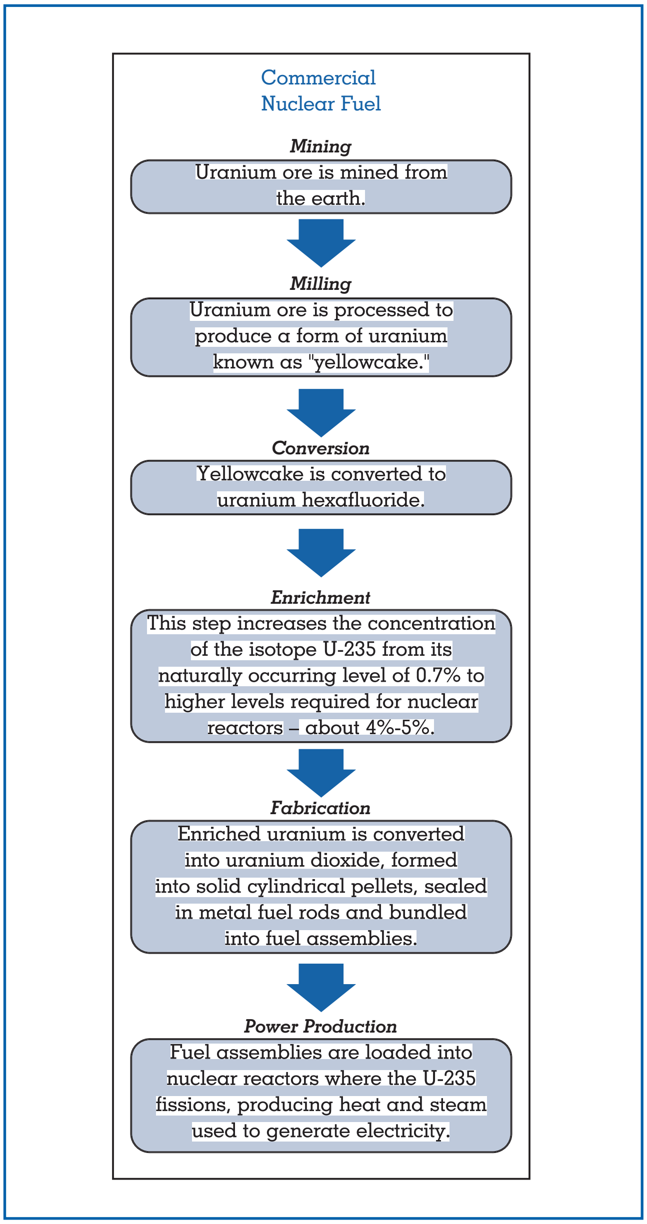

Figure 1.
Processes used in refining uranium for use in reactors
SOURCE: USEC, Inc.

During the conversion process, the object is to create uranium hexafluoride (UF_6), a highly corrosive substance that is gaseous at high temperatures, but is a white crystalline solid at lower temperatures. Uranium hexafluoride is easily transported in its crystalline form to an enrichment facility (the step taken after conversion), but the gaseous form is well suited for the enrichment process, itself. First, the UO_2 is combined with hydrogen fluoride (HF) to form uranium tetrafluoride (UF_4). This can be accomplished by reacting the UO_2 with either gaseous or liquid HF. The UF_4 is combined with gaseous fluorine to produce UF_6, and is shipped to a facility for enrichment.

Uranium Enrichment

Uranium-235 and U-238 behave differently in the presence of a controlled nuclear reaction. Uranium-235 is naturally fissile. A fissile element is one that splits when bombarded by a neutron during a controlled process of nuclear fission (like that which occurs in a nuclear reactor). Uranium-235 is the only naturally fissile isotope of uranium. Uranium-238 is fertile. A fertile element is one that is not itself fissile, but one that can produce a fissile element. When a U-238 atom is struck by a neutron, it likely will absorb the neutron to form U-239. Through spontaneous radioactive decay, the U-239 will turn into plutonium (Pu-239). This new isotope of plutonium is fissile, and if struck by a neutron, will likely split.

Nuclear fuel always contains a mixture of these uranium isotopes. The U-235, being naturally fissile, will sustain a controlled chain reaction in the nuclear reactor early in the fuel cycle. The U-238, being fertile, will eventually turn into plutonium, continuing to sustain the nuclear chain reaction late in the fuel cycle. The amount of U-235 initially blended into the nuclear fuel will dictate certain performance characteristics. Since naturally-occurring uranium is only approximately 0.7 percent U-235, any nuclear fuel containing more than 0.7 percent U-235 is said to be enriched. Light-water reactors, like those in the United States, use a fuel that has been enriched up to 5 percent. Some reactors are designed to use natural (unenriched) uranium, but they must rely on a medium other than light water to moderate the chain reaction. (These types of reactors typically use heavy water or graphite as a moderator for the nuclear reaction.) For these reactors, the U_3O_8 need only be refined and converted directly to UO_2 for use in fuel pellets, and enrichment is not necessary.

Uranium-235 is less massive than U-238, because each atom of U-235 contains three fewer neutrons than U-238. Although this difference appears insignificant, this 1 percent difference is precisely what allows the UF_6 to be divided into those molecules containing U-235 and those containing U-238. By separating the two quantities, enrichment plants can control the level of enrichment of the end product. Two processes for dividing the uranium isotopes are in large-scale commercial use. These are gaseous diffusion and centrifuge. A third enrichment process, laser enrichment, is being developed.

Gaseous Diffusion. Gaseous diffusion is responsible for producing over 90 percent of the world's enriched uranium. Gaseous diffusion has the ability to process large quantities of gaseous UF_6 at a time. Gaseous UF_6 is fed through a series of porous membranes that tend to filter out the heavier UF_6 molecules containing U-238 atoms. Gas that passes through the membrane will have a slightly higher percentage of U-235 molecules in the UF_6 than when it started, since some of the U-238 molecules did not pass through the membrane. The slightly enriched UF_6 is drawn off and forced through another series of membranes. Each iteration produces a slightly higher enrichment of U-235. After more than 1,500 iterations, the UF_6 is finally enriched to a usable form, at a U-235 concentration of 3 to 4 percent.

Centrifuge Enrichment. In a centrifuge, the UF_6 molecules are spun in a rotating cylinder. Because of the difference in mass between the UF_6 molecules containing U-235 and U-238, the lighter molecules remain at the center of the cylinder while the heavier molecules migrate toward the outside. The enriched UF_6 is drawn off the center of the centrifuge, and then centrifuged again. Similar to the diffusion process, each iteration produces a slightly higher enrichment of U-235. The centrifuge process is much more efficient than the diffusion process, producing a suitable enrichment after only ten to twenty iterations, and requiring significantly less energy to operate the enrichment plant than does a comparable diffusion plant. The capacity of a centrifuge facility is substantially less than the capacity of a diffusion plant, however, severely limiting its commercial application.

Laser Enrichment. Laser enrichment attempts to ionize gaseous U-235 atoms. By using a laser of a specific frequency, valence electrons of U-235 atoms can be removed without ionizing U-238 atoms. The positively charged U-235 atoms are attracted to a negatively charged metal plate, and liquid U-235 is collected. This process does not yet work with the UF_6 created from the existing uranium mining process, so its application is currently limited. Future laser enrichment processes will focus on using UF_6 in its enrichment technique.

Fuel Pellet Fabrication

Finally, the enriched uranium of converted back into UO_2. The UO_2 is pressed into small fuel pellets and packaged in a metal tube (made of a zirconium alloy) for use in a nuclear reactor.

Nuclear fuel can also be fabricated from existing stockpiles of fuel sources. Spent fuel can be reprocessed to extract the remaining U-238 for use in the next fuel cycle. Spent fuel also contains Pu-239, a direct replacement for the fissile U-235 in the enrichment process. Even military grade plutonium and highly enriched uranium can be reprocessed and diluted into a form usable in most nuclear reactors. The reprocessed isotopes are generally manufactured into mixed oxide (MOX) fuels and loaded into conventional nuclear reactors as fuel. The cost of increasing the fissile isotopes in MOX fuel represents a great cost savings over uranium enrichment, and thus reprocessing is increasingly becoming economically viable.

PLUTONIUM

Plutonium (symbol: Pu; atomic number: 93) is not a naturally occurring element. Plutonium is formed in a nuclear reaction from a fertile U-238 atom. Since U-238 is not fissile, it has a tendency to absorb a neutron in a reactor, rather than split apart into smaller fragments. By absorbing the extra neutron, U-238 becomes U-239. Uranium-239 is not very stable, and undergoes spontaneous radioactive decay to produce Pu-239.

Plutonium-239 is a fissile element, and will split into fragments when struck by a neutron in the nuclear reactor. This makes Pu-239 similar to U-235, able to produce heat and sustain a controlled nuclear reaction inside the nuclear reactor. Nuclear power plants derive over one-third of their power output from the fission of Pu-239. Most of the uranium inside nuclear fuel is U-238. Only a small fraction is the fissile U-235. Over the life cycle of the nuclear fuel, the U-238 changes into Pu-239, which continues to provide nuclear energy to generate electricity.

Not all of the Pu-239 will fission during the fuel cycle in a nuclear reactor. Some of the plutonium will not experience neutron bombardment sufficient to cause fission. Other plutonium atoms will absorb one or more neutrons and become higher numbered isotopes of plutonium, such as Pu-240, Pu-241, etc. Plutonium comprises just over 1 percent of nuclear reactor spent fuel—the fuel removed from the nuclear reactor after it has produced all the nuclear fission it can economically provide. Of the plutonium remaining in the spent fuel, slightly less than 60 percent will be fissionable Pu-239.

Because of the high concentration of Pu-240, the plutonium in spent fuel is unsuitable for military application (nuclear warheads). Plutonium-240 is a constant source of neutron decay and is highly unstable. Moreover, the Pu-240 cannot sustain a chain reaction. Military-grade plutonium consists of over 90 percent fissionable plutonium. Because it is impractical to separate the two isotopes of plutonium, special reactors are used to create Pu-239 with extremely small quantities of Pu-240. Even where nations are desperate for electric-generating capacity, the fear of rogue nations teaming to build and operate these special facilities to create military-grade plutonium is a main reason the International Atomic Energy Agency closely safeguards the transfer and use of nuclear energy technology.

Now that much of the world has agreed to nuclear disarmament, scientists and world leaders are searching for uses for the surplus weapons-grade plutonium. Instead of pursuing disposal options, one option is the use of mixed-oxide (MOX) nuclear fuel.

MIXED OXIDE FUEL

In order to deplete stockpiles of weapons-grade plutonium, it is possible to "burn" the fuel in a nuclear reactor. This option has two distinct advantages. First, the fissionable plutonium is a direct replacement for fissionable uranium in a nuclear reactor. Therefore, the plutonium will sustain a controlled chain reaction inside the reactor and provide the heat necessary to create steam for a power plant. Second, the plutonium not undergoing fission will become increasingly contaminated with other isotopes of plutonium (e.g., Pu-240) so that it will no longer be suitable for weapons applications. The longer the plutonium remains inside the nuclear reactor, the more Pu-240 is created as Pu-239 absorbs neutrons. The spent fuel from a reactor using MOX fuel will contain diminished amounts of Pu-239 and increased amounts of Pu-240, effectively removing weapons-grade plutonium from circulation.

Mixed oxide fuel is not appropriate for all nuclear reactors. Plutonium requires faster neutrons in order to operate in a sustained chain reaction. Light-water reactors operate in a highly moderated environment, and thus U-238 and Pu-239 do not make excellent fuel sources. Light-water reactors can handle up to approximately 30 percent MOX fuel. Heavy-water reactors, such as those in Canada, and other fast neutron reactors, can operate with 100 percent MOX fuel.

Other options for eliminating weapons-grade plutonium are to seal it permanently in solid radioactive waste and dispose of it in waste repositories, and to use the plutonium to fuel fast neutron reactors (without reprocessing the plutonium into a MOX fuel).

Plutonium has a much shorter half-life than uranium (24,000 years for Pu-239; 6,500 years for Pu-240). Plutonium is most toxic if it is inhaled. The radioactive decay that plutonium undergoes (alpha decay) is of little external consequence, since the alpha particles are blocked by human skin and travel only a few inches. If inhaled, however, the soft tissue of the lungs will suffer an internal dose of radiation. Particles may also enter the blood stream and irradiate other parts of the body. The safest way to handle plutonium is in its plutonium dioxide (PuO_2) form because PuO_2 is virtually insoluble inside the human body, greatly reducing the risk of internal contamination.

WASTE DISPOSAL

The main drawback to nuclear power is the production of radioactive waste. Spent fuel from a nuclear reactor is considered a high-level radioactive waste, and remains radioactive for a very long time. Spent fuel consists of fission products from the U-235 and Pu-239 fission process, and also from unspent U-238, Pu-240, and other heavy metals produced during the fuel cycle. That is why special programs exist for the handling and disposal of nuclear waste.

NUCLEAR FUSION

The nuclear fusion of light elements powers the sun and other stars. The fusion process in stars and supernovas creates from primordial hydrogen heavier elements, including those needed for chemistry and life. Nuclear fusion is analogous to the chemical reaction of burning, such as the joining (fusing) of hydrogen and oxygen to produce water vapor and release energy. Both processes produce something new while releasing energy.

Our planet contains large quantities of light elements that are theoretically suitable for providing energy from fusion reactions in central power plants. The potential energy resource from fusion is vast—so vast that the world's energy needs could be met for billions of years at current rates of consumption. Laboratory experiments, as well as nuclear explosions, have released fusion energy on the Earth, and it may be feasible to provide useful energy from fusion in the future in a controlled and safe manner. While the fusion process is a nuclear reaction, the results of the reaction do not include many of the problems with fission: First, there are no products like long-lived fission products that cause many of the problems associated with nuclear waste from fission. Second safeguarding uranium and plutonium is not an issue with fusion because those materials are not used. Fusion does not release compounds such as carbon dioxide that contribute to global warming through the greenhouse effect. Third, starting and maintaining a fusion reaction in a controlled manner appropriate for producing useful energy is difficult and always involves a limited amount of fuel at any given moment so that an accidental nuclear runaway reaction in a large quantity of reactants is not possible.

Fusion energy comes from rearranging electrostatic and nuclear forces inside the nucleus, and in this respect fusion is like fission. The rearrangements of both fission and fusion release energy in proportion to the decrease of mass during the reaction according to the famous formula from Albert Einstein's relativity, $E = mc^2$, where E is the energy released, m is the mass lost, and c is the speed of light.

Chemical reactions, such as the burning of carbon in coal with oxygen, also get energy from rearranging electrostatic forces, but those forces are much smaller and consequently chemical energies released per atom are much smaller than nuclear energies released per nucleus.

Nuclei suitable for fusion must come near each other, where "near" means something like the nuclear radius of 10^{-12} cm. For positively charged nuclei to make such a close approach it requires large head-on velocities, and therefore multimillion-degree Celsius temperature. In contrast, fission can occur at normal temperatures, either spontaneously or triggered by a particle, particularly an uncharged neutron, coming near a fissionable nucleus.

Above a temperature of 10,000 degrees or so, matter starts to become ionized, meaning that electrons separate from atoms. Ionized matter, containing ions and electrons, is called "plasma"—a term not to be confused with the "plasma" of physiology and medicine, which means a liquid in which cells are suspended.

Stars are giant spheres of plasma. Stars fuse hydrogen into helium for their primary source of energy. Omitting details of the catalytic role of carbon in stars, four hydrogens combine to yield one helium, two neutrinos, and two positively charged electrons (positrons) with a total kinetic energy of approximately twenty-eight MeV. The unit "MeV," or million electron volts, is convenient for discussions of nuclear energy, as is the "eV" or electron volt (or calorie and Btu) for treatments of chemical reactions. A million

Particle beam fusion accelerator II (PBFA-II) was designed to deliver at least 100 trillion watts of power and was the first machine with the potential to ingnite a controlled laboratory fusion reaction. (U.S. Department of Energy)

electron volts is 1.6×10^{-13} joule, 3.8×10^{-14} calorie, 1.5×10^{-16} Btu, 4.5×10^{-20} kWh (thermal), which makes the MeV sound like a very small unit until one considers that an MeV of released energy is typically associated with approximately one atomic mass unit (AMU), of which there are 6×10^{23} in a gram.

The fusion reaction of four hydrogens to make a helium yields 185,000 kilowatt-hours (thermal) per gram of original hydrogen fuel—an enormous result for such a small mass. Fusion occurs mostly in the core of stars at a temperature near 15 million degrees and the energy released migrates to the much cooler 6,000 degree surface to produce the radiation emitted, some of which is visible light.

While stars shine from the fusion of plain hydrogen, that reaction is unsuitable for use on the earth. In substellar sizes the energy released leaves the reacting region as electromagnetic radiation much too quickly. Releasing fusion energy on a human scale requires fusion fuels that react with each other more rapidly than the slow-burning basic fuels of stars.

REACTIONS FOR USEFUL ENERGY

The most plausible fusion reaction for producing energy commercially involves two isotopes of hydrogen, deuterium (D) and tritium (T), or ${}^{1}H^{2}$ and ${}^{1}H^{3}$. Deuterium contains one proton and one neutron for an atomic number of two. Tritium contains one proton and two neutrons for an atomic number of three. The reaction is

$$D + T \rightarrow {}^{2}He^{4} + n$$

with the release of 3.5 and 14.1 MeV in the helium and neutron, respectively.

Schematic of a fusion reactor

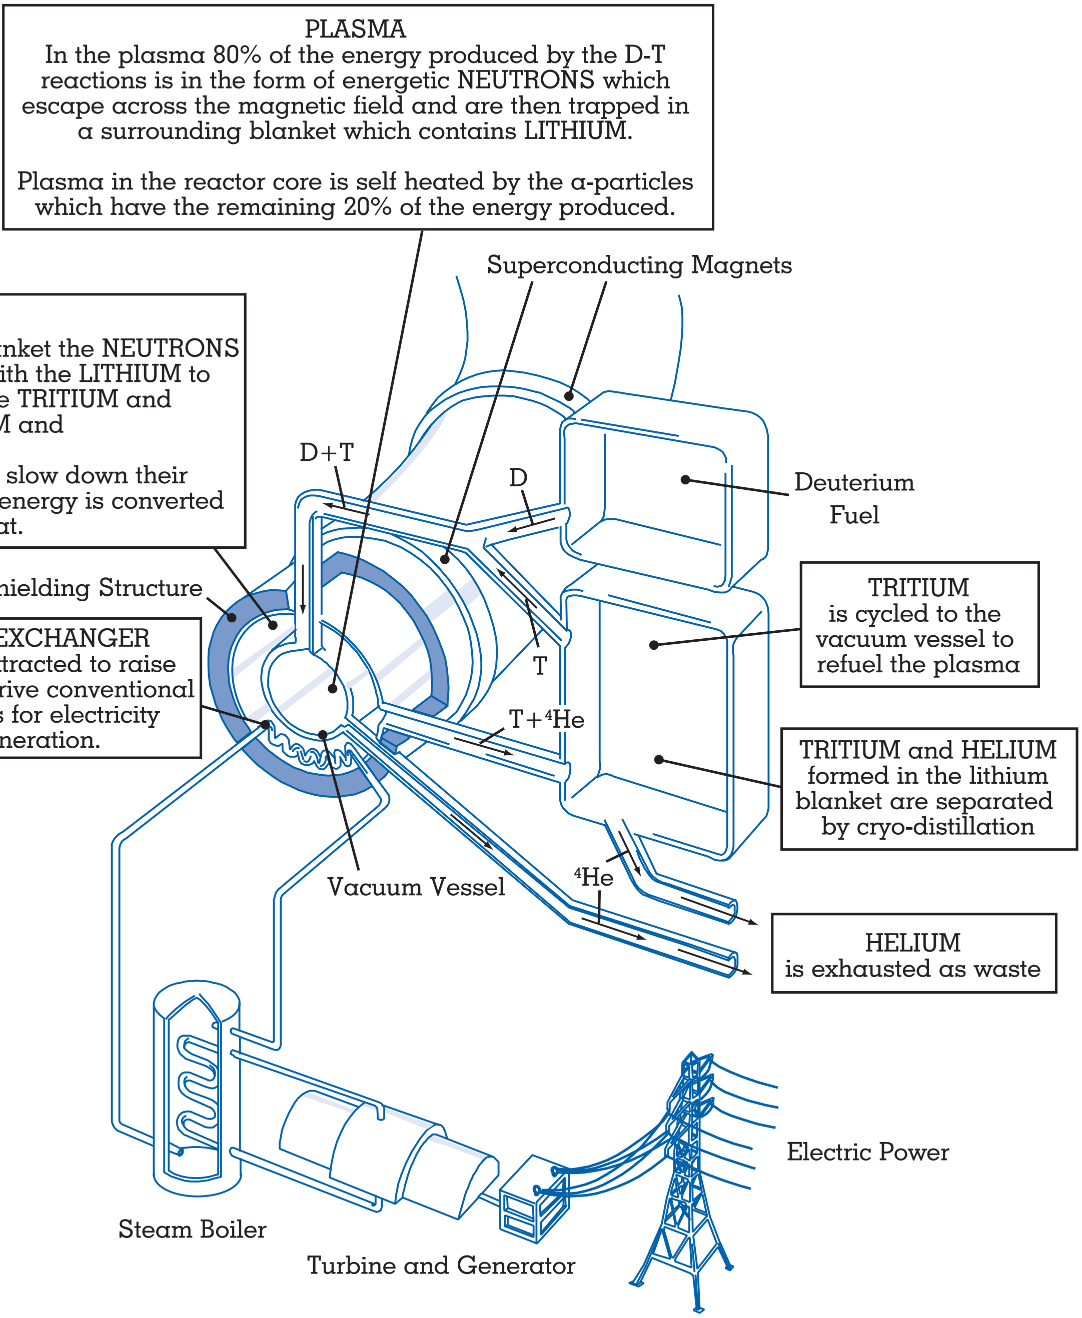

Figure 1.

Schematic of a fusion reactor, assuming a generally toroidal shape of the plasma and magnetic fusion. The principles emphasized are central hot core (red) at 100 million degrees, blanket and heat exchanger, shield, energy conversion, and the handling of D, T, and the "ash" He.

SOURCE: JET Joint Undertaking, Abingdon OX143EA, UK; Graphics Department; JG91.230.

Deuterium occurs naturally, mixed in with plain hydrogen in the tiny proportion of 0.015 percent; in other words, plain hydrogen is the more common isotope by a factor of 6,600. Tritium for fusion energy can be created from another nuclear process involving the interaction of the neutron (in the equation above) with lithium:

$$n + {}^{3}Li^{6} \rightarrow {}^{2}He^{4} + T$$
$$n + {}^{3}Li^{7} \rightarrow {}^{2}He^{4} + T + n$$

with the release of 4.8 MeV in the first reaction and the absorption of 2.5 MeV in the second reaction. The fuel resources for D-T fusion are, therefore, lithium and deuterium. Lithium occurs in brines, mines, and, at the high dilution of only 0.17 parts per million by weight, in sea salts. The resource of lithium in oceans dominates all other sources by a factor of approximately 10,000. And although lithium is plentiful, far fewer lithium atoms than deuterium atoms exist on the Earth making lithium the limiting the resource for D-T fusion.

An essential idea in fusion research is the following: The 3.5 MeV of energy carried by the ${}^{2}He^{4}$, which is also called an α-particle, stays in the fusing region to maintain the high temperature and keep the reaction going. The concept is called "ignition" by analogy to common chemical ignition of fuels in which a small initial spark starts a flame that continues on its own.

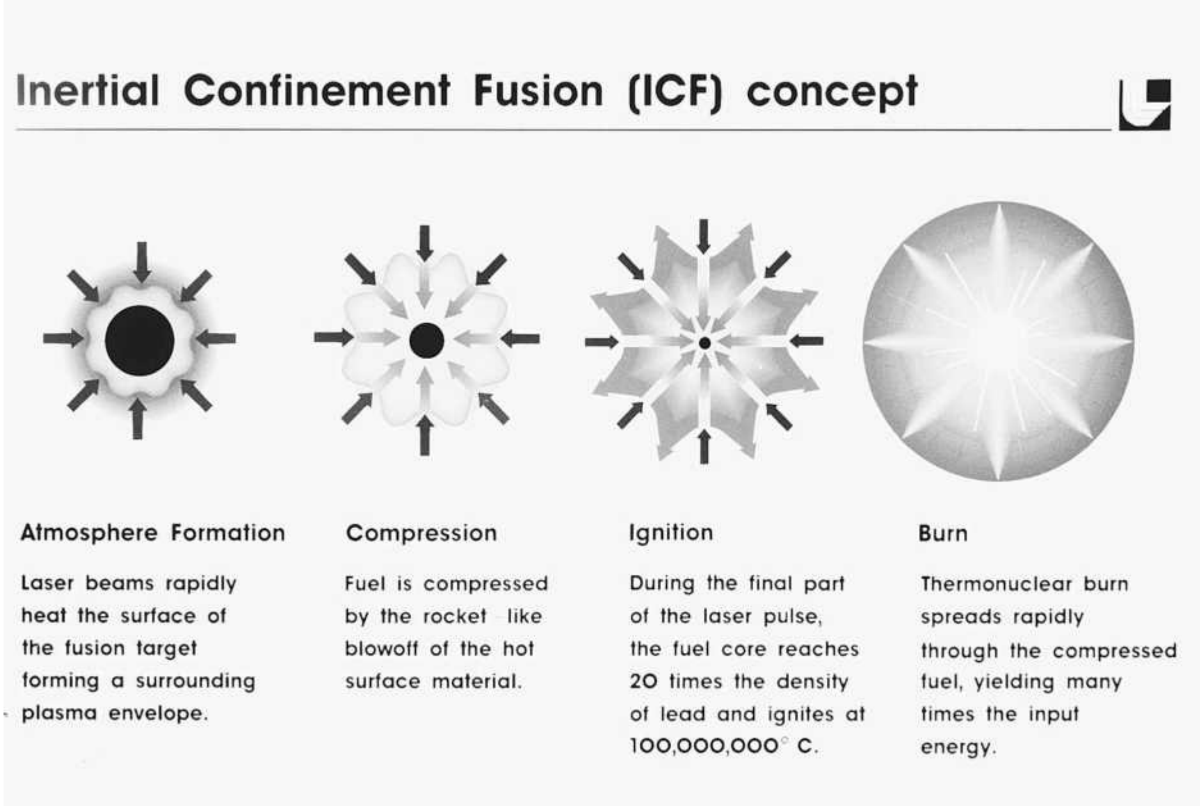
Other fusion reactions such as D plus ${}^{2}He^{3}$ and D plus D (not to mention the H plus H of stars) require far more difficult physical conditions than D plus T, but offer potential advantages in reduced neutron production, and even larger reserves of potential energy in the case of D-D.

CONDITIONS FOR USEFUL ENERGY

D-T fusion in substellar sizes on a human scale requires ultrahigh temperatures, approximately 100 million degrees, for the power produced to exceed the fundamental and irreducible cooling effect of power lost to electromagnetic radiation caused by the particles colliding with each other (bremsstrahlung, or braking radiation). Approximations to data on D-T reactivity lead to a simple and often quoted figure of merit for progress on fusion research, ntT, where n is the fuel particle density, t is an average time that energy stays in the fusion region, and T is the temperature. The best present experiments create ntT approaching the requirements for producing net energy, or 10^{21} m^{-3}-second-keV. (A keV is a kilo electron volt, which is approximately 11 million degrees.) An equivalent statement is that in some present experiments the ratio of fusion energy produced to the energy needed to assemble the hot particles, usually called Q, is near unity. A Q of unity is often called "scientific breakeven," to make clear the contrast with commercial feasibility which requires that fusion energy released be much more than the total energy to operate the machinery in the reactor power station.

The goal of research on nuclear fusion is to produce useful energy in the future as follows: A mixture of D and T is heated to ignition at 100 million degrees, and the fusion energy is released, largely carried by the 14 MeV neutrons produced, streams outwards to a sufficiently thick "blanket" containing lithium and a heat exchange medium, which could in fact be lithium or contain lithium. The neutrons interact with lithium to produce tritium that is retained at the reactor site for later use as fuel. The heat, which comes largely from absorbing the neutron energy in the blanket, is transferred to an external turbine engine to produce electricity with the standard efficiency of 35 to 40 percent. Low temperature heat— constituting of 60 to 65 percent—is not used for electricity. But it can be used for industrial processes, including space heating and refrigeration. The blanket absorbs most neutrons, and a shield outside the blanket absorbs any remaining neutrons and other escaping radiation. The region outside the blanket-shield is then largely free of radioactivity. The blanket, shield, and any material that must remain inside to operate the fusion reactor does become radioactive because of the interaction with the neutrons. The strength and nature of the radioactivity inside the outer surface of the shield has to do with the details of design and the materials used, but remote handling tools will be needed for maintenance. Equipment needed to create and maintain the reacting plasma is outside the shield: for example, electrical power supplies, lasers, ion beams, and superconducting magnets at a few degrees above absolute zero.

At the simplest level there is a remarkable feature of the fusion reactor: a 100 million degree reacting region is near the industrial heat source—the blanket, operating at several hundred degrees. Some kind of insulation must separate the reacting fusion region and the blanket. The two insulation options being explored are



Inertial Confinement Fusion (ICF) concept

Atmosphere Formation

Laser beams rapidly heat the surface of the fusion target forming a surrounding plasma envelope.

Compression

Fuel is compressed by the rocket like blowoff of the hot surface material.

Ignition

During the final part of the laser pulse, the fuel core reaches 20 times the density of lead and ignites at 100,000,000° C.

Burn

Thermonuclear burn spreads rapidly through the compressed fuel, yielding many times the input energy.

Representation of the inertial confinement fusion (ICF) concept. (U.S. Department of Energy)

magnetic fields for “magnetic fusion” or space for “inertial fusion.” The magnetic insulation is much like fiberglass in a walk or ceiling. Magnetic fields slow heat transfer from the motion of plasma particles, much as the fiberglass and trapped air slow the flow of heat through a wall. Space insulation is similar to that obtained in moving back from a blazing fire.

Enhancement of the fusion reaction has been explored in attempts to avoid the extreme requirements for temperature, plus the stringent conditions on density and time. An “atom” of a D or T nucleus and the short lived muon, which is 207 times more massive than the electron, has a much smaller size than a normal D or T atom, so much so that it might be possible to bring the D and T nuclei close enough for fusion at modest conditions. Certain metals can absorb hydrogen so densely that some spontaneous fusioning of D and T might occur. The latter idea is behind the announcement in 1989 of “cold fusion” in an electrolytic cell having platinum and palladium electrodes—an announcement that numerous investigations subsequently proved to be in error. Catalysis, or enhancement of fusion rates has not been pursued as an energy source in recent years.

INERTIAL APPROACH

Inertial confinement fusion has long succeeded in the context of military explosions—the hydrogen bomb. In the military application a fission bomb produces x-rays that drive an implosion of D-T fuel to enormous temperatures and densities such that fusion reactions occur during the short time that inertia keeps the fusing nuclei densely packed and hot.

For civilian purposes the inertial concept is to compress and heat a small sphere of D-T fuel with an external “driver” such as laser light, x-rays produced by lasers, or high energy ion beams. The resulting hot and extremely dense plasma burns the D-T mixture rapid-

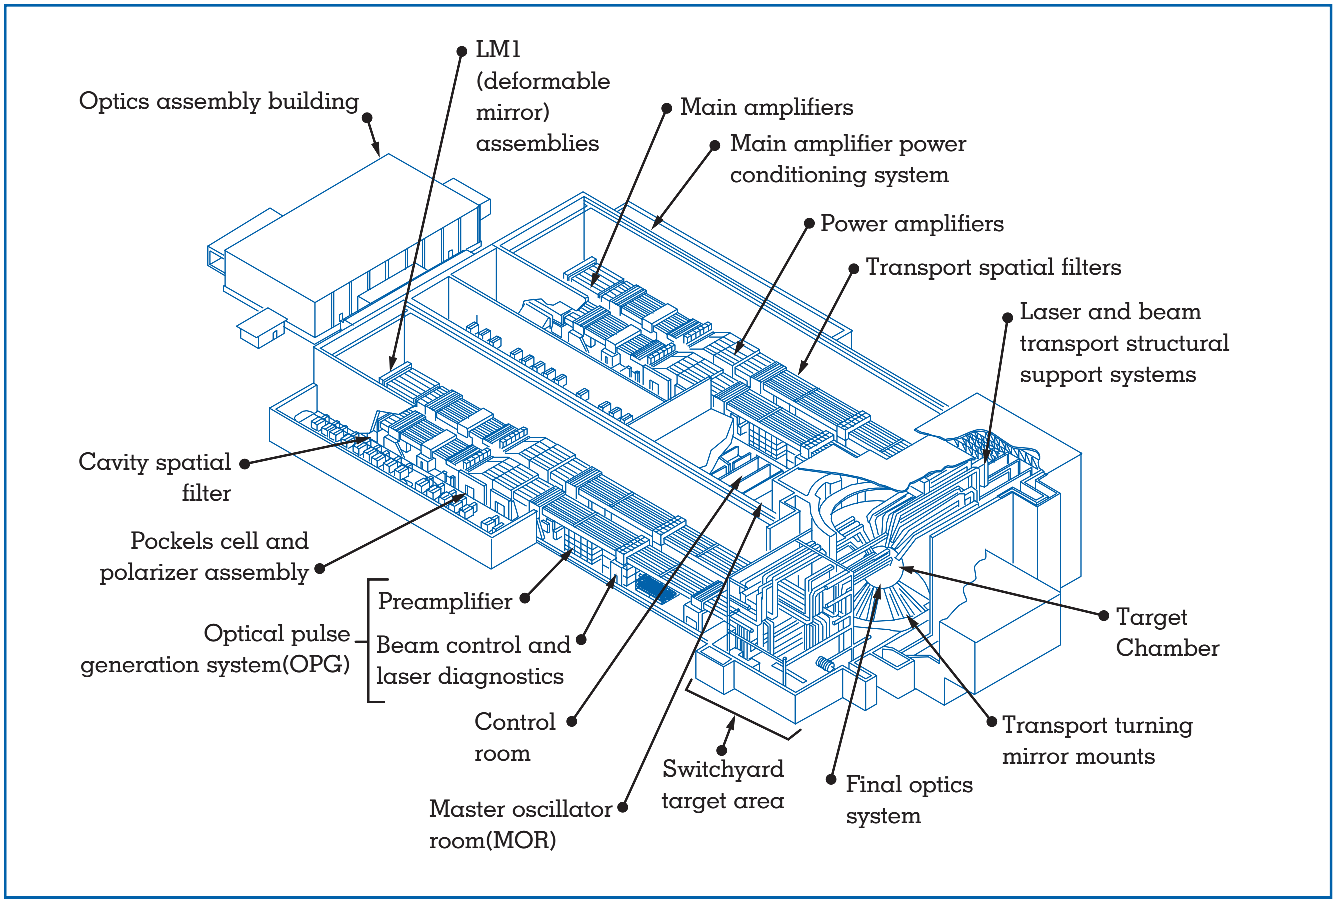


Figure 2.

SOURCE: LLNL ICF Annual Report 1997, p. 95.

ly before the microexplosion expands appreciably. Time scales are nanoseconds (billionth of a second) for each microexplosion, repeated steadily to produce power. Density scales are thousands times solid density. The mission of inertial fusion in the United States is primarily to address the science of high energy densities for the Defense Department program in stewardship of nuclear weapons. Applications to civilian energy needs are a secondary mission.

Much of the driver energy goes into ablation, or blowing-off the surface of the sphere of fuel to force the compression (implosion) by the rocket effect. As a result, the ntT needed for scientific break-even for inertial confinement is around twenty times higher than for magnetic confinement.

The largest inertial fusion program in the United States is the National Ignition Facility (NIF) now under construction at the Lawrence Livermore National Laboratory (LLNL) in Livermore, California (Figure 2). Completion of the stadium-sized construction project is planned for 2003 at an approximate total cost of $1 billion. The goal is to investigate the interaction between spherical targets and ultraviolet laser light producing x-rays in a “hohlraum”—cavity surrounding the target—at a power of 500 tera watts (trillion watts) for several nanoseconds for a total energy of 1.8 MJ (million Joules). Many other significant installations in the United States and around the world are investigating the potential of inertial fusion.

MAGNETIC APPROACH

Magnetic confinement has been pursued for civilian purposes since the 1950s. The idea is that a magnetic field, some of which might be generated by internal heating currents, slows the transfer of energy from the hot plasma core to the surroundings while extra heating power is applied from particle beams or radio frequency transmissions. Time scales are seconds for the energy replacement time, and indefinitely long for an energy-producing burn; density scales are ten thousands below atmospheric gaseous density.

In about 1968 the Soviet Union (now Russia) under the leadership of Academician Lev Artsimovitch took a large step forward in magnetic fusion with a concept called the "tokamak." The term is a Russian acronym for toroidal (inner-tube shaped) magnetic chamber. Since the mid 1970s the tokamak has dominated worldwide magnetic fusion research, culminating in highly successful D-T burning experiments in the United States with the Tokamak Fusion Test Reactor (TFTR) at Princeton University in New Jersey and the Joint European Torus (JET) in the United Kingdom. Numerous other tokamaks in many countries, including Japan (JT-60), France (Tore Supra) , Germany (ASDEX, TEXTOR), Italy (FTU), and the United States (D-III-D, Alcator-C), confirm and extend the progress while not using tritium.

Two essential ideas behind the tokamak are the externally supplied toroidal magnetic field that closes on itself repeatedly, and a slight twist to the field added by currents inside the reacting region. The closed magnetic field lines in the hot plasma do not strike a wall, so that energy is not instantly conducted to a wall. The twist is essential for good and stable confinement of energy. Prior to the emergence of the tokamak idea, the twist needed in closed, toroidal systems was provided often by external coils in the "stellarator" concept developed at Princeton University by astrophysicist Lyman Spitzer.

Many other magnetic fusion concepts have been pursued over the years: for example, the "magnetic mirror" with open field lines that always strike a wall somewhere but with good stability properties; linear and toroidal "pinches" featuring rapid compression and heating. Today the stellarator is enjoying a significant revival with large programs in

Mechanical Equilibrium and Absolute Trapping of Particles

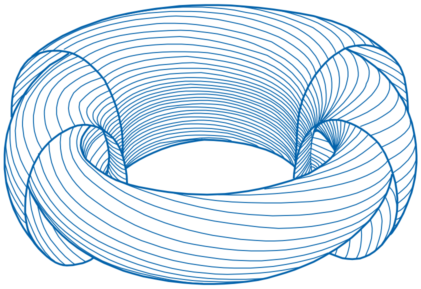

Figure 3.

Schematic representation of the magnetic structure of the Tokamak magnetic confinement device. The lines on the shells represent the direction of the total magnetic field, most of which comes from external coils. The portion that gives the twist, however, comes from current inside the hot plasma itself. The twisting is necessary for stable confinement.

SOURCE: *Transport and Structural Formation in Plasmas* by K. Itoh, S.-I. Itoh, and A. Fukuyama, Institute of Physics Publishing Ltd., 1999. p. 24.

Japan (LHD) and in Germany (W-7-AS), plus smaller experiments elsewhere. At a basic research level, there is interest in a broad array of magnetic approaches.

Still, the tokamak is getting most of the attention, particularly regarding the matter of a large project to follow JET and TFTR and burn D-T so successfully that the plasma ignites—continues to burn on its own—thereby demonstrating in a convincing manner that with further work, the tokamak can be developed into a commercially viable source of energy. The working name for the ignition project is the International Thermonuclear Experimental Reactor (ITER). In 1998, they completed an integrated engineering design, supported by research and development on crucial components, and a reliable budget and schedule. The term "thermonuclear" refers to the multi-million degree temperatures needed to produce energy from nuclear fusion. The four international parties to ITER—Japan, the European Union, the United States, and the Confederation of Independent States (Russia)—had intended to proceed with cooperatively funded construction at a site to be chosen jointly. The cost estimate of approximately 10 billion and political factors have caused ITER to reexamine the design goals, particularly toward a less costly device, but one retaining the most basic and interesting scientific and technical goals. ITER management hopes to go ahead with construction after the year 2000, and operate ignited plasmas in a decade or so.

For both inertial or magnetic fusion energy the long range, but nonspecific, plan is the following: develop concepts to achieve ignition of D-T, whether in ITER, NIF, or other facilities, and proceed to a demonstration reactor (often called DEMO) and then to commercial implementation. DEMO and commercialization are decades away. Even though the ignition DEMO path is being followed by most people working on fusion, researchers generally agree on the need to continue developing the science of fusion and alternative approaches because uncertainties continue about what will eventually prove to be a successful approach.

SUMMARY

Creating useful energy from fusion on the earth has proved difficult: The forty year effort looks like it still has decades to go. The following inherent potential advantages tend to encourage continued effort: abundant fuel in lithium and virtually inexhaustible fuel in deuterium; absence of the greenhouse emissions of coal, oil, natural gas; no issues regarding the control of a nuclear chain reaction; radioactivity induced by fusion neutrons depends on the design of the device, not the fundamentals of nuclear physics.

If and when projects producing energy on an industrial scale begin to appear in the middle of the twenty-first century, the theoretical advantages will be subject to confirmation. Fusion, magnetic or inertial, might then join the mix of energy resources.

NUCLEAR WASTE

KINDS OF NUCLEAR WASTE

Nuclear waste is radioactive material that has no immediate use. In the United States nuclear waste generally is divided into two main categories: high-level nuclear waste (HLW) and low-level radioactive waste (LLW). Two less common categories are tailings from uranium mining and milling, and a special category derived from particular aspects of nuclear weapons production and defense-related activities. This latter, less commonly discussed, category is called defense wastes and, because of its makeup, is sometimes called transuranic wastes; it makes up about half of the HLW in the United States. This article focuses on HLW and LLW from nuclear power reactors.

HLW comprises most of the radioactivity associated with nuclear waste. Because that designation can cover radioactive waste from more than one source, the term spent nuclear fuel (SNF) will be used to discuss HLW originating from commercial nuclear reactors. LLW comprises nearly 90 percent of the volume of nuclear waste but little of the radioactivity. Nuclear power reactors produce SNF and most of the nation's LLW, although there are approximately 20,000 different sources of LLW. The name SNF is a bit of a misnomer because it implies that there is no useful material left in the fuel, when in fact some fissionable material is left in it.

CONCERN FOR RADIOACTIVE WASTES

Nuclear waste is a concern due to the levels of radioactivity in it, especially in HLW. Relative to the wastes associated with other major methods of power production, the volumes are small. The concern is for the amount of radioactivity and the time of its duration. The time of radioactivity duration is measured in half-lives (the time required for half of the atoms of a given substance to disintegrate, at which time it becomes the new starting amount with which to begin the count again). Generally LLW not only has lower levels of radioactivity, it also has very low concentrations of long-lived radioactive substances. There are short-lived and long-lived substances in nuclear waste, with half-lives varying from seconds to thousands of years.

In the United States the federal government has taken responsibility for HLW, for both SNF and defense wastes, and for mill and mine tailings. Remediation of the effects of such tailings is well under way. Each state or groups of states (compacts) are responsible for the safe isolation of their own LLW. Three departments of the federal government have prime responsibility for matters related to nuclear waste: Department of Energy (DOE) and its predecessor agencies, which created most of the defense wastes; the Nuclear Regulatory Commission (NRC); and the Environmental Protection Agency (EPA). Regulations regarding care of nuclear wastes are also set by individual state agencies, especially for the LLW.

The federal government not only has responsibility for the safe isolation of SNF but also taxes on the generation of electric power to cover the cost of waste isolation at the rate of one mil/kWh ($0.001/kWh). Although the nuclear waste fund has been folded into the general federal budget, it comes from a special levy that can be changed to accommodate the needs of SNF handling. The office that manages this fund and that is responsible for SNF is in the U.S. DOE and is called the Office of Civilian Waste Management (OCRWM).

ORIGINS OF THE RADIOACTIVITY IN SPENT NUCLEAR FUEL

The nuclear waste generated from production arises when uranium atoms in the fuel split. Nuclear power reactors are fueled with assemblies of rods containing pellets, each about the size of a pencil eraser. About 3 percent of the uranium in these pellets is the fissionable isotope, or form, of uranium, U-235. This is the rarer of the two naturally occurring isotopes of uranium. In nature, the U-235 isotope is found in less than 1 percent of uranium ore—usually 0.5 to 0.7 percent of that ore. After uranium ore is mined and processed, the isotopes are separated, in a process called uranium enrichment. This is not a simple task and is mostly done by a gaseous diffusion plant. Usually the process is stopped when the mixture is about 3 to 3.5 percent of the fissionable form in the mix. (The majority uranium, U-238, is radioactive in its own right, emitting a short-range alpha particle, but it is not fissionable. When the fissionable isotope is extracted from uranium, the remaining material is called depleted uranium and has its own other uses, which will be addressed below.) The exact makeup of the reactor fuel varies some what but is mostly in the form of uranium dioxide, with the uranium being about 3 percent fissionable U-235.

There are three main products in the fissioning of uranium-235: tremendous amounts of energy, neutrons that perpetuate the chain reaction, and two new atoms. The splitting is such that eventually every element found on the periodic chart of the elements is made, especially in the flux of speeding neutrons that induced and perpetuated the fission. Every isotope of every element can be found in the waste. Many of the new isotopes produced are highly unstable—that is, they are radioactive. Many decay in seconds, but some exist in their unstable form much longer, eventually decaying into stable isotopes, though often with intermediates that are also radioactive. This results in radioactive decay chains. These chains of radioactive decay mean that SNF will be radioactive for a long time. It has been estimated that it will be approximately 7,000 years before the level of radioactivity in SNF drops to that of natural radioactivity, that of Earth itself. Since some parts of Earth will be radioactive forever, it can be said that SNF will be radioactive forever. In practice, one must decide what levels of radioactivity to call dangerous. That debate influences decisions about nuclear waste isolation. The debate about what is "safe" is not part of this particular topic. The amended version of the Nuclear Waste Policy Act (NWPA) calls for the safe isolation of HLW from the human environment for 10,000 years.

Besides fission products, the various forms of known but newly formed elements in the spent nuclear fuel, there is a small but significant amount of fissionable, or fissile, material in the SNF. This is quite important. There is some unused, unfissioned U-235 that has become too dilute to use. Like natural uranium ores in which chain reactions do not

Solid transuranic interim waste storage at the U.S. Department of Energy's Idaho National Engineering Laboratory in Idaho Falls, Idaho. (U.S. Department of Energy)

occur, the fuel will not sustain a chain reaction. But new fissile material also has been made in the intense neutron irradiation. Elements are made that are heavier than naturally occurring uranium, and because of their location on the Periodic Chart are referred to as transuranics. There are isotopes of plutonium and uranium made that can fission. None is present in concentrations that are great enough for a self-sustained chain reaction, but they do represent new fuel. The concentrations of U-239, Pu-239, Pu-240, Pu-241, and some short-lived intermediates are 1–2 percent of the SNF. Some of these are fissile material. Breeder nuclear reactors can be designed and run to produce significant amounts of these isotopes. "The SNF from a breeder reactor is rich in newly produced fissionable isotopes but it must undergo extensive reprocessing to become new reactor fuel. That reprocessing will adjust the concentration of fissionable isotopes and eliminate some of the fission products that tend to quench fission process."

HANDLING OF SNF

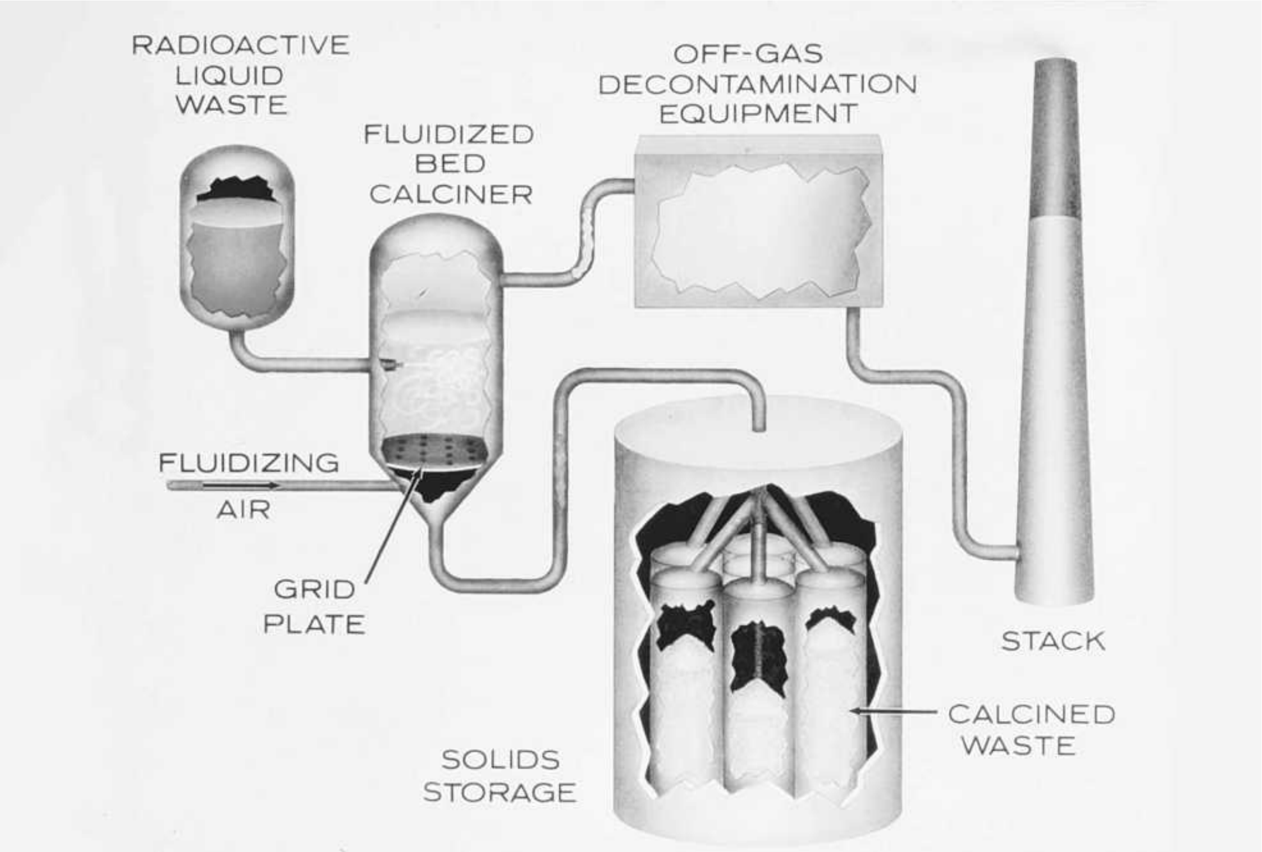
Workers wearing gloves can handle nuclear fuel that is being freshly installed into a nuclear reactor. This fuel assembly becomes dangerously and highly radioactive SNF after a short time in an operating nuclear reactor. Upon removal from a reactor (after about 18 months), a spent fuel assembly is now HLW and is far too "hot" thermally and radiologically to handle directly. It is removed remotely with a crane and stored in a bay of cooling water beside the reactor.

HLW still looks like a fuel assembly, a collection of long, skinny rods, each filled with fuel pellets, held in a rack that allows water to pass through and pick up thermal energy. The assembly is kept underwater to cool and also to shield the workers from the longer-range gamma radiation. The water also contains corrosion-inhibiting chemicals as well as chemicals to absorb the few neutrons emitted from lingering atoms of U-235 and other fissile material. Generally a ten-year cooling-off period allows that much of the heat to be emitted and the radioisotopes with short half-lives to have undergone decay. For power plants with limited pool storage there are two choices when the cooling pools are filled: rod consolidation and dry cask storage.

Rod consolidation can permit space saving by dismantling the fuel assembly racks. The rods are still maintained underwater. Rod consolidation is not a routine practice due to issues of heat dissipation and criticality, the possibility of a chain reaction continuing. Dry cask storage is the more common approach for the oldest fuel assemblies and calls for removal of the fuel assemblies from the cooling pool. Designs of the casks vary in detail, but they usually accommodate several spent fuel assemblies in a sealed steel container that is enclosed in a concrete box and/or metal canister. Usually these containers are stored and monitored at the plant site. As with all major operations at nuclear power plants in the United States, hearings before the NRC and the public are conducted on temporary SNF storage. Almost all dry cask storage occurs at the power plant site, where monitoring of the containers can be routine.

ULTIMATE ISOLATION OR REPROCESSING OF SNF

The ultimate disposition of HLW or SNF is a matter of significant importance and is controversial for some. In the United States all HLW, including SNF, has always been a federal responsibility, beginning with the Atoms for Peace Program in the 1950s. A



Cutaway view of the new waste calcining facility (NWCF) process. (U.S. Department of Energy)

study done by the National Academy of Sciences in 1957 indicated that nuclear waste disposal would not provide insurmountable technical problems and recommended deep geological isolation. Every country that has nuclear power plants has considered the safe isolation or disposal of HLW and has concluded that deep geologic isolation is the safest method. In the United States eight options, including deep-ocean-trench burial, space launches, Antarctica burial, and transformation into materials with shorter half-lives have all been studied. The media into which the HLW is to be isolated varies widely from country to country and include granite, salt beds, and tuffaceous material, welded volcanic ash, most commonly called tuff. United States attention is focused on Yucca Mountain, at the western edge of the Nevada Test Site, the location of above-and below-ground nuclear weapons testing in the past. It is a mountain of tuff.

YUCCA MOUNTAIN, NEVADA

The amended version of the NWPA has determined that only Yucca Mountain is to be characterized as a possible geologic repository for SNF and possibly some defense waste. It is approximately 100 miles northwest of Las Vegas, Nevada. The planned location of the SNF is approximately 1,000 feet above any groundwater and about the same distance below the surface. Characterization studies of the viability of Yucca Mountain are under way and have been since the early 1990s. The NWPA also prohibits studies of granite as a host rock. (Canada is considering SNF isolation in granite. Most of the eastern half of the United States is on granite.) Both private and governmental leaders—most concerned about tourism—in the state of Nevada are resisting the Yucca Mountain characterization studies. Furthermore, although the majority of scientists studying the mountain find no clear problems, a few find fault with the studies ad the site as a possible repository. The most difficult part of the studies involves predictions about the behavior of the tuff environment for 10,000 years and beyond. The fact that Yucca Mountain is in a region of ancient volcanic activity complicates the assessments. Most attention is devoted to water movement through the tuff and the vulnerability of the underlying earth to undergo any significant "stretching" in the foreseeable future. The Yucca Mountain project has a website listed in the bibliography for this article, with photos and links to scientific data being accumulated as well as links to opposition points of view.

Yucca Mountain, if it becomes the site for the isolation of SNF, will be laced with tunnels, waste in storage casks and monitoring equipment. A waiting period is planned while better isolation alternatives are sought. If Yucca Mountain is not used, it is to be refilled with the tuff material removed earlier. In the United States the SNF that would be isolated in Yucca Mountain would be waste that has not been reprocessed; it would be material that has come out of nuclear reactors and has been cooled at the plant site.

WASTE REPROCESSING

Since the amount of fissile material in the fuel assemblies is only about 3 percent of the uranium present, it is obvious that there cannot be a large amount of radioactive material in the SNF after fission. The neutron flux produces some newly radioactive material in the form of uranium and plutonium isotopes. The amount of this other newly radioactive material is small compared to the volume of the fuel assembly. These facts prompt some to argue that SNF should be chemically processed and the various components separated into nonradioactive material, material that will be radioactive for a long time, and material that could be refabricated into new reactor fuel. Reprocessing the fuel to isolate the plutonium is seen as a reason not to proceed with this technology in the United States.

Congress has decided that reprocessing will not be practiced in this country so that we will not be in the plutonium production business. This seems like a safe thing to do since this action will minimize terrorism threats. Reprocessing generates chemi cal wastes but greatly reduces the volume of the highly radioactive waste. It also isolates plutonium and unused fuel for possible use as new fuel. Reprocessing means that the volume of material calling for long-term isolation is reduced by one-third what it would have been before reprocessing.

THE VOLUME OF SNF

If one just concentrates on the radioactive material in SNF, the volume is very small, especially compared to waste from other power production practices. However, one can only discuss the separated radioactive material if it has undergone extensive reprocessing. If SNF is to be isolated, as in a place such as Yucca Mountain, with perhaps 70 miles of tunnels, the volume is that of the interior of this minor mountain. Isolation of up to 100,000 metric tons of SNF in Yucca Mountain means that for the United States, approximately all the SNF made to date and that expected in the operating lifetime of all current reactors can be put there. Approximately 2,000 metric tons of SNF are produced each year in the United States. Waste volume and placement depend on the amount of compaction and consolidation at the sites. The plans for the Yucca Mountain present a realistic and understandable picture of the volume of SNF.

A useful perspective may be seen about the amount of SNF by comparing it to the volume of other waste streams associated with power production. More than half of the electricity made in the United States comes from coal burning, where each large power plant generates bottom and fly ash in volumes measured in acre-feet annually. Each of these plants generates its own small mountain of ash. The gaseous wastes from coal burning and from methane and oil burning result in tons of carbon dioxide daily. This carbon dioxide is an infrared active gas and is thought by many to be contributing to global warming and climate change phenomena. The wastes associated with nuclear power are small in comparison, this is not surprising, considering the tremendous power in the nucleus of an atom.

LOW-LEVEL RADIOACTIVE WASTE

The other major category of nuclear waste, LLW, is generally that which is neither HLW nor the transuranic part of defense waste. Generally, LLW is generated in private and public labs, hospitals, and commercial enterprises and can involve lab clothing, paper, packing material and radioactive isotopes used in medical procedures, both diagnostic and therapeutic. Significant amounts of LLW are associated with defense wastes, but mostly are isolated at U.S. DOE facilities. Many pharmaceutical products require extensive use of radioactive tracers. Academic sources are minor. The major sources of LLW in volume and amount of radioactivity are nuclear power plants. Aside from the decommissioning of nuclear power plants, the volume of LLW is decreasing every year. This is because new technologies have become available to separate the radioactive material from that which is not radioactive. Also, generators of LLW are being more selective in the work that they do so that they generate less LLW each year. These changes have become about partly because the cost of isolating LLW has increased.

The LLW from nuclear power plants contains ion exchange resins as well as clothing, tools, and chemicals. Ion exchange resins, which comprise the majority of this LLW, are used to filter the water circulated in nuclear power plants. The ion exchange resins isolate and trap dissolved materials, much of which can be radioactive. Approximately three-fourths of commercially or privately generated LLW is in the form of the contaminated plastic beads that make up ion exchange resins.

The NRC categorizes LLW into Class A, B, or C. The wastes in Classes A and B contain materials that decay to safe levels in about 100 years. Class C wastes will require about 500 years to reach safe levels and contain mostly ion-exchange resins and filters. (There is a minor amount of LLW referred to as beyond class C material.) The majority of LLW is dry and is stored in cardboard or wooden crates. Some are in metal drums. LLW is most likely given shallow burial, compared to the deep geological isolation required for HLW. A difficult issues in LLW disposed involves a small amount of "mixed waste," where the radiological material is mixed with chemically or biologically hazardous substances. The contaminated chemicals may require special handling, since hazardous chemical wastes do not decay as do radioactive materials. In addition, a small amount of LLW consists of animal carcasses or waste and also needs special handling. Currently there are three commercial sites handling LLW for most of the states and compacts. The largest volume of LLW will come with the decommissioning and dismantling of nuclear power plants. In 1995 nearly 700,000 cubic feet of LLW were handled at commercial sites in the United States.

LLW is placed in sturdy, sealed containers. At the isolation site these containers are first put in concrete and/or metal vaults or bunkers and then buried in shallow trenches before being covered with backfill. Some of these are then paved over to prevent rainwater from entering the waste.

The LLW Forum coordinates information and regulations among and between the various state compacts and states. It maintains a website that is overseen by the Idaho Operations Office, which is part of the National Engineering Lab in Idaho. Although LLW is a responsibility of each compact, or of state for the LLW generated in that state, the regulations governing it are those of the U.S. DOE, the NRC, and the EPA. The regulations governing its isolation allow individual states to set additional requirements for handling the material. After being established, any particular compact can refuse to receive the LLW from other states.

OTHER RADIOACTIVE-WASTE SITES

The Waste Isolation Pilot Plant (WIPP) is in an excavated salt cavern in southern New Mexico, twenty-seven miles from Carlsbad. The WIPP site is 2,000 yards underground, and defense waste is being placed. There are plans to place there about 6 million cubic feet of material there containing fewer than five million curies of radio activity.

The most technically difficult category of HLW is that belonging to the U.S. DOE at its major plutonium production facilities in Hanford, Washington, and at the Savannah River facility near Aiken, South Carolina. Just sampling the material for characterization presents problems since much of it consists of radioactive acidic liquids. The rest of it in sludge form, and some is solid. A plant for the vitrification of that part of the material that can be made into glass bars is in operation at the Savannah River facility. The vitrification process encases the waste in glass "logs" to immobilize it and make it easier to handle. A conservative estimate is that it will take decades to clean up these facilities.

NUCLEAR WASTE IN OTHER COUNTRIES

The United States has the most radioactive nuclear waste and the most complicated array of waste types. Reprocessing of SNF is also practiced in some countries. Although costly, this practice reduces the volume of HLW requiring deep geologic disposal. (In the wide variety of elements in the fission products making up SNF, some are toxic heavy metals.) Reprocessing and the general lack of economy of scale in many other countries help to explain why there is less activity or progress related to HLW isolation elsewhere. Interim monitored retrievable storage is generally the focus of activity abroad. Different philosophies and cultures also mean that a wide variety of approaches to the problem are found. Some feel that the generation deriving the benefits of nuclear power is the one responsible for a solution. Others say that succeeding generations may have better technology or ideas about this problem than current generations: Current generations should not do anything permanent, committing future generations to the solutions seen by people living today. Among the technology that wold drastically reduce the cost of cleanup of waste sites robotics.

All the countries that produce nuclear waste have chosen the same alternative for the ultimate disposition of HLW, deep geological isolation, and they did so independently of one another. The United States has the most radioactive nuclear waste and the most complicated array of waste types of any "nuclear" country. Only in the United States can one find the same economy of scale for waste handling. Thus, it leads the world in most activities aimed at safe isolation. In France, Japan, and Great Britain, however, reprocessing is routinely practiced. Those countries reprocess HLW for many other countries. As mentioned above, reprocessing is not currently allowed in the United States.

France and Germany, local protests have dramatically slowed the choice of a final isolation site. As a result, interim storage is widely practiced in other countries. In Sweden, the waste is mixed in molten copper. The radioactive waste is immobilized in copper logs that are easily handled and stored in large underground caverns until a more permanent isolation is chosen. While most feel that those making the waste have the primary responsibility for its isolation, in Sweden they do not wish to commit future generations to solutions that might be vitrified; the glass "logs" are in concrete bunkers.

In the former U.S.S.R. vast areas of the country are contaminated by poor handling of nuclear waste, especially from that associated with the manufacturer of weapons. Some radioactive waste, especially from nuclear submarines has been isolated at the bottom of the Baltic Sea by the former Russian Navy.

CONCERNS

Transportation of HLW is among the most immediate concerns for the general public. Most experts agree that nuclear wastes, especially SNF, are being kept in places not intended for long-term storage and they acknowledge that the problem must be addressed. There is general agreement that SNF should be kept far from population centers (where the electricity is generated and used) and should be kept in a dry place, since water the most likely medium for its movement into the human environment. Movement of SNF is necessary, most likely by rail or roadway. Groups of U.S. DOE and state regulators are working together, continually revising transportation plans and designing and testing transportation casks. Some wish to see a combined transportation and burial cask, while others want very different qualities in each sort of cask. Planners build on past experience handling and transporting radiological materials. Extensive experience was gained when the first commercial nuclear power plant, at Shippingport, Pennsylvania, was decommissioned in 1989 and the reactor vessel was moved to Hanford, Washington, where it is buried.

Despite the challenges, many see nuclear waste issues as being mostly political and social. There is a growing awareness that technical answers alone will not solve the political and social concerns. Some consider nuclear waste issues small in comparison to the volume and challenges associated with other kinds of wastes, whether generated by power plants or other human activities.

OCEAN DRILLING

See: Oil and Gas, Drilling for

OCEAN ENERGY SYSTEMS

Two-thirds of Earth's surface is covered by oceans. These bodies of water are vast reservoirs of renewable energy. In a four-day period, the planet's oceans absorb an amount of thermal energy from the sun and kinetic energy from the wind equivalent to the world's known oil reserves. Several technologies exist for harnessing these vast reserves of energy for useful purposes. The most promising are ocean thermal energy conversion (OTEC), wave power plants, and tidal power plants. All of these produce electricity from the oceans' reserves of renewable energy. Because the ultimate source of energy from the oceans is solar radiation (or the gravitational force of the sun and the moon in the case of tidal energy), ocean energy systems are renewable, have no fuel costs, and are relatively nonpolluting when compared to conventional sources of energy, such as fossil fuels. To date, the technologies for harnessing the oceans' energy on a large scale are still in the early stages of development and have high initial costs, making them more expensive than conventional alternatives.

OCEAN THERMAL ENERGY CONVERSION

Each day, tropical oceans absorb the energy equivalent to 250 billion barrels of oil. If less than one-tenth of 1 percent of this energy could be converted into electricity it would supply twenty times the amount of electricity, consumed daily in the United States. Unfortunately, this energy is spread out over 23 million square miles of ocean, providing a large volume of slightly heated water.

Ocean thermal energy conversion (OTEC) power plants generate electricity by exploiting the difference in temperature between warm water at the ocean surface and colder waters found at ocean depths. To effectively capture this solar energy, a temperature difference of 35°F or more between surface waters and water at depths of up to 3,000 feet is required. This situation can be found in most of the tropical and subtropical oceans around the world that are in latitudes between 20 degrees north and 20 degrees south.

The 35 degree temperature difference is necessary because extracting a little bit of heat from a large volume of water is inherently inefficient. In order to harness thermal energy, two reservoirs of heat at different temperatures are required. In such a "heat engine," heat from the high-temperature reservoir (high-grade energy) flows to the low-temperature reservoir (low-grade energy).

The maximum possible efficiency at which a heat engine can work is defined by the Carnot efficiency equation $E = (T2–T1)/T2$, where E is the efficiency of the heat engine, T1 is the temperature of the cold reservoir (Kelvin), and T2 is the temperature of the hot reservoir (Kelvin). Given tropical surface water temperatures of 80°F (300 K) and cold deep ocean temperatures of 40°F (278 K), this yields a maximum theoretical efficiency of about 7 percent. In comparison, the temperature differences found in conventional steam turbines result in maximum theoretical efficiencies of around 60 percent.

An OTEC facility, like any electric power plant, must use energy to run pumps and other electrically driven devices. It requires large amounts of electric energy to pump huge amounts of water from great depths. When the typical operating losses associated with a real-world OTEC power plant are taken into account, it is a challenge for engineers to design a facility that will be a net producer of electricity.

The concept of OTEC was first envisioned by the French physicist Jacques-Arsene d'Arsonval, in 1881. The first working OTEC system was built in Cuba in 1930, by the physicist Georges Claude, who also invented the neon lamp.

OTEC power plants can be located either onshore or at sea. The electricity generated can be transmitted to shore by electrical cables, or used on site for the manufacture of electricity-intensive products or fuels (such as hydrogen). For OTEC plants situated on shore to be economical, the floor of the ocean must drop off to great depths very quickly. This is necessary because a large portion of the electricity generated by an OTEC system is used internally to pump the cold water up from the depths of the ocean. The longer the cold water pipe, the more electricity it takes to pump the cold water to the OTEC facility, and the lower the net electrical output of the power plant.

There are three potential types of OTEC power plants: open-cycle, closed-cycle, and hybrid systems. Open-cycle OTEC systems exploit the fact that water boils at temperatures below its normal boiling point when it is under lower than normal pressures. Open-cycle systems convert warm surface water into steam in a partial vacuum, and then use this steam to drive a large turbine connected to an electrical generator. Cold water piped up from deep below the oceans surface condenses the steam. Unlike the initial ocean water, the condensed steam is desalinated (free of salt) and may be collected and used for drinking or irrigation.

Closed-cycle OTEC systems use warm surface waters passed through a heat exchanger to boil a working fluid that has a low boiling point, such as ammonia or a chlorofluorocarbon. The vapor given off is passed through a turbine/generator producing electricity. Then cold deep ocean water is used to condense the working fluid and it is returned to the heat exchanger to repeat the cycle. Hybrid OTEC systems combine both technologies and produce both electricity, with a closed-cycle system, and fresh water, with an open-cycle system.

Unlike electrical generation from most other forms of renewable energy that vary with weather and time of day, such as solar and wind energy, OTEC power plants can produce electricity 24 hours per day, 365 days per year. This capability makes OTEC an attractive alternative to conventional base-load electric power plants powered by fossil fuels or nuclear fission. Fresh water production is just one of the potentialy beneficial by-products of OTEC. The cold deep ocean water can also be used for aquaculture (fish farming), as it is pathogen free and nutrient rich. It can also be the source of air conditioning and refrigeration in nearby buildings.

OTEC power plants can have some negative impacts on the natural environment, but overall they are a relatively clean source of electricity compared to conventional options. Cold water released at the oceans surface releases trapped carbon dioxide, a greenhouse gas, but emissions are less than 10 percent of those from a fossil fuel power plant producing a similar amount of power. Also, discharging the cold water at the oceans surface could change local concentrations of nutrients and dissolved gases. This can be minimized by discharging the cold water at depths of greater than 200 feet and/or by using the cold water for air conditioning or refrigeration before it is released.

Despite the fact that OTEC systems have no fuel costs and can produce useful by-products, the initial high cost of building such power plants (up to $5,000 per kilowatt) currently makes OTEC generated electricity up to five times more expensive than conventional alternatives. As such, at the present time OTEC systems are largely restricted to experimental and demonstration units. One of the major facilities for OTEC research is the Natural Energy Laboratory of Hawaii Authority at Keahole Point on the island of Hawaii. An experimental OTEC facility located there has had a maximum *net* power production of 100 kilowatts, at the same time producing 5 gallons per minute of desalinated water.

The most promising markets for OTEC are more experience in building OTEC power plants and stan-

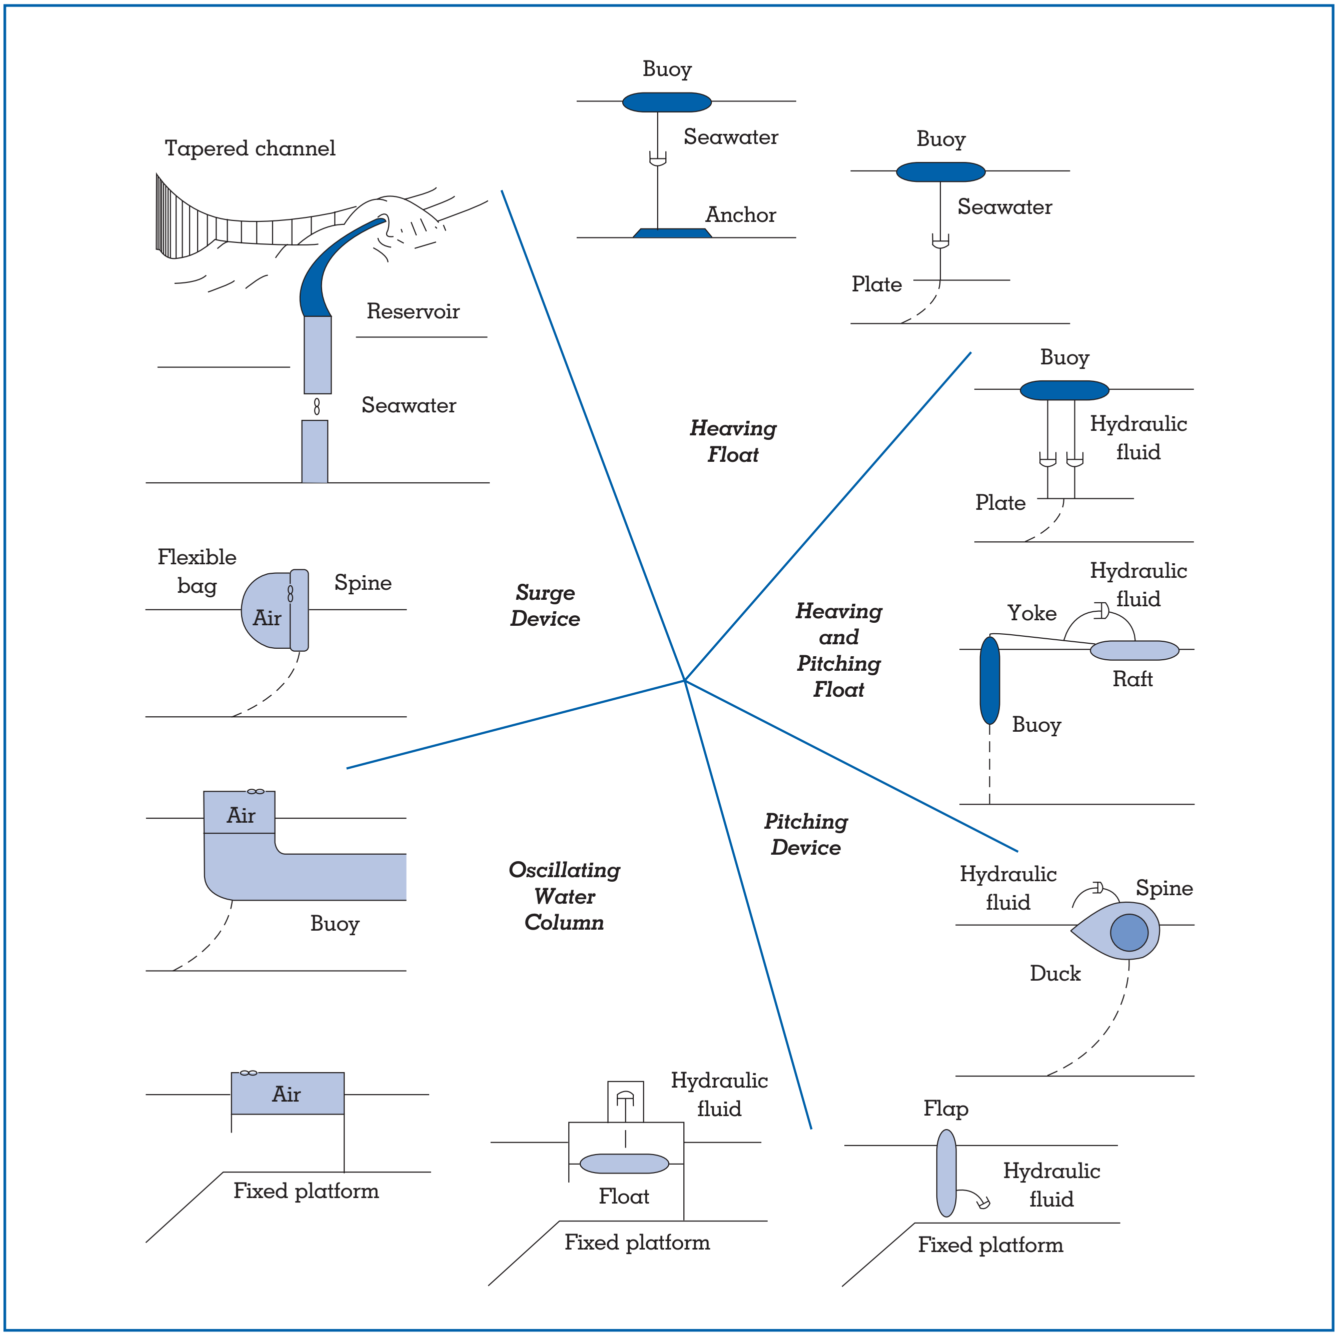

Figure 1.
Symbolic representation of various types of wave energy devices.

dardized plant designs could bring OTEC costs down in the future. However, the initial high costs, coupled with the risk of storm damage to expensive offshore or coastal OTEC facilities, may mean that OTEC electricity generation will never be competitive with conventional sources of electricity

WAVE POWER

Winds blowing across the surface of the world's oceans are converted into waves. The total amount of power released by waves breaking along the world's coastlines has been estimated to be 2 to 3 million megawatts, equivalent to the output of about 3,000 large power plants. Although this vast amount of energy is spread out along thousands of miles of coasts, in favorable locations, the energy density can average 65 megawatts per mile of coastline, an amount that can lead to economical wave-generated electricity. As of 1996, 685 kilowatts of grid-connected wave-generating capacity was operating worldwide.

Wave size is determined by wind speed and “fetch,” the distance over the oceans surface which the wind travels. Favorable wind energy sites are generally western coastlines facing the open ocean such as the Pacific Coast of North America and the Atlantic Coast of Northern Europe. Norway, Denmark, Japan, and the United Kingdom are the world leaders in wave energy technologies.

Although a wide variety of devices have been constructed to capture wave energy, commercial electrical generation from wave power is derived from one of three general types of devices: surface-following devises, oscillating water columns, and focusing, or surge devices.

Surface-following devices use a mechanical linkage between two floating objects or between a floating and a fixed object to produce useful mechanical power. This mechanical power can either be connected directly to a generator or transferred to a working fluid, such as water or air, which drives a turbine generator.

One high-efficiency-surface following device that has been tested is the “Salter duck,” named after its developer Steven Salter at the University of Edinburgh. It looks like a series of floating ducks that pivot about a stiff shaft; this pivoting motion drives a hydraulic fluid to produce electricity. Tests on the Salter ducks show that they are capable of capturing 80 percent of the energy carried by incoming waves.

Oscillating water columns (OWC) use the force of waves entering a fixed device to perform work or generate electricity. The simplest examples of these are navigational buoys; waves entering the anchored buoy compress air in a vertical pipe. This compressed air can be used to blow a warning whistle, or to drive a turbine generator producing electricity for a light. Japan has installed hundreds of OWC-powered navigational buoys along its coastlines since 1965. Larger OWC power plants include the United Kingdom’s experimental OSPREY (Ocean-Swell Powered Renewable Energy), a 2-megawatt offshore facility designed so that waves enter a fixed, submerged chamber, pushing air through a turbine with the rise and fall of each wave.

Focusing, or surge, devices are humanmade barriers that channel and concentrate large waves into a small area, drastically increasing their height. The elevated waves are channeled into an elevated reservoir. This water then passes through hydroelectric turbines on its way back to sea level, thus generating electricity. A 350-kilowatt grid-connected power plant has been operating on the North Sea coast of Norway since 1986. It uses a “tapered channel” design to focus the waves. The tapered channel system uses a narrowing concrete channel to funnel waves up into a reservoir located above sea level. This water then flows through a turbine on its way out, thereby generating electricity.

One of the problems associated with wave power plants is that, during severe storms, the energy unleashed by breaking waves can be over ten times that of the average wave for a coast. The original OSPREY power plant was destroyed by a storm shortly after its construction. The need to design wave power plants to survive such power adds a great deal to the cost of wave energy facilities. Although focusing devices are the most expensive of the three types of wave power plants to construct, their robust nature makes them less susceptible to damage by storms. The Norwegian Tapered Channel design has proven to be the most durable of any wave energy plants. In the late 1990s, this led to the production of two commercial multimegawatt power plants based on this design-one in Java, Indonesia, and one on King Island located between Tasmania and the Australian mainland.

Wave energy power plants consume no fuel during their operation and, as such, do not emit harmful pollutants. However, large-scale wave energy facilities can have an impact on nearby coastal environments. Offshore wave energy facilities such as surface followers or OWCs reduce the height of waves reaching the shore, potentially changing patterns of erosion and sedimentation. Focusing devices result in more erosion where the waves areconcentrated and more sedimentation in adjacent areas. The effect that these changes in erosion and sedimentation could potentially have on local ecosystems is variable and not fully understood by researchers.

TIDAL ENERGY

In coastal areas that have large tides, flowing tidal waters contain large amounts of potential energy.

The principle of harnessing the energy of tides dates back to eleventh-century England when tides were used to turn waterwheels, producing mechanical power. More recently, rising and falling tides have been used to generate electricity, in much the same manner as hydroelectric power plants.

Tides, the daily rise and fall of ocean levels relative to coastlines, are a result of the gravitational force of the moon and the sun as well as the revolution of Earth. The moon and the sun both exert a gravitational force of attraction on Earth. The magnitude of the gravitational attraction of an object is dependent upon the mass of an object and its distance. The moon exerts a larger gravitational force on Earth because, although it is much smaller in mass, it is a great deal closer to Earth than the sun. This force of attraction causes the oceans to bulge along an axis pointing toward the moon. Tides are produced by the rotation of Earth beneath this bulge in its watery coating, resulting in the rhythmic rise and fall of coastal ocean levels.

The gravitational attraction of the sun also affects the tides in a similar manner as the moon, but to a lesser degree. As well as bulging toward the moon, the oceans also bulge slightly toward the sun. When Earth, the moon and the sun are positioned in a straight line (called a full, or new, moon), the gravitational attractions are combined, resulting in very large "spring" tides. At half-moon, the sun and the moon are at right angles, resulting in lower tides called "neap" tides. Coastal areas experience two high and two low tides over a period of slightly longer than twenty-four hours. The friction of the bulging oceans acting on spinning Earth results in a very gradual slowing down of Earth's rotation, a phenomenon that will not have any significant effect on the planet for billions of years.

Certain coastal regions experience higher tides than others, which is a result of the amplification of tides caused by local geographical features such as bays and inlets. In order to produce practical amounts of electric power, a difference of at least 20 feet between high and low tides is required; the higher the tides, the more electricity can be generated from a given site, and the lower the cost of electricity produced. Worldwide, there are about forty sites with this magnitude of tidal range, and approximately 3000 gigawatts of power is continuously available from the action of tides. Due to the constraints of harvesting tidal energy, estimate that only 2 percent, or 60 gigawatts, can potentially be recovered for electricity generation.

The technology required to convert tidal energy into electricity is very similar to the technology used in traditional hydroelectric power plants. The first requirement is a dam or "barrage" across a tidal bay or estuary. Building dams is an expensive process, therefore the best tidal sites are those that exist where a bay has a narrow opening, thus reducing the length of dam which is required. At certain points along the dam, gates and turbines are installed. When there is an adequate difference in the elevation of the water on the different sides of the barrage, the gates are opened. This "hydrostatic head" that is created causes water to flow through the turbines, turning an electric generator to produce electricity.

Electricity can be generated by water flowing both into and out of a bay. Because there are two high and two low tides each day, electrical generation from tidal power plants is characterized by periods of maximum generation every twelve hours, with no electricity generation at the six-hour mark in between. Alternatively, the turbines can be used as pumps to pump extra water into the basin behind the barrage during periods of low electricity demand. This water can then be released when demand on the system its greatest, thus allowing the tidal plant to function with some of the characteristics of a "pumped storage" hydroelectric facility.

The demand for electricity on an electrical grid varies with the time of day, with demand highest during the day and lowest at night. Without pumped storage, the supply of electricity from a tidal power plant, which is dependent upon the slowly shifting times of the tides, can never match the demand on a system. But tidal power, although variable, is reliable and predictable and can make a valuable contribution to an electrical system that has a variety of sources. When tidal electricity is used to displace electricity that would otherwise be generated by fossil fuels or nuclear fission, it results in reduced emissions of greenhouse and acid gases, the risks associated with nuclear power.

Although the technology required to harness tidal energy is well established, because tidal power is expensive there is only one major tidal generating station in operation in the world today. This is a 240-megawatt power plant at the mouth of the La Rance River estuary on the northern coast of France, generating power roughly equal to the annual consumption of the nearby town of Rennes, which has a population of 200,000.

The Barrage de la Rance was the first hydroelectric power plant to generate energy using tidal power. (Corbis-Bettmann)

In operation since 1967, the La Rance generating station has been a very reliable source of electricity, producing electricity at a cost of 3.7 cents per kilowatt hour. Initially, La Rance was designed to be the first of many tidal power plants in France, but the country's nuclear program was greatly expanded in the late 1960s, thereby prohibiting the development of multiple tidal power plants. Elsewhere there is a 20-megawatt experimental facility at Annapolis Royal in Nova Scotia, and a 400-kilowatt tidal power plant near Murmansk in Russia.

Studies have been undertaken to examine the potential of several other tidal power sites worldwide. Scientists estimate that a barrage across the Severn River in western England could supply as much as 10 percent of the country's electricity needs (12 gigawatts). Similarly, several sites in the Bay of Fundy, in Cook Inlet, Alaska, and the White Sea in Russia have been found to have the potential to generate large amounts of electricity.

Like wave and OTEC power plants, one of the main barriers to the increased use of tidal energy is the initial cost of building tidal-generating stations. It has been estimated that the construction of the proposed facility on the Severn River in England would have a construction cost of $15 billion.

The major factors in determining the cost effectiveness of a tidal power site are the size (length and height) of the barrage required, and the difference in height between high and low tide. These factors can be expressed in what is called a site's "Gibrat" ratio. The Gibrat ratio is the ratio of the length of the barrage in meters to the annual energy production in kilowatt hours. The smaller the Gibrat site ratio, the more desirable the site. Examples of Gibrat ratios are La Rance at 0.36, Severn at 0.87, and Passamaquoddy in the Bay of Fundy at 0.92.

Tidal energy is a renewable source of electricity that does not result in the emission of gases responsible for global warming or acid rain, which are associated with fossil fuel-generated electricity. Use of tidal energy could also decrease the need for nuclear power. Changing tidal flows by damming a bay or an estuary could, however, result in negative impacts on aquatic and shoreline ecosystems, as well as on navigation and recreation.

OTHER OCEAN ENERGY TECHNOLOGIES

Theoretical concepts for generating electricity from ocean currents such, as the Gulf Stream, and salinity gradients (differences in salt content) are being investigated. More research and development is required before these concepts reach the stage of demonstration power plants.

OCTANE NUMBER

See: Gasoline and Additives

OERSTED, HANS CHRISTIAN (1777–1851)

Hans Christian Oersted, the son of an impoverished pharmacist, made the great discovery that electricity and magnetism are related. Oersted was born on the small Danish island of Langeland, about halfway between Copenhagen and Hamburg. There was no school in Langeland, so he and his younger brother, Anders Sandoe, went to the homes of neighbors who taught the boys to read and write. Later the town surveyor taught them mathematics, and the mayor taught them English and French. When he was twelve, Hans began to help his father in the pharmacy, and the work stimulated his interest in science.

In 1794 Oersted and his brother Anders matriculated at the University of Copenhagen. Hans studied the sciences, and Anders, who eventually became a leading jurist and a minister of state, studied law. The

Hans Christian Oersted. (Library of Congress)

brothers were recipients of a small state scholarship, but largely supported themselves at the university by tutoring. They lived together, shared costs, and devoted themselves wholeheartedly to their studies. In 1797 Hans Christian Oersted was awarded a degree in pharmacy and, in 1799, received a Doctor of Philosophy degree.

After graduation, Oersted secured a position as a part-time lecturer at the university; he also managed a Copenhagen pharmacy. Word of Alessandro Volta's discovery of a way of producing a continuous electric current reached Copenhagen in 1800, and Oersted began experimenting with acids and alkalis using a voltaic pile. The following year, he left Copenhagen and visited a number of famous scientists during the traditional year of travel taken by European students following graduation. If all the scientists he met, Oersted was most influenced by Johann Wilhelm Ritter, an eccentric German physicist whom he visited for several weeks in Jena. Ritter had also begun his career as a pharmacist and had already discovered ultraviolet light, thermoelectric currents, and the process of electroplating. Oersted returned to Copenhagen in 1803 and applied to the university for a position as professor of physics, then called "natural philosophy," but was refused. He continued lecturing at the university in the schools of medicine and pharmaceuticals, and at the same time managed the pharmacy, carried on electrochemical experiments, and published his results. In 1806 he was finally made a professor of physics at the University, although he not become a full professor until 1817.

From 1803 to 1820, Oersted's life centered around the cultural and academic life of what was then the small city of Copenhagen. He took part in political and academic debates, participated in a royal geological expedition in Denmark, and became a popular public lecturer. He was knighted and achieved the position of secretary of the Royal Society of Copenhagen. In 1813 he again visited Germany and France and published a book about electrochemical forces. In it Oersted commented on magnetic forces and clearly stated that the connection between electricity and magnetism should be investigated. Before the publication of Oersted's book, it had indeed been suspected by many scientists that magnetism and electricity were somehow related. It was known that iron rods were magnetized by the action of the electric currents passing through them as the result of lightning strikes. However, no scientific verification or understanding of the relation existed.

Oersted's discovery of the relation between magnetism and electricity in 1820 is often described as the result of a lucky accident occurring during the course of a laboratory demonstration. However, Oersted declared that he had actually prepared the experiment before the demonstration and only carried it out during the demonstration to some advanced students because that was the first opportunity. What Oersted observed was that a wire carrying an electric current caused a nearby magnetic compass needle to assume a position perpendicular to the wire, and if the current were reversed, the needle would reverse position.

After this initial discovery, Oersted waited three months, apparently for the construction of a more powerful current source. He then carried out sixty experiments to show that the magnetic field due to the current in a wire is circular around the wire. He showed that the effect is independent of the type of wire, and that it is independent of any intervening common materials. Later, he proved that the effect is proportional to the current in the wire.

On July 21, 1820, Oersted published a four-page Latin monograph, “Experiments on the Effect of a Current of Electricity on the Magnetic Needle.” He distributed the monograph to leading scientists throughout Europe and, in the following months, the monograph was reprinted in translation in the most important scientific journals throughout Europe and Britain. A whole new field of investigation and technology was opened. Within a year the laws of electrodynamics were formulated, the electromagnet was invented, and the first primitive electric motor was demonstrated. The first electric telegraph and the first primitive electric generator would soon follow.

Oersted was named a fellow of several learned societies, presented with medals, and awarded cash prizes. At home, Oersted became Denmark’s leading citizen. He continued his research, but as an international figure he traveled extensively, became fluent in many languages, and met with the leading scientists of the time. He gave frequent public lectures and became a director of the Royal Polytechnic Institute of Copenhagen. He also had a lifelong interest in literature and, in 1829, he founded a literary journal to which he frequently contributed articles about science. In 1850, the fiftieth anniversary of his appointment at the university was celebrated as a national holiday, and he was given a country home by the government. When he died in 1851, more than 200,000 people joined the funeral procession.

Oersted had a kindly and sympathetic personality. He had a successful marriage and a large family. In 1819 he befriended a poor fourteen-year-old boy who over the years became virtually another member of the Oersted family. The boy, Hans Christian Andersen, was to become the great Danish storyteller. Andersen often referred to himself as “little Hans Christian” and to Oersted as “great Hans Christian.”

OFFICE EQUIPMENT

TYPES OF EQUIPMENT

Energy use for office equipment ranks behind only lighting, heating, and air conditioning in the commercial sector. And because of growing use of office equipment, the hope is that more efficient equipment will offset the greater use.

Office equipment is an end use that generally is regarded to consist of five major products: personal computers, monitors, copiers, printers, and fax machines. This equipment can be defined by characteristics such as size and speed. Although office equipment is used in homes, this article focuses on office equipment energy use in actual offices.

Personal Computers (PCs)

PCs are desktop and deskside microcomputers that generally include a central processing unit (CPU), storage, and keyboard. PCs first appeared in office spaces during the 1980s. Prior to that time, many offices used simple terminals connected to mainframe computers. PC energy use assessments generally do not include laptops and PC servers—for example, new systems such as webservers—that are left on twenty-four hours a day.

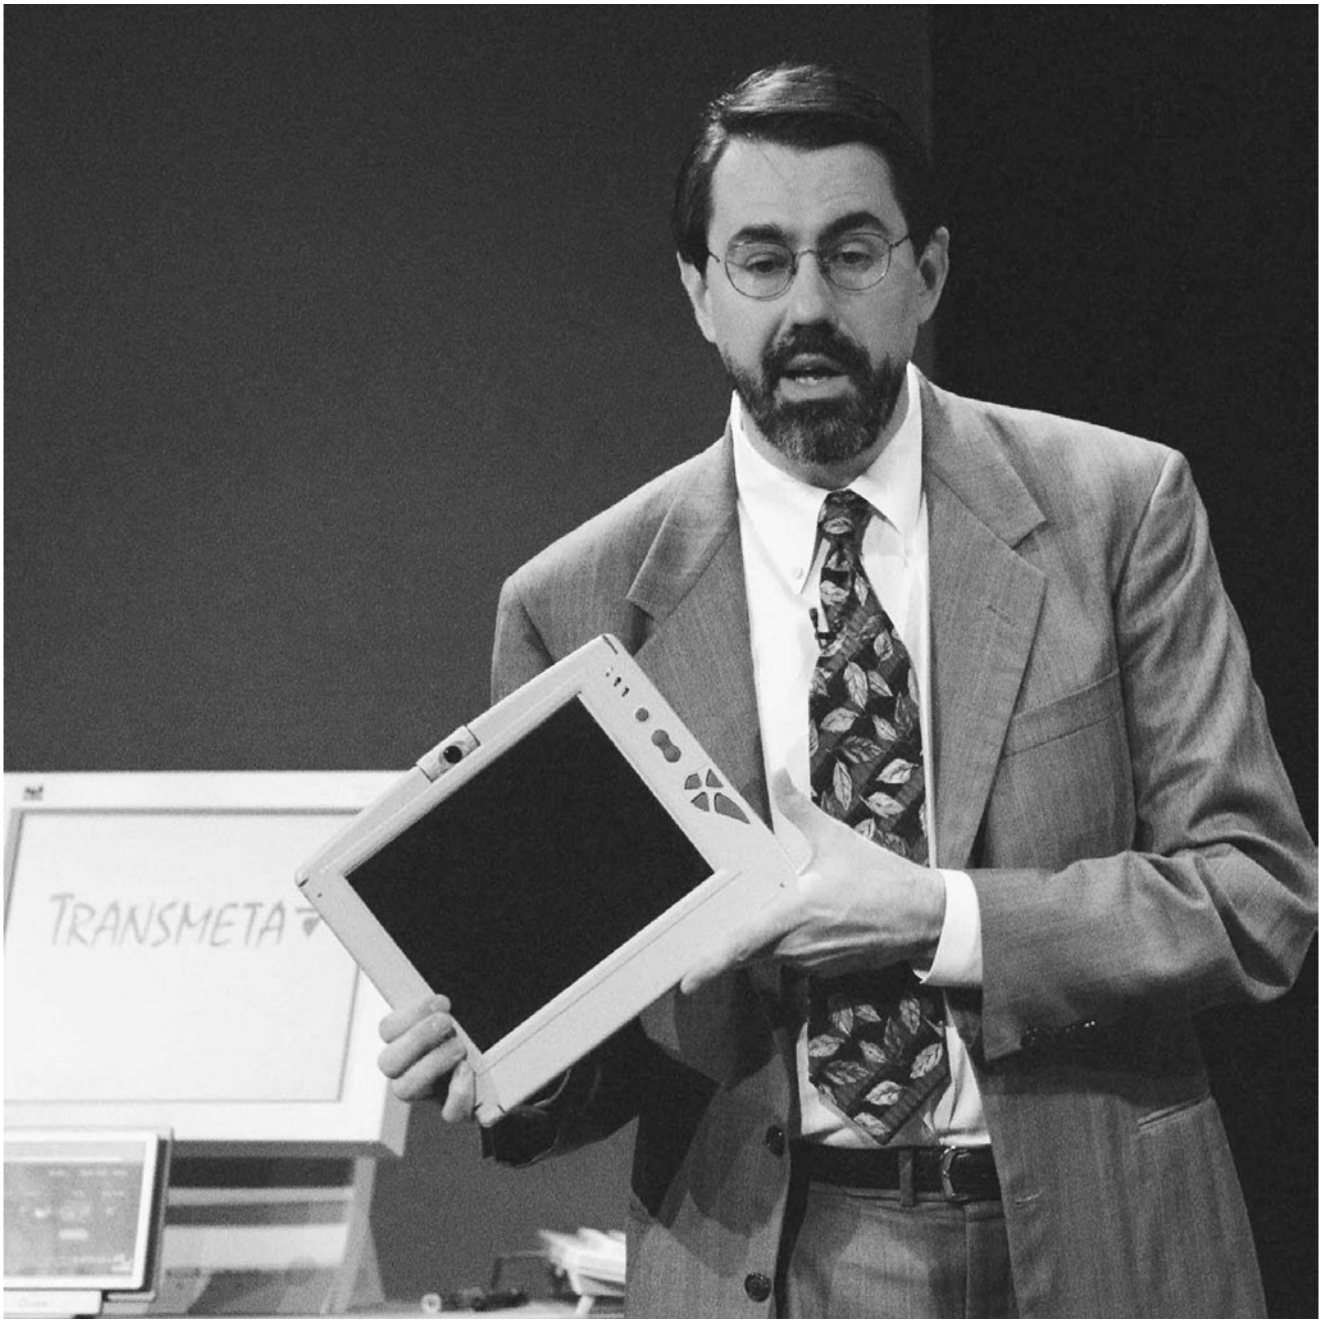
Monitors

Most monitors are display terminals that use cathode-ray tube (CRT) displays, which function by exciting a layer of phosphors with an electron gun. These devices include monitors used with PCs and terminals used with mainframes or minicomputers. Features such as color, resolution, and size influence power requirements. Most PC monitors are sold in screen sizes of fourteen inches, fifteen inches, seventeen inches, and twenty-one inches. In 1995, the typical monitor was fourteen inches and monochrome; by 2000, PC users were purchasing larger, higher-resolution color CRTs. Flat-panel displays such as those used in laptop computers are beginning to replace CRT monitors in desktop computers, though flat-panel models in 2000 cost considerably more than CRTs for the same display size. There are three types of flat-panel displays: liquid crystal (LCD), plasma, and electroluminescent emission (EL). Color LCDs are increasing their share of the monitor market because resolution is improving, costs are dropping, and they can be powered up and down more rapidly than most CRTs.

Copiers

The majority of copiers in the commercial sector use heat and pressure technologies to fix an image to paper. The basic principle consists of forming an image on a photosensitive drum with a laser or a lamp. The drum is then covered with toner, which is transferred to a sheet of paper and fixed to the paper by a fuser roll. The fuser is kept hot while the machine is in a standby mode, ready for the next copy. Some copiers have a low-power “energy-saver” mode in which the drum temperature is reduced; others have an “automatic off” feature, and some have both. Several factors influence energy use per page, such as whether duplexing (two-sided printing) is used and the size of the copy job. Single-page jobs are the most energy-intensive on a per-copy basis.

Copier characteristics vary with the speed of output, with faster machines adding more sophisticated handling of originals, duplexing, finishing of copies as with stapling and collating, and the ability to make more copies each month.



Transmeta Corp. CEO David R. Ditzel demonstrates the benefits of using the new "Crusoe" smart microprocessor and how it will revolutionize the field of mobile computing. (Corbis Corporation)

Printers

Since 1990 there has been rapid change from impact printing, such as daisy wheel and dot-matrix techniques, to nonimpact printing, dominated by energy-intensive laser printing. As is true for copiers, printer energy use is generally linked to print speed. Laser printing is relatively energy-intensive because of the heat and pressure requirements for the fuser. Most of the energy is consumed while the printer sits idle, keeping the fuser warm.

Inkjet printers are suitable in low-volume settings such as personal offices and the home. Inkjets provide low-cost color capability. Power use while the printer is idle is generally low, so that a distinct low-power mode is not needed.

Fax Machines

Facsimile machines, or fax machines, send and receive information from printed documents or electronic files over telephone lines. Three common types of fax machines to consider are direct thermal, laser, and inkjet. Direct thermal faxes apply heat to thermally sensitive paper, while inkjet and laser fax machines are similar to the printers discussed in the previous section. In 2000, laser fax machines had the broadest market share and are of greatest energy use. There were only a few fax machines in 1990 compared to ten years later. It is likely that the technology may change quickly again from 2000 to 2010. Fax cards used with computers suggest the possibility of a future with reduced paper communication by eliminating the need to print a document before sending it. Most contemporary fax machines reduce their power use when not active.

POWER REQUIREMENTS AND ENERGY STAR FEATURES

Office equipment energy use can be characterized by the power requirements in each "mode" of operation and by the number of hours per year for each mode. In 1993 the U.S. Environmental Protection Agency launched the Energy Star program, beginning with power management in PCs and monitors. This program now promotes the use of power management technology in all office equipment (see Table 1). The power modes in PCs and monitors can be described as follows:

Active mode: This is the power of the device when in operation.

Standby mode: This mode represents an intermediate state that attempts to conserve power with instant recovery. The system is idle.

Suspend mode: This mode, also known as sleep mode, has the lowest power level (without being off) but has a longer recovery time than for standby.

Off mode: The power in this mode is that drawn when the device is switched off (essentially zero), or for copiers when the device is unplugged.

Many office equipment models consume some electricity when nominally "off." This results in "leaking" or "standby" energy use. Usually this amounts to just 2 or 3 W, but in some copiers can be up to considerably more. Power management modes vary most widely in PCs, with the number of modes and sophistication of operation increasing. Power management is most transparent to the user with fax machines.

EQUIPMENT POWER LEVELS, OPERATING PATTERNS, AND ANNUAL ENERGY USE

Energy use of office equipment is primarily a function of three factors: the power characteristics of the device, the operation of power management, and manual turn-off patterns. Table 2 shows typical power levels for office equipment, though within each category there is a significant range. Printers and copiers are subdivided into categories based on their maximum speed of making images (in pages or copies per minute), with power levels and usage patterns varying across these categories.

In addition to the power levels above, extra energy is required for each image made by a device. While this varies considerably, a value of 1 Wh/image is common. For copiers, about 10 percent of annual energy use is used for making images, with the other 90 percent primarily used to maintain the copier in the "ready to copy" mode.

Power management capability has reached most office equipment, but on many devices the feature is not enabled or (for some PCs or monitors) is prevented from functioning. Equipment with functioning power management or that is turned off manually at night and on weekends use considerably less, and devices left fully on constantly use much more.

The Energy Star program has affected the office equipment market in several ways: increasing the portion of equipment capable of automatic power management; reducing low-power power levels; adding auto-off capability to many copiers; and increasing enabling rates of power management. All of this has saved energy for consumers with little or no additional manufacturing cost. Monitor power management has risen with larger screens becoming more common, though as LCD monitors replace CRTs the average should drop. The number of PCs and monitors that are properly enabled is likely to increase.

Another aspect of the Energy Star program is that "efficient" copy machines not only have the potential to lower direct use of electricity, they also should

Table 1.
EPA Energy Star Office Equipment Characteristics

NOTES: (1) PCs and monitors are to be shipped with the power saving features enabled and those features must be tested in a networked environment. Some PCs qualify for a second standard of 15 percent of the rating of the power supply, usually at least 30 W. For monitors, an initial low-power mode of 15 W is also required. (2) "NA" means "not applicable," which means that no requirement exists. (3) Additional Tier 2 requirement for copiers includes a required recovery time of 30 seconds for midspeed copiers (recommended for high speed copiers).

reduce paper use by encouraging double-sided copying, or duplexing. Paper costs in 2000 are about \$0.005/sheet. An average 40-cpm copier produces about 140,000 images per year. Approximately 124,600 pages are simplexed (copied on one side only) and 7,700 pages are duplexed (15,400 images). Doubling the duplex rate to handle 30,000 images per year saves about 15,000 pages per year or about \$75 per year, which is nearly twice the value of the energy savings.

In addition to the direct savings from reduced energy and paper, there are indirect savings from the energy embodied in the paper. This is about 16 Wh per sheet. Reducing annual paper use by 15,000 pages cuts embodied energy use by 300 kWh per year. By comparison, an Energy Star copier saves about 260 kWh per year directly.

Energy Star office equipment typically does not cost any more than the non–Energy Star devices, and power-management technologies have greatly improved since 1990. The first Energy Star PCs had slow recovery times from the low-power modes, which was one of the reasons power management was disabled by users. Some network technologies have not been compatible with PC power management. The PC operating system and hardware characteristics also influence the success of the power management. Monitor power management is gener-

Table 2.
Typical Power Requirements by Product Category

ally simpler to operate and saves more energy than PC power management.

Overall, office equipment currently uses about 7 percent of all commercial sector electricity, with that fraction projected to grow to about 8 percent by 2010. Total electricity used by office equipment would grow from 58 TWh in 1990 to 78 TWh in 2010 in the absence of Energy Star or any other government policies. While total energy use for office equipment has grown rapidly in recent years, this growth is likely to slow from 2000 to 2010 because the market is becoming saturated and because mainframe and minicomputer energy use is declining. Home office energy use is on the rise, but is still well below the energy use of office equipment in commercial buildings.

The likely energy and dollar savings in the commercial sector from the Energy Star program are significant on a national scale. Total electricity savings are estimated to range from 10 to 23 TWh/year in 2010, most likely about 17 TWh/year. Energy bill savings will exceed $1 billion per year after the year 2000. The cost of achieving Energy Star efficiency levels is estimated to be negligible, while the cumulative direct cost of funding the Energy Star program is on the order of a few million dollars. This policy therefore saves U.S. society large amounts of money with minimal expenditure of public funds.

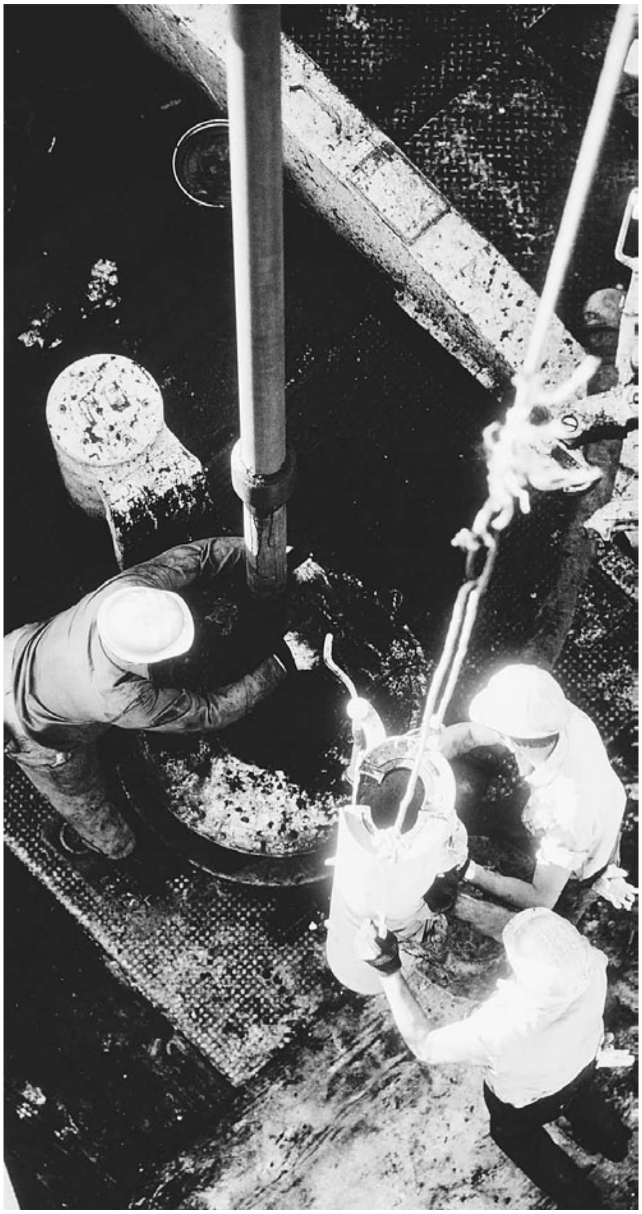
OIL AND GAS, DRILLING FOR

After all the exploratory analyses, drilling determines whether the exploration geophysicist has accurately located the reservoir (exploratory drilling) and whether the sites chosen for drilling into the same reservoir are optimal for efficient production (developmental drilling). When an exploratory hole produces neither oil nor gas, it is capped and abandoned. But if it does yield oil or gas, it is readied for production and becomes a completed well. To extract oil and gas requires drilling a well.

Drilling a well involves much more than making a hole. It entails the integration of complex technologies, requiring the driller to make individual decisions related to unexpected pressure regimes, practices, and rock formations. The resulting well is the sole conduit to move fluids from a reservoir to the surface—a conduit that must last at least fifty years and be flexible enough in design to allow for the application of future production technologies.

Drilling operators must confront and solve extremely difficult technical, safety, and control problems as they bore through layers of subsurface rock to access oil- or gas-bearing strata. Furthermore, drilling must protect the geologic formation, the ultimate productive capacity of the well, and the surface environment. Drilling problems must first be diagnosed using the information or data that is transmitted from the bottom of the well to the surface, where the information is collected on the rig floor.

Depending on the depth of the well, this time lag can consume valuable time needed to address the problem—either technical or geological—before it becomes worse and/or causes drilling operations to stop. Drilling a well involves all types of technical, geological, and economic risks. The greatest economic risk occurs when drilling operations must be halted after time and money have been invested. This is the nature of the challenge faced during the drilling process.



Oil rig workers begin drilling. (Corbis Corporation)

When a well has been drilled and lined with pipe, the connection between the geological formation and the well must be established. Well "completion" includes installing suitable metal pipe or casing, cementing this casing using rock section isolation devices, and perforating the casing to access the producing zones. In some reservoirs, the geological conditions dictate that "stimulation" processes be applied to improve reservoir permeability or fluid conductivity of the rock, thereby facilitating production through the well bore.

With an understanding of the nature of the rocks to be penetrated, the stresses in these rocks, and what it will take to drill into and control the underground reservoirs, the drilling engineer is entrusted to design the earth-penetration techniques and select the equipment. Substantial investments are at stake. Drilling and completion costs can exceed $400,000 per well, and offshore operations can easily escalate to more than $5 million per well. However, overall per-well costs (adjusted for inflation) have been dropping, falling more than 20 percent between 1980 and 2000. This technology-driven gain in extraction efficiency has more than made up for the higher costs associated with the increasingly more geologically complex operations and deeper depths faced in trying to extract the remaining oil and gas resources.

In the United States, 85 percent of wells are drilled by independent oil and gas operators, more than 90 percent of whom employ fewer than twenty people. Therefore, U.S. oil and gas production is dependent on the economic health of independent producers to offset the rising tide of imported crude oil.

Drilling is indeed a high-risk investment. Even with modern technology, drilling successful ex-ploratory wells can be elusive. In the United States, for exploratory wells drilled more than a mile from production, the chance of striking hydrocarbons are about one in ten, and exceeds one in forty for drilling in unproven frontier areas. Because of these daunting odds, the ever-increasing complexity of recovery, and the dwindling resource base, most energy experts in the late 1970s and early 1980s projected that the price of crude oil would double, triple, or quadruple by 2000. This did not happen. Profound advances in drilling technology as well as in other exploration and production technologies have allowed the inflation-adjusted price of crude oil to remain stable through the twentieth century except for short-term price distortions caused by geopolitical turmoil or misguided policies.

THE EARLY METHODS

On August 27, 1859, at a depth of only 69.5 feet, Francis Drake drilled and completed the first well at Titusville, Pennsylvania. By the end of the nineteenth century there were about 600,000 oil wells in more than 100 countries, with the United States and Russia dominating world production. In the United States, drilling was concentrated in the Appalachian oil fields until the Beaumont Texas, Spindletop Hill discovery on January 10, 1901, which then shifted exploration and production to the Southwest.

The world's largest petroleum reserves, in Turkey and the Middle East, were discovered just prior to World War I. Exploration and production continued to expand throughout the region in the 1920s, and culminated in the discovery of the vast oil resources of Saudi Arabia in 1938.

Early methods entailed cable-tool drilling. This crude impact-type drilling involved dropping a weighted bit by a cable and lever system to chisel away at the rock at the bottom of the hole. Periodically drilling had to be stopped to sharpen the bit and remove rock fragments and liquids from the bottom of the hole with a collecting device attached to the cable. Removal of liquids was necessary so the bit could more effectively chip away at rock. This dry method created the well-recognized "gusher," since a dry borehole allowed oil and gas to flow to the surface from the pressure of natural gas and water once the bit penetrated a producing reservoir. Usually considerable oil and "reservoir energy" were wasted until the well could be capped and controlled.

MODERN DRILLING

Rotary drilling became the preferred method of drilling oil and gas wells in the middle of the twentieth century (Figure 1). Using this method, the drill bit rotates as it pushes down at the bottom of the hole much like a hand-held power drill. Unlike in cable-tool drilling, the borehole is kept full of liquid during rotary drilling for two important reasons: The drilling mud circulates through the borehole to carry crushed rock to the surface to keep drilling continuous, and once the bit penetrates the reservoir, it does not create a gusher.

To drill a well, a site is selected and prepared. A drilling rig is transported to the site and set up. A surface hole is drilled, followed by drilling to the total planned depth of the well. The well is then tested, evaluated, and completed. Finally, production equipment is installed, and the well is put on production.

Drill-Site Selection and Preparation

Selection of the drill site is based largely on geological evidence indicating the possible accumulation of petroleum. The exploration drilling company wants to drill the well at the most advantageous location for the discovery of oil or gas. However, surface conditions also must be taken into consideration when selecting the drill site. There must be a nearly level area of sufficient size on which to set up the drilling rig, excavate reserve pits, and provide storage for all the materials and equipment that will be needed for the drilling program. All required legal matters must have been attended to, such as for acquiring a drilling permit and surveying of the drill site. When all of these matters have been resolved, work on site preparation will begin. Once the drill site has been selected and surveyed, a contractor or contractors will move in with equipment to prepare the location. If necessary, the site will be cleared and leveled. A large pit will be constructed to contain water for drilling operations and for disposal of drill cuttings and other waste. Many environmental regulations guide these practices. A small drilling rig, referred to as a dry-hole digger, will be used to start the main hole. A large-diameter hole will be drilled to a shallow depth and lined with conductor pipe. Sometimes a large, rectangular cellar is excavated around the main borehole and lined with wood. A smaller-diameter hole called a "rat hole" is drilled near the main borehole. The rat hole is lined with pipe and is used for temporary storage of a piece of drilling equipment called the "kelly." When all of this work has been completed, the drilling contractor will move in with the large drilling rig and all the equipment required to drill the well.

The Rig

The components of the drilling rig and all necessary equipment are moved onto the location with large, specially equipped trucks. The substructure of the rig is located and leveled over the main borehole. The mast or derrick is raised over the substructure, and other equipment such as engines, pumps, and rotating and hoisting equipment, are aligned and connected. The drill pipe and drill collars are laid out on racks convenient to the rig floor so that they may be hoisted when needed and connected to the drill bit or added to the drill strings. Water and fuel tanks are filled. Additives for the drilling fluid (drilling mud) are stored on location. When all these matters have been attended to, the drilling contractor is ready to begin drilling operations ("spud the well").

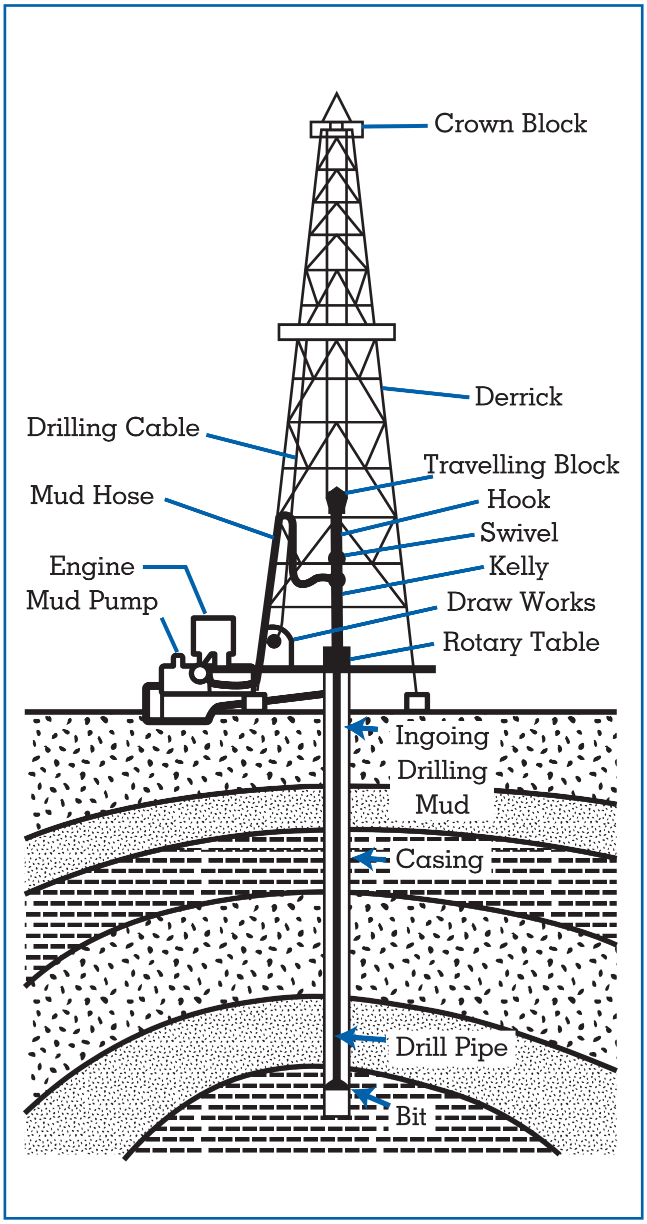


Figure 1.
A typical drilling rig operation. The string of pipe and drill bit rotate, with their weight adding to the cutting effectiveness of the bit. Borehole pressure is maintained by drilling mud, which also brings up the drill cuttings. Casing is used for weak formations or when there is risk of groundwater contamination.

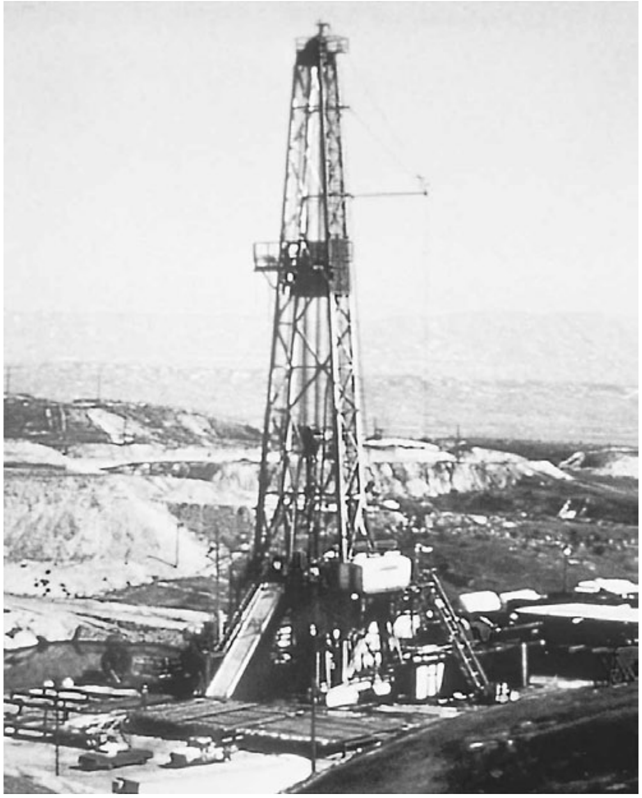
The drill string, consisting of a drill bit, drill collars, drill pipe, and kelly, is assembled and lowered into the conductor pipe. Drilling fluid, better known as drilling mud, is circulated through the kelly and the drill string by means of pipes and flexible hose connecting the drilling fluid or mud pumps and a swivel device attached to the upper end of the kelly. The swivel device enables drilling mud to be circulated while the kelly and the drill string are rotated. The mud pump draws fluid from mud tanks or pits located nearby. The drilling mud passes through the kelly, drill pipe, drill collars, and drill bit. The drilling mud is returned to the surface by means of the well bore and the conductor pipe where it is directed to a shale shaker, which separates the drill cuttings and solids from the drilling mud, which is returned to the mud tanks to be recirculated. As the drill string is rotated in the well bore, the drill bit cut into the rock. The drilling mud lubricates and cools the drill bit and the drill string and carries the drill cuttings to the surface.

Drilling the Surface Hole

When a well is spudded in, a large-diameter drill bit is used to drill to a predetermined depth to drill the surface hole, which is lined with casing. The casing protects aquifers that may contain freshwater, provides a mounting place for the blowout preventer, and serves as the support for the production casing that will be placed in the well bore if the drilling program is successful. The surface hole may be several hundred or several thousand feet deep. When the predetermined depth is reached, the drill string will be removed from the well bore. Steel casing of the proper diameter is inserted. Sufficient cement is pumped down the surface casing to fill the space between the outside of the casing and the well bore all the way to the surface. This is to ensure protection of freshwater aquifers and security of the surface casing. The casing and the cement are tested under pressure for twelve hours before drilling operations may be resumed. The blowout preventer is attached at the top of the surface casing. This device is required to control the well in the event that abnormal pressures are encountered in the borehole that cannot be controlled with drilling fluid. If high-pressure gas or liquid blows the drilling fluid out of the well bore, the blowout preventer can be closed to confine the gas and the fluid to the well bore.

Drilling to Total Depth

After the surface casing has been tested and the blowout preventer installed, drilling operations are resumed. They will continue until the well has been drilled to the total depth decided upon. Usually the only interruptions to drilling operations will be to remove the drill string from the well bore for the replacement of the drill bit (a procedure known as tripping) and for testing of formations for possible occurrences of oil or gas (known as drill-stem testing). Other interruptions may be due to problems incurred while drilling, such as the shearing off the drill string (known as "twisting off") and loss of drill-bit parts in the well bore (known as "junk in the hole").



Deep drilling oil rig at Naval Petroleum Reserve's Elk Hills site near Bakersfield, California. (U.S. Department of Energy)

As drilling operations continue, a geologist constantly examines drill cuttings for signs of oil and gas. Sometimes special equipment known as a mud logger is used to detect the presence of oil or gas in the drill cuttings or the drilling fluid. By examining the drill cuttings, a geologist determines the type of rock that the drill bit is penetrating and the geologic formation from which the cuttings are originating.

Today's conventional drill bit utilizes three revolving cones containing teeth or hardened inserts that cut into the rock as the bit is revolved. The teeth or inserts chip off fragments of the rock which are carried to the surface with the drilling fluid. The fragments or chips, while they are representative of the rock being drilled, do not present a clear and total picture of the formation being drilled or the characteristics of the rock being penetrated as to porosity and permeability. For this purpose a larger sample of the rock is required, and a special type of drill bit is used to collect the sample, called a core. The core is usually sent to a laboratory for analysis and testing.

If the geologist detects the presence of oil or gas in the drill cuttings, a drill-stem test is frequently performed to evaluate the formation or zone from which the oil show was observed. Drill-stem tests may also be performed when the driller observes a decrease in the time required to drill a foot of rock, known as a "drilling break." Since porous rock may be drilled easier than nonporous or less porous rock, a drilling break indicates the presence of the type of rock that usually contains oil or gas. A drill-stem test enables the exploration company to obtain a sample of the fluids and gases contained in the formation or interval being tested as well as pressure information. By testing the well during the drilling phase, a decision as to whether to complete it can be made. When the well has been drilled to the predetermined depth, the drill string will be removed from the well bore to allow insertion of tools that will further test the formation and particularly the well. These tools are suspended on a special cable. Specific properties of the formation are measured as the tools are retrieved. Signals detected by the tools are recorded in a truck at the surface by means of the electrical circuits contained in the cable.

Completing the Well

When drill-stem testing and well logging operations have been completed and the results have been analyzed, company management must decide whether to complete the well as a producing well or to plug it as a dry hole. If the evidence indicates that no oil or gas is present, or that they are not present in sufficient quantity to allow for the recovery of drilling, completion, and production costs and provide a profit on investment, the well probably will be plugged and abandoned as a dry hole. On the other hand, if evidence indicates the presence of oil or gas in sufficient quantity to allow for the recovery of the cost and provide a profit to the company, an attempt will be made to complete the well as a producing well. The casing is delivered and a cementing company is called in.

SlimDril drill bits are manufactured from polycrystalline with natural diamonds on the face of the bit for oil and natural gas drilling. (Corbis-Bettmann)

The well bore is filled with drilling fluid that contains additives to prevent corrosion of the casing and to prevent movement of the fluid from the well bore into the surrounding rock. The casing is threaded together and inserted into the well bore in much the same manner as the drill string. Casing may be inserted to the total depth of the hole, or a cement plug may have been set at a specific depth and the casing set on top of it. Cement is mixed at the surface, just as if the well were to be plugged. The cement is then pumped down the casing and displaced out of the bottom with drilling fluid or water. The cement then flows up and around the casing, filling the space between the casing and the well bore to a predetermined height. After cementing of the casing has been completed, the drilling rig, equipment, and materials are removed from the drill site. A smaller rig, known as a workover rig or completion rig, is moved over the well bore. The smaller rig is used for the remaining completion operations. A well-perforating company is then called to the well site. It is necessary to perforate holes in the casing at the proper depth to allow the oil and the gas to enter the well bore. The perforating tool is inserted into the casing and lowered to the desired depth on the end of a cable. Shaped charges are remotely fired from the control truck at the surface, and jets of high-temperature and high-velocity gas perforate the casing, the cement, and the surrounding rock for some distance away from the well bore.

A smaller-diameter pipe, called tubing, is then threaded together and inserted into the casing. If it is expected that oil or gas will flow to the surface via the pressure differential between the well bore and the formation, a wellhead is installed; it is equipped with valves to control the flow of oil or gas from the well. The wellhead is known as a "Christmas tree." If there is not sufficient pressure differential to cause the oil and the gas to flow naturally, pumping equipment is installed at the lower end of the tubing.

During well completion it is sometimes desirable or necessary to treat or "stimulate" the producing zone to improve permeability of the rock and to increase the flow of oil or gas into the casing. This may be accomplished by use of acid or by injection of fluid and sand under high pressure to fracture the rock. Such a treatment usually improves the ability of the rock to allow fluid to flow through it into the well bore. At this point the drilling and completion phases have ended.

The Drill Bits and Well Design

Designing more effective and durable drill bits is important because drilling depths of reservoirs can reach as deep as 5 mi (8,052 m). Worldwide use of the more expensive polycrystalline diamond compact (PDC) drill bit has slowly been gaining on the conventional roller cone bit because of faster rates of penetration and longer bit life. The 1998 PDC bit rotated 150 to 200 percent faster than similar bits a decade earlier, and averaged more than 4,200 ft (1,281 m) per bit as opposed to only 1,600 ft (488 m) per bit in 1988. This 260 percent improvement dramatically cuts time on site since the less often the drill bit needs changing, the less time and energy must be devoted to raising and lowering drill pipe. It also means that the 15,000-ft well in the 1970s that took around eighty days could be completed in less than forty days in 2000. Because wells can be drilled more quickly, more profitably and with less of an environmental impact, the total footage drilled by diamond bits went from about 1 percent in 1978 to 10 percent in 1985 and to 25 percent in 1997.

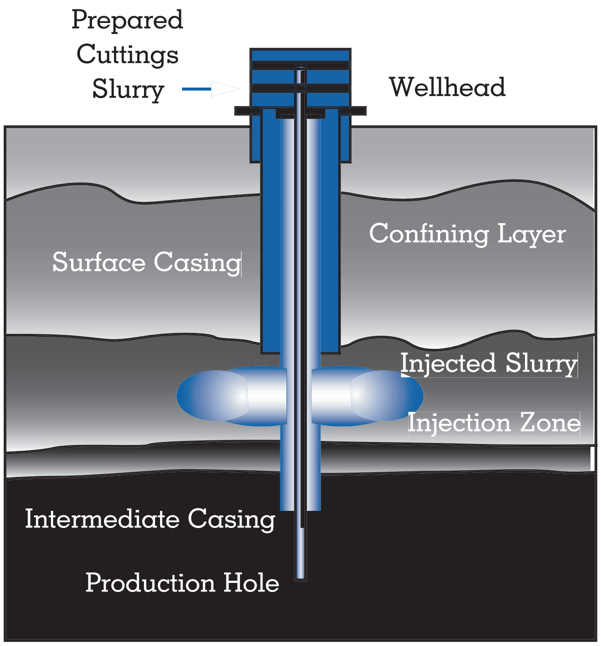


Figure 2.
To reduce the amount of waste and disposal costs, drill cuttings are increasingly being reinjected into the formations from which they came.

To reduce drilling and development costs, slimhole drilling is increasingly being used. Slimhole wells are considered wells in which at least 90 percent of the hole has been drilled with a bit fewer than six inches in diameter. For example, a typical rig uses a 8.5-in bit and a 5-in drill pipe, whereas a slimhole rig may use a 4-in bit and a 3.7-in drill pipe. Slimhole drilling is especially valuable in economically marginal fields and in environmentally sensitive areas, since the fuel consumption can be 75 percent less (mud pumps, drill power), the mud costs 80 percent less, the rig weight is 80 percent less, and the drill site is 75 percent smaller.

Another important advance for developmental drilling is coiled tubing technology. Often used in combination with slimhole drilling technology, coiled tubing is a continuous pipe and thus requires only about half the working space as a conventional drilling pipe operation. Moreover, coiled tubing

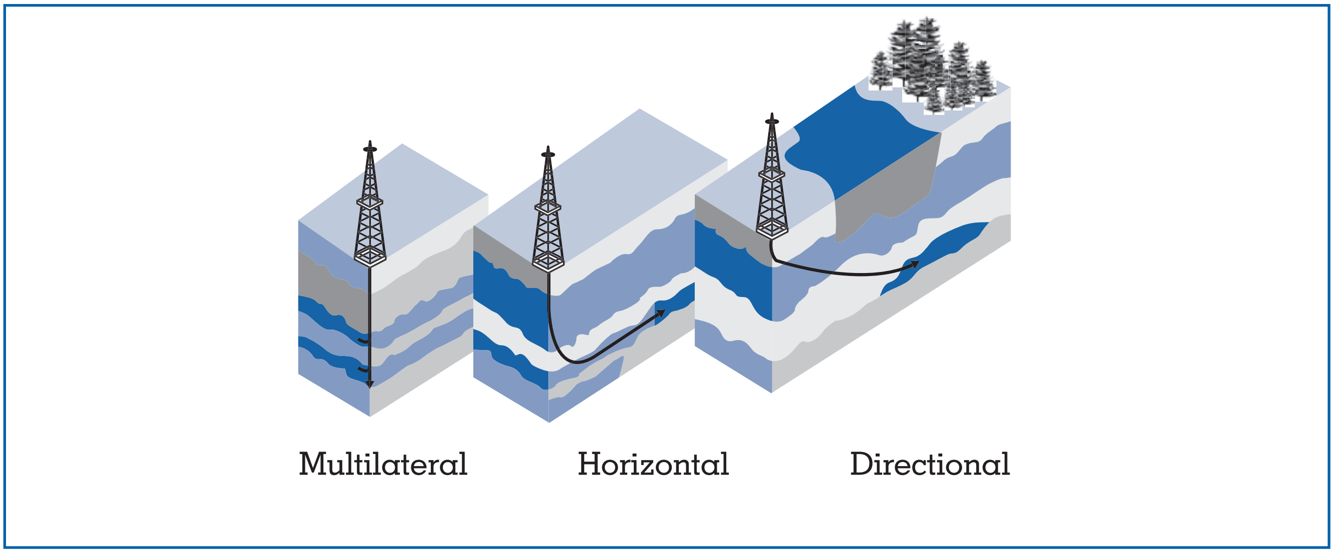

Figure 3.
Horizontal, Directional and Multilateral Drilling. Prior to 1988, fewer than 100 horizontal wells were drilled, but this total grew to more than 2,700, since horizontal drilling makes it possible to reach tight and thin reservoirs, and reservoirs inaccessible by vertical drilling. And because horizontal wells penetrate a greater cross section of any formation, more of the reserve can be extracted. Horizontal wells costs are 80 percent greater, yet production averages 400 percent more.

eliminates the costs of continuous jointing, reinstallation and removal of drill pipe. Since the diameter of coiled tubing is smaller than that of conventional pipe, coiled tubing also reduces operational energy use, noise, and the quantity of mud generated. The material of choice is currently steel, yet titantium is slowly replacing steel because titanium's greater strength promises a life cycle five to ten times longer than steel.

In weak formations or where groundwater needs to be protected, the borehole is lined with casing to prevent any transfer of fluids between the borehole and its surroundings. Strings of casing are progressively smaller than the casing strings above it, and the greater the depth of the well, the more casing sizes used. For very deep wells, up to five sizes of ever smaller diameter casings are used during the drilling process. This tiered casing approach has not only reduced the volume of wastes but also has been refined so that drilling cuttings can be disposed of by reinjecting them into the area around the borehole between the surface casing and the intermediate casing (Figure 2). In this way, wastes are returned to the geologic formations far below the surface, eliminating the need for surface disposal, including waste management facilities, drilling waste reserve pits, and off-site transit transportation.

Drilling is not a continuous operation. Periodically drilling must stop to check bottomhole conditions. To reduce the time lag between occurrence and surface assessment, measurement-while-drilling (MWD) systems are increasingly being used to measure downhole conditions for more efficient, safer, and accurate drilling. These systems transmit real-time data from the drill bit to the surface by encoding data as a series of pressure pulses in the mud column that is then decoded by surface sensors and computer systems. The accelerated feedback afforded by MWD systems helps keep the drill bit on course, speeds reaction to challenging drilling operations (high-pressure, high-temperature and underbalanced drilling), and provides valuable and continual clues for zeroing in on the reservoir's most productive zones. Since MWD systems provide a faster and more accurate picture of formation pore pressure and fracture pressure while the well is being drilled, it also substantially reduces the risks of life-threatening blowouts and fires.

HORIZONTAL, DIRECTIONAL AND MULTILATERAL DRILLING

Horizontal and directional drilling are non-vertical drilling that allow wells to deviate from strictly vertical by a few degrees, to horizontal, or even to invert toward the surface (Figure 3). Horizontal drilling is not new. It was first tried in the 1930s, but was abandoned in favor of investing in hydraulic fracturing technology (first introduced in 1947) that made vertical wells more productive. Rebirth of horizontal drillings began in the mid-1970s due to the combination of steerable downhole motor assemblies, MWD systems, and advances in radial drilling technology that made horizontal drilling investments more cost-effective. In 1996 more than 2,700 horizontal wells were dug, up from a very minimal number only a decade earlier.

In the simplest application, the borehole begins in a vertical direction and then is angled toward the intended target. The drill pipe still needs to move and rotate through the entire depth, so the deviation angle of the borehole needs to be gradual. A large deviation is made up of many smaller deviations, arcing to reach the intended target. The redirection of drill pipe is accomplished by use of an inclined plane at the bottom of the borehole. More recently, greater precision in directional drilling has been accomplished by using a mud-powered turbine at the bottom to drill the first few feet of the newly angled hole.

Horizontal and directional drilling serves four purposes. First, it is advantageous in situations where the derrick cannot be located directly above the reservoir, such as when the reservoir resides under cities, lakes, harbors, or environmentally sensitive areas such as wetlands and wildlife habitats. Second, it permits contact with more of the reservoir, which in turn means more of the resource can be recovered from the single well. Third, it makes possible multilateral drilling—multiple offshoots from a single borehole to contact reservoirs at different depths and directions. Finally, horizontal drilling improves the energy and environmental picture, since there is less of an environmental impact when fewer wells need to be drilled, and the energy future is brighter since more oil can be expected from any given well. Horizontal drilling has been credited with increasing the United States oil reserves by close to 2 percent or 10 billion barrels. Although horizontal drilling is more expensive than vertical drilling, the benefits of increased production usually outweigh the added costs.

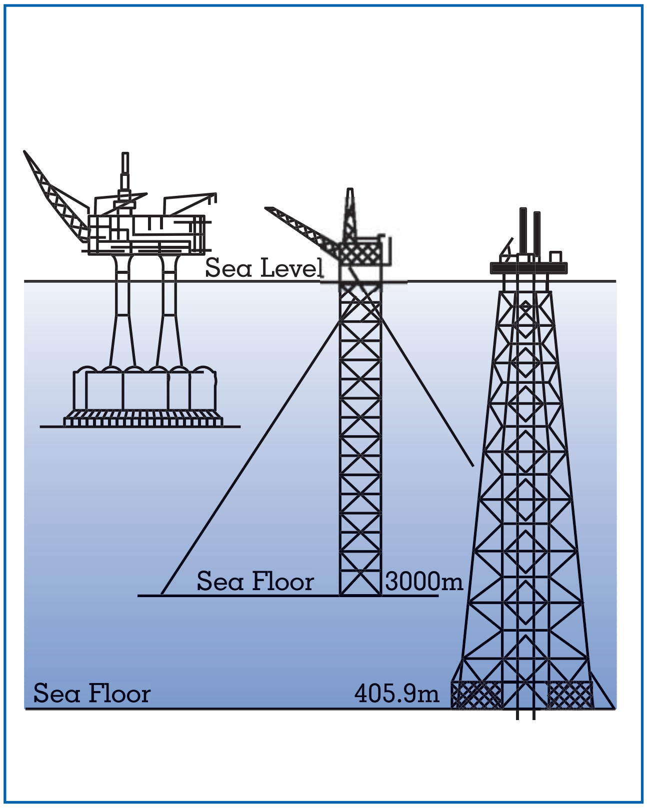

Figure 4.
Submersible base rigs. Flotational tanks built into the base are flooded so that the base rests on the ocean floor. The legs are constructed to the correct height for each site.

OFFSHORE DRILLING

Since oceans and seas cover more than two-thirds of the Earth, it came as no surprise when oil was discovered ten miles off the Louisiana coast in 1947. Fifty years later, offshore production had grown to approximately a third of all world output, most coming from the North Sea, the Persian Gulf, and the Gulf of Mexico. Technology has evolved from shallow-water drilling barges into fixed platforms and jack-up rigs, and finally into semisubmersible and floating drill ships (Figures 4–7). Some of these rigs are among the largest and most massive structures of modern civilization. And because drilling often takes place in waters as deep as 10,000 ft (more than 3,080 m) deep, as far as 200 mi (more than 300 km) from shore, and in unpredictable weather (it must be able to withstand hurricanes and uncontrollable releases of oil), the challenges facing designers, builders, and users of these rigs are daunting.

Offshore drilling operations entail much of the same technology as land-based drilling. As with onshore drilling, the offshore drill pipe must transmit rotary power and drilling mud to the bit for fixed rigs, floating rigs, and drill ships. Since mud also must be returned for recirculation, a riser (a flexible outer casing) extends from the sea floor to the platform. As a safety measure—to contend with the stress created from the motion and movement of the boat in relation to the sea bottom—risers are designed with material components of considerable elasticity.

Besides the much grander scale of offshore rigs, there are numerous additional technologies employed to contend with deep seas, winds, waves, and tides. The technical challenges include stability, buoyancy, positioning, mooring and anchoring, and rig designs and materials that can withstand extremely adverse conditions.

Shallow Water and Arctic Areas

For shallow-water drilling, usually water depths of 50 ft (15.4 m) or less, a drilling platform and other equipment is mounted on a barge, floated into position, and sunk to rest on the bottom. If conditions dictate, the drilling platform can be raised above the water on masts. Either way, drilling and production operations commence through an opening in the barge hull.

For drilling in shallow water Arctic environments, there is an added risk from the hazard of drifting ice. Artificial islands need to be constructed to protect the platform and equipment. Because of permafrost, drilling onshore in Arctic regions also necessitates building artificial islands. These usually are built from rock and gravel so that the ground does not become too unstable from permafrost melting around the drill site. To leave less of an environmental footprint, these artificial islands are increasingly being built from ice pads rather than gravel. Because the ice pads are insulated to prevent thawing, the drilling season in some Arctic areas has been extended to 205 days, and well operations to as long as 160 days. This heightens the chances of single-season completions that dramatically reduce costs, since equipment does not need to be removed to nontundra areas and brought back again.

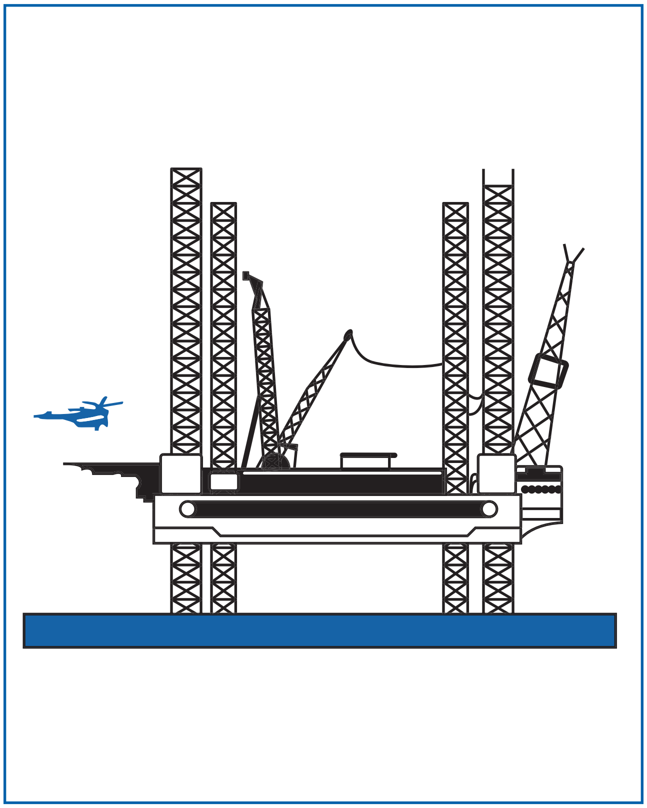

Figure 5.
Jack-up rigs. For drilling in water depths of up to 400 ft (122 m), the legs are cranked downward until they reach the sea floor and then jacked up so that the platform is 15 to 30 ft (4.6 m to 9.1 m) above the surface. Workers often reach the rig by helicopter (left).

Deep Water

For deeper drilling in open waters over the continental shelves, drilling takes place from drill ships, floating rigs and rigs that rest on the bottom. Bottom-resting rigs are mainly used for established developmental fields (up to 3,000 ft or 924 m); the semisubmersible and free-floating drill ships (up to 10,000 ft or 3,080 m) are the primary choice for exploratory drilling.

Where drilling and production are expected to last a long time, fixed rigs have been preferred. These rigs stand on stilt-like legs imbedded in the sea bottom and usually carry the drilling equipment, production

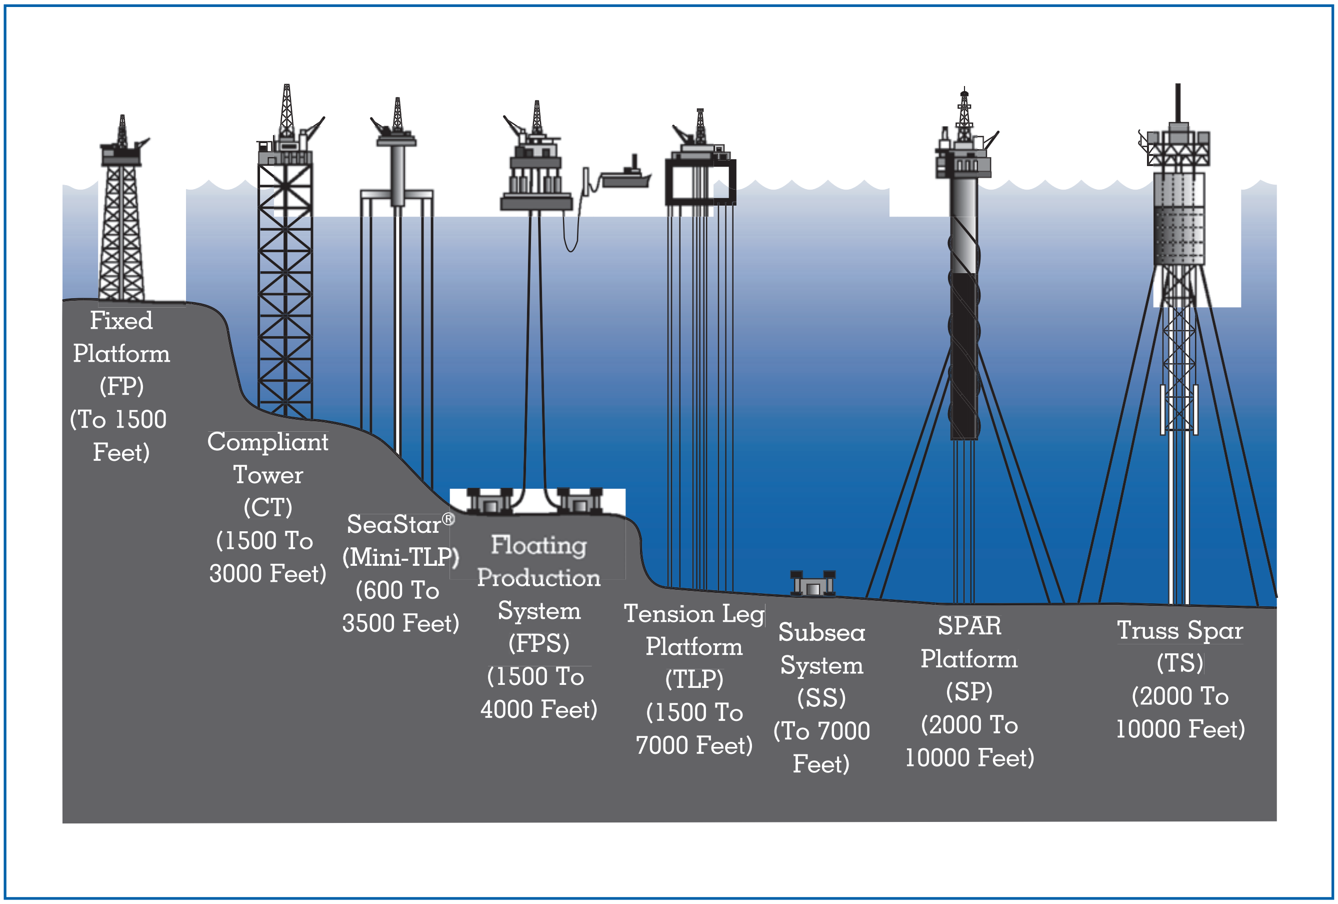

Figure 6.
Fixed rigs. Used in depths up to 1,500 ft (457 m), these rigs are imbedded in the ocean floor and tapered from bottom to top for stability. Compliant tower. Used in water depths from 1,500 to 3,000 ft (457 m to 915 m), these towers rely on mooring lines for stability.

equipment, and housing and storage areas for the work crews.

The jack-up platform, which is most prevalent, is towed to the site and the rack-and-pinion geared legs are cranked downward toward the bottom. Once the legs are stabilized on the bottom with pilings, the platform is raised 30 to 60 ft (9.2 to 18.5 m) above the surface. Another common fixed rig rests on rigid steel or concrete bases that are constructed onshore to the correct height. The rig is then towed to the drilling site, where the flotation tanks, built into the base, are flooded to sink the base to the ocean floor. For drilling in mild seas, a popular choice is a tender-assisted rig, where an anchored barge or tender is positioned alongside the rig to help with support. The hoisting equipment sits on the rig, with all the other associated support equipment (pumps, generators, cement units, and quarters) on the barge.

As more offshore exploratory operations move into deeper water—in 1997 there were thirty-one deep water rigs drilling in water depths greater than 1,000 ft (305 m) as opposed to only nine in 1990—there is sure to be more growth in the use of semi-submersible rigs and drill ships. In rough seas, semi-submersible drilling rigs are the preferred option since the hull is entirely underwater, giving the rig much more stability. The operational platform is held above the surface by masts extended upward from the deck. Cables are moored to the sea floor, with the buoyancy of the platform creating a tension in the cables that holds it in place.

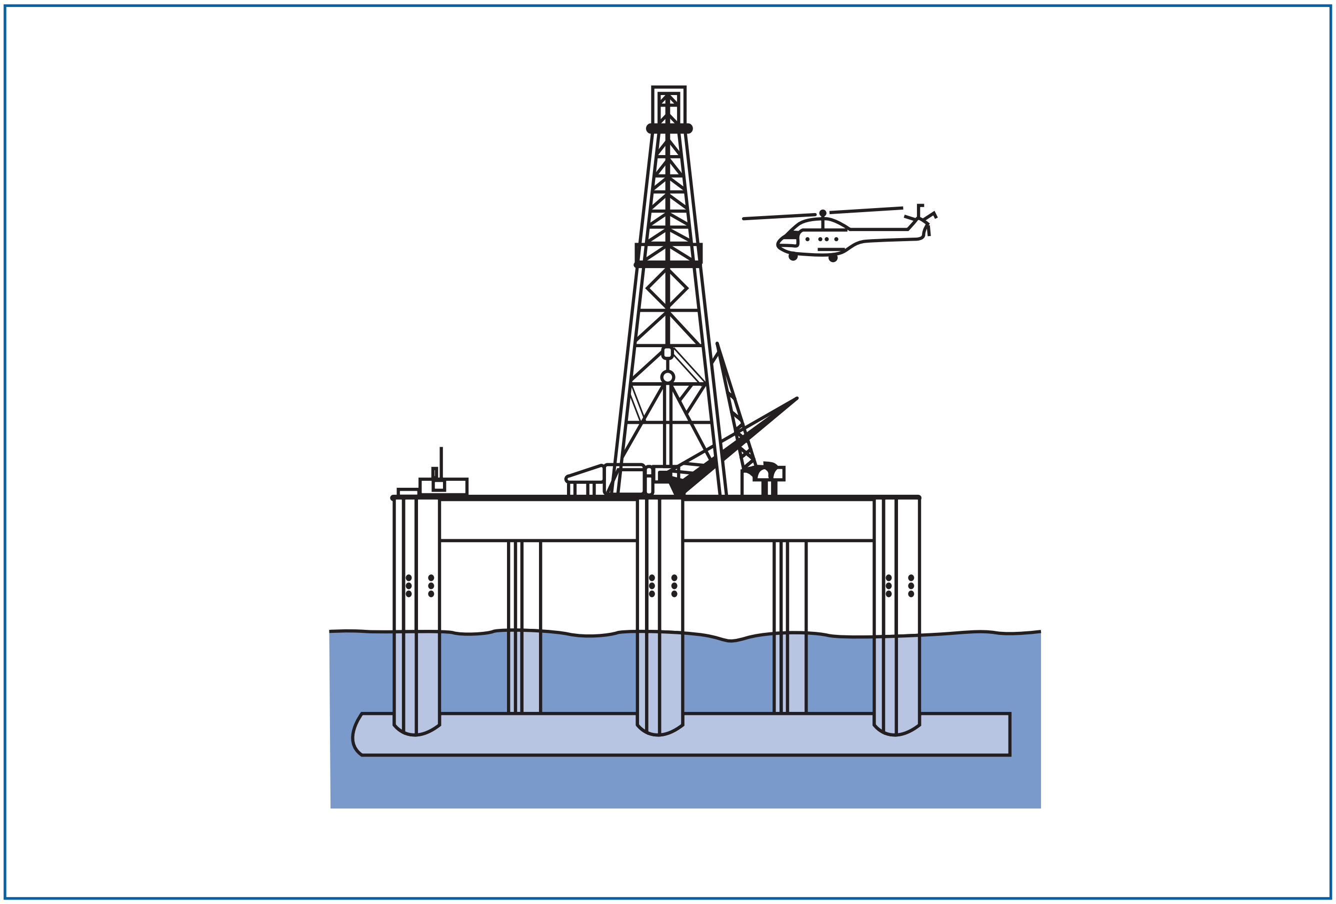

Figure 7.
Semisubmersible rigs. Huge cables and moorings anchor these floating rigs to the ocean bottom. The buoyancy of the rig creates the tension in the cables that keep the rig in place. When setting and removing mooring lines is excessively difficult or expensive, dynamic positioning systems are used instead.

When seas are less treacherous and there is greater need for mobility and flexibility, the drill ship is preferred over the semisubmersible. The drill ship has a derrick mounted in the middle over an opening for drilling operations, with several moorings used to hold the ship in position.

The use of dynamic positioning systems, instead of using moorings and cables, is becoming more popular in situations where it is expensive or extremely difficult to set and remove mooring lines. With the aid of advanced monitoring systems—gyrocompass wind sensors, global positioning systems, underwater sonar beacons, and hydroacoustic beacons—precise directional thrust propellers are used to automatically hold the vessel's orientation and position over the borehole. Despite the forces of wind, waves and ocean currents, at a water depth of 5,000 ft (1,526 m), a dynamic positioning system can reliably keep a drill ship within 50 ft (15.2 m) of the spot directly over the borehole.

Future Trends

As larger offshore discoveries become harder to find, more attention will be directed toward maximizing development from existing known reserves (workovers and recompletions), which seems to ensure a future for self-contained and jack-up rigs. There are certain to be reductions in size and weight of these new rigs. Self-elevating telescoping masts, which have improved dramatically in the 1990s, will become lighter and install more quickly. There also will be efficiency gains in equipment, and setup will be quicker, since modular units are becoming smaller, lighter, and less bulky.

The frontier remains deep water. Since the trend is toward longer-term operations, the design and materials of rigs that rest on the sea bottom will need to improve to handle the increased loads the extended reach needed in greater water depths. Productivity also will be increasing, since some of the latest ships can conduct simultaneous drilling operations using two drilling locations within a single derrick. Furthermore, because the costs of building and transporting massive drilling rigs can easily exceed several billion dollars, material research will continue to look for ways to prolong rig life cycles, and ways to better test structures regularly to avoid a catastrophic collapse. In particular, better welds, with fewer defects, will greatly extend the life cycle of offshore platforms from the continual forces of wind, waves, and ocean currents.

ANOTHER EQUIPMENT USE: CARBON DIOXIDE AND METHANE SEQUESTRATION

Since methane (CH_4) and carbon dioxide (CO_2) are greenhouse gases that governments of the world want reduced, the oil and gas industry—a major emitter of both—is looking for ways to effect such reductions. During drilling and production for oil and gas, significant amounts of CO_2 and CH_4 are produced. Where it is uneconomical to produce natural gas, this "stranded gas" is either vented as methane, flared (about 95% conversion to CO_2), converted to liquids (liquefied natural gas or methanol), or reinjected into the well. Over half of the oil exploration and production CO_2 emissions come from flaring, and almost all the methane emissions come from venting. The industry is trying to reduce emissions of both by better flare reduction practices, focusing on ways to convert more stranded gas to liquid fuels, and developing vapor recovery systems.

Another problem is when the carbon dioxide content of natural gas is too high and must be lowered to produce pipeline-quality gas. Although the current practice is to vent this CO_2, sequestration of CO_2 in underground geologic formations is being considered. Already, in the Norwegian sector of the North Sea, CO_2 has been injected into saline aquifers at a rate of 1 million tons a year to avoid paying the Norwegian carbon tax of $50 per ton of CO_2.

It may turn out that the same drilling technology that is being used to extract oil and gas, and that has been adapted for mining, geothermal, and water supply applications, will someday be equally useful in sequestering CO_2 in appropriate subsurface geologic formations.

OIL AND GAS, EXPLORATION FOR

Exploration for oil and gas has evolved from a basic trial-and-error drilling to the application of sophisticated geophysical techniques to predict the best locations for drilling.

BASICS OF OIL AND GAS TRAPS

Oil and gas are usually associated with sedimentary rocks. The three basic types of sedimentary rocks are shales, sands, and carbonates. The shales are the sources of the hydrocarbons while the sands and carbonates act as the conduits and/or the containers.

Source Rocks

Shales often are deposited with some organic matter, for example, microscopic plant or animal matter, that become part of the rock. When the shales are squeezed under the pressure of overlying rocks and heated by the natural heat flowing from the earth, oil and gas may be formed depending on the type of organic matter involved and the temperature to which the source rock is raised. If a rock is capable of producing oil or gas, it is referred to as a source rock because it is a source for the hydrocarbons. An important element of modern exploration is making certain that a new area being explored has source rocks capable of generating hydrocarbons.

The petroleum industry relies on organic geochemists to analyze the source rocks in new exploration environments. The geochemists evaluate the potential of a source rock for producing oil and gas by determining the amount and type of organic matter as well as the amount of heating and pressure applied to the rock. The whole process of making hydrocarbons can be compared to cooking in the kitchen. The final product depends upon the ingredients and the temperature of the oven (or sedimentary basin in the case of a source rock). Geochemists perform studies of potential source rocks in order to evaluate both the thermal history and the basic ingredients.

The important ingredient in a source rock is the organic matter or kerogen (Figure 1). Kerogen originally meant "mother of oil" but is used to today to describe the organic component of sediment not solvable in common solvents. Kerogens consist of basic biochemicals including carbohydrates, proteins, polyphenols, and lipids. Oil and gas are derived from kerogens rich in lipids. These types of kerogens are often deposited in lakes or marine environments. Other types of kerogens derived primarily from land plants are more prone to producing only gas. The geochemist has to identify the type of kerogen in a source rock in order to predict the types of hydrocarbons generated.

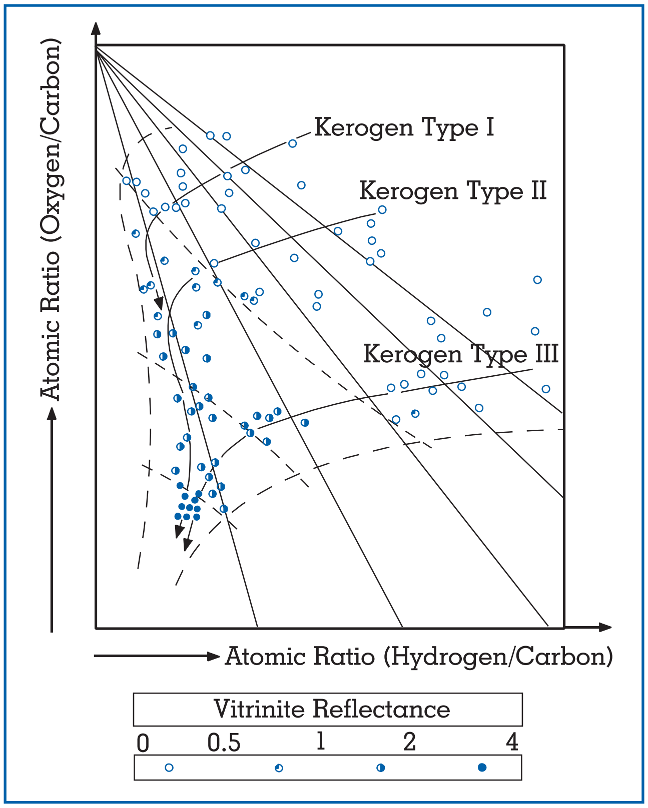

Figure 1.
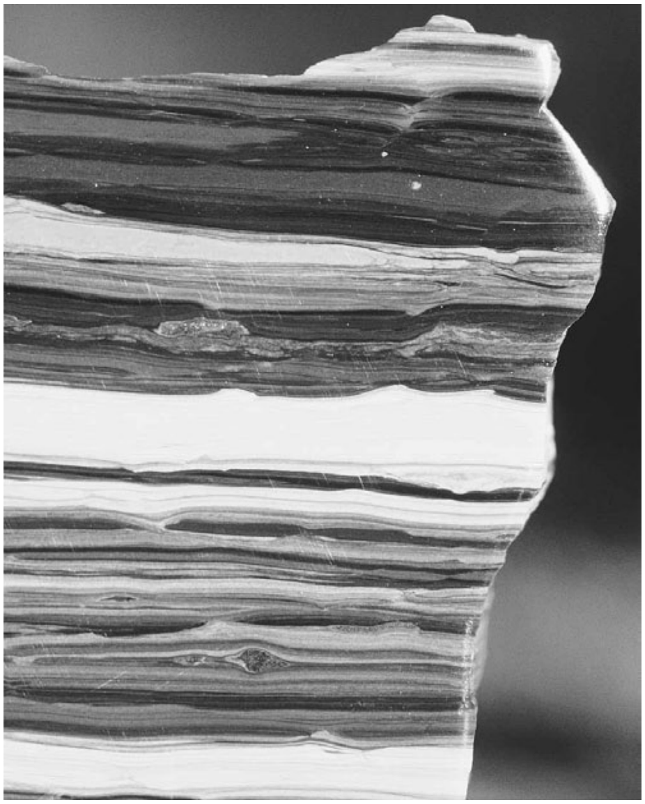
General scheme of kerogen evolution from diagenesis to metagenesis in the van Krevelen diagram.

As the source rocks are buried and their temperature increases, the individual kerogens undergo chemical changes that are referred to as maturation. When the temperature reaches around 60–70° C and the rocks are buried approximately 1000 m below the surface, hydrocarbons begin to be released from the kerogen. At first oil is produced from the rock if the kerogen is the right type. Next, "wet" gas (or a gas with many different components) and finally "dry" gas (or a gas made up primarily of methane) is produced. As the rock continues to cook beyond the dry gas stage, the residual kerogen is of little use for producing oil and gas. Just as in the kitchen, too much heating can spoil even the best of ingredients.

Geochemists try to determine where hydrocarbons begin to be liberated and how their quantity and composition may vary with increasing maturity. This is equivalent to evaluating the amount and type of kerogen present in the rocks as well as the maturity (or amount of cooking in the analogy used above) for the potential source rocks in a region being explored. In addition, geochemists try to estimate when and in what directions the hydrocarbons migrated. This helps with the exploration process because some traps may have been formed too late in order to hold hydrocarbons.

One important measurement made by geochemists is the Total Organic Carbon (TOC) measurement. The results are expressed as a weight percentage. When the TOC is less than 0.5 percent, the rock is considered unlikely to have enough kerogen to produce oil or gas.

Other measurements made by geochemists try to determine the state or level of maturity of a rock. Just as with cooking, the color and appearance of kerogen changes as the source rock matures. As a result, there are several schemes for using color changes to measure the maturity of a source rock. One example is called the vitrinite reflectivity. Vitrinite is a main component of coal and is also found dispersed in source rocks. The reflectance of light from the vitrinite is measured electronically under a microscope and is denoted R_0 (the vitrinite reflectance). When R_0 is less than 0.5 to 0.7 percent, the rock is immature and still in the diagenesis stage of maturing. For R_0 greater than 0.5 to 0.7 percent to around 1.3 percent, the rock is mature and in the oil window of development. When R_0 is greater than around 1.3 percent and less than 2 percent, this stage of maturity implies the source rock is producing condensate and wet gas. When R_0 is greater than 2 percent and less than 4 percent methane is the primary hydrocarbon generated (dry gas zone). When the reflectance is greater than 4 percent, the source rock has been overcooked. Vitrinite reflectance R_0 combined with the measurement of the TOC and a determination of the type of kerogen can then be used to predict the amount and type of hydrocarbons expected from a source rock. The type or kerogen in a source rock is determined using laboratory techniques to determine the relative quantities of hydrogen and oxygen in the kerogen. For example, if the atomic ratio of hydrodren to carbon of the kerogen is plotted on a graph against the atomic ratio of oxygen to carbon, different types of kerogens can be identified. Three categories of kerogen can be identified using this type of plot. Type I kerogen is rich in lipids and is an excellent source of oil. Type II is still a good source rock but is not as rich in lipids and not as oil prone at the Type I kerogen. Type III kerogen is primarily a gas prone kerogen. Armed with results of this type of study, the geochemist is able to make predictions regarding the quality of the source rocks in an exploration area and the expected products (oil, gas, or both) expected from them. In addition, geochemists work with geologists to predict the timing and the direction of flow of hydrocarbons as they are expelled from the source rocks. This information is then used in exploration to evaluate the relative timing between trap formation and the creation of the oil. A potential oil trap might be capable of holding a great deal of oil and still not have one drop of oil because the trap was formed after the oil had migrated past the trap.



A piece of oil shale formed in the bed of Uintah Lake has been polished to reveal strata. (Corbis Corporation)

Reservoir Rocks

Once the potential for hydrocarbons has been verified in a region, explorationists look for reservoir rocks that potentially contain the hydrocarbons. Reservoir rocks are typically comprised of sands or carbonates that have space, called “porosity,” for holding the oil. Sands are present at most beaches, so it is not surprising that a great deal of petroleum has been found in sands that were once part of an ancient beach. Other environments responsible for sandstones include rivers, river deltas, and submarine fans. An example of a carbonate environment is a coral reef, much like the reef located off the coast of Florida. The sediment deposited on reefs consists of the skeletons of tiny sea creatures made up primarily of calcium carbonate. The sandstone and carbonate rocks become a type of underground pipeline for transporting and holding the oil and gas expelled from the source rocks. These reservoir rocks have pore spaces (porosity) and the ability to transmit fluids (permeability). A rock with a high porosity and high permeability is considered a desirable reservoir rock because it can not only store more petroleum, but the petroleum will flow easily when being produced from the reservoir. Finding reservoir rocks is not always easy and much of the effort of exploration is devoted to locating them. One approach to looking for reservoir rocks is to make maps over a region based on data from wells (Figure 2). Geologists can use these maps to predict the range of distribution for the reservoir rocks. For example, if the reservoir rocks were deposited by a river system, the map can show a narrow patch of sand following the meander of an ancient river channel. Because the speed of sound in sands and carbonates (reservoir rocks) is usually faster than in the surrounding shales (usually the source rock), the difference can be used to identify reservoir rocks by the reflection character and strength on the seismic data. One popular seismic method for examining the strength of the reflection coefficient as a function of source-receiver separation (referred to as "offset") is called "amplitude-versus-offset" or "AVO." Another way to identify reservoir rocks is their anisotropy when compared to the anisotropy of shales. Anisotropy is used here to describe the directional dependence of a material property (the velocity in this case). Shales have a natural anisotropy that causes the speed of sound to travel faster horizontally than vertically. Reservoir rocks tend to have a different type of anisotropy caused by fractures or no anisotropy at all (they are said to be "isotropic" in this case). When searching for reservoir rocks, the key is to separate the type of anisotropy caused by shales from the anisotropy (or lack of it) due to the reservoir rocks that are present. This approach can be used to seismically evaluate the potential for reservoir rocks in a region. Still another seismic approach to predicting the presence of reservoir rocks is based on a geological interpretation of the seismic data called "seismic stratigraphy." All of the above methods are used to identify the presence of reservoir rocks in an area being explored.

Traps

Once the petroleum has been generated and squeezed from a source rock into a neighboring sand or carbonate, the petroleum is free to move through the porous and permeable formations until it reaches the surface or meets a place beyond which the petroleum can no longer flow. When the petroleum flows to the surface, the hydrocarbons are referred to as seeps. When the hydrocarbons are prevented from reaching the surface, they are "trapped" (see Figure 3). Traps are divided into two basic categories: structural and stratigraphic. Structural traps are caused by a deformation of the earth that shapes the strata of reservoir rocks into a geometry that allows the hydrocarbons to flow into the structure but prevents their easy escape. The deformation can be caused by thrust faults such as those responsible for mountain building or normal faults such as those found in subsiding sedimentary basins such as the Gulf of Mexico. Stratigraphic traps are the result of lateral variations in layered sedimentary rocks so that porous rocks grade into nonporous rocks, that will not allow the petroleum to move any further. The easiest traps to find have been structural traps, because deformation usually affects all adjacent layers or strata. This means that the effects are easier to see on seismic data. The stratigraphic traps are the most difficult to find because they occur without affecting much of the surrounding geology. Many reservoirs are constrained by both stratigraphic and structural trapping.

GEOLOGICAL MAPPING FOR OIL AND GAS

Geologists can be thought of as the historians of the earth. History is important to exploration success. When a well is drilled, a number of devices are lowered down the well to log or identify the different formations that have been penetrated. The geologist uses the logs from many different wells to put together an interpretation of the geology between wells. A

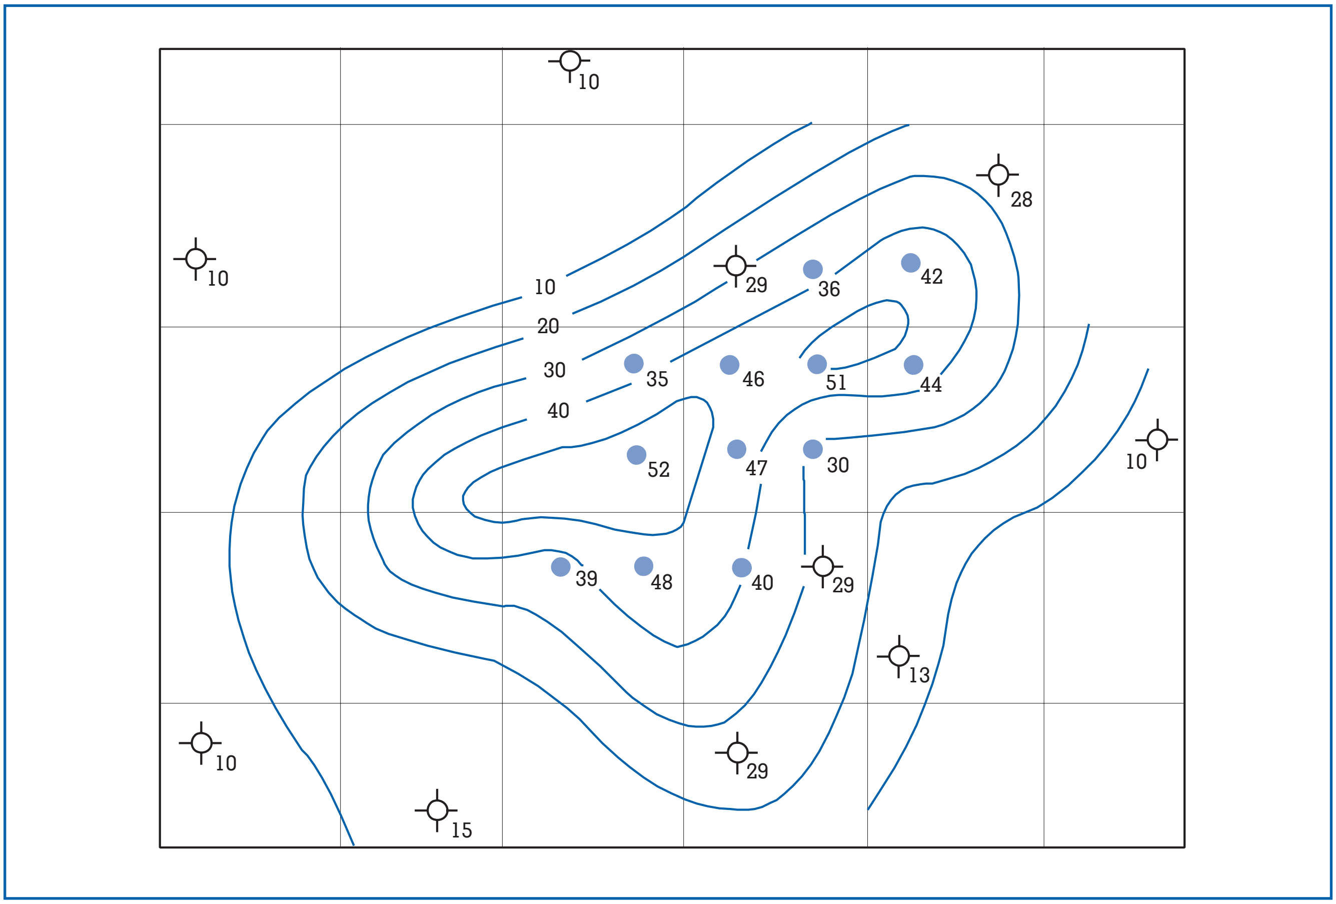


Figure 2.
Isopach maps depict thickness of a given interval.

part of the interpretation process involves making structure maps of the depth of sedimentary rock formations beneath the surface of Earth. In addition, geologists try to predict stratigraphic variations between wells using other mapping techniques. Besides being historians, geologists must solve geometric puzzles because they use the bits and pieces of information about rock layers observed from the well logs in order to form a complete picture of the earth. They can, for example compare well logs from two adjacent wells and determine if a fault cuts through one of the bore holes. The interpretation for modern geologists has been more challenging because many oil and gas wells purposely deviate from the vertical. Modem geologists employ numerous geometric tricks of the trade to assemble complicated 3-D interpretations of the earth and to identify where the reservoir rocks are located.

EARLY GEOPHYSICAL METHODS (1900s TO 1950s)

Geophysical methods are used to obtain information on the geology away from the wells where the location of oil- and gas-producing formations is known. In the early 1900s, the use of geophysics to find structural traps was accomplished by employing gravity and seismic methods. Gravity methods were the earliest geophysical method used for oil and gas exploration. The torsion balance gravimeter that was originally invented by Roland von Eotvos of Hungary (1890) later became an exploration tool. The first discovery by any geophysical method in the United States was made using a torsion balance in January 1924. Nash Dome was discovered in Brazoria County, Texas, by Rycade Oil Company, a subsidiary of Amerada. Sensitive gravity instruments measure the changes in the pull of Earth's

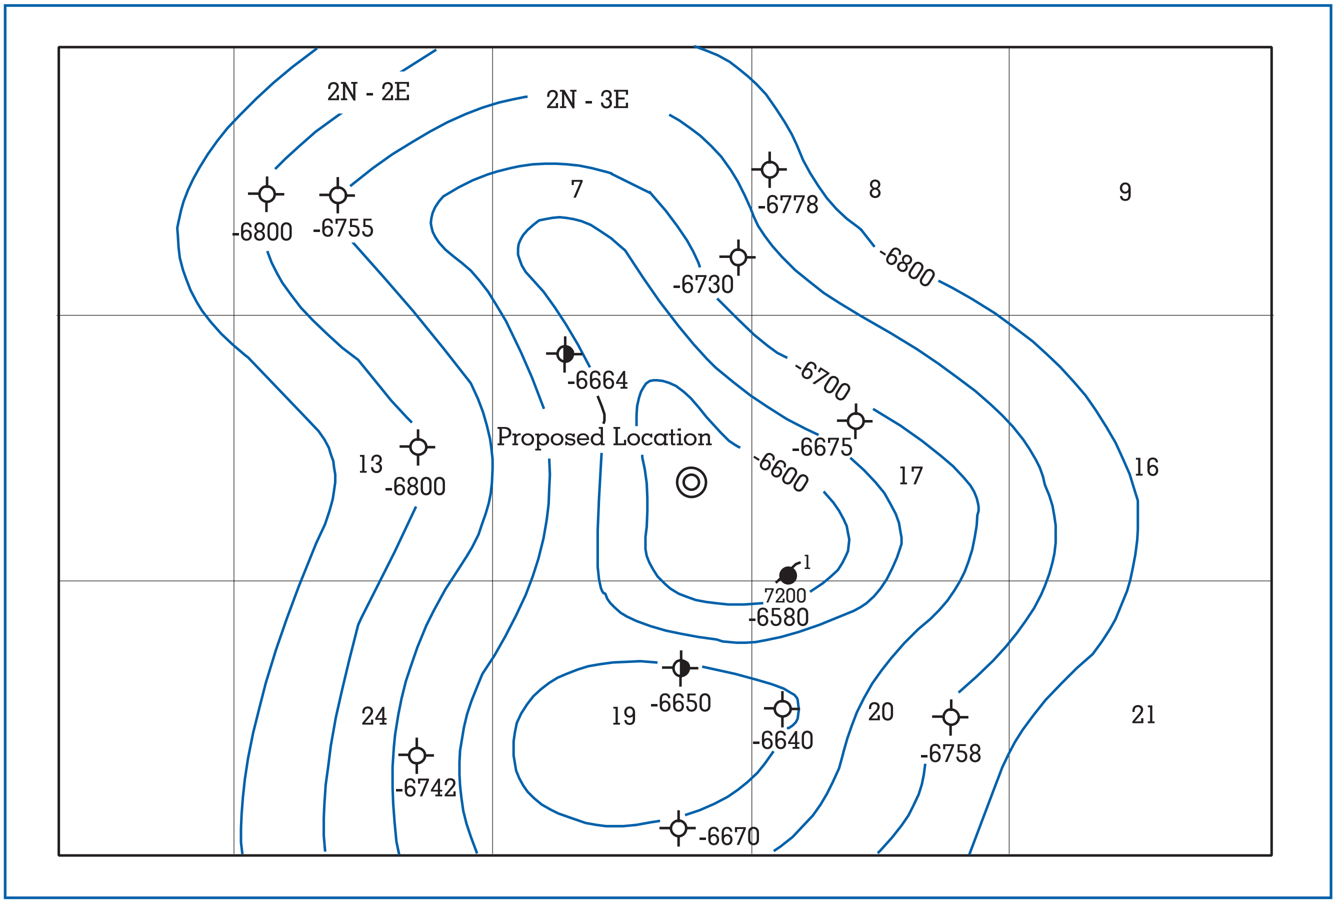

Figure 3.
Example of a structure map used to determine where oil is likely to be trapped.

gravity at different locations. The gravitational pull varies due to density variations in the different types of rocks. Because salt is lighter than most sedimentary rocks, gravity measurements were a popular approach to finding reservoirs associated with salt domes.

Sounding methods for spotting enemy artillery that were developed during World War I led to the major seismic exploration methods. On the German side, Ludger Mintrop developed the refraction exploration method that was most useful for early exploration of salt domes. Although Robert Mallet shot the first refraction survey in 1845, Mintrop recognized the commercial value of refraction surveying. He was able to verify the refraction method as an exploration tool by finding two salt domes in Germany in the period 1920–1921. In June 1924, shortly after the first torsion balance discovery, a Mintrop refraction crew (a company named "Seismos") discovered Orchard Dome in Fort Bend County, Texas. A patent filed in the United States in January 1917 by Reginald Fessenden, a Canadian by birth, laid down the fundamental ideas of using sound waves for exploration. The title of Fessenden's patent was "Methods and Apparatus for Locating Ore Bodies." In addition, the French, British, and U.S. wartime sound ranging efforts (for artillery) laid some of the foundation for the development of early seismic instrumentation and thinking developed by John Clarence Karcher. In 1921, Karcher used seismic reflections to map the depth to the top of the Viola limestone in Oklahoma. In 1927, Geophysical Research Corporation made the first seismic reflection discovery near Potawattamie County, Oklahoma. The successful well was drilled September 13, 1928. John Clarence Karcher and Everette Lee DeGolyer were the major contributors to this new exploration tool. Today the seismic

This is a team of trucks that create and record seismic vibrations, in an attempt to detect the presence of oil. (Corbis Corporation)

reflection method is the dominant form of exploration. The depth to the top of the oil and gas formations can be mapped with this technique, so the seismic reflection method can be used to directly identify structural traps.

Many other geophysical methods were attempted, but the gravity and seismic methods have survived the test of time. Gravity and seismic methods are often used in tandem because they give complementary information. This is helpful when exploring beneath salt or volcanic lava flows where seismic methods suffer difficulties. Some early work on magnetic measurements were accomplished, but magnetic surveys did not become popular until more sophisticated magnetometers were developed after World War II. When Conrad and Marcel Schlumberger joined forces with Henri Doll in the 1920s, they achieved the first geophysical logging of wells. The electric logs and other logs they developed played a major role in the early history of oil and gas exploration. The company they formed, Schlumberger Limited, has been an active contributor to numerous technological advances.

EXPLOSION OF TECHNOLOGY

In the 1950s the petroleum industry experienced an explosion of technology, a trend that continues today. One of the contributors in this effort was Harry Mayne, who developed common depth-point stacking, a method of adding seismic signals. The resulting stacked signals were then plotted in the form of a picture called a seismic section. The seismic sections, that appear as cross-sections of the earth, were initially used to find structural traps. The creation of the stacked sections benefited from digital recording that could be used to accurately record the amplitudes of seismic signals. True amplitude recording led to the discovery that the presence of hydrocarbons, especially gas, caused high-amplitude seismic reflections. These reflections, that appeared as bright spots on the seismic sections, enabled researchers to distinguish hydrocarbons from the surrounding rocks. Thus, in the 1970s bright-spot technology was developed by the petroleum industry to directly detect hydrocarbons from the surface. Shell Oil Company was the first company to use this new technology in the offshore region of the Gulf of Mexico, lowering the risk of falsely identifying oil and gas reservoirs. Unfortunately, other geological circumstances can create bright reflectors and some of these locations have been drilled.

As a result of these limitations in identifying stratigraphic traps, the industry sought a better understanding of stratigraphy. An important contribution to this understanding was the development of improved seismic methods to map stratigraphy. This improved method shaped the waveform leaving a seismic source into a shorter duration signal (the wave form is said to have been deconvolved). Enders Robinson, who had been a part of radar research efforts at MIT during World War II, introduced the deconvolution methods to the industry. Robinson applied some of the same radar technology to compress the seismic wavelets so that small changes in the stratigraphy could be mapped.

Seismic stratigraphy, originally developed by Peter Vail and his associates at Exxon, was another important contribution to the industry's ability to unravel the stratigraphy of the earth. As the industry pushed to find even more information about stratigraphic variations, methods were developed to use information about the shear-wave properties of rock as well as the compressional-wave velocities that had been the primary tool for seismic exploration. Shear waves or shear-related methods of exploration, such as AVO are used by the industry to identify changes in lithology (e.g., from sandstones to shales). These methods can also be used to evaluate bright spots or other types of reflection amplitude anomalies. For example, AVO methods are used to find rocks that have been fractured, thus making them into better reservoir rocks. In the early 1970s Jon Claerbout at Stanford University introduced an important seismic imaging principle that is still used today migrate seismic data accurately. "Migration" is a process used by geophysicists to plot seismic reflections in their true spatial positions. Today, many companies are using more sophisticated seismic imaging and analysis techniques called "inversion".

An important part of interpreting surface seismic data is the identification of the oil- and gas-bearing zones on the seismic data. Vertical seismic profile (VSPs) data are often recorded with a source on the surface and with receivers down the well to accomplish this task. In this way, the travel time to the reservoir can be measured along with other information relating the well data to the surface seismic data.

Another type of technology that has influenced oil and gas exploration is the acquisition of 3-D surface seismic data. This technology produces so much information that modern interpreters have been forced to give up looking at paper sections and use computers just to view their data. The 3-D seismic surveys are very much like a solid section of the earth. An interpreter can sit at a workstation and literally slice through the data viewing the seismic picture of the earth in almost every way possible. Some companies have assembled virtual reality rooms where the interpreter actually feels as if he or she is walking inside the earth to make the interpretation. Maps that might have taken months to produce in the early days of seismic mapping can now be accomplished in minutes. Computers are used not only for seismic processing and interpretation but for geological modeling and more accurate reservoir modeling. Integrated teams of scientists consisting of geologists, geophysicists, and petroleum engineers are pooling their talents to construct detailed 3-D models of reservoirs.

EXPLORATION TODAY

If the area being explored is a new one, the company has to make an assessment of the source rock potential. Next, they look for the reservoir rock and the trap. Sophisticated seismic methods including 3-D seismic surveys and VSPs are used to create a picture of where the oil and gas traps are located. They can also be used to determine when the traps were formed as well as the amount of oil and/or gas they contain. Seismic methods are often integrated with other geophysical measurements such as gravity, and magnetic or magnetotelluric measurements. In this way, the complementary data can be used to give a more complete picture of the geology.

EVALUATING RISK

Because financial risk is a major element of exploration, putting together a map that indicates where to drill is only part of the exploration process. Someone has to be convinced to put money into the effort to drill. Large companies go through multiple computer runs to evaluate the risks of drilling at a prospective site. Smaller companies tend to use a formula in which they multiply the probability of success times the current value of the oil that will be obtained if the well is successful. Next, they subtract from this product the probability of failure times the cost of drilling a dry well. The difference is called the "Expected Monetary Value" (EMV). If the EMV is a positive number, the well is judged to be a potentially profitable investment. Geophysical methods act to raise the probability of success for finding an economically successful well. However, the geophysical methods raise the cost of a dry well. Modern methods of geophysical exploration have raised the probability of success by as much as 30 percent in some instances over the original methods implemented in the 1920s. However, the question remains as to when the modern technology, such as 3-D seismic data, should be employed because it is more expensive. In offshore areas such as the North Sea, the deepwater Gulf of Mexico, and offshore Africa, there is the potential of finding large reserves. There is no question that 3-D data should be applied in these areas. The probability of drilling a successful well in these deep ocean areas is approximately the same as the shallow offshore areas, but what is driving deep ocean basin exploration is the potentially greater size of the reservoirs that remain to be found.

OIL AND GAS, PRODUCTION OF

The terms oil production and gas production refer to rates of extraction of liquid and gaseous hydrocarbon materials from natural underground deposits. Reserves and resources, on the other hand, refer to amounts of oil and gas that are present in the deposits, the difference between reserves and resources being whether or not the amounts can be economically recovered under current conditions. Supply refers to the amount of a product that becomes available for use in a given time, such as a year.

Worldwide production of crude oil increased through 1998 in response to increasing demand, although U.S. production was declining. The annual world supply of oil, which includes the annual production of crude oil and natural gas liquids grew from eighteen billion barrels in 1970 to twenty-seven billion barrels in 1998. A barrel is forty-two U.S. gallons. At the same time, the U.S. domestic supply declined from 4.3 billion barrels in 1970 to 3.5 billion barrels in 1998. So far, producing regions of the world have been able to meet the world demand without constantly escalating prices. However, the supply has become increasingly dependent on production in a few regions, notably the Middle East, where the remaining resources are concentrated. The rest of the world is becoming more dependent on these producers. Declining domestic production and growing demand have led to increasing imports of foreign oil into the United States. In 1997, one-half of U.S. consumption came from foreign imports.

Production of natural gas also has been increasing. World production of dry gas rose from sixty-six trillion cubic feet in 1987 to eighty-two trillion cubic feet in 1996. U.S. domestic dry gas production rose from seventeen trillion cubic feet in 1987 to nineteen trillion cubic feet in 1996, and the nation imported an additional three trillion cubic feet in 1996 to meet demand. Dry natural gas is produced from wellhead gas by removing most of the hydrocarbons heavier than methane. These heavy components, which tend to liquefy from the wellhead gas, are added as natural gas liquids to the oil supply and appear in the crude oil statistics.

Production of crude oil and natural gas involves technologies that have become increasingly complex as the remaining resources have become more difficult to locate and remove from their subsurface locations. Many new discoveries are made in sediments below the ocean floor in deep-water, and thus require removal of the oil and gas through long water columns. Other situations now require directional drilling of wells so that production involves transfers along wells that are far from vertical.

Most petroleum scientists believe that crude oil and natural gas formed over millions to tens of millions of years through the decomposition of organic matter buried by sediments. Generally, marine sediments have led to oil and gas, while freshwater

Gas production platform under construction in the Gulf of Thailand. (Corbis-Bettmann)

(swamp) sediments have produced coal and gas, although there are some exceptions. The liquid and gaseous hydrocarbons, in many cases, migrated through permeable subsurface rock, or along fractures, until they met an impermeable rock barrier, called a trap. There they collected to form an oil or gas reservoir. Oil and gas exploration teams using traditional and sophisticated geological techniques locate new reservoirs by studying the surface and subsurface geology in promising regions.

A reservoir is not a subterranean lake of pure oil or a cavity filled with gas. It is a porous and possibly fractured rock matrix whose pores contain oil, gas, and some water, or else, more rarely, it is a highly fractured rock, whose fractures contain the fluids. Such a reservoir is usually located in sandstone or carbonate rock. The rock matrix of an exploitable reservoir must be porous or fractured sufficiently to provide room for the hydrocarbons and water, and the pores and fractures must be connected to permit fluids to flow through the reservoir to the wells. In order to evaluate the production potential of a reservoir, a crew takes cores for analysis from appraisal wells drilled into the reservoir, and then examines properties of downhole formations using instruments lowered into the holes, a process called well logging.

When the exploration and appraisal phases at a reservoir are complete, a drilling crew drills production wells to extract the valuable hydrocarbons. Generally, a well is not left unlined. A pipe, called the casing, lines the well to protect the hole and the interior well structures, especially the tubing that transfers the oil or gas to the surface. In order to begin production, the well crew perforates the casing in the formations that contain the oil or gas and installs appropriate packing, plugs, valves, tubing, and any other necessary equipment required to remove the product.

A major factor in the production process is the driving force that moves the oil or gas to the borehole and lifts it to the surface. The fluid is, of course, under high pressure in the reservoir. If the pressure at the borehold exceeds the pressure of the rising column of oil or gas inside the tubing, it will flow out by itself. There are natural mechanisms that can provide the drive (energy) required to raise the product to the wellhead. One is the potential energy of the compressed oil or gas in the formation. The magnitude of this energy depends on the compressibility of the fluid or fluids involved. For gas, this mechanism is very effective because gas is quite compressible. As the formation gas expands into the borehole under the reduction of pressure at the borehole, it enters the tubing of the well and flows up to the surface. A gas well generally does not need to be pumped.

The situation is more complicated for oil because oil is relatively incompressible and is much denser. The natural driving pressure from the oil decompression is quickly reduced as oil flows into the borehole and, furthermore, the back-pressure produced by the heavy column of oil in the tubing is much greater than is the case for gas. Thus, one could expect this drive mechanism to be quickly lost. However, if the oil reservoir is in contact with either a large reservoir of water below it or a reservoir of gas above it, this contiguous fluid reservoir can supply the energy to maintain the drive for a much longer period. One says in such a case that the reservoir is water-driven or gas-cap-driven. There is, in fact, a third possibility called solution gas drive that originates from gas that is dissolved in the oil. When the formation pressure declines to a certain point, called the bubble point, the dissolved gas will begin to come out of solution. When this happens, the greater compressibility of the gas phase thus formed can contribute to an extended drive. However, this condition can be a mixed blessing because the gas can become the major product from the well, and it is less valuable than the oil.

The contiguous reservoirs of gas or water that contribute the drive pressures for an oil well can cause a problem. Gas and, in some cases, water, are more mobile than oil in an oil reservoir. As a result, during production the oil-gas or oil-water surface can move toward the region of reduced pressure around the borehole. If the interface reaches the borehole, the driver fluid will enter the well and be produced along with the oil. Since gas is not as valuable as oil, and water is unwanted, several measures are taken to limit ground water extraction. For example, in a gas-cap-driven reservoir, the production crew can locate the perforated section, where the oil enters the well, near the bottom of the pay zone so as to keep the collection point as far as possible from the oil-gas boundary. On the other hand, a water-driven well can be completed near the top of the zone to accomplish the same purpose. Reducing the rate of production from the well, and hence the drop in pressure around the borehole, is another way to avoid this problem.

The initial pressure in a reservoir is usually high enough to raise the oil to the surface. However, as production proceeds and the reservoir becomes depleted, the formation pressure falls and a new source of energy is required to maintain the flow of oil. A common practice is to inject either gas or water into the producing formation through special injection wells in order to maintain the pressure and move the oil toward the collection points in the producing wells. This procedure is called pressure maintenance or secondary recovery. Its success depends on maintaining a stable front between the oil and the injected fluid so that the oil continues to arrive at the collecting wells before the injected fluid. To the extent that the gas or water passes around the oil, arrives at the producing wells, and becomes part of the product coming up to the surface, the process fails to achieve its full objective. This undesirable outcome can occur, as noted above, when the mobility of the injected fluid exceeds that of the oil, as is the case for injected gas and for injected water with heavy oils. Gravity also can play a role in the success of secondary recovery depending on the geometry of the reservoir and the location of the injection and production wells.

In addition to pressure maintenance in a reservoir, there are other ways to maintain or improve well productivity as the formation pressure falls. A pump can be used to raise the oil, a process called artificial lift. One type is the familiar beam pump with its surface power unit driving up and down one end of a center-mounted beam while the other end executes the opposite down-up motion. The second end is attached to a string of “sucker rods” that extend down to the bottom of the well and operate a pump arrangement, consisting of a cylinder, plunger, and one-way valves. Other types of pumps in use eliminate the sucker rod and may have the power unit at the bottom of the well. A method for extending the period of natural flow is gas lift. In this procedure the well operators inject gas bubbles into the tubing to reduce the weight of the column of liquid that must be lifted to the surface. A third way to improve productivity is to "workover" an existing well. Mud, sand, or corrosion products may be plugging the perforations, or tubing, packing, pumps, or casing may be damaged and need repair. A workover crew will carry out repairs remotely from the surface or else remove interior components of the well for service.

Infill drilling is another possible way to extend production. For a variety of reasons, some oil may not be available to the original wells in the reservoir. Some wells may be spaced too far apart to capture the oil between them. Gas or water flooding may have bypassed some oil, or fractures or faults may block off certain parts of the reservoir from the rest so that they cannot be drained from existing wells. In these cases drilling new wells between existing ones can be an effective way to capture more of the resource.

Secondary recovery, infill drilling, various pumping techniques, and workover actions may still leave oil, sometimes the majority of the oil, in the reservoir. There are further applications of technology to extract the oil that can be utilized if the economics justifies them. These more elaborate procedures are called enhanced oil recovery. They fall into three general categories: thermal recovery, chemical processes, and miscible methods. All involve injections of some substance into the reservoir. Thermal recovery methods inject steam or hot water in order to improve the mobility of the oil. They work best for heavy oils. In one version the production crew maintains steam or hot water injection continuously in order to displace the oil toward the production wells. In another version, called steam soak or "huff and puff," the crew injects steam for a time into a production well and then lets it "soak" while the heat from the steam transfers to the reservoir. After a period of a week or more, the crew reopens the well and produces the heated oil. This sequence can be repeated as long as it is effective.

Chemical processes work either to change the mobility of a displacing fluid like water, or to reduce the capillary trapping of oil in the rock matrix pores. Reducing the mobility of water, for example by adding polymers, helps to prevent "fingering," in which the less viscous water bypasses the oil and reaches the production well. The alternate chemical approach is to inject surfactant solutions that change the capillary forces on the oil and release it from pores in which it is trapped. Another way to mobilize the oil is to inject a fluid with which the oil is miscible at reservoir conditions so that the oil trapped in the pores can dissolve in the fluid and thus be released. Carbon dioxide, nitrogen, and methane have been used for this purpose.

When oil or gas from a reservoir reaches the surface at the wellhead, it is processed to meet specifications for transportation and delivery to a customer such as a refinery or pipeline. The first step is usually to collect the output of a group of producing wells through a pipeline network into a gathering station where field processing takes place. In the case of crude oil, the objective is to produce a product relatively free of volatile gases, water, sediments, salt, and hydrogen sulfide, and fluid enough to transport to the refinery. In the case of wellhead gas, the objective is to produce a field-processed gas relatively free of condensable hydrocarbons, moisture, and various

Oil well pumps in Midway-Sunset Oil Field. (Corbis-Bettmann) gas contaminants such as hydrogen sulfide and carbon dioxide.

The field processing facilities separate the components of the wellhead liquids and gases using their differing physical and chemical properties. Tank and baffle arrangements that utilize density differences are effective for initial separation of the water, oil, and gas. Drying agents to take water out of the separated hydrocarbons, screens, or other means to remove mists of small droplets in the gas, and heat, de-emulsifying agents, or electrostatic means to eliminate emulsions can further refine the components. For wellhead gas, refrigeration of the raw gas will remove heavier molecular weight hydrocarbons, such as propane and butane, improving the quality of the purified gas and coincidentally producing valuable hydrocarbon liquids.

After field processing of wellhead products is complete, the oil and gas production phase of the industry passes into the refining stage, where the crude oil and field gas are further processed to make the products that ultimate users will purchase. The prices that refiners will pay determine the maximum allowable costs for oil and gas exploration and production. An oil or gas producer must be able to provide the product at a competitive price. For a vertically integrated oil company, no actual sale may take place, but the economics are much the same.

Oil and gas development in new fields is a somewhat risky business for several reasons. The future trend in the price of crude oil or natural gas is uncertain, especially since existing low-cost producers in the world can exert considerable monopoly power in the industry. Furthermore, the amount of product that a reservoir will produce at a given cost is uncertain, and there is a long delay between the time when the expenses of developing a new field are incurred and the time when the revenues come in from the sale of the products. These uncertainties affect the likelihood that an investment in a new prospective development will be worthwhile. Even the continuation of production in an existing field can pose uncertainty. For example, when should operators shut down operations in a declining oil field? Shutting down marginally profitable wells because the price of crude oil has dropped may be an irreversible action because of governmental decommissioning requirements, or even just the cost of restarting. Yet the price may go up again shortly so that profitable operations could resume. Thus, the business aspects of oil and gas production play a major role in decision-making in this extractive industry, and the players must be attuned to the risks involved.

ONSAGER, LARS (1903–1976)

Lars Onsager was a Norwegian-American chemist and physicist who received the 1968 Nobel Prize in Chemistry for “the discovery of the reciprocal relations bearing his name which are fundamental for the thermodynamics of irreversible processes.”

Onsager was born on November 27, 1903, to Ingrid and Erling Onsager. The family lived in Oslo (then Kristiania), Norway, where his father was a barrister. He grew up with two younger brothers, Per and Knut. Onsager's mathematical acumen was apparent early. At the age of fifteen he discovered for himself how to solve cubic equations. His school performance enabled him to skip one year at school, and at the age of sixteen he was ready for university studies. He entered the Norwegian Institute of Technology at Trondheim, where he graduated in 1925 with a chemical engineering degree.

As a freshman in Trondheim, he had studied the most recent theory, attributed to Peter Debye and Erich Hückel, of electrolytic solutions, a topic to which he returned continually throughout his life. His first contact with the scientific world was when he, at the age of twenty-two, entered Debye's office in Zürich, saying without introducing himself: "Good morning, Herr Professor, your theory of electrolytic conduction is incorrect" (Hemmer et al., 1996). Debye, impressed by Onsager's arguments, hired him as his assistant. Onsager's revision of the Debye-Hückel theory resulted in the so-called Onsager limiting law for electrolytic conduction, an important result in good agreement with experiments.

In 1928 Onsager emigrated to the United States, first to Johns Hopkins University, then in the same year to Brown University. Here he struggled with an attempt to base symmetry relations found in his work on electrolytes on general physical laws. Thus he considered more general irreversible processes than conduction and diffusion, the basic ingredients in electrolytic conduction. Irreversible transport processes are centered around fluxes of matter, energy, and electric charge and their dependence upon the forces that give rise to them. The processes are called irreversible because the fluxes are unidirectional and cannot run in the reverse direction. The main effects are well-known: diffusion (transport of matter) due to a concentration gradient or concentration difference (e.g., across a membrane), heat conduction (transport of energy) due to a temperature gradient or temperature difference, and electrical conduction (transport of electric charge) due to a potential difference.

However, a potential may give rise to more than one type of flux. There are cross-effects: A temperature difference can also result in diffusion, called thermal diffusion, and a concentration difference can result in a heat current. The general relation between fluxes J_i and the driving potentials X_i is of the form of linear relations

$$J_i = \Sigma_j L_{ij} X_j, \tag{1}$$

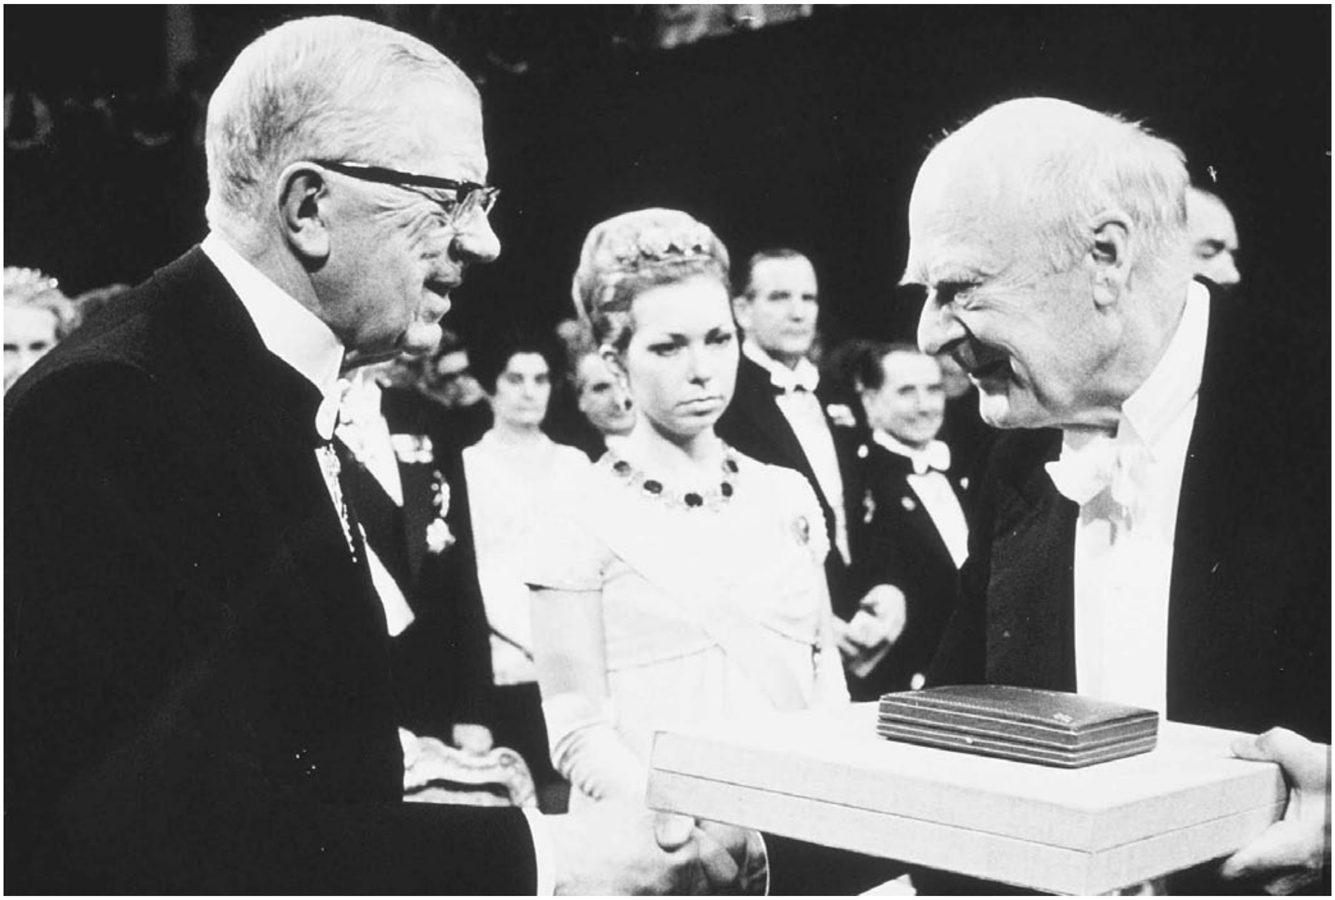
with coefficients L_{ij}, when the fluxes are not too great. Onsager showed that the coefficients of the cross-effects were equal:

$$L_{ij} = L_{ji}. \tag{2}$$

These are the famous Onsager reciprocal relations. Thus there is symmetry in the ability of a potential X_i to create a flux J_j, and of the ability of a potential X_j to create a flux J_i. The reciprocal relations are experimentally verifiable connections between effects which superficially might appear to be independent.

Such symmetries had been noticed in special cases already in the nineteenth century. One example was heat conduction in a crystal, where the X_i are the temperature gradients in the three spatial directions. Cross-effects between electric conduction and diffusion, and between heat conduction and diffusion, were also studied. Reciprocal relations of the form $L_{ij} = L_{ji}$ were confirmed experimentally for these cases, but a general principle, from which these would follow, was lacking. This situation changed dramatically in 1931 when Onsager, then at Brown University, derived the reciprocal relations. In the derivation, Onsager used the fact that the microscopic dynamics is symmetric in time, and he assumed that microscopic fluctuations on the average follow macroscopic laws when they relax towards equilibrium. The Onsager formulation was so elegant and so general that it has been referred to as the Fourth Law of Thermodynamics. It is surprising to note that the immediate impact of Onsager's work, which later earned him the Nobel Prize, was very minor, and that it was virtually ignored during the following decade.

Onsager spent the summer of 1933 in Europe. During a visit to the physical chemist Hans Falkenhagen, he met Falkenhagen's sister-in-law, Margrethe (Gretl) Arledter. They fell in love and married in September the same year. Another important event in 1933 was Onsager's move to Yale University, where he remained until his retirement. In the course of time the Onsager family grew to include one daughter and three sons. At Yale he was first a Stirling and Gibbs fellow, then assistant professor, associate professor, and finally in 1945 J. Willard Gibbs Professor of Theoretical Chemistry.



Lars Onsager (right), receiving the 1968 Nobel Prize in Chemistry from King Gustav Adolf of Sweden (left). (Archive Photos, Inc.)

Although Onsager's first appointment at Yale was a postdoctoral fellowship, he had no doctorate. It disturbed him that everybody called him "Dr. Onsager," and he decided to seek the Ph.D. from Yale. He was told that any of his published works would do for the thesis, but he felt he should write something new, and he quickly submitted a lengthy dissertation on Mathieu functions. Both the Department of Chemistry and the Department of Physics, found it difficult. The Department of Mathematics, however, was enthusiastic and was prepared to award the degree, whereupon the Department of Chemistry did not hesitate in accepting the thesis.

If Onsager's great achievement with the thermodynamics of irreversible processes met with initial indifference, Onsager's next feat created a sensation in the scientific world. In a discussion remark in 1942, he disclosed that he had solved exactly the two-dimensional Ising model, a model of a ferromagnet, and showed that it had a phase transition with a specific heat that rose to infinity at the transition point. The full paper appeared in 1944. For the first time the exact statistical mechanics of a realistic model of an interacting system became available. His solution was a tour de force, using mathematics almost unheard of in the theoretical physics of the day, and it initiated the modern developments in the theory of critical phenomena. Basing their decision especially on this work, the faculty at Cornell University nominated Onsager for the Nobel Prize in both physics and chemistry.

Although the reciprocal relations, electrolyte theory, and the solution of the Ising model were highpoints in Onsager's career, he had broader interests. From about 1940 Onsager became active in low-temperature physics. He suggested the existence of quantized vortices in superfluid helium, and provided the microscopic interpretation of the oscillatory diamagnetism in metals. In 1949, four years after he became an American citizen, he laid the foundation for a theory of liquid crystals. In his later years he studied the electrical properties of ice and took much interest in biophysics.

The importance of Onsager's work on irreversible processes was not recognized until the end of World War II, more than a decade after its publication. From then on irreversible thermodynamics gained momentum steadily, and the reciprocal relations have been applied to many transport processes in physics, chemistry, technology, and biology. The law of reciprocal relations was eventually recognized as an enormous advance in theoretical chemistry, earning Onsager the Nobel Prize in 1968. Thus more than a third of a century passed before Onsager's work was suitably recognized. In his presentation speech at the Nobel ceremonies S. Claesson said: "Here we thus have a case to which a special rule of the Nobel Foundation is of more than usual applicability. It reads: 'Work done in the past may be selected for the award only on the supposition that its significance has until recently not been fully appreciated.'"

Onsager was reluctant to publish. Many of his original discoveries appeared first in the discussion periods at scientific meetings and were not published for years, if at all. He was very much an individualist. Although he had students and coworkers, especially in his later years, he preferred to work alone. Therefore, he never created a school around him. As a person, Onsager was modest and self-effacing, with a wry sense of humor. He had an awesome memory and was at ease with history, language, and the literature of the West. Games of all kinds appealed to him.

After retirement he went to the Centre for Theoretical Studies at Coral Gables, Florida, where one of his main interests was the question of the origin of life. He died at Coral Gables on October 5, 1976.

OTTO, NIKOLAUS AUGUST

(1832–1891)

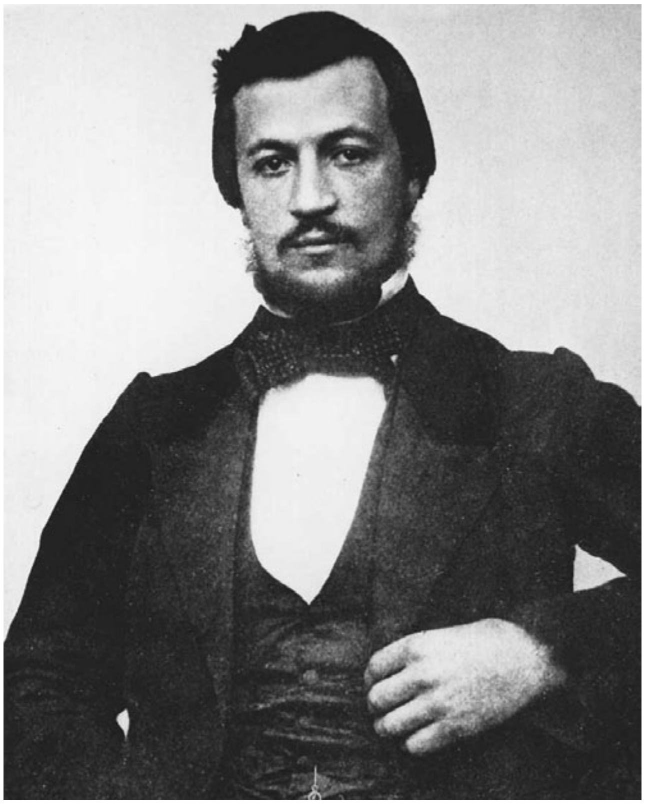
Otto was born in the village of Holzhausen, near Frankfurt. His father, an innkeeper, died when Otto was a small boy. This was a period of declining prosperity in Germany, although Otto's mother had hoped her son might receive a technical education, Otto was forced to leave school and take up employment in a Frankfurt grocery store. His brother Wilhelm, who had a textile business in Cologne, then secured him a position as a salesman in tea, sugar, and kitchen ware to grocery stores. Otto's travels took him along the German border with France and Belgium as far as Cologne where in 1859 he met Anna Gossi and began a nine-year courtship.

In 1860 Jean Lenoir built the world's first mass production internal combustion engine, a noncompression double-acting gas engine. Otto saw the potential of the Lenoir engine and perceived that the future development of the internal combustion engine would be dependant on its fuel source. In an attempt to make the engine mobile he devised an alcohol-air carburetor, and with his brother filed for a patent in 1861. Hampered by a lack of funds and a technical education, Otto spent all his leisure time in developing an engine that would surpass that of Lenoir. In 1861 Otto commissioned a Cologne instrument maker, Michael Zons, to build an experimental model Lenoir engine. Otto carried out a series of experiments with the purpose of lessening piston shock loading at the start of combustion. In one series of experiments he turned the engine over drawing in the explosive mixture, the piston was then returned to top center compressing the mixture that was then ignited. Otto found that ignition took place with great violence. This undoubtedly set the scene for the development of Otto's compression engine. In 1862

Zons built for Otto a flat four-cylinder engine. Each cylinder contained a free "cushion" piston, this engine, however, was a failure. In 1863 Otto had Zons built a one-half horsepower atmospheric engine.

In 1864 Otto's luck took a turn for the better when his engine came to the attention of Eugen Langen. Langen was a partner in a sugar refining business that he had expanded into refining sugar beets as well as cane sugar, using processing equipment of his own design. Although Langen could see the deficiencies in Otto's design he quickly made up his mind to invest in the engine. With the help of his father, Langen raised sufficient capital to form a company. In March 1864 Otto and Langen signed an agreement forming N.A. Otto & Cie, the world's first company to be set up to manufacture internal combustion engines. By 1867 the engine design was perfected and a patent applied for. The improved engine was exhibited at the 1867 Paris Exposition. After a series of tests that examined the engine efficiency and performance, the Otto and Langen engine was found to consume less than half the gas of the best noncompression engine and was awarded a gold medal. Although orders now flooded in, the partners still lacked sufficient funds. New partners were sought and Otto, whose stock holding, fell to zero, accepted a long-term employment contract. In 1872 Gasmotoren-Fabric Deutz AG came into being with Langen in control and Otto as Technical Director. Gottlieb Daimler joined the firm as production manager bringing with him Wilhelm Maybach to head the design department. Improvements were made to the engine probably by Maybach, but Daimler demanded they be patented in his name, an action that led to disputes between him and Langen. Langen also had to arbitrate numerous disagreements between the autocratic Daimler and the oversensitive Otto. Through the use of licenses and subsidiaries, Otto and Langen established an international industry with engines being built in most industrialized nations.

Around 1872 Otto returned to the problem of shockless combustion. It occurred to him, if only air was brought into the cylinder first and then the gas/air mixture, the charge would become progressively richer towards the source of ignition. Otto built a small hand-cranked model with glass cylinder to study his stratification idea by using smoke. A prototype four-stroke cycle engine was constructed in 1876. Although, at the time, Daimler thought Otto's new ideas would prove a waste of time, Langen assigned Otto an engineer and let him continue his research. Otto's ideas concerning stratification were patented in 1877. The new engine had a single horizontal cylinder and bore some similarity to the Lenoir engine. The important difference was in the admission of gas and air, also gas flame ignition. Otto seemingly had more faith in ignition by flame rather than electrical spark. The basic elements of the modern four-stroke engine are to be found in this experimental engine. A slide valve controlled air intake with a second cam operated slide valve controlling gas admission. As the piston began its outward stroke, the air valve opened and the gas valve remained closed until the piston had completed half its travel. At the end of the stroke, the valves closed and the piston began the return stoke compressing the air gas mixture. At the end of the return stroke, the gas air mixture is ignited and the piston commences its second outward stroke, the power stroke. At the end of this stroke the exhaust valve opens, and the piston returns exhausting the burnt gasses. In Otto's new design there was one power stroke for every four strokes of the piston or two revolutions of the flywheel.



Nikolaus August Otto. (Granger Collection, Ltd.)

Wilhelm Maybach redesigned Otto's prototype engine for mass production. The "Otto Silent" engine rapidly established the gas engine as a practical power source and Deutz jealously protected their position as the world's sole supplier of Otto's new engine. Through litigation and threats of action Deutz pursued any manufactures who attempted to infringe on the Otto patent. These actions, while effectively emasculating other engine builders, acted as a stimulus for basic research into the correctness of Otto's ideas on stratified charge and in turn the validity of his patent. Deutz's manufacturing competitors in endeavoring to discredit the stratified charge theories discovered an obscure patent filed by Frenchman A. B. de Rochas in 1862. Although de Rochas's patent had never been published, through a failure to pay the required fees, nor was there any evidence he had produced a working engine, his patent was used to challenge Deutz's monopoly. During litigation Otto strove to establish prior invention, but suffered, as have many other inventors, from inadequately documenting his research work. Although Otto must be considered the true inventor of the four-stroke cycle, patent law is more a matter of establishing priority of ideas than production of working machines. The Otto patents were overturned in Germany in 1886. In Britain, Otto's designs were licensed by Crossley who successfully defended their position by having the de Rochas patent ruled inadmissible.

Although his ideas were vindicated in Britain, the loss of his German patents were a blow to Otto's pride from which he apparently never recovered. Otto died five years later in 1891. Otto's only son Gustov became an engineer and aircraft designer in Munich, and in 1901 founded an airframe company that produced aircraft for World War I.

P

PARSONS, CHARLES ALGERNON (1854–1931)

Charles Algernon Parsons was born in London on June 13, 1854, the son of a wealthy, aristocratic Anglo-Irish family that was scientifically very distinguished. His father, William Parsons (third Earl of Rosse), a member of parliament, was an engineer, astronomer, and telescope-maker who had built the largest telescope in the world. His mother, Mary Countess of Rosse, best remembered as a photographer, was adept at architectural design and cast-iron foundry work.

The greater part of Parsons' childhood was spent at the family's castle and estate at Parsonstown (now Birr), County Offaly, Ireland. The workshops there were extensive, and he grew up surrounded by tools and machinery. He was privately educated by, among others, Sir Robert Ball, a man who encouraged him to spend time not just in the classroom, but also in the workshops. With these facilities and the guidance of his parents and tutor, he developed an exceptional talent for engineering.

The key to Parsons' success lies in the nature of his early training in science and engineering. In a letter concerning the design of yachts, he wrote that "they seem to design by rule of thumb in England—they should rely on model experiments, which would put them right." This is illustrative of an approach to engineering that was highly practical. He solved problems by building experiments and then meticulously observing and analyzing the results. It was an aspect of his character that was formed by the time he left Birr for his university education.

In July 1871, Parsons entered Trinity College Dublin, where he studied mathematics. In 1873, he entered St. John's College Cambridge and took his B.A. degree in mathematics in 1877. Thus, at the age of 23 he graduated from the university armed with a battery of practical and theoretical skills that allowed him to gain unique insights into the engineering problems of the time.

Having spent five years at the university honing his theoretical skills, Parsons then returned to the practical by entering the engineering firm of W. G. Armstrong & Co. in Newcastle-upon-Tyne. As a premium apprentice he was allowed to spend some of his time constructing his own experiments, provided that he paid the material and labor costs himself. Using this time, he developed a high-speed, four-cylinder epicycloidal steam engine.

The Armstrong company was not interested in producing the engine; therefore in 1881, Parsons moved to Kitson's of Leeds who took it into production. At Kitson's he occupied himself with experiments in rocket powered torpedoes that, although unsuccessful, provided useful background for his next project, the steam turbine.

Parsons left Kitson's and joined Clarke, Chapman & Co. of Gateshead as a junior partner. This was the turning point in his career, his previous working life having been devoted to learning and developing his skills. In 1884, he decided "to attack the problem of the steam turbine and of a very high speed dynamo." During the next ten years of his life, he made huge strides in the construction of dynamos and steam turbines.

In the late 1880s the Industrial Revolution was demanding ever-increasing amounts of energy. Electrical power was an obvious solution to this demand; however, it was not yet possible to generate very high power. Parsons realized that high-speed

Charles Algernon Parsons. (Library of Congress)

dynamos were the answer, and that the best source of rotational energy would be a steam turbine, whose nonreciprocating nature makes it capable of far higher speeds than conventional reciprocating engines.

Turbine designers had been experimenting with machines in which the blades were driven by a high-velocity steam jet that expanded through them in a single stage. It had been shown that steam-jet velocities of the order of 1000 m/s were required.

For a steam turbine to work efficiently, it is necessary that the velocity of the tips of the turbine blades be proportional to the velocity of the input steam jet. If the velocity of the input steam jet is high, it is necessary to increase the radius of the blades so that their tip velocity becomes correspondingly high. These long rotor blades subject the entire assembly to unmanageable mechanical stresses at high speed.

Parsons realized that he could, by using multiple rings of turbine blades on the same shaft, allow the steam to expand in stages through the turbine, and therefore extract energy more efficiently from the steam jet. This allowed him to utilize much lower jet velocities, of the order of 100 m/s, with correspondingly shorter turbine blades.

Parsons attacked the problem with characteristic gusto, so much so that by 1885 his first prototype was running successfully, giving 4.5 kW at 18,000 rpm. In 1889, frustrated by what he perceived as a lack of progress, he broke his partnership with Clarke Chapman and set up on his own in Heaton. He lost all his patent rights to the steam turbine; however, he was not daunted by this and simply developed a radial-flow machine that circumvented his own patents. In a radial-flow turbine, the steam expands outwards at right-angles to the rotational axis in contrast to the axial-flow machine where the steam expands along the length of the rotational axis.

Parsons realized that his invention was ideal for powering ships. Having received an unenthusiastic response from the admiralty, he set about proving his point in a characteristically irreverent manner. He built the *Turbinia*, a vessel powered by steam turbine and screw propellers. On the occasion of her diamond jubilee in 1897, Queen Victoria was reviewing the royal navy fleet at Spithead when Parsons appeared in the *Turbinia* and raced through the fleet at the then unbelievable speed of 30 knots. The point was well made, and on November 21, 1899, HMS *Viper* had her trials, reaching a speed of 32 knots.

Parsons was, first and foremost, a compulsive inventor. He spent his days inventing everything from children's toys to the Auxetophone, a mechanical amplifier for stringed musical instruments. His success as an inventor lies in his inquisitive nature and the fact that he was equally comfortable with theory and practice.

Parsons loved travel and the sea. It was on a cruise to the West Indies that he died aboard ship on February 11, 1931, in Kingston Harbor, Jamaica.

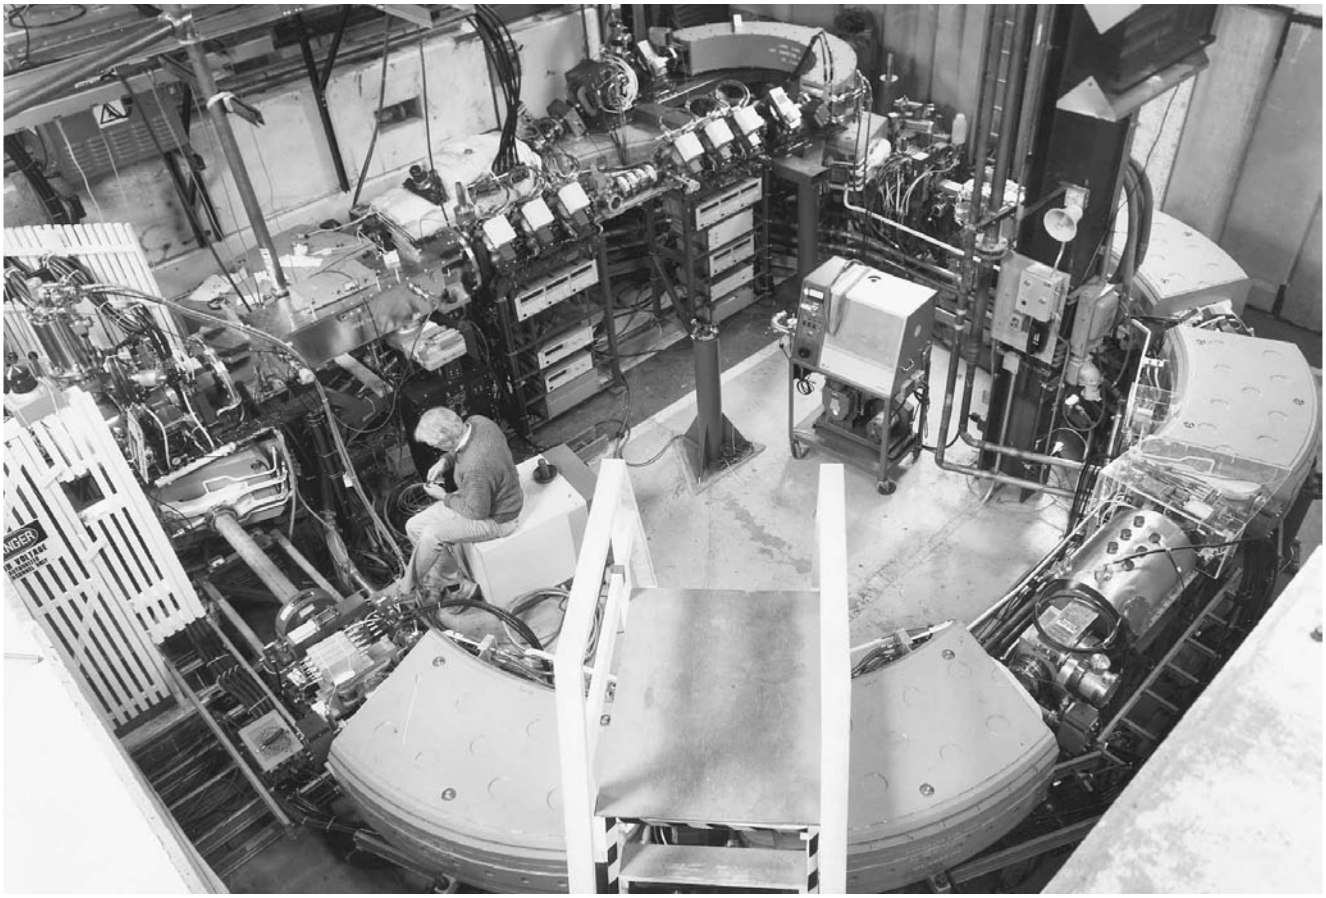
PARTICLE ACCELERATORS

A particle accelerator is a device that accelerates charged particles—such as atomic nuclei and electrons—to high speeds, giving them a large amount of kinetic energy. The most powerful accelerators give particles speeds almost as great as the speed of light in a vacuum (300,000 kilometers per second), which is a limiting speed that electrons and nuclei can approach but cannot reach.

If a particle is moving much slower than the speed of light, for example, one-tenth the speed of light, then its kinetic energy is proportional to the square of its speed, in accordance with Newtonian mechanics. For example, if an accelerator quadruples the kinetic energy of a slowly moving particle, its speed doubles. However, if the particle is already traveling fast, for example, at 90 percent of the speed of light, and the accelerator quadruples the kinetic energy of the particle, then the speed cannot double, or the particle would go faster than the speed of light. In this case, one has to use Einstein's more general formula for the relation between speed and kinetic energy, according to which the speed goes from 90 percent of the speed of light to a little under 99 percent. No matter how much the kinetic energy of the particle is increased by the accelerator, the particle still will travel slower than light. If the particle is traveling at 99 percent of the speed of light, no matter how much energy it is given, its speed can only increase by about 1 percent. For this reason, powerful accelerators are really particle energy boosters and not speed boosters.



Fermilab designed and built the proton therapy accelerator as the first proton accelerator specifically for the treatment of cancer. (U.S. Department of Energy)

ACCELERATOR PHYSICS

The basic unit of energy used in accelerator physics is the electron volt (eV), which is the energy acquired by an electron when accelerated through a potential difference of one volt. An electron volt is a very small unit compared to an energy unit such as a food calorie (kilocalorie). A kilocalorie is about 26 billion trillion times as large as an eV. Common multiples of eV are MeV (million eV), GeV (billion eV), and TeV (trillion eV).

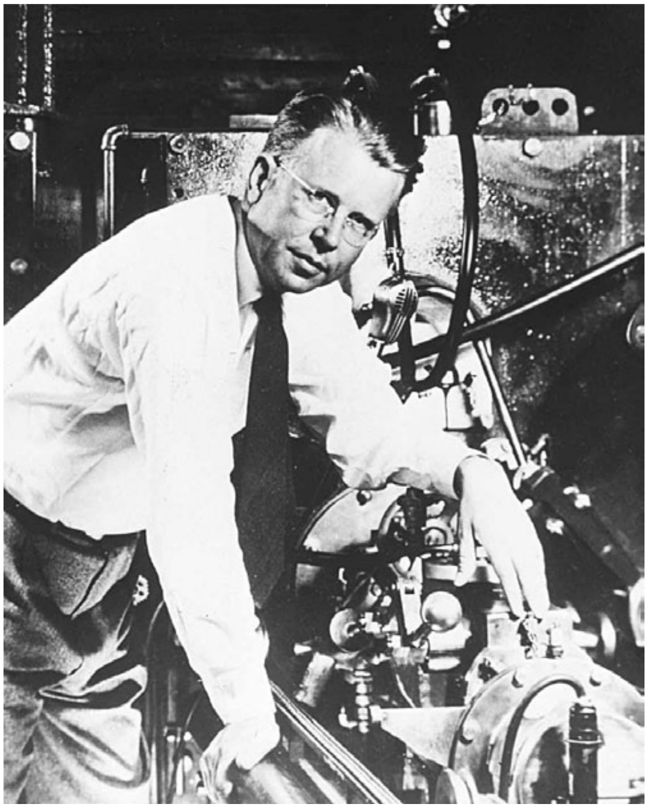
It is instructive to compare the kinetic energy acquired by a particle to its rest energy. If an airplane travels at 1000 kilometers per hour, its rest energy is more than 2 million million (2 (10^{12})) times its kinetic energy. In contrast, the highest energy electron accelerator gives an electron a kinetic energy almost 200,000 times its rest energy. The speed of such an electron is very nearly equal to the speed of light. If a burst of light and a 100 GeV electron leave a distant star at the same time, and it takes the light 2,500 years to reach the Earth, the electron will reach the earth about one second later.

The main reason particle accelerators were invented and developed is so that scientists can observe what happens when beams of particles strike ordinary matter. However, particle accelerators are also used in a wide variety of applications, such as irradiating cancers in people.

HISTORY

The development of particle accelerators grew out of the discovery of radioactivity in uranium by Henri Becquerel in Paris in 1896. Some years later, due to the work of Ernest Rutherford and others, it was found that the radioactivity discovered by Becquerel was the emission of particles with kinetic energies of several MeV from uranium nuclei. Research using the emitted particles began shortly thereafter. It was soon realized that if scientists were to learn more about the properties of subatomic particles, they had to be accelerated to energies greater than those attained in natural radioactivity.

The first particle accelerator was built in 1930 by John Cockroft and Ernest Walton. With it, they succeeded in accelerating protons (hydrogen nuclei) by means of a high-voltage source. The protons reached an energy of 300,000 eV. The following year Robert Van de Graaff succeeded in obtaining a high voltage by means of a charged moving belt. Subsequently, accelerators of the Van de Graaff type accelerated particles to more than 10 MeV.



Ernest Lawrence with cyclotron. (Corbis Corporation)

The Cockroft–Walton and Van de Graaff accelerators are linear; that is, they accelerate particles in a straight line. A short time later Ernest Lawrence got the idea to build a circular accelerator, called a cyclotron, and with the help of M. Stanley Livingston he constructed it in 1932. This first cyclotron accelerated protons to about 4 MeV. Since then, many other cyclotrons have been built, and they have been used to accelerate particles to more than 50 times as much kinetic energy as the original one. Also, other kinds of circular accelerators, such as synchrotrons, have been constructed.

OPERATION

The principle of a circular accelerator is that forces from properly arranged electromagnets cause the charged particles of the beam to move in circles, while properly arranged electrical forces boost the energy of the particles each time they go around. The radius of the circle depends on the mass and speed of

1. The first accelerator, built by J.D. Cockroft and E.T. Walton in 1930 at the Cavendish Laboratory of the University of Cambridge, England, accelerated protons to an energy of 300,000 electron volts (eV). At this energy, the protons have a speed of about 7,600 kilometers per second, and are traveling about 2.5% of the speed of light. The first circular accelerator, or cyclotron, was built by Ernest Lawrence with the help of M. Stanley Livingston in 1932 at the University of California in Berkeley.
2. The highest energy accelerator in existence today, the Tevatron, is at the Fermi National Accelerator Laboratory, located west of Chicago. It accelerates both protons and antiprotons to an energy of about 1 trillion electron volts (TeV). At this energy, the protons and antiprotons have a speed almost as great as the speed of light, which is 300,000 kilometers per second. The difference in speed is only about one part in 2 million.
3. The Large Hadron Collider is an accelerator scheduled for completion in the year 2005 at the CERN laboratory near Geneva Switzerland. It will accelerate protons to an energy of 8 TeV. At that energy, the protons will have a speed only about one part in 130 million slower than the speed of light.
4. Accelerators are responsible for many fundamental discoveries as well as many practical applications. An example of a fundamental discovery was the observation of the W and Z particles that carry the weak force that is responsible, along with the strong and electromagnetic forces, for the fact that the sun shines. An example of a practical application is the use of accelerator beams to kill cancerous tumors in patients.
5. In the coming decades, by colliding particles at ever greater energies, physicists hope to discover what causes mass to exist.

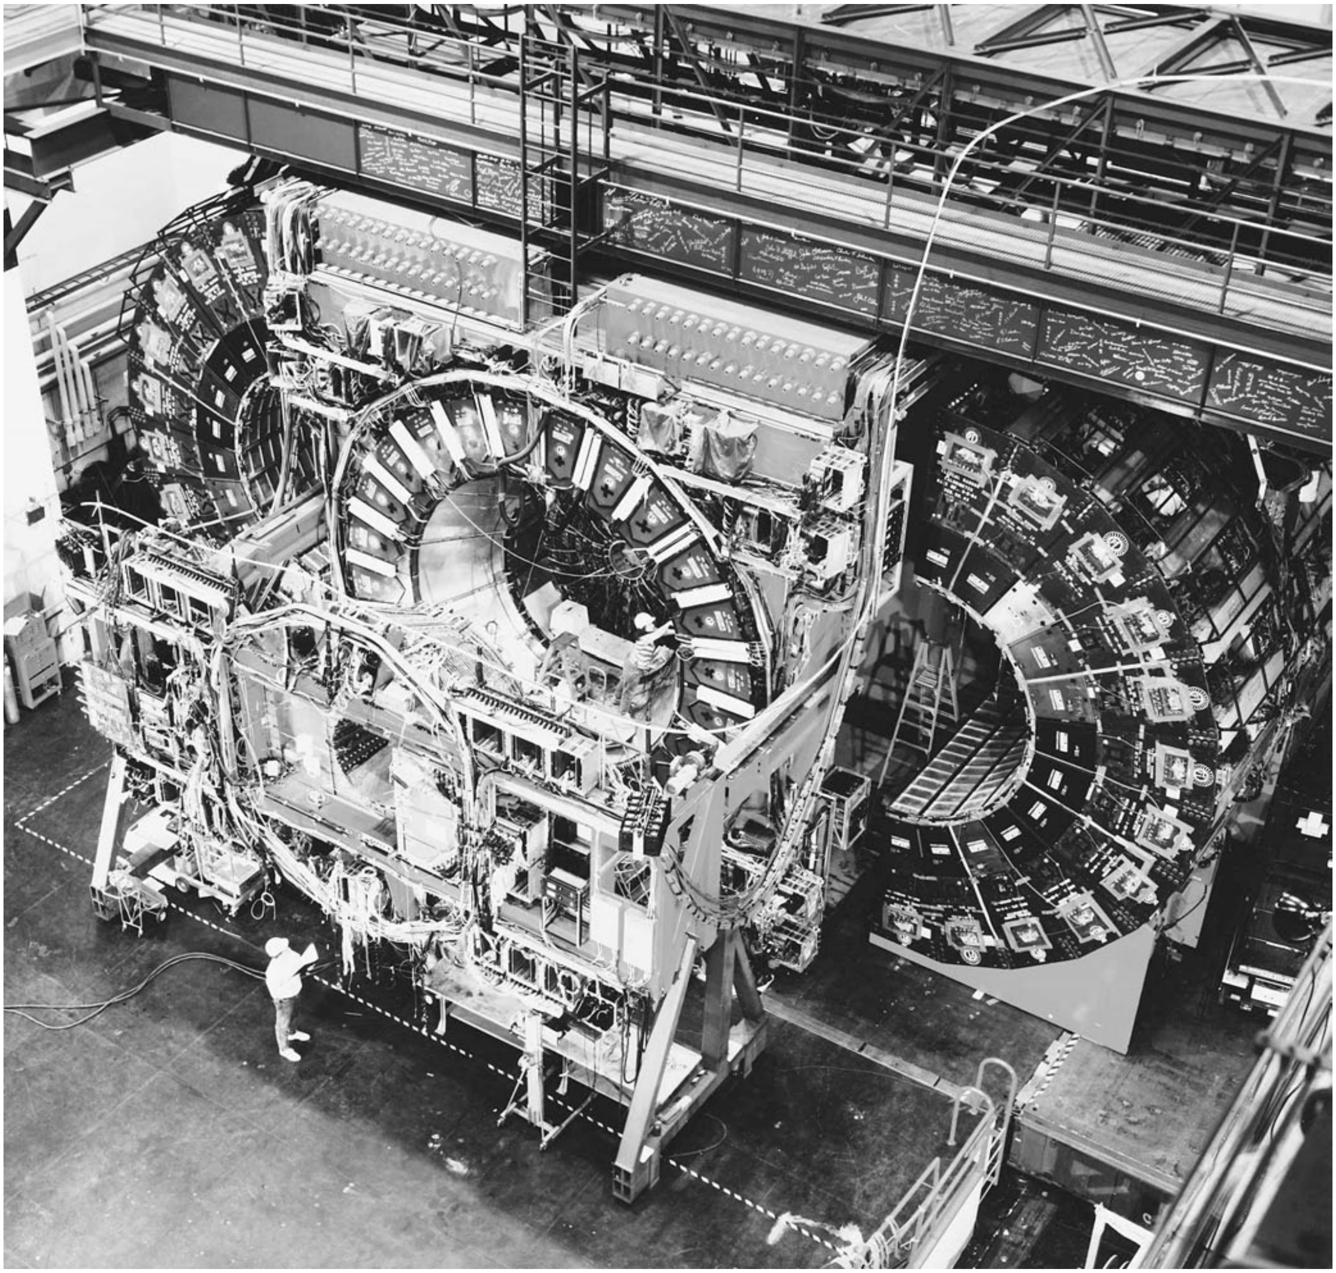
the particle and on the strength of the magnetic forces. In a cyclotron, the magnetic forces are kept constant, and as the particles gain energy they spiral outward into larger and larger circles. In a synchrotron, as the particles gain energy the magnetic forces are increased enough to keep the particles going around in the same circle.

After a beam of particles is accelerated to its final energy, it can be made to strike atoms in a target fixed in space or else collide with particles in a high–energy beam traveling in the opposite direction. Accelerators with two beams going in opposite directions are called colliders. In all particle accelerators, the particles move in an enclosed region from which nearly all the air has been removed. Otherwise, too many of the particles in the beam would collide with the molecules of air rather than with the target.

If subatomic particles moving at speeds close to the speed of light collide with nuclei and electrons, new phenomena take place that do not occur in collisions of these particles at slow speeds. For example, in a collision some of the kinetic energy of the moving particles can create new particles that are not contained in ordinary matter. Some of these created particles, such as antiparticles of the proton and electron, can themselves be accelerated and made to collide with ordinary matter.

If one wants to achieve the highest possible energy, the accelerator of choice is a collider. If two particles moving in opposite directions with the same kinetic energy collide with each other, the total kinetic energy of both particles is available to create new particles. On the other hand, when a beam strikes a stationary target, the law of conservation of momentum requires that the struck particle and any created particles carry off the same total momentum as the particle in the beam initially had. This fact requires the final particles to have significant kinetic energy—energy that cannot be used to create additional particles.

The highest energy accelerators in existence are synchrotron colliders. The one with the highest energy is called the Tevatron, and is located at the Fermi Accelerator Laboratory near Chicago. Each beam has an energy of about a TeV (hence the name), about 250,000 times the energy achieved in Lawrence's first cyclotron. The Tevatron accelerates protons in one beam and antiprotons (antiparticles of the proton) in the other beam. The antiprotons are accelerated after being created in collisions of protons with a target. The Tevatron is about six kilometers in circumfer-



The Collider Detector at Fermi National Accelerator Laboratory, home of the Tevatron. (Corbis Corporation)

ence and gives both protons and antiprotons kinetic energies of about 1,000 times their rest energies.

When an electrically charged particle is accelerated, it radiates electromagnetic energy. The higher the energy of the particle, the more energy it radiates, and, for a given energy, the smaller the mass of the particle and the smaller the radius of the circle in which it goes, the more energy it radiates. In a synchrotron, the particles go around the accelerator thousands of times, each time radiating electromagnetic energy, appropriately called synchrotron radiation.

Synchrotron radiation is not a serious problem for proton synchrotrons, but it is for high energy electron synchrotons because the mass of the electron is only about one two-thousandth as large as the mass of the proton. For this reason, a high-energy electron synchrotron has to have a large circumference or it wil radiate too much power to be economically useful. The largest electron synchrotron is located at the European Laboratory for Nuclear Research (CERN) near Geneva, Switzerland, and partly in France. Sited in an underground tunnel, it has a circumference of 27 kilometers. It gives electrons kinetic energies of about 100 GeV or 200,000 times their rest energy. After attaining this energy, the beam of electrons is made to collide with an equally energetic beam of positrons (antiparticles of electrons) going in the opposite direction.

SYNCHROTON RADIATION

If the object of a synchrotron is to accelerate electrons to the highest possible energy, synchrotron radiation is a serious obstacle that limits the energy attainable. On the other hand, the electromagnetic radiation from a synchrotron can be useful for experiments on the properties of solids and for other purposes. For this reason, some electron synchrotrons are built primarily for the synchrotron radiation they emit.

To avoid the problem of synchrotron radiation, linear electron accelerators have been built. The principle of acceleration is not a static voltage, as in the Cockroft–Walton and Van de Graaff accelerators, but a traveling electromagnetic wave that has the right phase to accelerate the electrons as they travel inside a long straight tube. The longest linear accelerator is located in California at the Stanford Linear Accelerator Center. It is two miles long and accelerates electrons and positrons to an energy of about 50 GeV, after which they are made to collide.

The 27-kilometer tunnel of the CERN laboratory also houses a proton collider that is scheduled for operation beginning in the year 2005. This collider will be the highest energy accelerator in the world, with the protons in each beam attaining energies of about 8 TeV, which is about 8000 times the rest energies of the protons. Although so far, electron synchrotrons have achieved electron kinetic energies that are the highest multiple of their rest energies, proton synchrotons, which are less limited by synchroton radiation, have achieved the highest actual particle energies.

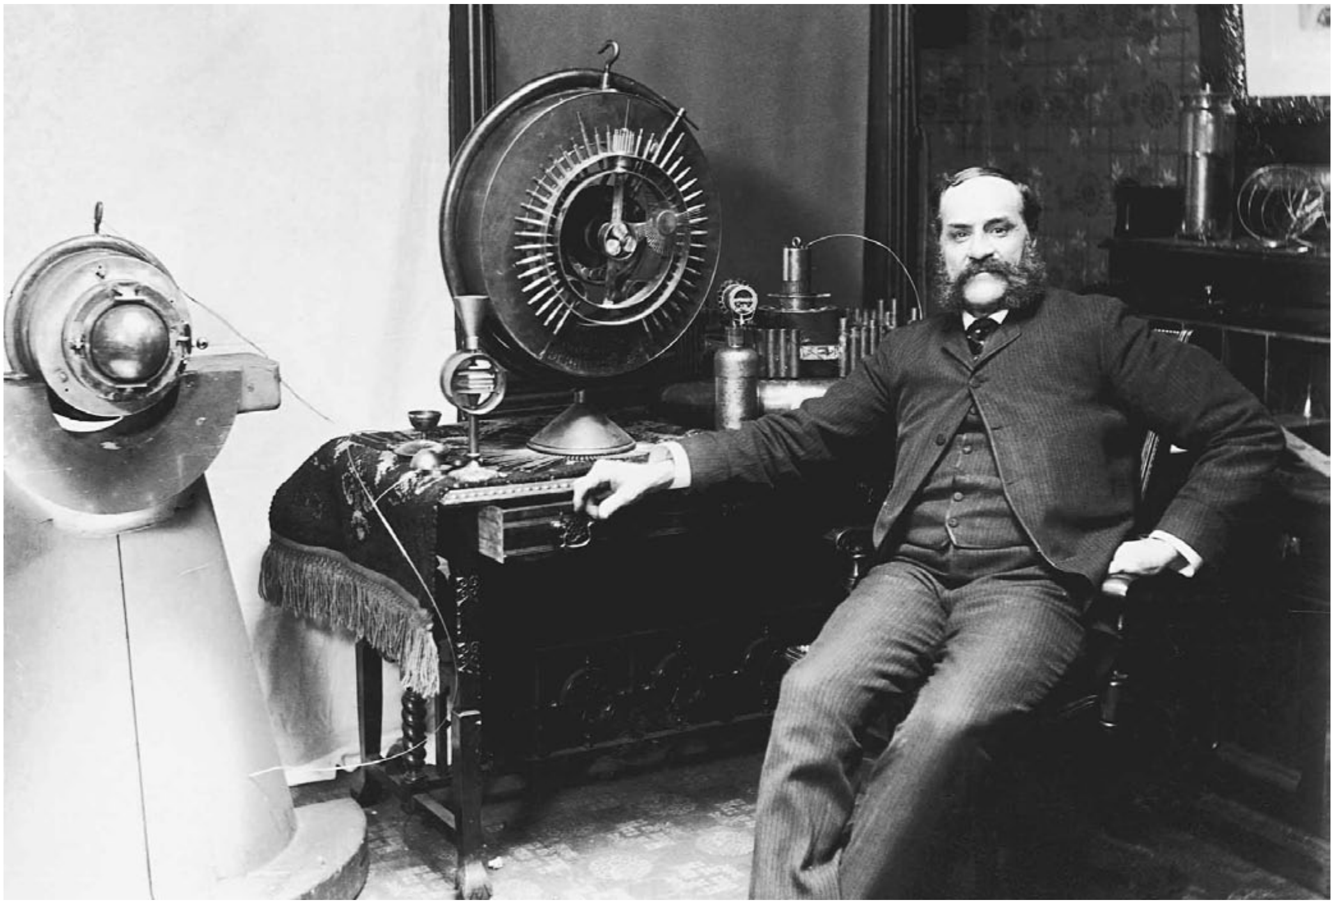
PEAK LOAD MANAGEMENT

See: Electric Power, Generation of

PERPETUAL MOTION

The idea of perpetual motion, which has been around for centuries, is to make a device that will produce more work output than the energy input—in short, to get something for nothing. Robert Fludd in 1618 was one of the first to discover it is impossible to get something for nothing. He designed a pump to drive some of the output from a water wheel to recirculate water upstream, which would then run over the wheel again. The remaining portion of the output could then be used to operate a flour mill. The only problem with this device is that it took more energy to pump the water than the entire energy output of the water wheel. Friction will always cause such a water wheel to "grind" to a halt even in the absence of doing useful work.

Would-be inventors frequently employ magnetic or electrostatic interactions because these forces are less understood (by them). For instance, a weight can be lifted by a magnetic field, perhaps produced by a superconducting magnet, with no power loss. Then, when the magnetic field is turned off or taken away, the falling weight can be harnessed to do useful work. The magnet can continually lift and drop the weight. The details can be quite complicated, but when any design is correctly analyzed it is always found that the energy required to turn the magnetic or electric field on and off, or to move the field from place, to place exceeds the work obtained by the falling weight. The first perpetual motion device using magnetic forces



John W. Keely (1827–1898) seated next to what he claimed was the first perpetual motion machine. It was proved to be a fake, but not until after he died. (Corbis Corporation)

was proposed by John Wilkins in the 1670s. Wilkins proposed using the magnetic material lodestone, not a superconducting magnet.

To prove that a particular design of a perpetual motion machine will not work can be very time consuming, and the predictable negative result has never been worth the effort. Therefore, the U.S. Patent Office has a policy to not examine applications covering perpetual motion machines unless the applicant furnishes a working model.

The nonexistence of perpetual motion machines, despite centuries of effort to design them, has been used to support the law of conservation of energy. This law is based, however, not on this negative result, but on all the experiments performed to date in which energy is carefully accounted for. It has never been observed to fail. This law is, therefore, a good basis from which to analyze perpetual motion machines. It clearly states that the goal of getting more energy output than the energy input is impossible. It also gives a basis for considering another lesser goal of perpetual motion, which is to produce a device that will run forever with no further external inputs.

There are many systems in nature that for practical purposes are perpetual. The rotation of the Earth does not change perceptibly in any person's lifetime. Very careful measurements can detect such changes, and they are predictable based on the tidal interaction with the sun and the moon. At the current rate of decrease, the Earth's rotation relative to the Sun would stop in 5.4 billion years. Systems that are unchanging for practical purposes, but which are running down ever so slowly, do not count as perpetual motion.

There are clocks that do not need winding or battery replacement. They run by taking advantage of small changes in atmospheric pressure or the movement, or by utilizing solar cells. These do not count as perpetual motion either because they use the flow of energy from other sources to maintain their motion.

The electrons of atoms in their ground state are in perpetual motion. Also, in a gas, each atom has an average kinetic energy (motion) depending on the temperature of the gas. These motions don't count either because humans demand something on their own scale that they can see or take advantage of before they consider it as true perpetual motion.

Perpetual motion itself would not defy the conservation of energy. A pendulum swinging forever at the same amplitude does not change its energy. However, energy comes in several different forms and it is impossible to keep a system in a single energy mode because of all the possible interactions with the environment.

The pendulum, for instance, will encounter air resistance, transforming its kinetic energy into random motion or heat in the air. If the pendulum were mounted in a vacuum, it would swing for a longer period of time, but any friction in the support would eventually bring it to rest. Suppose that the support could be made absolutely frictionless, would that do it? Again, no, because as the pendulum moves back and forth in the light of the room, the light pressure is greater as the pendulum moves toward the light than it is when it moves away. The light itself will slow and eventually stop the pendulum. Suppose the frictionless pendulum were mounted in a dark vacuum? That still would not do it, because the heat (infrared) radiation from the walls of the chamber will slow the pendulum the same way as the light does. The frictionless pendulum mounted in a dark vacuum chamber at absolute zero might do it if the small tidal effects gravitational interaction of the moving pendulum with the surroundings (including the Earth) could be neglected, which they cannot. Without gravitational interaction, the pendulum would not swing downward. If true perpetual motion is pursued, no interaction, no matter how small, can be neglected.

The consideration of the simple pendulum illustrates the basic problem behind devising a perpetual motion machine. The problem is the fact that energy exists in several forms and is transformed from one form to the other, especially when motion is involved. Even if friction is eliminated, there are still the electromagnetic radiation and gravitational interactions which, given the present understanding of physics, would be impossible to eliminate.

Since transformation of energy from form to form is inevitable, what about devising a system that will just pass the energy around and thus keep going forever? The problem with such a device is more subtle. It involves the second law of thermodynamics. Once the energy of a pendulum swinging in air, for example, is transferred as heat to the air, there is no way to transfer all of the heat energy back to the kinetic energy of the pendulum. According to the second law, some energy could be returned to the pendulum, but not all of it. Gradually, even with a perfect heat engine (Carnot cycle or Stirling cycle) operating to restore energy to the motion of the pendulum, its swinging would eventually die away.

There would remain some very small residual motion of the pendulum due to the air molecules striking it at random (Brownian motion), but that does not count in the "game" of perpetual motion. In the condition of residual motion, the pendulum is just another (big) molecule sharing equally in the average kinetic energy of all the individual air molecules. In other words, the pendulum eventually comes to thermal equilibrium with the air.

One statement of the second law of thermodynamics is that there is a tendency in nature for an isolated system (no external inputs) to move toward conditions that are statistically more probable (higher entropy). For the swinging pendulum, given a certain energy, there is only one amplitude at which it can swing. That is, there is only one way the pendulum can have this energy. When this energy is transformed as heat to the air, there are almost an infinite number of ways for the air molecules to contain the same energy. The swinging pendulum mode is just one mode out of many for the energy to exist in the system. Thermodynamics does not predict that all the energy can never return to the swinging mode; it just states that in the foreseeable duration of the universe it is not likely to happen because there are so many other possibilities.

Similar considerations apply to all other schemes to produce perpetual motion. No matter how it is designed, an isolated system will always tend toward a condition of thermal equilibrium, which never involves motion of objects on a human scale, and is thus not "perpetual motion."

PETROLEUM CONSUMPTION

NATURE OF PETROLEUM

Crude oil generally appears as a dark-colored liquid. It is found underground under pressure and therefore wells must be drilled in order to bring it to the surface. Part of the crude oil is in the form of a gas. The latter separates out from the oil upon reaching the lower surface pressures, and is commonly referred to as natural gas.

Structurally, oil is made up of hydrocarbon molecules containing various combinations of carbon and hydrogen. The configurations of these molecules depend on the number and arrangement of the carbon atoms. These may be linked in straight chains, branched chains, and circular, or ring formation. With respect to molecular weight, the lighter molecules (fewer than 4 carbon atoms) tend to be gases; the medium weight molecules compose liquids; and the heavier (15 or more carbon atoms) are heavy liquids and solids.

Hydrocarbons are segmented into a variety of categories. Each category possesses a distinct molecular profile and, in turn, set of chemical and physical properties. Each class of hydrocarbons therefore has historically served different markets. Crude petroleum is composed of four major hydrocarbon groups: paraffins, olefins, naphthenes, and aromatics.

The paraffins are saturated hydrocarbons with formula $C^nH^{(zn+z)}$. All possible positions on the carbon atoms that can combine with other atoms are occupied by hydrogen, and paraffins are chemically inactive under a wide range of conditions.

There are two major types of paraffin molecules found in crude oil: "normal" paraffins are those with straight or linear carbon chains; "iso-" paraffins are branched (i.e., portions of the molecule that are attached at angles to the main, linear chain). The former tend to lower the octane number of gasoline resulting in engine knock. Because of their superior burning properties, they are desirable components of diesel fuel, kerosene, and fuel oils. Compared to the normal paraffins, the iso-paraffins are selected for use in automotive and aviation fuel due to the high octane numbers they impart to gasolines.

In contrast to the paraffin group, the olefins are unsaturated compounds. Simple olefins (mono-olefins) contain a single double bond [-c=c-] with formula, C^nH^{zn}. Thus, all available positions around the carbon atoms are not occupied by hydrogen, and olefins are far more reactive than the paraffins. The "di-" olefins $C^nH^{(zn-z)}$ contain two double bonds between carbon atoms. These bonds break apart readily resulting in a highly unstable intermediate that can combine easily with other molecular types. Diolefins have a low octane number and tend to produce gummy materials that affect combustion and foul surfaces. In contrast, the mono-olefins have a high octane number and, with only a single double bond in a molecule, are stable enough to prevent the rapid buildup of gum-like residues.

The naphthenes and aromatics both have cyclic (or ring-like) molecular structures and both possess high octane numbers. Napthenes are saturated and aromatics contain alternate double bonds on their ring. They are typically found in gasoline. The naphthenes also are an important part of kerosene.

In addition to the above hydrocarbon groups, crude oil also contains a number of inorganics, including sulfur, nitrogen, oxygen, metals, and mineral salts. Not all crudes are the same. They differ in average molecular weight (boiling point, viscosity) and composition according to the geographical locations at which they are found.

PRODUCTS AND MARKETS OF CRUDE OIL

Crude oil is the source for over 3,000 petroleum-based products for both industrial and consumer applications. The technique of distillation, the first stage processing of petroleum, exploits the different boiling points of the various petroleum fractions to separate out and isolate for use the different portions of the crude. The type and proportions of hydrocarbons present in each fraction depends upon the type of crude oil used and the range of temperatures employed. The major products produced directly from crude oil from distillation processes include gasoline, kerosene, lubricants, and waxes.

These various fractions are processed further into additional products. These value-added operations generally involve chemical transformations often using catalysts. They include cracking, hydrogenation, reforming, isomerization, and polymerization. The main output from these processes is fuels and petrochemicals.

Gasoline has been the primary product extracted from petroleum since the 1920s. The major portion of the gasoline group used for automotive and aviation purposes is cracked gasoline obtained through the thermal or catalytic cracking of the heavier oil fractions (e.g., gas oil). A wide variety of gasoline types are made by mixing straight run gasoline (gasoline obtained through distillation of crude oil), cracked gasoline, reformed and polymerized gasolines with additives, such as tetraethyl lead, alcohols, and ethers.

Kerosene is heavier than gasoline and lighter than gas oil. The lighter portion of kerosene is most suitable as an illuminant for lamps. The heavier portions of kerosene traditionally have been used as stove oil. Since the 1950s, kerosene has been used as a major component in jet fuel.

Gas oil, which is heavier than kerosene, is the raw material of choice in cracking and other refinery operations. Cracking of gas oil produces a variety of fuels for automotive, industrial, and domestic (furnace) use.

The heaviest products obtained directly from oil are lubricants, waxes, asphalt, and coke. These products have both domestic and industrial uses. Lubricants, for example, are applied in the operation and maintenance of industrial equipment and machinery. Asphalt, because it is not reactive to chemicals in the environment, is a superb material of construction in the building of roads and in roofing. It is also used in the waterproofing of concrete, the manufacture of black paints, and as a material for tire threads, battery housing, electrical insulation, and other applications. The heaviest of all the petroleum products, coke, is used extensively as a major component of industrial electrodes and as a commercial fuel.

PRODUCTION PATTERNS

United States

Between the 1860s and the mid-1880s, the bulk of petroleum crude came form Pennsylvania, particularly the area near Pittsburgh. This oil, which had a high paraffin content and low level of impurities, could be readily distilled into illuminant products and lubricants.

After 1885, oil production moved into the Midwest, chiefly Ohio and Indiana. While these fields held large amounts of oil, compared to Pennsylvania, the crude was of an inferior grade. It had both a high asphalt and sulfur content. The former reduced its use as an illuminant; and the high sulfur content created a foul smell that made it unsuitable for domestic consumption. At the turn of the century, the Standard Oil Trust, adopting a new type of separations technology, was able to remove the sulfur from "sour" crude and produce commercially usable "sweet" fuel products, including kerosene.

By 1900, other products from petroleum began to take on importance. Lubricants especially became prominent. This was due to the growth of industrialization in the United States, a shortage of naturally occurring lubricants (e.g., vegetable and whale oils), and an intense and creative marketing effort on the part of Rockefeller and his Standard Oil Trust. By 1910, Standard Oil Trust was also marketing coke and asphalt to a variety of manufacturers as well as the construction industry.

During the period 1900 and 1919, there was tremendous growth in U.S. oil production. Geographically, oil production also underwent important changes. In 1900, total annual U.S. oil production reached 63.6 million barrels. By this time, major production had shifted from the Northeast to the Appalachian region and the Midwest, and in particular the famous Lima-Indiana fields. In 1900, these areas together produced over 91 percent of total U.S. oil.

By 1920, total U.S. oil production had grown seven-fold, to 442.9 million barrels. The Appalachian and Lima-Indiana fields no longer dominated oil production: in 1920, in aggregate, they accounted for less than 8 percent of total production. Now the mid-continental fields of Louisiana and Oklahoma represented over 56 percent of U.S. output. California also had grown rapidly as an oil producing region accounting for nearly a quarter of all U.S. oil production. With the opening of the Spindle Top fields in Texas, this period also saw the beginning of oil producing dominance in the Gulf states. In 1920, this region already drilled more than 6 percent of all U.S. oil. The Rocky Mountain region and Illinois also increased their status as oil producing areas; together they also accounted for over 6 percent of total U.S. oil output.

Over the next two decades, oil production within the United States continued a generally upward path as producers discovered new fields and worked established fields more intensely. By 1929, total U.S. oil output exceeded the one billion barrel per year level. Despite the Depression, and in part due to the still growing demand for automotive gasoline, oil production grew over 39 percent over the following twelve years, topping off at over 1.4 billion barrels in 1941.

At this time, the four important producing areas were the mid-continental states, The Gulf region, California, and Illinois. The Mid-Continental states continued to generate over 50 percent of the nation's oil. But its share had fallen from 1920 levels, from over 56 percent to about 51 percent. California too had seen a decline in its share, from about 24 percent to 16 percent. The fastest growing area was the Gulf region: between 1920 and 1941, its share of U.S. oil production had climbed from 6 percent to 16 percent.

Annual domestic crude oil production expanded over 50 percent between 1945 and 1959, from 1.7 billion barrels annually to almost 2.6 billion, induced by a rise in domestic oil prices. During this period, Texas was the largest single producing state followed by California, and Louisiana. These states combined accounted for 60 to 80 percent of total domestic production through the period. There was also a resurgence of production in Illinois and Kansas, and the emergence of new fields in Colorado, New Mexico, and Wyoming.

Overall, U.S. oil production continued to climb through the 1960s as the Gulf, Mid-Continental, and West Coast fields were more actively exploited. In particular, drilling went deeper and off-shore sites were mined to a greater extent than previously. By 1973, U.S. producers were shipping about 3.4 billion barrels of oil annually. A major shift in oil production came in the 1970s with the construction of the Alaskan pipeline. By the late 1980s Alaska accounted for well over 10 percent of U.S.-produced crude. By the end of the 1990s, this figure had risen to close to 19 percent, or about one-fifth of total U.S. oil production.

But overall there was a steady contraction in domestic production during the 1970s and 1980s. This unprecedented decline was the result of increasing imports of foreign oil, especially from the Middle East, Venezuela, and Mexico, and fluctuations in the price of crude worldwide, largely due to OPEC policies. By 1983, U.S. production had declined to 3.2 billion barrels per year.

The tail end of the century has seen a continued decline in U.S. oil production as a result of the precipitous fall in prices. In 1997, U.S. production stood at only 2.3 billion barrels, or less than 1959 production volume. This declining petroleum activity has continued from 1997 to early 1999, during which period the number of rotary oil drillingrigs fell from 371 to 111.

The fact remains however that the United States still has considerable untapped supplies of petroleum. It is estimated that total remaining recoverable U.S. oil from all sources may exceed 200 billion barrels, or about 70 years worth of energy, assuming the current rate of U.S. consumption. During the first decade of the twenty-first century, producers will be extracting more oil from such regions as the Gulf of Mexico and other redundant off-shore sites. Employing new types of alloys in their equipment, they will also be drilling deeper into the ground to reach more corrosive high sulfur crudes and other previously untouched reserves.

International

As the automobile came to control the market for fossil fuel, the United States increasingly dominated world oil production. From the end of the nineteenth century to the World War I period, U.S. share of world oil production grew from around 40 percent to over 70 percent. By the early 1920s, there were other oil-producing powers, notably Mexico and Russia, although they could not compete with the United States in the production and processing of petroleum.

Over the next twenty years, world production rose from nearly 1.4 billion barrels per year to over 2 billion barrels. Foreign countries greatly increased their production and refining capability. Between 1929 and 1941, U.S. exports of petroleum abroad declined (although Canada remained the leading foreign consumer of American oil). During this period, foreign production increased its world share from 34 percent to 41 percent.

This growth resulted from additional countries entering as major producers of petroleum. By 1941, Venezuela was producing over one-half of the crude oil extracted in the Western Hemisphere. During this period as well, the Middle and Near East first began to flex its muscles as an oil producing region. Iran, Iraq, the Bahrain Islands, and Saudi Arabia were the major oil-producing countries in the region. As a whole, by the end of World War II, the region supplied about 13 percent of the total world production. Middle East oil wells tend to be much more economical than those in North America. There are fewer dry holes, and each mideast well produces on average ten times the volume of a U.S. well.

Following the war, there was a steady increase in imports into the United States relative to total supply. During this period, the U.S. share of world oil production declined from 60 percent to 40 percent (1959). Crude oil imports as a percentage of total crude oil going to refineries increased from about 5 percent to 12 percent and the U.S. industry for the first time shifted its position from a net exporter to a net importer of mineral oils. At the same time, U.S. companies were establishing a strong presence abroad. Indeed, much of the oil produced abroad and imported into the United States at that time was owned by American-based companies.

Petroleum imports into the United States have continued to increase through the 1970s, 1980s, and 1990s. In terms of energy content, between 1970 and 1996, the energy contained in petroleum imported into the United States almost tripled, from 7.47 to 20.1 quadrillion Btus. Between 1970 and 1997, the Middle East countries in particular have greatly expanded their imports into the United States, from 222 million barrels to 1,349 million barrels. By the latter half of the 1990s, imports as a percentage of total domestic petroleum deliveries had reached the 50 to 60 percent level.

It is believed that world reserves may total 2 trillion barrels. This represents sufficient energy to last at the least to the end of the twenty-first century. Oil production worldwide is on the rise. Both Canada and Mexico have been expanding production. Brazil is becoming an important oil producing center. In Eastern Europe, and especially Romania, new oil is being drilled in and around the Black Sea. The former Soviet Union, especially in and around the Caspian Sea, has access to one of the world's richest oil reserves. Southeast Asia, especially Indonesia and Malaysia, are extending their petroleum production and processing capabilities. Western Europe is working regions of the North Sea. Other promising oil-producing countries include Australia, India, Pakistan, China (off-shore), and parts of the West Coast of Africa.

U.S. CONSUMPTION PATTERNS

The Nineteenth Century

From the late 1850s to the turn of the century, the major interest in petroleum was as a source of kerosene, as both a fuel and illuminant. As early as the 1820s, it was generally known from chemical experiments that illuminants, heating fuels, and lubricants could be obtained relatively cheaply from the distillation of crude oil.

In the 1840s, America's first petroleum reservoir was discovered in Tarentum, Pennsylvania. By the late 1850s, lubricants and kerosene were being extracted commercially from crude oil.

At this time, the petroleum industry was still a small scale affair and largely decentralized: production, transportation, refining, and distribution of refined products were undertaken by separate companies. Periods of overcapacity caused price declines that cut deep into the profits of producers. In the last two decades of the nineteenth century, John D. Rockefeller imposed order on the industry by building a fully integrated corporation: The Standard Oil Trust.

The Early Twentieth Century: 1900–1920

The period 1900 to 1919 set the stage for the takeoff of oil as a major energy source. The four main products for consumption extracted from petroleum were naphtha and gasoline, illuminating oil, lubricating oil, and fuel oil. During these years demand for these products increased in the wake of significant increases in the auto population, especially in the urban areas, growing industrialization, and an expanding national income.

Thus we find that between 1900 and 1919, total energy consumption more than doubled from 7,529 trillion Btus to 18,709 Btus and the percentage of total energy consumed in the United States in the form of oil increased from less than 5 percent to about 12 percent. On the other hand, the trend for coal was downward as its percentage of total energy dropped from over 89 percent to 78 percent.

Use for the various petroleum products grew at different rates. The expansion in consumption of fuel oil production was an important trend. Increasingly, fuel oil, due to its lower price, more complete consumption, and relative ease of transport, became the fuel of choice over coal in industrial, commercial, and residential facilities as well as a fuel in rail and ship transport. During these years, fuel oil output showed the greatest increase, nearly 2,387 percent, from 7.3 million barrels to 180.3 million barrels.

Even more important was the growing importance of gasoline. At the turn of the century, virtually all of the gasoline produced (6.2 million barrels) was used as a solvent by industry (including chemical and metallurgical plants and dry cleaning establishments). But by 1919, 85 percent of the 87.5 million barrels of gasoline produced went into the internal combustion engine to power automobiles, trucks, tractors, and motor boats. During this period, production of gasolines grew from 6.7 million barrels to 97.8 million barrels.

At the same time gasoline was finding its first large markets, kerosene was in the fight of its life with the burgeoning electrical power industry. (The temporary exception occurred in the rural areas without access to electricity.) Not surprisingly, gasoline and kerosene exhibited a widening price differential: between 1899 and 1919, the per gallon price for gasoline exceeded that for kerosene and the price differential grew over 86 percent, from 1.3 cents to 12.3 cents. Overall, production of Illuminating oil increased from 29.5 million barrels to 56.7 million barrels.

With respect to the various byproducts of petroleum, including paraffin wax and candles, lubricating jellies, asphalt, and coke, total value of this group grew 543 percent, from $12.3 million to $79.1 million. But this good performance would be the last major growth for the group. The one exception was asphalt which would continue in demand as a material of choice for the highway and roofing construction industry. By 1920, more than 1.3 million tons of the substance entered the market, up from the 44,000 tons produced annually at the turn of the century.

The 1920s and 1930s

Over the next ten years (1919–1929), U.S. annual energy demand grew from nearly 18.7 to 25.4 quadrillions Btus. The percentage of energy represented by petroleum increased from a little over 12 percent to 25 percent. Natural gas also nearly doubled its share, from 4.3 perent to 8 percent. Coal continued to lose ground as a source of energy, from 78 percent to 63 percent of total energy consumption.

With respect to petroleum products, during the 1920s, the amount of kerosene placed on the market remained unchanged at close to 56 million barrels annually for the period, and lubricant output increased somewhat, from 20.2 to 35.6 million barrels. Production of both gasoline and fuel oil outpaced all other petroleum products in growth. For example, output of fuel oil increased two and one half times, from near 182 million barrels to close to 449 million barrels.

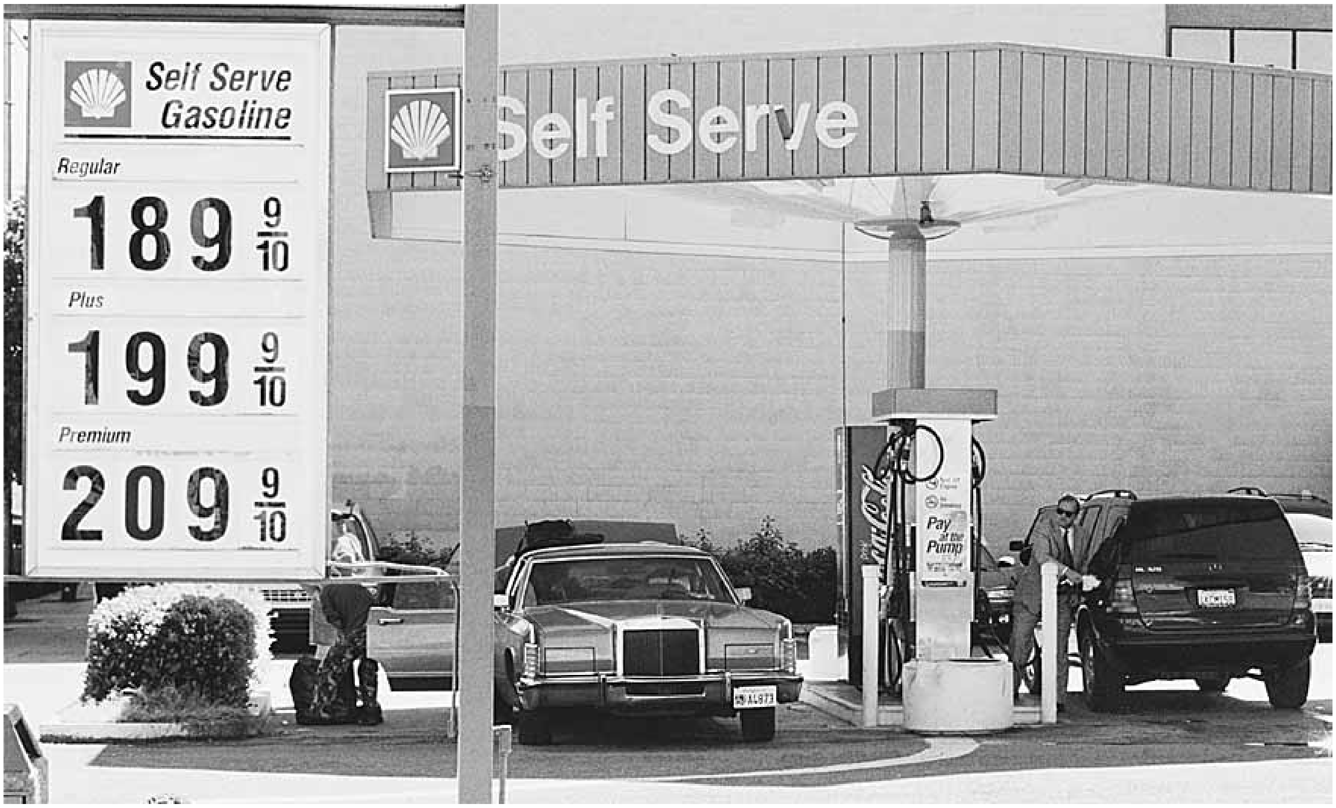
But these years put the spotlight on gasoline above all. The years following World War I saw a rapid growth in the number of automobiles on the road and in miles of highway constructed. The number of registered vehicles increased from 7.6 million to over 26.5 million and the length of surface highways expanded from 350,000 to over 694,000 mi. As a result, the average distance traveled per car grew from 4,500 mi to 7,500 mi and the average annual consumption of gasoline per car rose from 400 gal to over 590 gal. In response, during the 1920s, gasoline output expanded fourfold from 94.2 million barrels to over 435 million barrels. By 1930, gasoline accounted for almost 48 percent of all petroleum products produced in the United States.

From the onset of the Depression (1929) to the beginning of World War II (1941), petroleum's share of total U.S. energy consumption continued to expand, from 24 percent to more than 34 percent (while natural gas increased its share from 8 to 11 percent). Coal continued to lose share in the nation's energy output, from 62 percent to 54 percent. Over the same period, output of motor fuel, while not matching the growth of the previous decade, nevertheless continued its upward trend, from 256.7 million barrels to 291.5 million barrels.

It was during the 1930s that aviation solidified its position as a major and expanding gasoline market. Through the 1930s, consumption of aviation fuel increased over eightfold, from only 753 thousand barrels in 1929 to over 6.4 million barrels at the start of World War II. The other petroleum products—kerosene, lubricating oils, asphalt—saw growth as well, but behind gasoline and refinery products as a whole.

The Rise of Petrochemicals and World War II

By the start of World War II, fossil fuel products were being used increasingly to make advanced organic synthetics. The petrochemicals industry began in the years immediately following World War I. In the 1920s and 1930s, petrochemicals—chemicals made from either petroleum or natural gas—focused



The San Francisco metropolitan area had the nation's highest average price per gallon of gas as consumer costs escalated during 2000. (Corbis Corporation)

on making and utilizing for chemical synthesis the basic olefin compounds: ethylene, propylene, and the butylenes. These were generated in increasing volumes from the refinery plants as off-gases or byproducts of the cracking process. From these building blocks issued a range of chemical products and intermediates. Compared to coal, the traditional raw material, petroleum offered companies such as Union Carbide and Dow Chemical, the efficient, large-scale production of a great variety of synthetics.

Even with direct access to the basic raw materials, the refiners were slow to enter the field. Eventually, in the years leading up to World War II, the refiners began to perceive how their refining operations could be supplemented by petrochemical manufacture. By the start of world War II, they were beginning to compete in earnest with the chemical industry in petrochemical synthetics markets. Between 1929 and 1941, the byproduct refinery gases consumed by both the chemical and petroleum industries for the purpose of manufacturing chemicals more than doubled, from 38.6 million barrels to 83.4 million barrels.

This activity expanded greatly during World War II. Refiners, such as Jersey Standard, Sun Oil, Shell, and Sacony-Vacuum, pioneered the mass production of advanced and strategically critical petrochemicals including butadiene for use as raw-material for synthetic rubber, toluene for in advanced explosives, as well as high-octane motor fuel and aviation gasoline.

The Postwar Period: 1945–2000

The postwar period witnessed increased use of petroleum both for chemicals and energy. Petrochemicals enabled the production of synthetic fibers and high-performance plastics as well as synthetic resins and rubber. By the early 1950s, 60 percent of organics were produced from petroleum. By the early 1970s, over 2,000 chemical products, having a combined weight of over 25 million tons, were derived from petroleum within the United States By the 1990s, petrochemicals represented over 90 percent of all man-made commercial organics.

Petroleum made further gains as a source of energy in the United States in the form of gasoline and liquid gas. The portion of total energy consumption in the United States represented by petroleum and petroleum liquid gas rose from over 34 percent to nearly 46 percent. During these years, the production of gasoline increased from 695 million barrels to 1.5 billion barrels.

If chemicals and gasoline represent the high-growth areas for petroleum, the other petroleum products, for the most part, did not perform quite as well. The exception was kerosene. Output of kerosene rose from 100 million barrels in 1949 to over 200 million barrels in 1959, a result of increased demand in jet fuel. At the same time, demand for fuel oil declined as customers switched to natural gas.

From the 1970s through the 1990s, consumption of petroleum fluctuated closely with prices that to a large extent depended on OPEC supply policies. The OPEC oil crisis of 1973, in particular, forced oil prices upward and, in turn, caused a sharp reduction in petroleum consumption. Between 1973 to 1975, for example, in the face of high oil prices, U.S. consumption of petroleum declined to a level of 16 million barrels per day (bpd). In the 1975 to 1979 period, prices declined and consumption increased to a level near 19 million bpd. The period 1984 to 1994 was one of price reduction and growing consumption. During these years, crude oil prices declined regularly from $36/barrel to a low of $12/barrel in 1994. Then, between 1994 to 1996, with tightening supplies worldwide, prices increased to $18.50/barrel. There was another reversal during the late 1990s as prices steeply contracted, in some areas of the United States to below $10/barrel. By 1997, consumption of petroleum reached 18.6 million bpd, or the level close to that achieved by the 1978 record consumption. Overall, petroleum consumption in absolute terms in the United States has increased at an average of 0.5 percent between 1972 and 1997.

Even so, the last three decades of the twentieth century have been a period of a declining presence for petroleum in the U.S. energy picture. Between 1970 to 1996, energy consumption represented by petroleum has declined from 44.4 percent to 38.1 percent. This contraction is the result of increasing efficiency in the use of energy and growth of such alternate energy sources as nuclear, natural gas, and, more recently, coal. However, a fall in petroleum prices and the decommissioning of nuclear power plants will result in a resurgence of petroleum usage. By the year 2020 government predictions are that petroleum will comprise over 40 percent of the nation's total consumed energy.

THE TRANSPORT AND STORAGE OF PETROLEUM

The petroleum transportation and distribution network constitutes a major portion of the industry's total infrastructure and represents a large capital expenditure for producers. This means that production often outpaces demand.

Economies of scale dictate full-capacity use as companies must keep the infrastructure working at full throttle in order to maintain their investment. This is especially true of the pipeline that must be run at a throughput for which it was designed because the costs per barrel involved in operating pipelines varies inversely with level of throughput. Over the last century, the transportation and distribution network has expanded greatly all the while undergoing significant innovation.

Pipelines

The U.S. pipeline system began in the 1870s and is today composed of a maze of trunk lines and side pipelines that split off in numerous directions and over many miles. The pipeline grew over the years with the volume of oil production. Since the turn of the century, the U.S. petroleum pipeline has expanded from less than 7,000 mi to nearly 170,000 mi. The greatest growth of the pipeline system occurred in the period between the wars in the Mid-Continent and Gulf regions. This network expansion was required not simply to carry larger volumes but also because fields increasingly were further removed from population centers (and thus markets) as well as refining and distribution points.

The carrying capacity of the pipeline did not depend only on the laying down of more pipe. A number of technical improvements expanded the capacity of a given mile of pipe. Pipe making technology has extended pipe size from only 5 in. at the turn of the century up to 12 in. by the 1960s. Larger pipes carrying oil longer distances required greater pumping force. At first, this was provided by steam-powered engines at pumping stations. By the 1920s, these were replaced, at first by diesel engines, and soon thereafter electric power.

From the 1930s and well into the postwar period, pipeline technology advanced through the application of numerous improvements that increased the economies of laying down pipe and facilitated oil transport over long distances and in a variety of climatic conditions. These included new methods of welding pipe joints, the introduction of seamless tubing and pipe, new types of pipe linings and materials of construction to fight against corrosion and advance streamline oil flow, and development of automatically controlled central pipeline pumping stations and remote controlled line stations.

Shipping

Prior to 1900, water transport of oil was carried out in makeshift vessels, such as barges and converted freighters and ore-carrying ships. These were often contracted out (in contrast to pipelines that more often were owned by the producers). There was an increase in water transport of oil during the first two decades of the century.

The larger companies led the way in acquiring water transport fleets. Increasingly after World War I, producers, to be sure of sufficient capacity when required and to avoid charter prices, invested in their own tankers. In this period, about one-third of all U.S. oil was shipped by barge or tanker at some point in its trip to the refiner or market. This figure has increased to over 60 percent through the post-World-War-II period. In the years leading up to World War II, approximately 400 U.S. vessels were involved in oil transport. It is estimated that in the postwar period, the number of oil carrying vessels has fluctuated between 200 and 600 vessels.

Oil tankers today can be either single- or double-hulled. The capacity of tankers usually lies between 1 to 2 million barrels. They are often designed for special purposes. For example, in the 1970s, specially constructed tankers were used in the transport of Alaskan oil. A new generation of oil tankers is being designed as the fleet built during the 1970s and 1980s ages. Designs of the newer double-hulled tankers are most concerned with preventing oil spills, minimizing corrosion, improving maneuverability, advancing engine power and efficiency, strengthening hull structures, and installing vapor-control systems.

Storage

Oil has been stored in tanks since the late nineteenth century. Stored oil is essentially inventory waiting to be distributed to markets. Storage tanks are used to hold both crude oil and the variety of distilled and refined products.

There are two types of storage tanks: underground and aboveground. The former are typically found at service stations. Aboveground tanks are usually used to store crude oil and various refined products. They are often installed at marketing terminals, at various points along a pipeline, and at refineries. In addition, both types of storage tanks are utilized by a wide range of industrial facilities to hold oil used in fueling heir operations. It is estimated that there are 3 to 4 million tanks store oil in the United States.

Technology has improved storage facilities so that oil can be held for longer periods of time with minimal degradation of the liquid, internal corrosion and structural damage, evaporation loss, and leakage. Storage of crude is an expensive operation. Evaporation, corrosion, and leakage increase the costs of storing oil, as do insurance expenses as well as opportunity costs involved in keeping inactive large amounts of petroleum. Accordingly, producers attempt to reduce their inventories of crude and so minimize their reliance on storage. This means the maintaining of continuous flow conditions from well to refinery.

PETROLEUM AND THE REGULATORY CLIMATE

Since the 1970s, the petroleum industry has been increasingly affected by the regulatory push at the international as well as federal and state levels. Oil spills, such as the one involving the Exxon Valdez in Alaska in the 1980s, put the regulatory spotlight on the environmental dangers inherent in moving oil by marine tanker. Since the 1970s, The International Maritime Organization (IMO), in conjunction with the U.S. Department of Transportation (DoT) and the U.S. Environmental Protection Agency (EPA), has stepped up its efforts to implement measures to increase protection of the environment on U.S. and international waters.

The pipelines and storage facilities also present environmental hazards, mainly from leakage and subsequent seepage of oil into the soil and groundwater. Pipeline regulations are the responsibility of the EPA and the DoT. DoT's Office of Pipeline Safety in particular is responsible for regulating interstate hazardous liquid pipeline systems. With respect to storage tanks, both the under- and above-ground types are regulated by the EPA under the Resource Conservation and Recovery Act (RCRA). The major regulation affecting oil-bearing underground storage tanks (USTs), effective on December 22, 1998, required the upgrade of tanks including improved leak detection systems as well as measures to prevent future corrosion of tanks.

PIEZOELECTRIC ENERGY

Piezoelectric energy is a form of electric energy produced by certain solid materials when they are deformed. (The word *piezo* has its roots in the Greek word *piezein* meaning "to press.") Discovery of the piezoelectric effect is credited to Pierre and Jacques Curie who observed in 1880 that certain quartz crystals produced electricity when put under pressure.

Quartz is a crystalline piezoelectric material composed of silicon and oxygen atoms and is illustrative of a piezoelectric material. If no forces are applied to a quartz crystal the distribution of charges is symmetric at the sites of the atoms and there is no net internal electric field. Squeezing or stretching a quartz crystal displaces atoms from their normal positions producing a separation of positive charges and negative charges (electrons) that give rise to a net internal electric field. A voltage develops across the whole crystal making it, in a sense, a battery. As with a battery, an electric current is produced by the voltage when something is connected to the crystal.

The piezoelectric effect will not be used to produce energy to energize a light bulb, for example, yet there are many applications. One common usage is as an igniter in an outdoor gas-fired grill used for cooking. A spring-loaded plunger released by a button on the front of the grill gives a sharp blow to a piezoelectric crystal. The voltage produced generates a spark between two separated metal contacts near the incoming gas, causing the gas to ignite.

Another important but little-known piezoelectric effect is found in some electronic systems. Speaking produces pressure variations that propagate through the air. Forces are produced on anything in contact with this vibrating air so that when contact is with a piezoelectric crystal, tiny voltage variations are produced. A crystal microphone is designed to make use of this piezoelectric effect.

Pressure gauges used to monitor pressures in the fluids pumped throughout an automobile engine are also often based on the piezoelectric effect. An experimenter in a laboratory can apply a known pressure to a piezoelectric crystal and measure the voltage produced. Once the relationship between voltage and pressure is known, a pressure can be inferred from a measure of the voltage. In this manner, the piezoelectric material functions as a pressure gauge. A variety of gases and oils that rely on piezoelectric gauges are pumped throughout the working components of an automobile engine.

Interestingly, a reverse piezoelectric effect is the basis for a number of applications. In this reverse process, a piezoelectric crystal vibrates when an electric current is provided from an external source such as a battery. The precise frequency of these vibrations is used to great advantage in watches and other timepieces. The most common piezoelectric crystal used is quartz. Quartz occurs naturally, but quartz crystals can also be grown in the laboratory. The most common crystals in timepieces are tiny U-shaped tuning forks that vibrate 32,768 times per second. An electronic circuit in the timepiece records time by counting the vibrations. If you peek inside a "quartz" watch you will not see wheels and a spring as in a mechanical watch. Rather, you will see a battery that provides electric current for the crystal and an electronic circuit. You might also see the U-shaped tuning fork.

Since discovering and making use of the piezoelectric effect in naturally occurring crystals such as quartz and Rochelle salts, scientists have produced a wide range of piezoelectric materials in the laboratory. An early example is barium titanate, used in an electrical component called a capacitor. Currently, most piezoelectric materials are oxide materials based on lead oxide, zirconate oxide, and titanium. These very hard piezoelectric materials are termed piezoceramics.

Piezoelectricity is also a natural by occurring phenomenon in the human body. Studies have shown that piezoelectricity causes electric potentials in dry bones of humans and animals. Whether or not this is the cause of the electric potentials that occur in wet, living bone is debatable. More than likely, any piezoelectric effect occurring in moist bone is overshadowed by other sources of electric potentials.

POTENTIAL ENERGY

Potential energy is the energy that something has because of its position or because of the arrangement of its parts. A baseball in flight has potential energy because of its position above the ground. A carbohydrate molecule has potential energy because of the arrangement of the atoms in the molecule.

A diver standing on a platform above the water has potential energy because of a capacity for doing work by jumping off. The higher the diver is above the water and the greater the diver's mass, the greater the potential energy—that is, the capacity for doing work. It is the gravitational force that pulls the diver downward and into the water. For this reason, the potential energy of the diver is called "gravitational potential energy." As an equation, gravitational

The bow stores elastic potential energy as the hunter pulls on it. The energy is transferred to the arrow as kinetic energy upon release. (Corbis Corporation)

potential energy (U) measured in joules (J) is given by $U = mgh$, where m is the mass in kilograms (kg), g is the acceleration due to the gravitational force (9.80 meters/second^2, and h is the height in meters (m). An 80-kg diver 3 m above the water would have 2,350 J of gravitational potential energy.

Any type of potential energy is associated with a force and involves some favorable position. A compressed spring in a toy gun does work on a projectile when the spring is released. Before release, the spring had potential energy that we label "elastic potential energy." The force involved is that of the spring, and the favorable position is the amount of compression. Other examples of elastic potential energy are involved in flexing the bow of a bow and arrow, flexing a vaulter's pole, compressing the suspension springs of an automobile, and stretching a rubber band.

A loss in potential energy by a system is accompanied by a gain of energy in some other form. All the potential energy of a mass held above a spring is converted to kinetic energy just before the mass hits the spring. The mass loses kinetic energy as it pushes against the spring, but the spring gains potential energy as a result of being compressed. Water atop a dam in a hydroelectric power plant has gravitational potential energy. In falling, it loses potential energy and gains kinetic energy. When the water impinges on the blades of a water turbine, the rotor of the turbine gains rotational kinetic energy at the expense of the water losing kinetic energy.

Molecules have potential energy associated with electric forces that bind the atoms together. In a chemical reaction liberating energy—heat, for example—the atoms are rearranged into lower potential energy configurations. The loss of potential energy is accompanied by an increase in other forms of energy.

Protons and neutrons in the nucleus of an atom have potential energy associated with nuclear forces. In a nuclear reaction liberating energy, the nuclei are rearranged into lower potential energy structures. The loss of potential energy is accompanied by an increase in other forms of energy. A single nuclear reaction in a nuclear power plant liberates nearly 10 million times the energy of a single chemical reaction in a coal-burning power plant.

POWER

Power is the rate of doing work or the rate of converting energy. A unit of work or energy is called a joule. A person doing 4,000 joules of work in four seconds would be doing work at a rate of 1,000 joules per second. A joule per second is called a watt (W) in honor of James Watt, inventor of the steam engine. Hence, the person developed a power of 1,000 watts. When a hundred watt light bulb is lit, electric energy is converted to heat and light at a rate of one hundred joules per second. In the United States, the power developed by engines and motors is usually expressed in horsepower (hp). The horsepower unit was coined by Watt who estimated the rate at which a typical work horse could do work: One horsepower equals 746 watts. In an effort to use metric units for all physical quantities, there is a trend in Europe to rate engines and motors in watts.

In terms of the rate at which work is done or energy is converted, consider that

- the human heart in a person at rest does work at a rate of about 0.01 watt,
- a flashlight converts energy at a rate of about four watts,
- a student in daily activity does work at a rate of about ninety watts or about 0.1 hp,
- an automobile engine develops about 40,000 watts, a large electric power plant produces about 1,000,000,000 watts of electric power, and
- the solar input to the earth (at the top of the atmosphere) amounts to about hundred million billion watts.

When the power is a large number, as in the case of an electric power plant, it is convenient to express the power in megawatts (MW) where one megawatt equals one million watts. An electric power of 1,000,000,000 watts would be expressed as 1,000 MW. A large coal-burning or nuclear power plant produces about 1,000 MW of electric power. The sum total of the electric power produced by all electric power plants is expressed in units of gigawatts (GW). One gigawatt equals one billion watts. An electric power of 1,000,000,000,000 watts would be expressed as 1,000 GW.

A unit of energy divided by a unit of time is a unit of power. If you are burning wood at a rate of 10,000 Btu per hour then Btu per hour denotes power. Similarly, a unit of power multiplied by a unit of time is a unit of energy. Electric power in a home is usually measured in kilowatts (kW) (i.e., thousands of watts, and time in hours [h]). Therefore, kilowatts multiplied by hours (kWh) is a measure of energy. A light bulb rated at one hundred watts (0.1 kW) converts electric energy at a rate of one hundred joules per second. If the bulb is on for two hours then the electric energy provided by the power company is 0.1 kW × 2 h = 0.2 kWh. The power company would be paid for 0.2 kWh of electric energy. Typically, the cost is about 10¢/kWh, so the amount due the company is two cents. It is interesting that electric utilities are referred to as power companies when we pay them for energy, not power.

Each cyclist must convert the energy stored in his or her muscles into torque to move the pedals. To go uphill, the necessary rate of work (power) increases as does the required torque. (Corbis Corporation)

A bicyclist has to expend energy to cycle up a steep hill. The energy the cyclist expends is determined by the product of the power the cyclist develops and the time the cyclist is pumping (energy = power × time). The cyclist may choose to develop a relatively large amount of power and pump for a short period of time. Or he may prefer to take it easy developing a relatively small amount of power and pump for a longer period of time. The energy would be the same in both cases, but the effort would be different. Even after shifting to the lowest gear, cyclists often find that it is still easier to make their way up a hill by traversing back and forth across the road. The traversing takes less effort (less power), but requires more time. This is also why roads up a mountain take winding paths rather than trying to go directly up—vehicles with less reserve capacity power can still climb the mountain.

By definition, a force (F) acting on some object as it moves some distance (x) along a line does work (W):

$$W = Fx.$$

This idea says nothing about the time involved in doing the work. Asking for the rate at which work was done (i.e. the power) and how fast was the object moving, we find power (P) equals force times velocity (v):

$$P = Fv.$$

The power developed by a person pushing a box on a floor with a force of 300 newton (N) at a speed of 1 m/s is 300 W or about 0.4 hp.

A force is required to rotate an object. The response to the force depends not only the size of the force, but also on the manner in which the force is applied. A bicyclist must push down on a pedal to cause the sprocket to rotate. But if the shaft to which the pedal is attached is vertical, no rotation results. The greatest response occurs when the bicyclist pushes down on the pedal when the shaft is horizontal. The concept of torque is used to describe rotational motion. The bicyclist pushing down on the pedal when the shaft is vertical produces zero torque. The maximum torque is produced when the shaft is horizontal. In this case the torque is the product of the force and the length of the shaft. For any other position between vertical and horizontal, the torque is the product of the force, shaft length, and sine of the angle made by the shaft and direction of the force. A force develops power when linear motion is involved and a torque develops power when rotational motion is involved. The power developed by a force is the product of force and linear velocity ($P = Fv$) and the power developed by a torque is the product of torque and angular velocity ($P = T\omega$).

Power and torque are directly related. An automobile engine develops power when producing a torque on the drivetrain. Generally, the owner of an automobile is more interested in power than torque. However, technicians in the automobile industry usually evaluate the performance in terms of torque rather than power. The power developed in the drive chain of an automobile is essentially constant. But the rotational speed of the drivetrain depends on the torque developed. The larger the torque, the smaller the rotational speed.

PRESSURE

Pressure is force divided by the area over which the force acts:

$$\text{pressure} = \text{force}/(\text{area of contact})$$

or

$$P = F/A.$$

In the metric system, pressure has a unit of newtons per square meter, which is called a pascal (Pa). Although the pascal is the scientific unit and is preferred, pounds per square inch (lbs/in^2) is common in the United States. For example, in most of Europe, tire pressure is recorded in pascals (typically 220,000 Pa), whereas tire pressure in American cars is measured in pounds per square inch (typically 32 lbs/in^2). As a point of reference, the pressure that the earth's atmosphere exerts on anything at the earth's surface is roughly 100,000 Pa or 15 lbs/in^2.

A large pressure does not necessarily mean a large force because a large pressure can be accomplished by making the contact area small. For example, a 160-pound man having fifty square inches in his shoe soles produces a pressure of 3.2 lbs/in^2 on the ground when he stands flatfooted. But the same person wearing ice skates having 2.5 square inches in the runners of the blades produces a pressure of 64 lbs/in^2 when standing on ice. When a person pushes down on the head of a thumbtack, the pressure at the point is quite large because the contact area of the sharp thumbtack is small.

Blaise Pascal, the French scientist for whom the pascal pressure unit is named, was the first to discover that a pressure applied to an enclosed fluid is transmitted undiminished to every point of the fluid and the walls of the containing vessel. The earth's atmosphere exerts a pressure on the surface of water in a swimming pool (a container) and this pressure is felt equally throughout the pool including the walls. This principle is employed in a hydraulic press that has many applications. The pressure due to the force f on the piston of area a is P = f/a. The piston of area A feels a force F creating a pressure P = F/A. According to Pascal's principle, the two pressures are equal so that F/A = f/a or F = (A/a)f. If the area A is larger than a, then the force F is larger than f. Therefore, a small force on the left piston causes a larger force on the right piston. Lifting an object requires an upward force larger than the weight of the object. This is why rather massive objects such as automobiles, trucks, and elevators can be lifted with a hydraulic press. For example, a car weighing 10,000 N (about 2,000 pounds) can be raised with a hundred N force if the ratio of the areas of the pistons (A/a) is one hundred.

Work is done by both forces when the pistons move and the larger force cannot do more work (force × displacement) than the smaller force. Accordingly, the larger piston moves a much smaller distance than the smaller piston. Theoretically, if the ratio of the areas is one hundred then the smaller piston must move one hundred times further than the larger piston.

The mechanism for rotating the wheels in a car or truck has its origin in pistons in the engine that are forced to move by expanding gases in the cylinders. The expanding gas is a result of igniting a mixture of gasoline vapor and air. An expanding gas exerts a force on a piston doing work as the piston moves. In principle, it is no different than a person doing work by pushing a box on the floor of a hallway. The energy for the work comes from the energy of the gas produced by the ignition of the gasoline vapor and air mixture. As in the calculation of work done by a constant force the work done by the gas is the product of the force (F) and displacement (d, the distance the piston moves). Because the force on the piston is equal to the pressure (P) times the area (A) of the piston the work (W) can be written W = PAd. The quantity Ad is just the change in volume (ΔV) of the gas so that the work can also be written as $W = P\Delta V$. This is the basic idea in determining the performance of engines, which are used to power cars, trucks, and all sorts of other equipment.

The air pressure created by the clown's lungs on the inner walls of the balloon force it to expand. (Corbis Corporation)

The expansion of a balloon when it is inflated is evidence of the pressure exerted on the interior walls by molecules blown into the balloon. If you tie off the open end of the balloon, you can squeeze the balloon with your hands and actually feel the result of the pressure in the balloon. If you were to cool the balloon you find that the pressure goes down. Warming causes the pressure to increase. This happens also with the pressure in an automobile tire after it has warmed by running on a road. When there is no change in the pressure, temperature, and volume, we say the gas is in equilibrium. The pressure, volume, and temperature of a gas in equilibrium and how they are related is an important feature for describing the behavior of a gas when the gas does work. The relationship for all possible variations of P, V, and T is very complicated, but for moderate temperatures (around 300 K or 70°F) the equilibrium state of all gases is given by $PV = NkT$ where N is the number of atoms (or molecules) and k is the Boltzmann constant, 1.38×10^{-23} joules/kelvin. A gas is said to be ideal if it subscribes to the relationship $PV = NkT$ and the equation is called the ideal gas equation.

PROPELLERS

A propeller converts through helical motion the energy supplied by a power source into thrust, a force that moves a vehicle forward in a fluid medium. They are used primarily for marine and aerial propulsion, but they are found on other technologies such as hovercraft and wind turbines as well. Propellers, which are essentially a series of twisted wings, or blades, connected to a central hub, are efficient energy transmission devices for those applications. The blades strike the air or water at a certain angle, called the pitch, and create an area of low pressure in front of the propeller. As a result, the blades generate thrust through either fluid or aerodynamic means by pushing forward through the low-pressure area. Slip, or the energy lost as the propeller rotates, offsets the full output of thrust. The effectiveness of the propeller is measured by propulsive efficiency, the ratio of engine power to the actual thrust produced minus slip, during one complete revolution of the propeller. Because this process resembles the twisting movement of a carpenter's screw as it advances through wood, marine propellers are often called "screws" and aerial propellers are called "airscrews."

There exists a wide range of propellers for different applications. Fixed pitch propellers, most commonly found on ships and small aircraft, are simple in operation and efficient for one operating regime. Transport aircraft use variable-pitch propellers that can alter their pitch (sometimes automatically) to perform efficiently over a variety of conditions. Counter-rotating propellers are two propellers placed in tandem and operating from the same power source. They produce thrust efficiently, but they are also very complicated in design. Feathering propellers can set their blades parallel to the movement of either water or air in case of engine failure, which increases passenger safety. Reversible pitch propellers decrease landing distances for aircraft and aid in the maneuvering of ships by changing the direction of thrust. Depending on their application and operating regime, propellers can be made from wood, metal, or composite materials.

The concept of the propeller originates from three important antecedents. First, the Greek mathematician Archimedes developed a method of transporting water uphill through helical motion during the third century B.C.E. Second, the emergence of windmills in western Europe in the twelfth century C.E. indicated an inverse understanding of the principles and capabilities of thrust. Finally, Leonardo da Vinci's adaptation of the Archimedean helical screw to the idea of aerial propulsion during the fifteenth century inspired later propeller designers. These ideas influenced the development of both marine and aerial propellers but were mainly conceptual. It was not until the nineteenth and twentieth centuries that the availability of adequate power sources such as steam and internal combustion engines would make propellers feasible power transmission devices.

MARINE PROPELLERS

Propellers for the marine environment appeared first in the eighteenth century. The French mathematician and founder of hydrodynamics, Daniel Bernoulli, proposed steam propulsion with screw propellers as early as 1752. However, the first application of the marine propeller was the hand-cranked screw on American inventor David Bushnell's submarine, *Turtle* in 1776. Also, many experimenters, such as steamboat inventor Robert Fulton, incorporated marine propellers into their designs.

The nineteenth century was a period of innovation for marine propellers. Reflecting the growing importance of the steam engine and the replacement of sails and side paddle wheels for propellers on ocean-going vessels, many individuals in Europe and America patented screw propeller designs. Two individuals are credited with inventing the modern marine propeller: English engineer Francis P. Smith and American engineer John Ericcson. Both placed important patents in 1836 in England that would be the point of departure for future designs. Smith's aptly named ship *Archimedes* featured a large Archimedean screw and demonstrated the merits of the new system. Swedish-born Ericcson employed a six-bladed design that resembled the sails on a windmill. He immigrated to the United States in 1839 and pioneered the use of screw propellers in the United States navy. The first American propeller-driven warship, the U.S.S. *Princeton*, began operations in 1843. Other notable screw propulsion designs included British engineer Isambard Kingdom Brunel's 1843 iron-hull steamship, the *Great Britain*, which was the first large vessel with screw propellers to cross the Atlantic. In 1845, the British Admiralty sponsored a historic "tug-of-war" between the paddle wheel-driven H.M.S. *Alecto* and screw propeller-driven H.M.S. *Rattler*. The victory of the *Rattler* indicated the superiority of propellers to both sail and paddle wheel technology. However, naval vessels did not rely exclusively on screw propulsion until the 1870s. The early twentieth century witnessed the universal adoption of screws for oceangoing ships, which include the majority of vessels from the largest battleships to the smallest merchant marine vessels.

A worker walks underneath a ship's propeller in a dry dock in Canada. (Corbis Corporation)

Typical marine propellers are fixed pitch and small in diameter with very thin, but broad, blade sections. They are made from either cast metal, corrosion-resistant metal alloys such as copper, or composite materials. Marine propellers normally operate at 60 percent efficiency due to the proximity of the ship's hull, which limits the overall diameter of the propeller and disturbs the efficient flow of water through the blades. As a result, the blades have to be very wide to produce adequate thrust. Marine propeller designers use innovations such as overlapping blades and wheel vanes to offset those problems and improve efficiency.

Another important consideration for marine propeller design is cavitation, the rapid formation and then collapse of vacuum pockets on the blade surface at high speed, and its contributions to losses in propulsive efficiency. The phenomenon can cause serious damage to the propeller by eroding the blade surface and creating high frequency underwater noise. Cavitation first became a serious problem in the late nineteenth and early twentieth centuries when innovations in steam and diesel propulsion technology drove propellers at unprecedented speeds. The introduction of gearing to make propellers rotate more efficiently at high revolutions and blades designed to resist cavitation alleviated the problem. However, research in the 1950s found that cavitation was a desirable trait for many high-speed marine propeller designs such as hydrofoils.

AERIAL PROPELLERS

As early as the eighteenth century, flight enthusiasts gradually began to consider the aerial propeller a practical form of transmitting propulsion. French mathematician J. P. Paucton revived the idea of the aerial propeller in Europe in his 1768 text, "Theorie de la vis d'Archimede." His *Pterophore* design used propellers for propulsion as well as for overall lift. Pioneers of lighter-than-air flight such as the French aeronauts Jean-Pierre Blanchard and Jean Baptiste Meusnier, used propellers on their balloons and airships in the 1780s. The increased attention given to the development of a practical heavier-than-air flying machine during the late nineteenth century ensured that experimenters rejected power transmission devices such as flapping wings, oars, sails, and paddle wheels, and incorporated propellers into their designs. Even though the propeller became a common component of proto-aeroplanes such as wings, aeronautical enthusiasts did not recognize the importance of propeller efficiency.

Wilbur and Orville Wright first addressed the aerial propeller from a theoretical and overall original standpoint during the successful development of their 1903 *Flyer*. They conceptualized the aerial propeller as a rotary wing, or airfoil, that generated aerodynamic thrust to achieve propulsion. They determined that the same physics that allowed an airfoil to create an upward lifting force when placed in an airstream would produce horizontal aerodynamic thrust when the airfoil was positioned vertically and rotated to create airflow. As a result, the Wrights created the world's first efficient aerial propeller and the aerodynamic theory to calculate its performance that would be the basis for all propeller research and development that followed. Used in conjunction with the reciprocating internal combustion piston engine, the aerial propeller was the main form of propulsion for the first fifty years of heavier-than-air flight.

Others built upon the achievement of the Wrights by improving the overall efficiency of the propeller. American engineer William F. Durand developed the standard table of propeller design coefficients in his landmark 1917 National Advisory Committee for Aeronautics study, "Experimental Research on Air Propellers." Besides the need for an aerodynamically efficient blade shape, propellers needed to be efficient over a variety of flight regimes. Developed simultaneously by Frank W. Caldwell in America, H. S. Hele-Shaw and T. E. Beacham in Great Britain, and Archibald Turnbull in Canada in the 1920s and becoming widely adopted in the 1930s, the variable-pitch mechanism dramatically improved the performance of the airplane. It linked aeronautical innovations such as streamline design, cantilever monoplane wings, and retractable landing gear with the increase in power brought by sophisticated engines, fuels, and supercharging. The properly designed variable-pitch propeller has been critical to the economic success of commercial and military air transport operations since the 1930s.

After World War II, the variable-pitch popeller was combined with a gas turbine to create the turbine propeller, or turboprop. The use of a gas turbine to drive the propeller increased propulsive efficiency, fuel economy, and generated less noise than conventional piston engine propeller aircraft. Turboprop airliners, first developed in Great Britain, began commercial operations in the early 1950s and were considered an economical alternative to turbojet airliners. Propellers are the most efficient form of aerial propulsion because they move a larger mass of air at a lower velocity (i.e., less waste) than turbojets and rockets. That efficiency is only present at speeds up to 500 mph (800 km/h). Beyond that, the tips of the rotating propeller suffer from near-sonic shockwaves that degrade its aerodynamic efficiency to the point where it loses power and cannot go any faster. Given that limitation and the higher efficiencies of turbojets at speeds above 500 mph for long distance flights, the propeller appeared to be obsolete as a viable energy conversion device for air transport. What occurred was that each propulsion technology proved the most efficient in different applications. The high efficiency of the aerial propeller, between 85 to 90 percent, and its lower operating costs created a strong economic impetus for air carriers to encourage the improvement of propeller-driven aircraft for the rapidly expanding short haul commuter market in the 1970s.

Further attempts to improve the efficiency of airplanes resulted in advances in propulsion technology based on the aerial propeller. Introduced in the 1960s, the turbofan, a large, enclosed multiblade fan driven by a turbojet core, harnessed the efficiency of the propeller while developing the thrust of the turbojet. NASA's long-range aircraft energy efficiency program of the 1980s developed the propfan, which is an advanced turboprop that employs multiple scimitar-shaped blades with swept-back leading edges designed for high speed. Propfans are capable of operating at speeds comparable to those generated by turbofan and turbojet-powered aircraft at a 25 percent savings in fuel.

The extreme climatic and physical environments in which propellers operate test the limits of aerodynamics, mechanical engineering, and structural theory. Depending upon the size of the power source, aerial propellers can be made from wood, metal, or composite materials and feature from two to six long and slender blades. The blades must be able to withstand exposure to harsh weather and stand up to aerodynamic loading, engine vibration, and structural bending while efficiently creating thrust.

A significant characteristic of the aerial propeller since its invention has been noise. Aircraft propellers, especially those made of metal, often produce an extremely loud "slapping, beating" sound when operating at high speeds. The increased use of propeller-driven commuter aircraft in the 1970s contributed to the growing noise pollution around busy urban airports. Measures to quiet aircraft included propeller synchronization to prevent high frequency vibration on multiengine aircraft and the use of elliptical blades, thinner airfoil sections, smaller propeller diameters, and lower rotational speeds.

Technologies other than conventional aircraft use aerial propellers for propulsion. Helicopters and vertical and short takeoff and landing aircraft (V/STOL) use rotor blades shaped to produce aerodynamic lift much like a propeller produces thrust. Hovercraft, or air-cushion vehicles, use propellers designed to be efficient at slower speeds for both movement and maneuverability when mounted on swiveling pylons. The search for an alternative energy source to fossil fuels in the 1970s encouraged many experimenters to use propellers to catch the wind and generate electricity through a turbine. Wind turbines benefit from advances in propeller design to create energy rather than converting the energy of a power source into forward movement.

PROPERTY RIGHTS

In many situations, property rights are easily determined. Boundaries to stationary, observable assets such as land can be defined and enforced clearly. Property rights to crude oil and natural gas are far more troublesome, for two reasons. Both resources lie below the surface, making it difficult to locate the exact limits of the deposits, and they migrate within subsurface reservoirs. Some reservoirs cover many square miles, including hundreds of property owners, each with a competing claim to the oil and gas. Moreover, other reservoirs straddle national boundaries, encouraging international competition for the oil and gas. For these reasons energy production from crude oil and natural gas can involve serious common-pool losses. Although there is much to be gained from cooperation among property owners to avoid these losses, reaching a cooperative solution can be very difficult.

The problems of the common pool were most dramatically illustrated in Garrett Hardin's famous 1968 article "The Tragedy of the Commons." Exploitation of valuable resources when property rights are absent or poorly defined can be extremely wasteful. Because the parties must capture the resource before it is appropriated by another, time horizons become distorted, with undue emphasis on short-term production and neglect of long-term investment. Even if the trend of market prices indicates that resource values would be greater from future, rather than current, use, production will not be postponed. The losses are compounded by excessive capital investment in extraction and storage.

Common-pool problems characterize many resources where it is difficult to define property rights to restrain access and use. In North America, common-pool conditions in oil and natural gas production are created when firms compete for hydrocarbons in the same formation under the common-law rule of capture (which also governs fisheries and many other natural resources).

Under the rule of capture, ownership is secured only upon extraction. In the United States, production rights are granted to firms through leases from those who hold the mineral rights, typically surface land owners. Each of the producing firms has an incentive to maximize the economic value of its leases rather than that of the reservoir as a whole. Firms competitively drill and drain, including the oil of their neighbors, to increase their private returns, even though these actions can involve excessive investment in wells, pipelines, and surface storage, higher production costs, and lower overall oil recovery.

Oil production requires pressure from compressed gas or water to expel oil to the surface. There are three main types of reservoir drives to flush oil to wells: dissolved gas drive, gas-cap drive, and water drive. With a gas drive, the oil in the reservoir is saturated with dissolved gas. As pressures fall with oil production, the gas escapes from solution, expands, and propels oil to the surface. Hence it is important to control gas production so it remains available to remove the oil. With a gas-cap drive, the upper part of the reservoir is filled with gas, and oil lies beneath it. As oil is withdrawn, the compressed gas expands downward, pushing oil to the well bore. As with a dissolved gas drive, gas production from the gas cap should be restricted to maintain reservoir pressure to expel the oil. Finally, with a water drive, the oil lies above a layer of water. The compressed water migrates into the oil zone as the oil moves to the well and helps to push it from the rock formation. High oil recovery rates require that subterranean water pressures be maintained.

Maximizing the value of the reservoir requires that full reservoir dynamics be considered in drilling wells and in extracting oil. Gas and water must be recycled through the strategic placement of injection wells; wells with high gas-oil or water-oil ratios must be closed or not drilled; and the rate of oil production must be controlled to maintain underground pressure.

Each reservoir generally has a dominant drive, an optimal pattern of well locations, and a maximum efficient rate of production (MER), which, if exceeded, would lead to an avoidable loss of ultimate oil recovery. Unfortunately, oil, gas, and water are not evenly distributed within the reservoir. With multiple leases above the reservoir, some lease owners will have more oil, gas, or water than will others, and coordination among competing firms in well placement and in controlling production rates is difficult. Efficient production of the reservoir suggests that some leases not be produced at all. Further, since each firm's production inflicts external costs on the other firms on the formation, some mechanism must be found to internalize those costs in production decisions.

Maintaining subsurface pressures; effectively placing wells; coordinating timely investment; and controlling oil production across leases while protecting the interests of the various lease owners under conditions of geologic and market uncertainty are formidable challenges. Yet, if they are not adopted, common-pool losses are likely.

Common-pool problems in oil and gas have been observed since commercial production began in the United States in 1859. The solution, unitization, also has been understood for a long time. With unitization, a single firm, often with the largest leased area, is designated as the unit operator to develop the reservoir, ignoring lease boundaries. With unitization, optimal well placement and production are possible as is coordination in other activities to increase overall recovery from the reservoir; These activities include pressure maintenance; secondary recovery; and enhanced oil recovery (EOR), whereby heat, carbon dioxide, or other chemicals are injected into the reservoir.

All lease owners share in the net returns of unitized production, based on negotiated formulas. As residual profit claimants, the lease owners now have incentives to develop the reservoir (rather than the lease) in a manner that maximizes its economic value over time. When producers expect unitization to occur, exploration is encouraged because greater recovery rates and reduced costs are anticipated. Bonuses and royalties to landowners are higher because the present value of the oil and gas resource is greater with unitization.

Despite its attractions for reducing common-pool losses, use of unitization has been more limited than one would expect. Joe Bain (1947, p. 29) noted: "It is difficult to understand why in the United States, even admitting all obstacles of law and tradition, not more than a dozen pools are 100 percent unitized (out of some 3,000) and only 185 have even partial unitization." Similarly, in 1985 Wiggins and Libecap reported that as late as 1975, only 38 percent of Oklahoma production and 20 percent of Texas production came from field-wide units.

To be successful, a unit agreement must align the incentives of the oil-producing firms over the life of the contract to maximize the economic value of the reservoir without repeated renegotiation. Unit contracts involve a number of difficult issues that have to be addressed by negotiators. Because remaining production often lasts twenty years or more, unit agreements must be long-term and be responsive to considerable uncertainty over future market and geological conditions. They must allocate unit production and costs among the many firms that otherwise would be producing from the reservoir. Additionally, they must authorize investments that may be made later to expand reservoir production, and distribute the ensuing costs among the individual parties.

These are formidable tasks for unit negotiators. The negotiating parties must agree to a sharing rule or participation formula for the allocation of costs and revenues from production. There may be different sharing rules for different phases of unit production, such as primary and secondary production, and the rules should apply to all firms on the reservoir. This arrangement is termed a single participating area. There should not be separate participating areas for oil and gas; otherwise, different incentives for oil and gas production will emerge. Development, capital, and operating costs must be allocated in proportion to revenue shares in an effort to align all interests to maximize the economic value of the reservoir. In

STAKING A CLAIM: THE HOMESTEADING ALTERNATIVE

Property rights assignment by homesteading is based on a theory of philosopher John Locke. Locke believed “as much land as a man tills, plants, improves, cultivated and can use the product of, so much is his property.” Such labor, Locke continues, “enclose(s) it from the common.”

In a Lockean world, mineral rights do not accompany surface rights in either original or transferred ownership. Minerals would not be owned until homesteaded by the acts of discovery and intent to possess. In the case of oil and gas, initial ownership would occur when the oil or gas entered the well bore and was legally claimed by the driller. The reservoir would then turn from a “state of nature” into owned property. The homesteader (discoverer) could be the property owner directly overhead, another land owner, or a lessee of either.

The oil and gas lease under homestead law would simply be the right to conduct drilling operations on a person’s surface property. The lease would not constitute a claim to minerals found under a particular surface area as under the rule of capture rule. Since the reservoir could be reached from different surface locations with slant drilling, the economic rent of a homestead lease would be far less than the value of a capture-rule lease. The difference in value would accrue to the driller-finder, thereby encouraging production by making drilling more efficient and profitable.

Under a homestead theory of subsurface rights, the first finder of a mineral area would have claim to the entire recognized deposit. In the case of oil and gas, the geologic unit is the entire reservoir, however shaped, as long as it can be proven to be contiguous. Separate and distinct reservoirs in the same general area, whether vertical or horizontal, would require separate and distinct discovery and claim. Alien wells draining a claimed reservoir would be liable for trespass if the homesteader can reasonably prove invasion (whether by well distance, well depth, crude type, geological formation, reservoir pressure, etc.). The pool owner would also be able to use his discovery as chosen. The pool could be left untapped, depleted, or used for storage. The reservoir space, in addition to the virgin contents of the reservoir, is newfound property.

The operation of homestead property rights system can be facilitated by pragmatic rules established either by law or judicial opinion. When a new oil or gas field is discovered, the surrounding acreage could be declared off-limits for other producers until the discoverer has a “reasonable” opportunity to drill frontier wells to delineate the field. An exception would be made if another operator had begun to drill before the nearby discovery was made so long as opportunistic slant drilling did not occur. If the discoverer does not drill development wells to delineate the field, then other operators may drill and become co-owners of the same contiguous reservoir upon discovery, requiring cooperation to minimize drilling costs.

While the homestead theory was never seriously considered in the United States experience, it has been recommended as part of a subsoil privatization program for Latin America. The major attraction is increased economic efficiency: Production and management of a contiguous oil and gas reservoir is most efficiently done by one operator, and homesteading creates one owner in place of multiple owners under the rule of capture.

that case, each party will share in the net returns from production and hence will have an incentive to minimize development and production costs and to maximize revenues. Further, a single unit operator must be selected to develop the field. Multiple unit operators lead to conflicting objectives and hinder the coordinated production practices necessary to maximize the value of the reservoir. Supervision of the unit operator by the other interests must be determined, with voting based on unit participation.

All of these issues can be contentious, but reaching agreement on the revenue sharing or participation formula is the most difficult. Shares are based on estimates of each firm's contribution to the unit. Those firms with leases that reflect a natural structural advantage (e.g., more resources or easier access to resources) seek to retain this advantage in the unitization formula. Such firms are unlikely to agree to a unitization agreement that does not give them at least as much oil or gas as they would receive by not unitizing. Even if the increase in ultimate recovery from unitization is so great that these parties will receive more from unit operations than from individual development, they have a much stronger bargaining position in negotiations than less-favored tract owners. The former can hold out for the most favorable allocation formula, secure in the knowledge that the regional migration of oil will continue toward their tracts during any delay in negotiations. Indeed, holding out may increase the value of a structurally advantageous location. If the firms form a subunit without the participation of the owners of better-located tracts, the pressure maintenance operations of the unit may increase the amount of oil migration toward the unsigned tracts. The holdouts, then, benefit from the unit without incurring any costs of the pressure maintenance activity.

The information available to the negotiating parties for determining lease values depends upon the stage of production. During exploration, all leases are relatively homogeneous, and unitization agreements can be comparatively easy to reach using simple allocation formulas, often based on surface acreage. Information problems and distributional concerns, however, arise with development as lease differences emerge. Because reservoirs are not uniform, the information released from a well is descriptive of only the immediate vicinity. There will be disagreements over how to evaluate this information in setting lease values. As a result of disagreements over subsurface parameters, unit negotiations often must focus on a small set of variables that can be objectively measured, such as cumulative output or wells per acre. These objective measures, however, may be poor indicators of lease value.

Conflicts over lease values and unit shares generally continue until late in the life of a reservoir. As primary production nears zero, accumulated information causes public and private lease value estimates to converge, so that a consensus on share values is possible. Without unit agreement, secondary production from all leases may be quite limited. The timing of a consensus on lease values, however, suggests that voluntary unit agreements are more likely to be reached only after most of the common-pool losses have been inflicted on the reservoir.

Reaching agreement on these issues is a complex process. In a detailed examination of seven units in Texas, Wiggins and Libecap showed in 1985 that negotiations took four to nine years before agreements could be reached. Moreover, in five of the seven cases, the area in the final unit was less than that involved in early negotiations. As some firms became frustrated, they dropped out to form subunits, which led to a partitioning of the field and the drilling of additional wells but generally did not minimize common-pool losses. For example, 28 subunits, ranging from 80 to 4,918 acres, were established on the 71,000-acre Slaughter field in West Texas. To prevent migration of oil across subunit boundaries, some 427 offsetting water injection wells were sunk along each subunit boundary, adding capital costs of $156 million.

Other costs from incomplete unitization are shown on Prudhoe Bay, North America's largest oil and gas field, which was first unitized in 1977. Two unit operators, separate sharing formulas for oil and gas interests, and a disparity between revenue sharing and cost sharing among the working interests have resulted in protracted and costly conflicts. The parties on the field do not have joint incentives to maximize the economic value of the reservoir, but rather seek to maximize the values of their individual oil or gas holdings. Because ownership of oil and gas in Prudhoe Bay is very skewed, with some firms holding mostly oil in the oil rim and others holding mostly natural gas in the gas cap, the firms have been unable to agree to a complete, reservoirwide agreement. Disputes have centered on investment and whether natural gas should be reinjected to raise oil production, or liquefied and sold as natural-gas liquids. In 1999 Libecap and Smith showed that skewed ownership in the presence of gas

Prudhoe Bay Oil Field. (Corbis Corporation)

caps characterizes other incomplete unit agreements elsewhere in North America.

Most states, as well as the U.S. government, have some type of compulsory unitization rule to limit the ability of a minority of holdouts to block a unit. Mandatory unitization began in the United States in Louisiana, in 1940. Due to political opposition by small firms that receive regulatory-related benefits, Texas, surprisingly, has not had a compulsory unitization law. Texas court rulings have tended to restrict unitization.

Although unitization is most problematical in North America, where there generally are more operators on a given oil field, the problems of coordinated production to avoid common-pool losses exist elsewhere. In the North Sea, Argentina, Ecuador, and the Caspian Sea, lease and national boundaries often do not coincide with reservoir boundaries. Under these conditions a nation may engage in competitive drilling to drain the oil and gas before its neighbor does. This incentive appears to explain the initial pattern of Norwegian drilling only along its boundaries with the United Kingdom (Hollick and Cooper, 1997).

PROPULSION

Whenever anything is set in motion, there must be some type of propulsive force that moves it. Propulsion is a key element of many activities, including athletic events, recreation, transportation, weapons, and space exploration. This article explains the basic principles involved in any propulsion system, differentiates the types of propulsion systems, and discusses some practical aspects of propulsion.

BASIC PHYSICS

Momentum/Impulse

To change an object's speed it is necessary to exert a net force on it for some duration of time. The product of the force and the length of time it is applied is called the impulse and is the same as the change of momentum. Any increase in speed is directly proportional to the impulse and inversely proportional to its mass:

$$\begin{aligned}\text{Change of Speed} &= \text{Force} \times \text{Time/Mass}\\ &= \text{Impulse/Mass}\end{aligned}$$

A 1,000 kg (metric ton) car accelerating from 0–30 m/s (68 mph) in 6 seconds, thus requires an average force of 5,000 newtons. This is a force approximately half the weight of the car. It is likely that the car would "burn rubber" as the drive wheels spun on the road during this acceleration. To accelerate to the same speed in 12 seconds would require a force of only 2,500 newtons.

Energy/Work

An increase of speed corresponds to an increase of kinetic energy. This increase of kinetic energy is a result of the net force acting in the direction of motion through some distance. Net force times distance is the work done on the object:

$$\begin{aligned}\text{Change of Kinetic Energy} &= \text{Force} \times \text{Distance}\\ &= \text{Work}\end{aligned}$$

Kinetic energy equals 1/2 mass × speed^2. Therefore, a formula for the change of the square of the speed is

$$\begin{aligned}\text{Change of speed}^2 &= 2 \times \text{Force} \times \text{Distance/Mass}\\ &= 2 \times \text{Work/Mass}\end{aligned}$$

The car used in the example above would travel 90 meters during its acceleration (assumed constant) to 30 m/s in 6 seconds. The increase in kinetic energy would be 450,000 joules, which exactly equals the work input of 5,000 newtons × 90 meters.

In the case of maintaining the speed of an object against opposing forces such as friction or air resistance, the energy analysis is more appropriate than a momentum analysis. For friction forces, the conservation of energy requires that work by propelling force is equal to the energy dissipated by friction, or, in the case of lifting an object at constant speed through a gravitational field, that the work by propelling force is equal to the gain in potential energy.

In designing a rocket with sufficient propulsive power to launch a satellite into orbit, all three energy considerations are involved. The satellite gains speed (more kinetic energy), it is lifted upward against gravity (more potential energy), and it encounters air resistance (energy dissipated by friction).

Whatever the type of propulsion, it is necessary to exert a force on the object for a period of time or through a distance.

Newton's Third Law

The force of propulsion must be exerted by some object other than the one being propelled. Forces always appear as pairs. As expressed by Newton's third law, the object being propelled and the propelling agent interact by equal, opposite and simultaneous forces. For instance a runner pushes against the starting blocks and the starting blocks push against the runner, impelling him forward. A ship's screw pushes against the water propelling it backward, and the water pushes against the ship's screw, propelling the ship forward. The rocket exhaust thrusts against the rocket, propelling it forward as the rocket thrusts the exhaust backward. And the wind pushes against the sail, propelling the boat forward as the sail pushes against the wind, slowing it down or deflecting its motion.

Efficiency

There are numerous ways to look at the efficiency of propulsion systems, depending on the goal of the system. One way might be to define it in terms of an energy ratio—the ratio of the energy required to achieve the desired motion to the energy consumed by the propelling agent. For instance, consider accelerating the one-ton car to 30 m/s, giving it a kinetic energy of 450,000 joules. Suppose during the acceleration the engine uses 1/2 cup of gasoline with a heat of combustion of 4,200,000 joules, then the energy efficiency would be 450,000/4,200,000 = 10.7 percent.

Other definitions of efficiency arise where energy considerations are irrelevant. In rocket propulsion, for instance, the goal is to give a certain mass of payload a very large speed. A more useful measure here might be the ratio of the speed boost given to the payload mass compared to the total mass of fuel, including its container and the engine.

The most well-known propulsion efficiency is the amount of energy (fuel) required to move a vehicle a certain distance against opposing forces. Efficiencies of road vehicles, for instance, are usually measured in miles per gallon.

TYPES OF PROPULSION

Propulsion can be classified according to the type of object with which the propulsive device interacts. It might interact with (A) a massive object, (B) a fluid medium in which it is immersed, (C) material that it carries along to be ejected, or (D) a flowing stream.

Thrust Against a Massive Object

The object interacts directly with another relatively massive object. For example, with every fall of a foot, a runner interacts ultimately with the earth, as do automobiles, trains and bicycles. A pitcher pushes against a mound of dirt as he throws a ball, and bullets interact with the gun.

Thrust Against the Ambient Medium

The object interacts with a relatively lightweight medium such as air or water that it encounters along its path. A ship takes some of the water in which it floats, propels it backward, and the ship is in turn propelled forward. Other examples of this type are propeller airplanes and jet planes. The jet plane takes in air (23 percent oxygen by weight) through which it is flying, adds some fuel to it, and the chemical reaction with the oxygen (burning) results in a high-velocity exhaust. The mutual interaction between the exhaust (which, in the case of the fan jet, mixes in even more air) and the airplane propel it forward. Unlike a thrust against a massive object, which barely moves, the fluid carries away significant amounts of kinetic energy during the interaction.

Rockets

The object to be propelled carries the material to be pushed against, and usually carries the energy source as well (fuel and oxidant). Some examples of this type are: rockets, inflated balloons released to exhaust their air, and ion engines. The inflated balloon would be propelled by interaction with its released air even if it were released in space. It does not push against the air around itself. In fact, the ambient air only tends to impede its motion.

Flowing Streams

The object interacts with a flowing medium. Sails interact with the wind, rafts float downstream, a spacecraft is propelled by the stream of photons (light) from the sun. This is more of a "channeling" type of propulsion in that the propelled object deflects the flowing stream in such a way that it is forced to move in desired direction.

COMPARISON

Theoretically, the first type of propulsion, where the interaction is with a relatively immovable object, is the most energy efficient. In the absence of friction, it is theoretically possible to convert 100 percent of the available energy into kinetic energy, the energy of motion. This is because the more massive immovable object takes away a very small amount of kinetic energy even though it shares equally (but oppositely) in the impulse or change of momentum.

A common energy source for this type of propulsion is an internal combustion engine, in which fuel is burned and expanding gasses convert the energy into mechanical motion. This process is governed by the laws of thermodynamics, which limit the efficiency to much less than 100 percent. Further losses are encountered through transmission and through rolling friction. The efficiencies are in the 20 percent range for automobiles.

Human propulsion, which depends on muscle power, obtains its energy through the metabolism of food. This process has an efficiency of about 30 percent for a long-distance runner during a race. A cyclist who pedals at a tenth horsepower (climbing a 5 percent grade at 5 miles per hour) for eight hours, and who eats a diet of 3,000 calories, has an efficiency of 17 percent for the day, assuming no additional work is done.

The efficiency of propulsion for a given energy source will always be less when the interaction is with a fluid medium such as air or water. For example, the kinetic energy of the wind generated by the propellers of an airplane is energy that is dissipated and does not end up as part of the airplane's kinetic energy.

In this second type of propulsion the efficiency depends on the speed of the object relative to the speed at which the medium is being pushed backward. The greatest theoretical efficiency occurs when the propeller of the ship, for example, pushes a large quantity of water backward at a relative speed just slightly greater than the speed of the ship moving forward. Practical limits on the size of the screw determine that the water is usually pushed backward much faster than the ship's speed in order to get adequate thrust. The efficiency turns out to be very small when the screw is pushing water backwards at high rates of speed.

The jet engine also interacts with the ambient medium as it goes along, so it is basically the same type of propulsion as with the propeller. The decision of whether to use a propeller or a jet engine for an airplane depends on the design speed. The dividing line is about 300 miles per hour. The propeller is more efficient at pushing large quantities of air at relatively low speeds, so it is the choice for low-speed flight. Since it is always necessary to push the air backward at a relative speed greater than that at which it is desired to fly, a jet engine is necessary for high speed flight.

When the efficiency of transportation, by whatever propulsion method, is measured on a distance per amount of energy basis (miles per gallon), it is found that two very important factors are speed and aerodynamic design. At normal road speeds, and for subsonic (most commercial) aircraft, the wind resistance for a given size and shape depends on the square of the speed. The fuel consumption for a given vehicle is influenced directly by the friction forces, including wind resistance. An aircraft flying the same distance will need four times the energy to overcome wind resistance flying at 400 miles per hour as it uses flying at 200 miles per hour. The actual fuel consumption difference is less than this because of constants such as the amount of fuel needed to take off and to gain altitude.

The same rule is true of automobile travel. An automobile traveling at 70 miles per hour will need nearly twice the energy to overcome wind resistance as if it made the same trip at 50 miles per hour. Again, the difference in fuel consumption will be less due to the effect of rolling friction (nearly independent of speed), the fuel used to accelerate up to speed after every stop, and the energy used to operate lights, air conditioner, etc.

The third type of propulsion is best typified by a rocket engine. The rocket must carry its energy supply and ejecta material as well as the object to be launched. The energy supply is usually two chemicals that, when they combine, give off a large amount of heat, vaporizing the reaction products. This hot gas is ejected at high velocity, propelling the rocket. The two chemicals may be hydrogen and oxygen, which combine to produce very hot water (steam). The fuel might also be a solid mixture of chemicals that are designed to react at a controlled rate.

To achieve the goal of the greatest speed with a given mass of fuel, it is necessary that the ejecta come out of the rocket as fast as possible. Therefore, the efficiency (or effectiveness) of rocket fuels is better measured in terms of the speed of the ejected material than by energy efficiency.

One advantage of the rocket is that the payload can reach speeds in excess of the relative speed of the ejecta, which is not the case with a jet engine. The thrust of the jet engine goes to zero when its speed through the air reaches the relative speed of the ejecta, whereas the thrust of the rocket stays the same no matter what the speed. The jet engine has the advantage that it uses the air it encounters along the way as both the oxidant for the fuel and most of the ejecta. It, therefore, does not need to carry nearly as much mass as the rocket to accomplish the same impulse.

An ion rocket engine does not need to carry its energy supply like the chemical rocket does. It can use solar cells to collect energy from the sun to provide an electric field to accelerate ions (charged xenon atoms, for instance) that provide a thrust when they are ejected at high speed. Since the energy is "free," the energy efficiency is not relevant. The relative speed of the ejected ions from NASA's Deep Space 1 ion propulsion system is about 62,000 miles per hour, which is ten times that from conventional chemical rockets. Therefore, for a tenth of the "fuel," it can achieve the same boost in speed as a conventional rocket. By this measure the ion rocket engine is ten times more efficient than the chemical rocket.

The ion engine produces a very tiny thrust, about the weight of a sheet of typing paper, but exerts it continuously for a long period of time (several months). This very long time multiplied by the relatively small thrust (force) still results in large impulse to the space probe. Because it is not possible to push more xenon ions through the engine in a given time only low thrust is possible. Greater thrust would require a much larger engine and a more powerful source of energy.

Nuclear energy could be a compact source for application in an ion engine, but no practical devices have yet been constructed. Nuclear energy would be necessary for the ion drive of an interstellar mission for which solar energy would not be available.

Launching a satellite from earth could not be done with the low thrusts of currently conceived ion rockets. Chemical rockets, which can generate large amounts of thrust, will be needed for the foreseeable future.

The fourth type of propulsion makes use of a flowing stream. In this case, as in the ion engine, the energy efficiency is irrelevant because the supply of energy is unlimited for practical purposes.

The sailboat being propelled downwind is easy to understand. Also it is not too hard to see that turning the sail at an angle to bounce the wind off to the side propels the boat at some angle to the wind. What is amazing is that it is possible for the sailboat to be propelled faster than the wind, and to make headway upwind. These feats are possible because it is easier to move a boat in the direction of its keel (lengthwise) than it is to move it abeam (crosswise).

Another flowing stream that might be used for propulsion in the future consists of photons (light particles) from the sun. These photons have momentum and thus exert a small pressure on everything they strike. If reflected from a mirror, the mirror would act exactly like a sail in the wind. The pressure of the light would always be at right angles to the plane of the mirror. Therefore, it would be possible to use a large, lightweight reflecting surface as a sail to navigate anywhere in the solar system. The solar sail, like the ion engine, would generate a very small thrust. At the earth it would be only 7 newtons per square kilometer (4 pounds per square mile) of reflecting sail.

RAILWAY PASSENGER SERVICE

Travelers usually have a choice among several transportation alternatives, most prominent being automobile, bus, airplane and railway. Rail was the preferred means of travel in the mid-nineteenth century and continuing until the 1920s, but began to decline afterward because it could not compete with the greater mobility of the automobile and the greater speed of air travel. Despite this decline, rail passenger service may yet find a new role where its potential to be more fuel-flexible, environmentally friendly, and energy efficient can be realized. Moreover it has the flexibility to avoid the congestion delays of air and roadway traffic that is likely to only worsen.

About 60 percent of transport energy in the United States is used for passenger transport, almost entirely by autos, light trucks and aviation. In fact, rail passenger services in the U.S. carry only about 2 percent of total passenger-kilometers (a passenger-kilometer is one passenger moved one kilometer), with the remainder carried by auto, air and bus. In other countries the rail role is larger, ranging from 6 to 10 percent of passenger-kilometers in many European countries to about 20 percent in India and as high as 34 percent of passenger-kilometers in Japan. Depending on the country, energy in transport could be saved by making rail passenger services more energy-efficient (not so important in the United States but much more so in Europe, India and Japan) or, probably more important, in getting passengers to switch from less-energy-efficient modes to potentially more efficient modes of rail passenger service.

Rail passenger service offers many alternatives, with different characteristics and customers. In urban areas, slow (50 km/hr), frequent-stop trolleys ("streetcars") have long operated in many cities, often in the same right-of-way where autos and buses drive. There are "light rail trains" (LRT), midway in speed (up to about 80 km/hr) and capacity between trolleys and traditional subways, operating in a number of large metropolises. "Heavy rail" metros (up to 110 km/hr) form the heart of the transport network in many of the world's largest cities. Many cities supplement their metros with longer-range, higher-speed (up to 140 km/hr) suburban rail services, and some have mixtures of all of these (e.g., Cairo and or Moscow).

In the intercity market there are glamorous high-speed trains (200 to 300 km/hr) such as the Japanese Shinkansen, the French TGV, and Amtrak's Metroliner. Such trains carry enormous numbers of passengers in Japan (almost 300 million per year), France (about 65 million), and Germany (more than 20 million). These trains provide high-quality, city-center-to-city-center passenger service in competition with air (below 500 km or so) and auto (over 150 km or so). Though they are important, only rarely do these high-speed trains carry a sizeable percentage of the country's total rail passengers.

The workhorses of most rail passenger systems are ordinary passenger trains operating at 70 to 160 km/hr. Table 1 shows the rail passenger traffic carried by most of the world's railways. The top three railway systems account for more than half of the world's passenger services, and the top six account for over two-thirds. Table 1 demonstrates another important point: the *entire* developed world accounts for only 30 percent of rail passenger transport. North American, European, and Japanese experiences are not representative of the vast bulk of the world's rail passengers.

Table 1.
The World's Rail Passenger Traffic

ENERGY USE BY RAIL PASSENGER TRAINS

Rail passenger energy efficiency depends on many variables, and a complete analysis would consume volumes of argument. In large part, though, an analysis of energy consumption in passenger transport begins with four basic factors: surface contact friction (rolling wheels), air drag (wind resistance), mass and weight (which influence acceleration/deceleration requirements and contact friction), and load factor (the percentage of occupied seats or space).

Surface friction is a source of rail's advantages in transport energy efficiency. Under similar conditions, steel wheels on steel rail generate only about 20 to 30 percent of the rolling friction that rubber wheels on pavement generate, both because rails are much smoother than pavement and because steel wheels are much more rigid than rubber tires, so steel wheels deform much less at the point of contact with the ground. Each rail wheel has only about 0.3 sq in of surface in contact with the rail, whereas an automobile tire can have 20 to 30 sq in of rubber in contact with the pavement. The greater rubber tire deformation takes energy that is wasted as heat in the tread, and the lower the pressure, the greater the deformation. Slightly offsetting this difference is the friction of the rail wheel flange, which keeps the train on the track.

Air drag is minimal at very low speeds, but it rises rapidly with increasing speed. In fact, drag is related to speed squared, and the power required to overcome drag is related to speed cubed, and it affects all vehicles. With good design of rolling bearings, rolling friction does not increase as rapidly with speed as does air drag, so in most cases air drag begins to exceed rolling friction at speeds above 60 to 100 km/hr in rail passenger vehicles, and it dominates energy requirements at speeds above about 150 Km/Hr. Streamlining can reduce air drag for any vehicle, but rail again has an inherent advantage because, for the same number of passengers, trains can be longer and thinner than buses or airplanes, and the thinness of the form affects air drag significantly.

Mass affects energy consumption because it takes energy to accelerate the vehicle and its passengers, and most of this energy is subsequently wasted as heat in the braking system when the vehicle slows. Weight also increases rolling friction. Surprisingly, rail passenger vehicles are relatively heavy. A fully loaded five-passenger automobile will have a gross weight of no more than 800 pounds per occupant and a bus slightly less, whereas a fully loaded rail passenger coach will have a gross weight of between 2,000 and 3,000 pounds per occupant. The average train, including locomotive, diner, and sleeping cars, can average 4,000 pounds or more per passenger.

Engineering models of tractive effort calculation derive from a basic model, generally called the Davis formula (after its initial formulator, W. J. Davis). The Davis formula calculates the resistance (Rt, in pounds per ton of weight being pulled) as:

$$Rt = (1.3 + 29/w + bV + CAV^2/wn)/wn$$

In this formula, w is the weight in tons per axle; b is a coefficient of flange friction (0.03 for passenger cars); V is the speed in miles per hour; C is the air drag coefficient (0.0017 for locomotives, 0.00034 for trailing passenger cars); and A is the cross-sectional area of locomotives and cars (120 sq ft for locomotives, 110 sq ft for passenger cars).

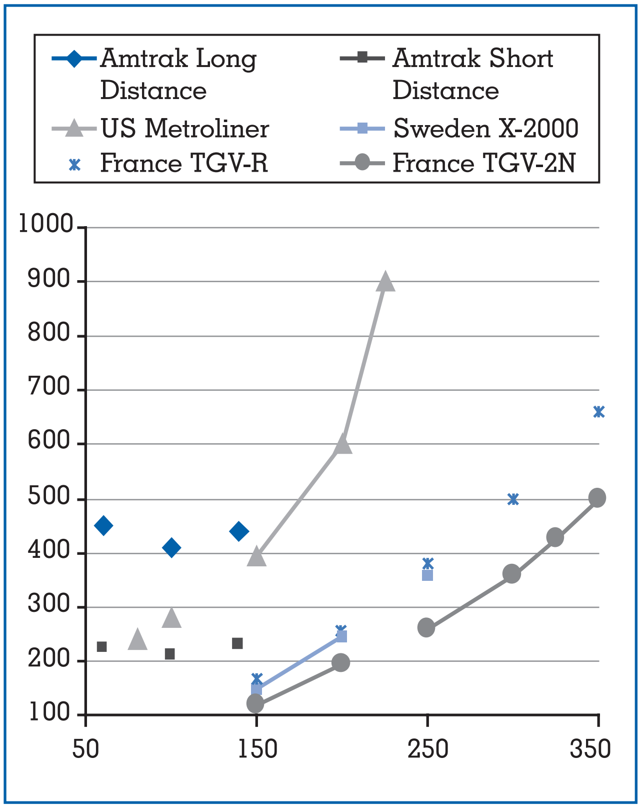

Figure 1.
Rail Passenger Fuel Consumption at Various Speeds (KJ/P-km for full trains).

The coefficients shown for the formula are examples; they would differ with changing designs of freight and passenger rolling stock and are specific to each train. The purpose here is to show the form of the relationship, not the exact values. Figure 1 displays energy consumption on various full-passenger trains over a range of speeds. Energy consumption rises rapidly with speed—and the energy consumed by the highly streamlined TGV or Swedish X-2000 is far less than the energy consumed by the boxy Metroliner.

The figure leaves out another important determinant of energy efficiency: *load factor*. Roughly speaking, a half-empty vehicle consumes twice as much energy per passenger-kilometer as a full vehicle, and a one-fourth-full vehicle four times as much. No matter what the potential energy advantages might be, empty trains waste energy, and full autos can be highly efficient. Unless modes are compared while operating at the appropriate load factor, the energy efficiency conclusions reached can be seriously flawed—and it is not necessarily valid to assume the same load factor for all modes. Indeed, the annual average load factor for Amtrak in the United States is only 46 percent, while the average load factor for U.S. airlines is 65 percent. Commuter trains do run full (or more than full) in the loaded direction during rush hour, but they often run nearly empty in the outbound direction and during midday, and actually average less than 35 percent load factor.

Even after the readily quantifiable engineering and operating issues are argued, the picture is still incomplete. Energy consumption in passenger transport is also affected by a large number of less predictable, real-world factors. Mountainous countries, for example, cause reduced railway efficiency because railways cannot climb steep grades (the downside of reduced rolling friction), so railway lines usually have to be 30 to 50 percent longer than highways between the same two end points in mountainous terrain. Bad maintenance practices and older equipment can severely reduce energy efficiency and increase pollution. These factors, and others such as driver expertise, can easily dominate the engineering and operating factors that can be readily measured.

Taking all these factors into account, well-calibrated computer models show that U.S. freight trains of various types could theoretically operate at energy consumption rates of 75 to 140 kJ per ton-km (kJ/t-km) of cargo depending on the type of train, with low-speed, heavy coal trains being the most efficient and high-speed, high-drag, double-stack container trains being the most energy-consuming. In 1997, the actual rail industry average of 250 kJ/t-km was nearly twice the theoretical upper bound of 140 kJ/t-km, reflecting the running of partially empty trains, wagon switching, and locomotive idling practices, among other factors. Though the technology is effectively the same, average energy consumption in Kenya Railways freight traffic is more than 1,000 kJ/t-km as a result of far less than optimum operating and maintenance practices.

Similar variations occur in reported cases of rail passenger service where engineering models show trains potentially operating at 200 to 400 kJ per passenger-kilometer. In practice, though, passenger trains are rarely full, and some trains, such as many long haul Amtrak trains, carry sleepers and diners which add significantly to the weight of the train but do not add many passenger seats. Commuter trains do not usually carry diners, of course, but they often operate essentially empty on their midday trips or on trips against the flow of rush-hour traffic. Thus the theoretically high rail passenger energy efficiency gets transmuted into an Amtrak system-wide average of 1,610 kJ per passenger-kilometer and an average for all United States commuter railways of 2,131 kJ per passenger-kilometer. Because of the effect of actual practices, the optimal efficiency from the engineering model is, in practice, a factor of four to eight better than what is experienced.

In general, the range of reported experience supports the conventional wisdom. Rail is potentially the most efficient method of motorized passenger travel; but bus is almost the equal of rail. Motorcycles are also quite efficient (and this assumes only the driver—motorcycles with passengers are the most energy-efficient vehicles of all). Automobiles and airlines do typically consume more energy per passenger-kilometer than rail.

More important, though, is the fact that there are significant overlaps in the energy consumption ranges, depending on the factors discussed above. While rail and bus are generally a toss-up, there are conditions in which a fully loaded Boeing 747-400 can be more energy-fficient than a partially loaded Amtrak Metroliner. A fully loaded automobile can well be a better energy and environmental choice than an empty bus or an empty train. There is no single answer, and actual conditions are very important.

Though only partly energy-related, passenger trains have additional features that deserve highlighting, such as the potential for electrification, space efficiency, and impact on urban form.

Electrification

Because trains travel path is well defined, where train traffic is dense it can be economically feasible to construct either overhead electric power supply wires (the “catenary” system) or ground-level electric supply systems (usually called the “third rail”), which permit trains to be powered directly by electric traction motors. Though a few cities have electric trolley buses, the cost of building and operating a system to supply electricity to buses, autos, and trucks is normally so high as to restrict road travel to use of fossil fuels, though advances in battery technology and hydrogen fuels may eventually reduce this dependence.

Electric traction power in railways offers three significant advantages: diversity of fuels, easier control of pollution, and high tractive effort per unit of train weight. Because electricity can be generated by a wide range of fossil fuels such as coal or natural gas, electric trains are not solely dependent on petroleum products for their operation. In fact, hydroelectric or nuclear power uses no fossil fuels at all (though each has its own environmental implications), and some countries, such as Switzerland, can use hydropower to drive almost all of their passenger and freight trains. Even when the electricity used by trains is generated by fossil fuels, the pollution is far more easily controlled from a single electric power station than from thousands of cars and buses, and the pollution and engine noise will be emitted at the power station and not in the city centers.

Because it takes time for an electric motor to overheat when exposed to high power currents, properly designed electric motors can operate for limited periods of time at power ratings as much as twice the level at which they can operate continuously. This means that electric motors can deliver short bursts of acceleration that require power well beyond the power needed for cruising. Diesels, by contrast, are limited by the power of the engine, and cannot exceed this rating even for short periods of time. In addition, in the diesel-electric system, which almost all diesel trains use, the diesel engine drives a generator, which in turn feeds electric traction motors, which drive the train; this involves extra weight, so that diesel systems are heavier than all-electric systems. As a result, electric traction has advantages where high acceleration is required, or where (as in high-speed trains) the weight of the train must be controlled to reduce the forces the train exerts on the track. Offsetting the performance advantages of electric traction is the added cost of the catenary or third rail and transformers needed to feed the train with electricity.

Most urban rail passenger systems are electrically operated because electric power permits high acceleration and thus closer spacing of trains. Most high-speed trains are electrically driven because diesel engines of the high power required are too heavy (and damage the track), and gas turbines do not handle acceleration well because they are not energy-efficient at speeds other than the optimum speed for which the turbine is designed. Ordinary, longer-haul passenger trains are a mix of diesel and electric traction: Diesel traction is far cheaper on light-density lines, and high acceleration and light weight are not so important on slower trains.

Because railway electric motors can be made to slow a train as well as drive it, the energy of braking can be regenerated onboard and put back into the catenary or third rail for use by other trains. Regeneration has not been prevalent in railways because of the complexity and weight of the onboard equipment involved, and regeneration has generally not been economically feasible where the catenary is providing alternating current (ac) traction current because of the difficulty of matching the frequency and phase of the regenerated power to the power in the catenary. Technology is changing in this respect, and ac regeneration is emerging as a possibility where train traffic is dense enough to support the added investment.

Railway electric traction systems use either ac or direct current (dc). Third rail systems operate on dc at 600 to 700 V. Overhead systems can be found with either 1,500 or 3,000 V dc, or using ac at a range of voltages (from 11,000 to 50,000) and frequencies (16 2/3 to 60 Hz). The modern standard for overhead catenary systems is usually 25,000 V and either 50 or 60 Hz depending on the industrial standard for the country (50 Hz for most of Europe, 60 Hz for the United States and Japan).

The total energy efficiency of a diesel system is not much different from an electrically driven system—a point that many energy comparisons neglect. The percentage of the energy in diesel fuel that is actually translated into tractive effort seems low, about 26 percent, in comparison with electric drive trains, which convert 90 percent of the power received from the wire or third rail into traction. However, the percentage of the fuel consumed in a power plant that is converted into electric energy is only about 40 percent (slightly higher in modern, compound cycle plants), and electric systems lose energy due to resistance in the transmission lines and transformers. Measured by the percentage of the initial fuel's energy that is actually translated to tractive effort on the train, there is not a great deal of difference between diesel at about 26 percent efficiency and electric traction systems that deliver about 28 percent of the initial fuel energy into tractive effort at the rail.

Space Efficiency

The land area required for a double-track railway (a minimum right-of-way approximately 44 ft wide) is less than that required for a four-lane highway (at least 50 ft wide at an absolute minimum, and usually much more). Depending on assumptions about load factors, a double-track railway can carry 20,000 to 50,000 passengers in rush hour in each direction, about twice to four times the peak loading of a four-lane highway (2,200 vehicles per lane per hour). Putting a double-track railway underground is also much cheaper than the equivalent capacity by highway because rail tunnels are smaller and require much less ventilation. Overall, high-density railways can carry three to eight times the amount of traffic a highway can carry per unit of land area used, and can do so with limited and controlled environmental impact.

Urban Form

Because of their ability to handle massive numbers of people effectively, using little space and emitting little or no pollution (in the urban area, at least), railways can support the functioning of much denser urban areas than auto-based urban sprawl; in fact, the term "subway" was coined to describe the underground railway that consumes almost no surface space. Where urban congestion is important (in Bangkok there have been estimates that traffic congestion lowers the gross domestic product of Thailand by several percentage points), various rail options can have a high payoff in moving people effectively. In densely populated countries, as in most of Europe and Japan, longer-haul rail passenger service plays a similar function of moving people with minimum burden on land space and overloaded highway and air transport facilities.

Technology in transport is also on the move. Automobiles have seen advances in engine design (reducing energy and pollution), body design (reducing air drag), radial tires and tread design (reducing rolling friction), and replacement of steel with plastics and aluminum (reducing weight). As a result, auto energy mileage per gallon of fuel, which was about 13.5 miles per gallon in the United States in 1970, has improved to about 21.5 miles per gallon in 1997 (a 37% improvement), and there are vehicles now available that can produce 50 to 70 miles per gallon. Diesel engine technology has improved in parallel, as has vehicle design for both rail and bus vehicles, yielding roughly a 46 percent improvement in rail efficiency since 1970. Advances in aircraft design and size, along with improved engines, have kept pace with the surface modes. Since the basic technology in engine, air drag, and vehicle frame weight management is similar and is available to all modes, there is reason to believe that all modes will (or could) improve, but this is no convincing basis for arguing that any of the modes will dramatically improve its energy efficiency relative to the others.

CONCLUSIONS

The energy/transport relationship is complex and resists easy generalization. Against this backdrop, what useful conclusions can be drawn about the role of passenger rail services in saving energy or reducing environmental impacts from transport?

In the urban arena, energy-efficient rail passenger services can reduce air pollution and help manage urban congestion. Rail passenger services can be vital to the form and function of large cities by putting large movements of people underground or overhead without consuming undue space. This potential cannot be reached, however, unless rail services are carefully planned and managed so that they operate where needed and at high load factors. Rail's effects are likely to be localized, though, and the potential will be limited if competitive modes are not fully charged for the congestion and pollution they cause. Urban rail probably does not offer much to the effort to control greenhouse gas emissions, because of the relatively small amounts of energy involved and because of urban rail's inherently low load factors.

Rail's contribution in the intercity passenger area is less clear. Where population density is high and travel distances short, and especially where fuel prices and tolls are high and airline travel expensive, there is a need for rail passenger service that can operate efficiently. This describes conditions in Japan, and parts of Western Europe and possibly the northeast corridor in the United States, where high-density and high-speed rail services do exist. But with rail passenger services carrying less than 2 percent of the intercity traffic in the United States, the contribution of this traffic to energy-efficiency objectives is probably minimal. Where populations are high and extremely poor, and where rail tariffs are kept low, there is also a significant demand for rail passenger services, as in India, China, the CIS countries, and Egypt. It is possible that rail passenger service in these countries is making a contribution to the reduction of energy consumption and thus to control of CO_2 emissions. In the "middle" countries, including the United States and Canada (outside a few dense urban corridors), which have long distances and low population densities, it seems doubtful that rail passenger services can make a measurable contribution to energy efficiency and CO_2 reduction. In all countries it is unlikely that intercity rail passenger services will be useful in reducing localized urban air pollution.

RANKINE, WILLIAM JOHN MACQUORN (1820–1872)

William Rankine has been credited with many things derived from his brilliant career, with perhaps the most unique being the transition of his empirical work into scientific theories published for the benefit of engineering students. He is considered the author of the modern philosophy of the steam engine and also the greatest among all founders of and contributors to the science of thermodynamics.

Born in Edinburgh, Scotland, on July 5, 1820, Rankine received most of his education from his father, David Rankine, a civil engineer, plus various private tutors. The elder Rankine worked as superintendent for the Edinburgh and Dalkeith Railway, imparting to his son a love of steam engines. On top of this fine education came two inspiring years at the University of Edinburgh, which helped launch his career in civil engineering, even though he left without earning a degree. He spent a year assisting his father, then worked in Ireland for four years on projects including railroads and hydraulics. Returning to Scotland, he apprenticed under Sir John Benjamin MacNeil, a respected civil engineer of his time. Rankine remained in this profession until the late 1840s before switching to the practice of mathematical physics.

At the age of thirty-five, Rankine was appointed by the Queen's Commission to the Chair of Civil Engineering and Mechanics at the University of Glasgow in Scotland. This Regius Chair was established in 1855 with great distinction at the fourth oldest university in Great Britain. Despite the great achievements of British inventors, most self–educated, they were often deprived of an appropriate claim to true professional recognition in the areas of architecture and engineering. As a professor, Rankine argued passionately with his University commissioners for the establishment of a diploma in engineering science, later adding a Bsc in science. These were just a few of the achievements that earned him accolades as a pioneer in engineering education.

Rankine's most famous textbook, *A Manual of the Steam Engine and Other Prime Movers* (1859), set an engineering standard for years to come, delivering systematic instruction to upcoming engineers. This publication was credited with affording inventors a new basis beyond their experimentation to advance the development of the steam engine. Other books Rankine authored include *A Manual of Applied Mechanics* (1858); *A Manual of Civil Engineering* (1862); and *A Manual of Machinery and Millwork* (1869). He also published numerous practical manuals on civil and mechanical engineering and scientific tables for construction, carpentry, architecture and surveying. Somehow in his spare time, he found time to write for entertainment, including *Songs and Fables* (1874) and *A Memoir of John Elder* (1871). His research led to such renowned legacies as the Rankine cycle, for ideal operation of a steam engine, as well as his Rankine Tables for cycle efficiencies (comparing performances of steam engines and steam turbines), the construction strength of columns, and his Rankine absolute temperature scale. Many of his tables remain in use today.

Moving into other fields of practical applications, Rankine developed improved strength for iron rails by conducting fatigue testing of existing railroad ties. He was a pioneer in promoting a theory of open water sailing vessels that debunked a simple but common belief of his time—that metal ships could not be made to float. Through his successful research, the size, length, and safety of ships was significantly improved. Through his knowledge of thermodynamics, he played a key role in the advancements in refrigeration equipment. His study of soil mechanics (earth pressures) led to improved retaining walls.

Rankine's works placed him among the greatest of many famous scholars at the University of Glasgow—from Adam Smith in modern economic science, to James Watt with his invention of the double acting steam engine, to Rankine's peer in thermodynamics, William Thomson (Lord Kelvin), after whom the absolute scale of temperature was named. Before passing away on Christmas Eve, 1872, in Glasgow, Rankine served as president of the Institute of Engineers in Scotland and honorary member of the Literary and Philosophical Society of Manchester.

Making a statement on the importance of recording and teaching the history of technology, Rankine began his *A Manual of the Steam Engine and Other Prime Movers* as follows: "Nations are wrongly accused of having, in the most ancient of times, honored and remembered their conquerors and tyrants only, and of having neglected and forgotten their benefactors, the inventors of the useful arts. On the contrary, the want of authentic records of those benefactors of mankind has arisen from the blind excess of admiration, which led the heathen nations of remote antiquity to treat their memory with divine honors, so that their real history has been lost amongst the fables of mythology."

RECYCLING

See: Materials

REFINERIES

The process of refining begins with the delivery of crude oil—a mixture of thousands of different hydrocarbon compounds that must be separated into fractions of varying boiling ranges in order to be used or converted into products such as gasolines, diesel fuels, and so on. Crude oils from different sources vary widely in terms of density (gravity), impurities (sulfur, nitrogen, oxygen, and trace metals), and kinds of hydrocarbon compounds (paraffins and aromatics). In general, the heavier the crude oils, the less transportation fuel (gasoline, diesel fuel and jet fuel) boiling-range components are contained in the crudes. The average crude oil charged to U.S. refineries in 1998 contained about 20 percent material in the gasoline boiling range and about 25 percent in the middle distillate (diesel and jet fuel) boiling range. The U.S. market requirements are about 50 percent gasoline and 35 percent middle distillate fuels per barrel of crude oil charged to U.S. refineries.

CRUDE OILS

Crude oils are classified by major hydrocarbon type (paraffinic, intermediate, or naphthenic), gravity (light or heavy), and major impurities—high sulfur (sour), low sulfur (sweet), high metals, etc. Everything else being equal, the heavier the oil the lower the value of the oil, because a smaller percentage of that particular crude is in the transportation fuel boiling range. The boiling ranges of the heavier fractions can be reduced, but the additional processing is costly, adding anywhere from fractions of a cent to several cents per gallon. The same is true of the sulfur, nitrogen, oxygen, and metal contents of crude oils. The impurities have to be removed by reaction with hydrogen, and hydrogen processing is very expensive.

Paraffinic crude oils are defined as those crude oils containing waxes, naphthenic crude oils as those containing asphalts, and intermediate crude oils those containing both waxes and asphalts. Usually the residues—material boiling above 1050°F (565°C)—of naphthenic crude oils make good asphalts, but the intermediate crude oils can contain enough wax so that the asphaltic part may not harden properly, and therefore they cannot be used to produce specification asphalts.

Refinery processes are available to reduce the boiling points of components of the crude oils that boil higher than the transportation fuels by cracking the large high-boiling-point molecules into smaller molecules that boil in the desired transportation fuel boiling range. Lighter materials can also be converted to transportation fuels (usually gasoline) by processes such as alkylation or polymerization. There are also processes to improve the quality of the transportation fuel products because the crude oil components with the proper boiling range do not have the other characteristics required. These include octane and cetane numbers for gasoline and diesel fuel, respectively, and low sulfur and nitrogen contents for gasoline, diesel, and jet fuels.

Over 50 percent of the crude oils used in the United States are imported, because U.S. crude oil production has passed its peak and has been declining in recent years. Also, other countries (Mexico, Saudi Arabia, and Venezuela) have been buying full or part ownership into U.S. refineries in order to ensure there will be a market for their heavy, high-sulfur crude oils. These efforts to ensure a market for their imported crude oils have resulted in more equipment being installed to crack the very heavy portions of the crude oils into as much transportation fuel boiling-range material as is economically feasible. As of January 1, 1999, U.S. refineries had the ability to crack more than 50 percent of the crude oil charged to the refineries. As the demands for heavier products decreases, additional cracking equipment will be added to some U.S. refineries to increase the cracking ability to 60 percent or higher. Also, as the demand for cleaner burning transportation fuels with lower concentrations of aromatics and olefins increases, additional process equipment will be added to produce larger volumes of alkylates.

Most of the U.S. refineries are concentrated along the Gulf Coast, because most imported crude oils come from Venezuela, Mexico and Saudi Arabia and a large amount of U.S. domestic crude oil is produced near the Gulf Coast in Texas, Louisiana, Mississippi and Oklahoma. California also has a concentration of refineries that process crude oil from deposits in California and Alaska, in order to avoid the costs of transferring crude oils and products over or around the Rocky Mountains while also satisfying the large demands for transportation fuels in the West. These logistics explain in large part why over 54 percent of U.S. refining capacity is in the states of Texas, Louisiana, and California. Texas contains the most with more than 26 percent, Louisiana is second with almost 16 percent, and California is third with more than 12 percent. Environmental regulations, resistance to "having a refinery in my neighborhood," and economics have stopped the construction of completely new refineries in the U.S. since the 1970s. It is improbable that any will be built in the foreseeable future. Since the mid-1970s, all new complete refineries have been built overseas.

Because transportation fuels vary in boiling range and volatility depending upon the type of engine for which they are suitable, refineries are designed to be flexible to meet changes in feedstocks and seasonal variations in transportation demands. Typically, spark ignition engines require gasolines and compression ignition engines (diesels) require diesel fuels. Jet fuel (similar to kerosene) is used for most commercial and military aircraft gas turbines. Jet fuel demand fluctuates widely depending on the economy and whether the United States is involved in military operations. Most of the refineries in the United States are fuel-type refineries; that is, more than 90 percent of the crude oil feedstocks leave the refineries as transportation or heating fuels. Although there are other profitable products, they are small in volume compared to the fuels and it is necessary for the refinery to make profits on its transportation fuels in order to stay in operation. In 1999, there were 161 refineries in the United States, owned by eighty-three companies, and having a capacity of over 16,000,000 barrels per day (672,000,000 gallons per day). Worldwide, there are over 700 refineries with a total crude oil feed rate of more than 76,000,000 barrels per day. In the United States, for refinery crude oil feedstock capacities and crude oil purchases throughout the world, the standard unit describing amount is the barrel. The term *barrel* is outmoded and refers to the 42 U.S. gallon capacity British

Starter Material	*Boiling Point or Range*		*Product*	*Uses*
	°F	*°C*		
Methane & Ethane	-259°F -132°F	161°C - 91°C	Fuel gas	Refinery fuel
Propane	- 44°F	- 42°C	LPG	Heating
i-Butane	+11°F	-12.2°C		Feed to alkylation unit
n-Butane	31°F	-0.5°C	LPG, lighter fluid, gasoline	Gasoline blending or to LPG
Propylene and butylenes				Feed to alkylation or polymerization units
Light naphthas	80-180°F	27-82°C	Light gasoline	Gasoline blending or isomerization unit
Heavy naphthas	180-380°F	82-193°C	Heavy gasoline	Catalytic unit feed
Kerosine	380-520°F	193-271°C	Kerosine	Jet fuel
Atmospheric gas oil	520-650°F	271-343°C	Light gas oil	Blending into diesel fuels and home heating oils
Vacuum gas oils	650-1050°F	343-566°C		Feeds to FCCU and hydrocracker
Vacuum resid	1050°F+	566°C+	Vacuum tower bottoms (VRC)	Heavy and bunker fuel oils, asphalts

Table 1.
Characteristics of Some Typical Refineries

wooden salted-fish barrel used to haul crude oil to the refineries in horsedrawn wagons in the later part of the nineteenth century. Most of the world uses either metric tons or cubic meters as the unit of measurement.

REFINING SYSTEMS

All refineries are similar and contain many of the same basic types of equipment, but there are very few that contain exactly the same configuration, due to differences in the crude oils used as feedstocks and the products and product distributions needed. In addition, most refinery processing is very expensive, and many of the smaller companies do not have the necessary capital to install the latest highly capital-intensive technology such as alkylation units and hydrocrackers. Instead they use less costly units such as fluid catalytic cracking units (FCC) and polymerization units. However, except for the least complicated refineries, topping and hydroskimming refineries, they all have processes to change boiling range and improve quality.

A small number of refineries produce lubricating oils, but the total volumes produced are only about 3 percent of crude oil charged to U.S. refineries. Processes to make lubricating oil blending stocks are expensive from both capital and operating costs viewpoints. Nevertheless, the business is still profitable because lubes demand high retail prices. Older processes use solvent extraction to improve the temperature-viscosity characteristics (viscosity index) and low-temperature refrigeration tech-nologies, such as dewaxing, to lower the pour points of the lube oil blending stocks. Newer plants use selective hydrocracking and high-pressure hydrotreating to produce high-quality lube oil blending stocks. The newer equipment is so expensive that many of the new facilities are joint projects of two or more companies in order to gain enough volume throughout to justify the high capital investments.

Some refineries also install processes to produce petrochemical feedstocks. However, from a volume viewpoint, it is not a large part of refinery income. Even though profit margins can be high, most refineries restrict their capital investments to those

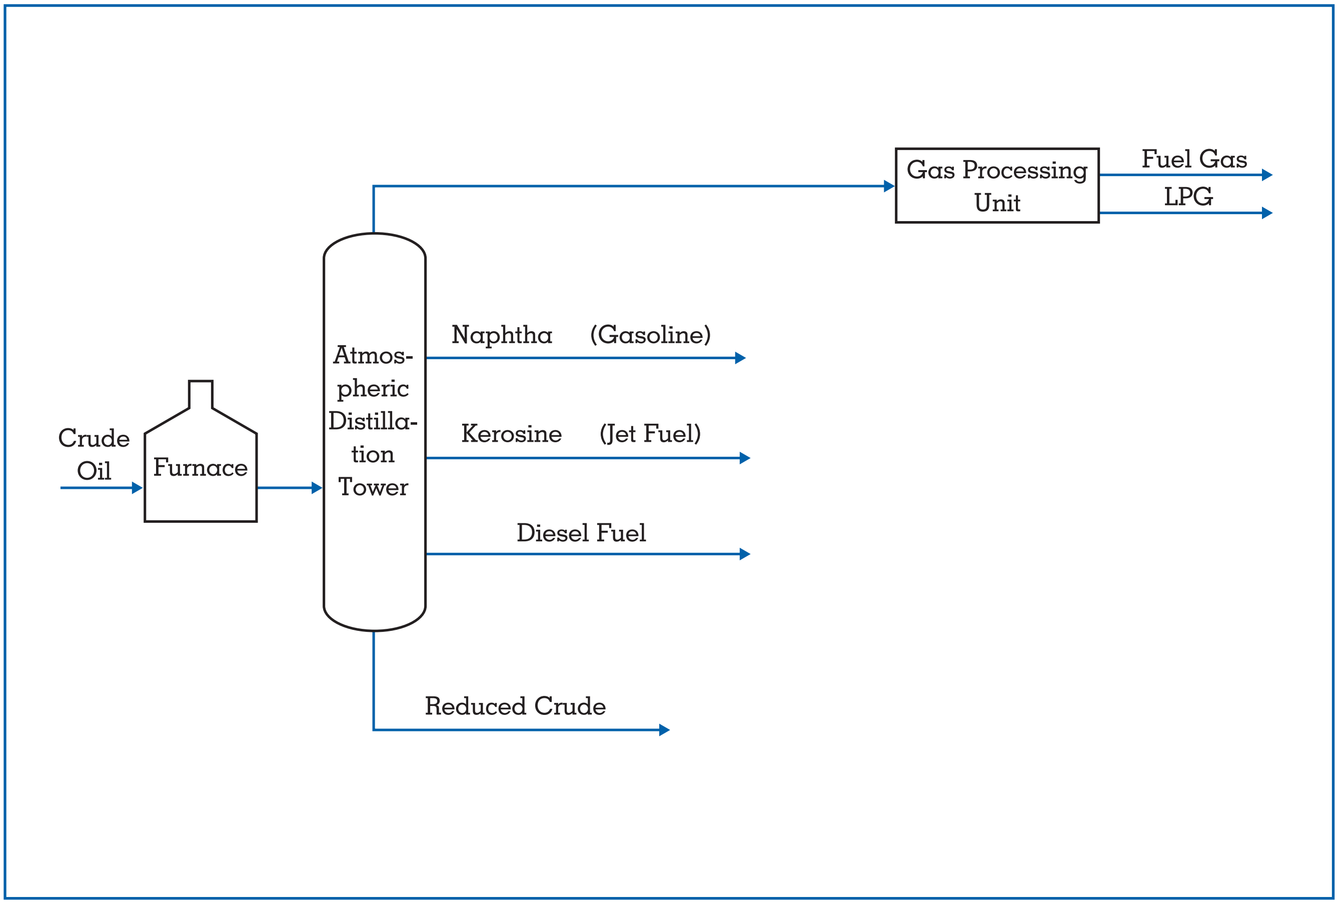

Figure 1.
Diagram of a Topping Refinery.

needed to produce transportation fuels. The most common petrochemical feedstocks produced are olefins (chiefly ethylene and propylene) and aromatics (benzene, methylbenzene [toluene], ethylbenzene, and xylenes [BTX compounds]). BTX compounds are produced in a catalytic reformer by operating at high reactor temperatures to produce 102 to 104 research octane products containing over 75 percent aromatics. Using solvent extraction, fractionation, and adsorption technologies the products are separated into individual aromatic compounds for sale as petrochemical feedstocks.

Topping and Hydroskimmimg Refineries

The *topping* refinery (see Figure 1) is the simplest type of refinery, and its only processing unit is an atmospheric distillation unit which *tops* the crude by removing the lower–boiling components in the gasoline, diesel fuel, and diesel fuel boiling ranges (those boiling up to 650°F [343°C]). The bottoms product from the atmospheric distillation unit (atmospheric resid, atmospheric reduced crude, or ARC) is sold as a heavy fuel oil or as a feedstock to more complex refineries containing conversion equipment that can convert the high–molecular–weight components into transportation fuel boiling–range products. Until recently the topped components could easily be converted into retail products by blending additives (such as lead compounds) into them. When lead compounds were banned from gasolines in the United States, it was necessary to add equipment to improve the octanes of the gasoline boiling–range components. Catalytic reforming units increased the octanes of the naphthas by converting paraffin molecules into aromatic compounds plus hydrogen. As a result, a topping refinery producing unleaded gasoline is a hydroskimming refinery.

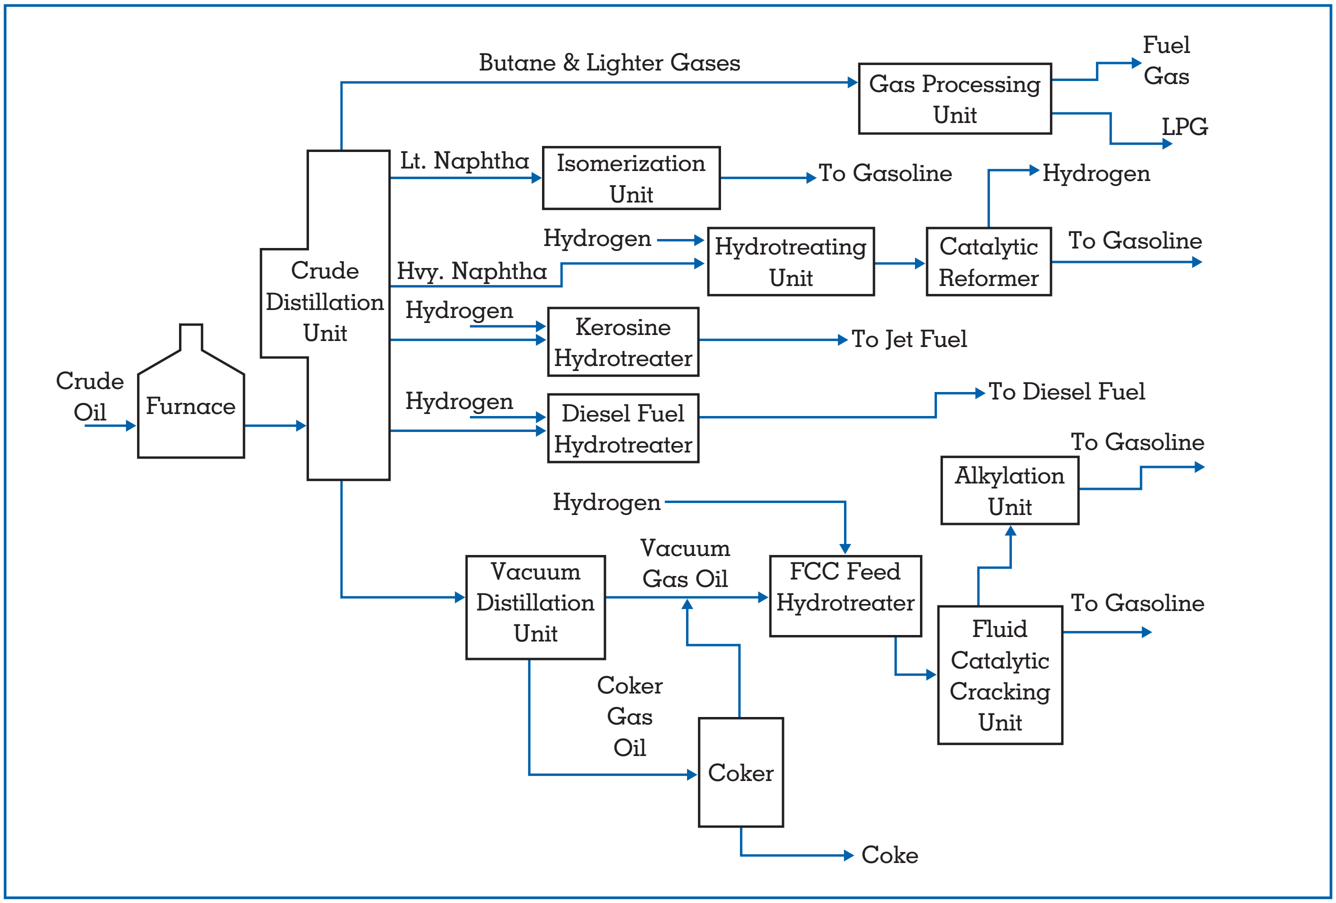

Figure 2.
Integrated Refinery.

Conversion and Integrated Fuels Refineries

Although a small amount of crude oils charged (less than 5 percent) to U.S. refineries is converted to specialty products, the remainder is either used in the refinery as a fuel or is processed into asphalt or fuel products including motor fuels and heating oils. The market for heavy fuel oils—those with boiling ranges above 650°F (343°C)—in the United States is less than 7 percent of the crude oil charged to U.S. refineries. It is therefore necessary to change the boiling ranges of the heavier portions of the crude to meet the product demands of the transportation fuels. Refineries with the necessary boiling-range conversion equipment are integrated or conversion refineries (see figure 2). The majority of the conversion equipment is to reduce boiling point—these are cracking units. When the molecules are cracked to reduce boiling range, secondary reactions produce some light hydrocarbons with boiling points too low for typical transportation fuels. Conversion equipment is also included to increase the boiling points of these components to permit blending into gasolines. As a result, about 70–80 percent of the crude oil charged to U.S. refineries is converted into gasolines, diesel and jet fuels, and home heating oils.

REFINERY PRODUCTS

Refineries produce more than 2,000 products, but most of these are very similar and differ in only a few specifications. The main products, with respect to volume and income, are liquefied petroleum gases (LPG), gasolines, diesel fuels, jet fuels, home heating oils (No. 1 and No. 2), and heavy heating oils (No. 4, No. 5, No. 6, and bunker fuel oil). Some refineries also produce asphalts and petroleum coke.

LPGs are gases that are liquefied at high pressures—up to 250 psig (17 bars)—and consist mainly

Generic name	*Characteristics*
Naphtha	Any liquid hydrocarbon material boiling in the gasoline boiling range
Middle distillate	Liquid hydrocarbons boiling in the jet fuel, diesel fuel, and home heating oil ranges
Gas oil	Hydrocarbons boiling at temperatures above 400°F (205°C) that have been vaporized and reliquefied
Coke	A solid residue from cracking operations, mostly carbon but with a small amount of high-molecular-weight hydrocarbons

Table 2.
Generic Names of Selected Refinery Products.

of mixtures of propane and butanes. These are sold in pressurized cylinders and are used for heating. Their selling price is related to the heating value.

Gasolines are the largest volume refinery products. In 1998, for instance, more than 330,000,000 gallons were consumed each day in the United States. This amounts to more than one million tons per day. The best known specifications for gasoline are octane numbers and Reid vapor pressure (RVP). The octanes are numbers determined by laboratory tests and can be related to performance of gasolines at normal road operating conditions. Octane numbers measure the resistance of the gasoline to self–ignition (knocking) and are determined by comparison with reference fuels. Self-ignition causes a decrease in engine efficiency and power, and when it occurs there are noticeable reductions in mileage and acceleration. Research octane number can be correlated with city driving performance (RON) and motor octane number (MON) with highway driving performance. Federal regulations require that the arithmetic average of these octanes ([RON + MON]/2) be posted on the pumps dispensing the gasolines. In 1998, about 70 percent of the gasolines sold in the United States were regular grade, and 30 percent premium grades. Regular gasoline posted octanes are 87 for lower elevations and 85 or 86 at higher elevations (above 3,000 feet). The octane requirement of an engine decreases with elevation. Refiners try to produce gasolines with the RON and MON as close together as possible, so their gasolines perform equally well for both city and highway driving but it is not practical. Refinery processing equipment has major effects on the sensitivity to driving conditions of the gasolines produced. Typically the RON and MON of gasolines will differ by six to twelve octane numbers (RON–MON). For gasolines the RON is always higher than the MON.

Reid vapor pressure determines ease of starting, engine warmup time, and tendency for vapor lock to occur. Vapor pressure is regulated by the addition of n–butane to the gasoline mixture. During summer months, EPA regulations limit the maximum vapor pressure of gasolines to as low as 7.2 psi in the southern U.S. and Rocky Mountain areas in order to reduce hydrocarbon vapor emissions into the atmosphere. During the cold months of winter, RVP is increased in northern areas to as high as 14 psi to make starting of cold engines possible and for the engines to warm up quickly. Normal butane not only increases RVP, but it also acts as an octane booster. During the summer months when less n–butane can be blended into gasolines, additional amounts of some other, more costly, octane booster must be added to compensate.

The cetane number determined in the laboratory by comparison with reference fuels is of value in that it is an indication of the ease of self–ignition. Diesel engines do not use a spark to ignite the fuel–air mixture in the cylinder but rely on the diesel fuel to self–ignite when injected with a high–pressure injection pump into the hot compressed air in the cylinder. The quicker the fuel self–ignites, the more efficient the engine. Many small refineries do not have cetane number determination equipment, so they substitute a cetane index equivalent to the cetane number and calculated from the fuel's gravity and average boiling point. The Environmental Protection Agency (EPA) requires that highway diesel fuels sold in the United States must have a cetane index (CI) of at least 40 and a sulfur content of less that 0.05% by weight (500 ppm). During 1998, almost 150 million gallons of diesel fuels and 60 million gallons of jet fuel were used in the United States per day.

REFINERY OPERATIONS

Refineries are unique businesses in that they operate on small profits per unit volume of product but produce very large volumes of product. This means that a regulatory adjustment (such as sulphur content) that creates a small change in operating costs per gallon of product (fractions of a cent) can mean the difference between profit and loss. The industry therefore strives to optimize refinery operations to lower costs and to improve efficiency.

One of the significant problems for refinery is the small amount of water emulsified in the crude oils coming into refineries. This water contains inorganic salts that decompose in the process units and form compounds that are corrosive to equipment and poison catalysts used in the processes. To prevent these costly problems, the first process in the refinery, desalting, reduces the water and salt content of the crude oils. Following desalting, the crude is sent to the distillation units (crude stills) to be separated into fractions by boiling range. The first of the crude stills, the atmospheric distillation unit, vaporizes and separates those components boiling below about 650°F (345°C) into four general categories; butane and lighter (methane, ethane, and propane) gases, light and heavy naphtha fractions, kerosene, and atmospheric gas oil. (Gas oil is a generic name for any hydrocarbon boiling above the end boiling point of gasoline that has been vaporized and condensed into a liquid.) The unvaporized material boiling above 650°F is removed from the bottom of the distillation column as vacuum resid or atmospheric reduced crude (ARC). The naphtha fractions are in the gasoline boiling range but, before blending into gasoline, their quality has to be improved by increasing their octanes and reducing the sulfur contents. The kerosene is hydrotreated (reacted with hydrogen) to reduce the sulfur content and blended into jet fuel. And the atmospheric gas oil is hydrotreated to reduce the sulfur content and is blended into diesel fuels and home heating oils (No. 1 and No. 2 heating oils).

The atmospheric reduced crude is the feedstock for the vacuum distillation unit. To prevent thermal decomposition (cracking) of the higher boiling point hydrocarbons in the crude oil, the pressure in the vacuum distillation fractionation column is reduced to about one-twentieth of an atmosphere absolute (one atmosphere pressure is 14.7 psia or 760 mm Hg). This effectively reduces the boiling points of the hydrocarbons several hundred degrees Fahrenheit. The components boiling below about 1050°F (565°C) are vaporized and removed as vacuum gas oils, the unvaporized material is removed from the bottom of the unit as vacuum reduced crude (vacuum resid or VRC). The vacuum gas oils are sent as feedstocks to either fluid catalytic cracking units or to hydrocrackers. The fluid catalytic cracking units crack the vacuum gas oils into gasoline blending stocks (up to 70 percent by volume on feed) and gas oil blending stocks for diesel fuels and home heating oils. The gasoline blending stocks have octane numbers in the high eighties and, if the sulfur contents are sufficiently low, can be blended directly into gasolines. The gas oil blending stocks have low cetane numbers and poor burning characteristics that limit the amounts that can be blended into diesel fuels and home heating oils.

If the crude oils from which the vacuum reduced crudes are made have the proper qualities (low wax and high asphaltenes), the vacuum-tower bottoms can be blended into asphalt products and sold to pave roads and make roofing materials and sealants. The vacuum reduced crudes also can be sold as heavy fuel oils or used as feedstocks to a severe thermal cracking unit (coker) to convert them into lower boiling hydrocarbons plus solid coke residues. The coker converts the vacuum tower bottoms into feedstocks for other refinery processing units to make gasolines, light heating oils, and, if used as hydrocracking unit feedstocks, produce gasoline, diesel fuel, and jet fuel blending stocks. Historically, the heavy fuel oils have sold, on a volume basis, for about 70 percent of the prices paid for the crude oils from which they were produced. When crude oil is selling for twenty dollars per barrel, heavy fuel oil will be selling for about fourteen dollars per barrel. This discounting is necessary because the amount of heavy fuel oil available exceeds demand. The alternate cost of processing the vacuum tower bottoms in the refinery is much higher than the cost of processing crude oil. The vacuum reduced crudes sell at a loss, or they are converted into salable products by processing the liquid products from a coker in other refinery processing units. The coke produced by the coker can be sold as a fuel, to make anodes for aluminum production, or to make electrodes for electric steel furnaces.

Fluid catalytic cracking units (FCC or FCCU) are the major processing units to reduce boiling ranges of those crude oil components that have boiling points higher than the final boiling points of the transportation fuels—typically above 650°F (343°C). These

Imperial Oil refinery in Edmonton, Alberta, Canada. (Jack Fields/Corbis)

units circulate finely divided (about the size of very fine sand particles) silica-alumina-based solid catalyst from the reactor to the regenerator and back. The reactor operates at temperatures between 950 and 1,100°F (510–595°C) to crack the large molecules in the gas oil feed selectively into smaller molecules boiling in the gasoline boiling range of 80–400°F (27–205°C). When the cracking takes place in the reactor, coke is also produced and is laid down on the surface of the catalyst. This coke layer covers the active cracking sites on the catalyst, and the cracking activity of the catalyst is reduced to a low level. Conveying the catalyst to the regenerator, where the coke is burned off with air, restores the catalyst activity. This cycle is very efficient: the heat generated by burning the coke off the spent catalyst in the regenerator supplies all of the heat needed to operate the unit. The regenerated catalyst leaving the regenerator has had its activity restored to its original value and at a temperature of about 1,300°F (705°C) is returned to the riser–reactor and mixed with fresh feed to continue the cracking reactions. By controlling the reactor temperature, the conversion of the feed to gasoline boiling range components can be maximized during the summer when gasoline demand is at its highest. In practice, up to 70 percent by volume of the product is in this boiling range. The product is rich in aromatic and olefinic compounds, which makes the high quality FCC gasoline very suitable for blending into the final refinery gasoline products. The remainder of the feed is converted into butane, lighter gases, and catalytic gas oils (typically called cycle gas oils) that are blended into diesel fuels or home heating oils, or used as feedstocks to hydrocrackers. During the winter, when gasoline demand is lower and home heating oil is needed, the severity of the operation is lowered by reducing the reactor temperature, and the yields of the cycle gas oils stocks used for blending into home heating oils and diesel fuels is more than doubled. The gasoline boiling-range products are reduced by one-quarter to one-third. The butane and lighter gases are separated into components in the FCC gas recovery plant. The propylenes, butylenes, and isobutane are used as feedstocks to alkylation units to make alkylate gasoline blending stocks. Alkylates have blending octanes in the nineties and have low sensitivities to driving conditions (they perform equally well for highway and city driving with RON and MON within two numbers of each other). The hydrocarbons in alkylates are also less environmentally damaging and show less health effects than olefins or aromatics. For those refineries without alkylation units, the propylenes can be used as feedstocks to polymerization units to produce polymer gasoline blending stocks. The polymer gasoline has a blending octane of approximately 90 but performs much more poorly under highway driving conditions than in the city (about sixteen numbers difference between the RON and MON).

Some refineries have hydrocracking units in addition to the FCC unit. Hydrocracking units operate at high hydrogen pressures and temperatures and are constructed of high-alloy steels. This makes them very expensive to build and operate. They are able to use feedstocks containing high concentrations of aromatics and olefins and produce jet fuel and diesel fuel products as well as naphthas for upgrading and blending into gasolines. The FCC units operate most efficiently with paraffinic feedstocks and produce high yields of high-octane gasoline blending stocks. Hydrocrackers give higher yields than FCC units, but the naphtha products have octanes in the seventies and the heavy naphtha fraction—180–380°F (82–195°C)—must be sent to the catalytic reformer to improve its octane. It is possible to make specification jet and diesel fuels as products from the hydrocracker.

In any cracking process, secondary reactions produce light hydrocarbons whose boiling points are too low to blend into gasolines. These include both olefins and paraffins. Olefins contain at least one double bond in each molecule and are very reactive whereas paraffin molecules contain only single bonds and are considered unlikely to undergo chemical reactions. Some of the light hydrocarbon olefins produced can be reacted with each other (polymerization) or with isobutane (alkylation) to produce high–octane hydrocarbons in the gasoline boiling. The olefins used are propylenes and butylenes; ethylene is also produced from cracking operations but is not used in refinery processing.

Crude oil components with boiling ranges in the gasoline blending range have low octanes, and the octanes must be increased in order to make a product suitable for modern automobiles. For light naphthas containing molecules with five and six carbons (pentanes and hexanes), octanes can be improved from thirteen to twenty numbers on the average by isomerization processes. These processes convert normal paraffins into isoparaffins that have more compact molecules with higher octane numbers. The heavy naphthas with hydrocarbons containing from seven to ten carbon atoms, have their octanes increased into the nineties by converting paraffin molecules into aromatic molecules by reforming the molecules into ring structures and stripping off hydrogen. This process is catalytic reforming. Catalytic reforming is the only refinery process in which the operator has any significant control over the octane of the product. The more severe the operation (the higher the temperature in the reactor), the greater the percentage of aromatics and the higher the octanes of the products—but the smaller the volume of products produced. Usually the units are operated to produce products (reformate) with research octane numbers (RON) in the range of 96 to 102 to be blended with other naphthas to give the desired quality (pool octanes) sold to consumers.

Other refinery processes used to improve product quality include hydrotreating (hydrodesulfurization, hydrodenitrogenation, and demetallization), sweetening, and visbreaking. Hydrotreating reduces impurity contents of all of the impurities except metals by reacting hydrogen with the impurity to produce low-boiling compounds that are gases and can be separated from the liquid material. These reactions are carried out at high temperatures and pressures in reactors filled with catalysts containing metals that promote the reaction of hydrogen with the impurity. Hydrogen reacts with sulfur to form hydrogen sulfide, with nitrogen to produce ammonia, and with the molecules containing metals to deposit the metals on the catalyst supports. The processes operate at temperatures between 600°F (315°C) and 750°F (400°C) and pressures from 400 psig (27 bars) to 1600 psig (110 bars). Because these processes operate with hydrogen at high temperatures, the equipment is made of very expensive high–alloy steels. Energy and hydrogen costs result in high operating costs, much higher per barrel of feed than the FCC unit.

Refiners use sweetening processes to remove mercaptans that give a very unpleasant odor to gasolines and middle distillates (the skunk uses mercaptans to protect itself). This is done by washing the hydrocarbon stream with a caustic solution followed by a wash with water to remove the caustic.

Visbreaking is a mild thermal cracking process that reduces the viscosity of heavy fuel oils and reduces the amount of low-viscosity blending stocks that must be added to the heavy residuals to meet viscosity specifications of the specific heavy fuel oil. The amount of heavy fuel oil production by a refinery is reduced by 20–30 percent if a visbreaker is used. The refinery profitability is improved with visbreaker operation, because heavy fuel oils are low value products.

Small refineries usually produce the products in greatest demand, such as gasolines, jet and diesel fuels, and heavy fuel oils. Larger refineries produce a much broader slate of products because, with much higher feed rates, they can make economical volumes of small volume products. In addition, environmental requirements have made it much more difficult for small refineries because of the large capital investments required for the equipment to reduce impurities. Published economic studies indicate that refineries of less than 80,000 barrels per day of capacity do not produce sufficient income to justify the expensive equipment necessary for reformulated fuel production. Having fewer large refineries increases the transportation costs of getting the products to the necessary markets, but the increased size gives economies of scale. There are always fixed costs of labor and management that are independent of equipment size, and the incremental costs of higher charge rates are much less per unit volume than the total of fixed and operating costs. Depreciation costs per unit volume of throughput also decrease with the size of the equipment. In 1998, U.S. refineries operated at above 95 percent of rated charge capacity. This is much higher than it has been in the past. Even so, they have not been able to keep up with domestic demand, and imports of finished products have been increasing.

Operating costs vary a great deal from one refinery to another. Factors include the types of processes and equipment, the amount of the crudes that have to be cracked and alkylated to achieve the products desired, the degree of hydrogenation needed to meet product and environmental specifications, and the complexities and locations of the refineries. Energy is the single largest component of operating cost, so the costs of crude oils are major factors. For a simple hydroskimming refinery, the energy needed to process the crude oil can be as low as 2 percent of that in the crude oil, while for a very complex refinery with a large number of hydrogenation processes, it can be 8 percent or more of that in the crude oil.

SAFETY AND ENVIRONMENTAL CONCERNS

The increasingly stringent environmental quality improvements for transportation fuels as specified by the EPA is putting constraints on present processing technologies. Process equipment needed for the newer technologies to meet future environmental restrictions is very costly and requires long lead times to design and build. Since the removal of low-cost lead compounds, used until the 1970s to increase the octanes of gasolines, refineries have been providing the replacement octane improvement needed by increasing the high-octane aromatic and olefin content of gasolines and also the amount of high-octane blending compounds containing oxygen (alcohols and ethers). The EPA is reducing the maximum aromatics and olefins content of reformulated gasolines for health and pollution reasons. There also is concern over the appearance of ethers in ground waters because of possible health effects, and it may be necessary to restrict their usage in gasolines. There is not enough ethanol available today to replace these components while providing the volumes of high-octane gasolines needed (over one million tons per day of gasolines used in the United States in 1998). Other ways must be used to provide the high octanes needed and to reduce degradation of the environment.

The United States is unique among the major countries in that supply and demand has determined price structures in the petroleum industry. Today, even though the products are much better than fifty years ago, the before-tax retail prices of gasolines, diesel fuels, and heating oils are much less on a constant-value dollar basis than they ever have been before. Even with the federal and state taxes included, the retail prices on a constant-value dollar basis are equivalent to those paid during the Depression years. In Europe, for example, taxes account for up to 80 percent of the costs of motor fuels that sell at retail for three to four times as much as they do in the United States.

U.S. production of crude oils has already peaked, and it is predicted that world production of crude oils will reach its maximum between 2010 and 2030. This does not mean that an adequate supply of crude oil will not be available, but supply and demand will create price structures that will make other sources of fuel more competitive. Global warming may also impose restrictions on the use of hydrocarbon fuels but, at the present time, there are no alternatives that do not require long lead times and very expensive and time consuming periods for building plants to produce the alternative fuels. If the alternatives cannot be marketed in existing petroleum facilities, it will also require that broad systems be built to market the fuels. It is difficult to conceive of the efforts that must be made to replace gasoline in the United States. Methanol has been mentioned as a replacement, but if the total annual production of methanol in the United States in 1998 was used in automobiles instead of gasoline, it would only be enough to operate them less than a week. During 1998, there were problems with electricity blackouts and restrictions of use in the United States without the added imposition of the power needed to charge batteries for replacement of gasolines in automobiles. conversion from petroleum fueled to electric powered vehicles will require the building of many more generating plants to supply the electricity necessary to meet transportation needs. When petroleum based fuels are replaced for transportation, several fuels probably will be used rather than one. Local deliveries, long distance deliveries, and travel will each use the most economical and environmentally friendly fuel.

REFINING, HISTORY OF

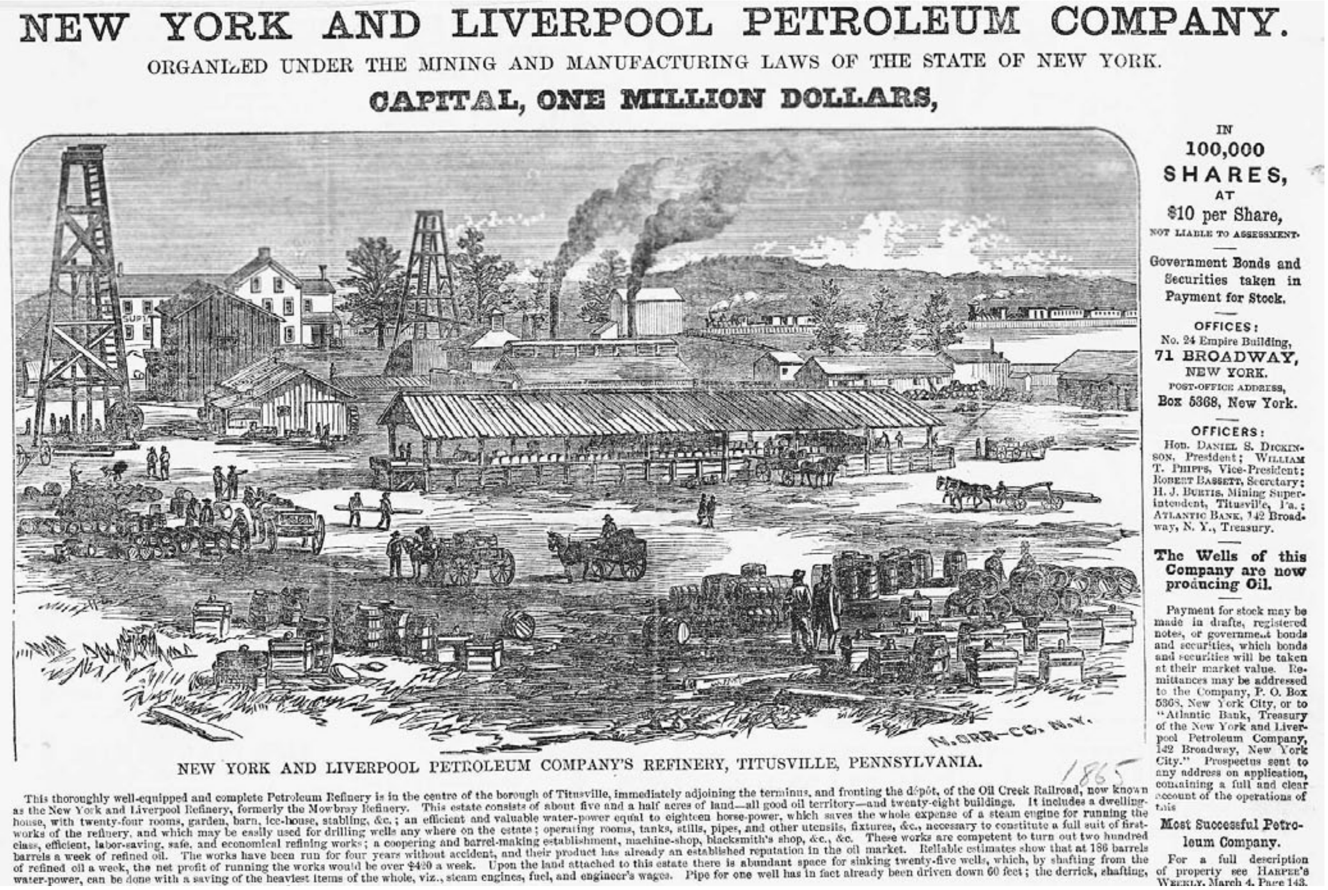
The U.S. petroleum refining industry has played a central role in the expansion of this country's energy capacity over the last century. Currently, petroleum refiners generate products which account for approximately 40 percent of the total energy consumed in the United States (with respect to Btu units). The industry is characterized by a small number of large, integrated companies with multiple high-capacity refining facilities.

Between 1982 and 1997, the total number of U.S. refineries had declined from 300 to 164 operating companies. This contraction was due for the most part to the closing down of the smaller refining operations, i.e., refineries with less than 50,000 barrels of crude oil per day (BPD) capacity. While the smaller refineries still generally account for up to half of all U.S. facilities, in aggregate they control barely 14 percent of total U.S. crude refining capacity.

PROCESS DESCRIPTION: OVERVIEW

In general, refining consists of two major phases of production. The first phase of production acts on the crude oil once as soon as it enters the plant. It involves distilling or separating of the crude oil into various fractional components. Distillation involves the following procedures: heating, vaporization, fractionation, condensation, and cooling of feedstock.

Distillation essentially is a physical operation, i.e., the basic composition of the oil remains unchanged. The second phase of production, which follows distillation, is chemical in nature in that it fundamentally alters the molecular composition of the various oil fractions. These processes depend on heat and pressure and, virtually in all cases, the use of catalysts. These processes are designed to improve the octane number of fuel products. For example, in the process of isomerization, rearrangement of the molecules occurs, resulting in different chemical configurations (e.g., branched vis-à-vis linear structures) but with the atomic composition remaining constant. Polymerization involves the formation of larger molecules (polymers) from smaller ones. Reforming transforms hydrocarbons into other hydrocarbons, often to make aromatics from nonaromatic petroleum constituents (e.g., paraffins and naphthenes).



NEW YORK AND LIVERPOOL PETROLEUM COMPANY.

ORGANIZED UNDER THE MINING AND MANUFACTURING LAWS OF THE STATE OF NEW YORK.

CAPITAL, ONE MILLION DOLLARS,

IN
100,000
SHARES,
AT
$10 per Share,
NOT LIABLE TO ASSESSMENT.

Government Bonds and Securities taken in Payment for Stock.

OFFICES:
No. 24 Empire Building,
71 BROADWAY,
NEW YORK.
POST-OFFICE ADDRESS,
Box 5368, New York.

OFFICERS:
Hon. DANIEL S. DICKINSON, President; WILLIAM T. PHIPPS, Vice-President; ROBERT BASSETT, Secretary; H. J. BURTIS, Mining Superintendent, Titusville, Pa.; ATLANTIC BANK, 142 Broadway, N. Y., Treasury.

The Wells of this Company are now producing Oil.

Payment for stock may be made in drafts, registered notes, or government bonds and securities, which bonds and securities will be taken at their market value. Remittances may be addressed to the Company, P. O. Box 5368, New York City, or to "Atlantic Bank, Treasury of the New York and Liverpool Petroleum Company, 142 Broadway, New York City." Prospectus sent to any address on application, containing a full and clear account of the operations of this

Most Successful Petroleum Company.

NEW YORK AND LIVERPOOL PETROLEUM COMPANY'S REFINERY, TITUSVILLE, PENNSYLVANIA.

1865

This thoroughly well-equipped and complete Petroleum Refinery is in the centre of the borough of Titusville, immediately adjoining the terminus, and fronting the dépôt, of the Oil Creek Railroad, now known as the New York and Liverpool Refinery, formerly the Mowbray Refinery. This estate consists of about five and a half acres of land—all good oil territory—and twenty-eight buildings. It includes a dwelling-house, with twenty-four rooms, garden, barn, ice-house, stabling, &c.; an efficient and valuable water-power equal to eighteen horse-power, which saves the whole expense of a steam engine for running the works of the refinery, and which may be easily used for drilling wells any where on the estate; operating rooms, tanks, stills, pipes, and other utensils, fixtures, &c., necessary to constitute a full suit of first-class, efficient, labor-saving, safe, and economical refining works; a coopering and barrel-making establishment, machine-shop, blacksmith's shop, &c., &c. These works are competent to turn out two hundred barrels a week of refined oil. The works have been run for four years without accident, and their product has already an established reputation in the oil market. Reliable estimates show that at 186 barrels of refined oil a week, the net profit of running the works would be over $420 a week. Upon the land attached to this estate there is abundant space for sinking twenty-five wells, which, by shafting from the water-power, can be done with a saving of the heaviest items of the whole, viz., steam engines, fuel, and engineer's wages. Pipe for one well has in fact already been driven down 60 feet; the derrick, shafting,

New York and Liverpool Petroleum Company refinery in Titusville, Pennsylvania, 1865. (Corbis Corporation)

The most important of the second phase refinery operations is cracking. Cracking breaks down large hydrocarbon molecules into smaller and lighter molecular units. At first performed using high temperatures and pressures only, by the 1930s, catalytic cracking was begun. Catalytic cracking went further than earlier cracking technology to reduce the production of less valuable products such as heavy fuel oil and cutter stock.

Cracking represents a fundamental advance in refining process technology. Innovation here was mostly responsible for increasing the throughput capability of the industry and heightening octane numbers for both motor and aviation fuel. Cracking technology was central to the success of the U.S. petroleum industry in delivering needed fuel for both the marketplace and the strategic requirements of World War II.

Cracking process technology has been a distinctly American achievement. Although Europeans helped transfer some important cracking innovations to the United States, it was the U.S.-based companies and their engineers who converted these yet unrealized prototypes into commercially viable, full-scale plants.

Cracking technology evolved out of the need to solve a series of increasingly complex technical problems. Ultimate success in handling such difficult problems as carbon buildup on the catalyst surface, non-uniform distribution of thermal energy, and catalyst breakage and equipment failure came with development of the fluid catalytic cracking process in the early 1940s.

EARLY REFINING TECHNOLOGY

In the late nineteenth and early part of the twentieth centuries, refining operations were in essence distillation procedures. The refinery did little more than separate the petroleum into various fractions for commercial use. Prior to World War I, gasoline was not a dominant product of the refinery. The most commercially useful products resided in the lower (e.g., denser) range of the petroleum fractions. In order of importance, these products consisted of kerosene (for heating and light), and a variety of oils, waxes, and lubricants for industrial and home use.

The machinery employed in the early refineries was rather small in scale and operated inefficiently. Generally, equipment consisted of a series of shell tubes or stills. These were placed in the horizontal position and were connected one to another from the top through the use of vapor pipes. These pipes directed the vapors from the stills into condensers which cooled the gases and so caused the products to separate out. These products were then collected in sequence, often at one point in the plant, as liquids of varying densities and properties.

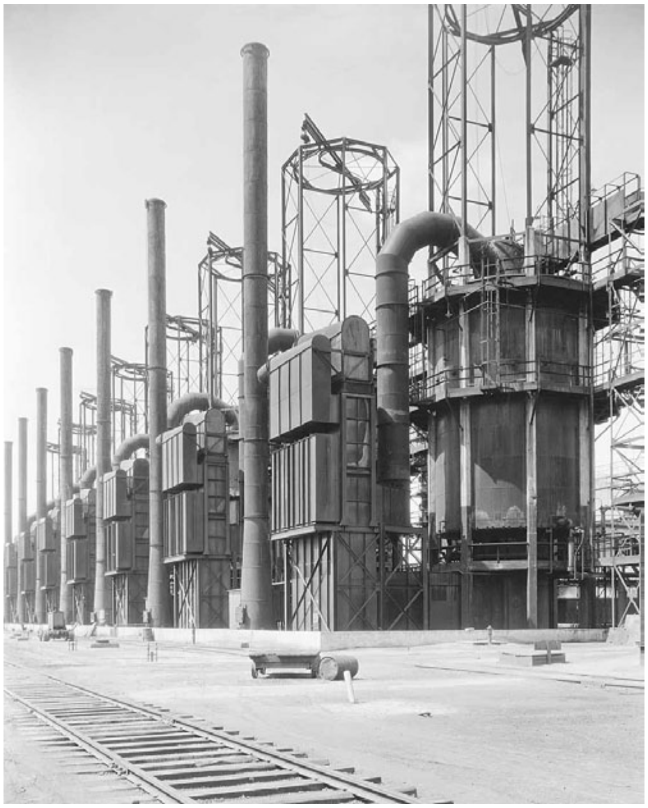
Despite various mechanical attempts to increase throughput, operations were at first conducted in batches, which required the plant to be shut down for the still and ancillary equipment to be cleaned out. Until cracking technology entered the picture, refinery operations were inefficient as they captured for use barely 50 percent of the available petroleum.

THERMAL CRACKING TECHNOLOGY

The initial impetus for development of a cracking process came in the years prior to World War I with the greater demand for gasoline products for the emerging automotive industry. Although early experimental work on the high-pressure cracking of petroleum was conducted in Europe in the late nineteenth century, the commercial breakthrough came in the years leading up to World War I by Standard Oil (Indiana). In 1913, William Burton, a petroleum chemist at Standard Indiana, conceived of commercially breaking down the molecular components comprising petroleum into smaller molecular units by the force of high pressure.

While his experiments yielded acceptable gasolines, serious problems arose as Burton attempted to scale up his process. The short cycles forced on producers by extensive coking worked against continuous operations. The carbon buildup interfered with heat transfer from the furnace to the petroleum and resulted in the formation of "hot spots" and in turn damage to the vessel. Pressure control was also a problem.

An assistant of Burton at Standard Indiana, E. M. Clark modified Burton's still in a fundamental way. Clark perceived that Burton's problems arose because heat and pressure were being applied to a static mass of petroleum within the autoclave. This situation was conducive to the formation of carbon at the bottom of the vessel and made it difficult to control pressure and obtain a uniform cracking throughout the charge. Clark retained Burton's use of high pressures but within the context of the tube still. In this design, oil flowed through, and was cracked within, banks of tubes. Each tube measured five feet in length. The hydrostatic pressures within the tubes produced uniform flow conditions. These banks of tubes were suspended in a furnace. Partially cracked charge was then directed upward to an overhead "soaking" tank. Here, cracking continued to completion under pressure but without the application of heat.



View of cracking stills at a Sinclair oil refinery. (Corbis Corporation)

An important aspect of Clark's technology was that the oil being cracked, which flowed through the tubes and in a near vapor state, was maintained in a continually dynamic or turbulent condition. This meant that the coke particles which formed were prevented from adhering to the sides of the tubes. Further, as a result of the high surface/volume ratio of the still, heat transfer through the tubes was facilitated and higher pressures could be applied. Thus, whereas the Burton process operated at a maximum of 100 psi, Clark's tube still handled pressures of up to 1,000 psi.

The first commercial Tube-and-Tank cracking plant came on line in 1922. Overall, compared to the Burton Process, the Tube-and-Tank Process allowed larger volumes of petroleum to be processed under conditions of intense cracking and longer production cycles.

In the 1920s, a number of new thermal cracking technologies emerged that, in essence, were variations of the Burton-Clark designs. These included most notably the Cross and Holmes-Manley processes. These processes provided innovations in such parameters as operating conditions, methods of removing coke, and the number and configuration of the overhead soaking chambers.

These processes remained batch-type operations. As such they reached capacities in the range of 1,000–3,000 barrels per day (BPD). A truly novel approach to thermal cracking emerged from the facilities of the Universal Oil Products company in the late 1920s. To a greater extent than the other thermal cracking technologies, the so-called Dubbs Process approached continuous operations. Important elements of this technology were the continuous recycling of heavier byproducts back into the cracking section for further processing and the so-called bottom draw-off technique that continuously removed heavy liquid from the bottom portion of the soaking drum. This procedure reduced the rate of carbon buildup in the system and so increased the time over which the still could operate before being shut down for cleaning.

CATALYTIC CRACKING TECHNOLOGY

By the early 1930s, thermal cracking had achieved a fairly high level of operation. Both the Dubbs (UOP) and Tube-and-Tank (Jersey Standard) Processes represented the state of the art in the field. Between the end of World War I, when the Burton Process was still revolutionary, and the early 1930s, octane ratings of gasoline increased 36 percent. This improvement resulted from the existence of more advanced thermal plants and the increasing use of additives, especially tetraethyl lead. Moreover, the quantity of gasoline produced increased. Not only were the Dubbs and Tube-and-Tank technologies inherently more efficient than earlier thermal designs, but they were also readily scaled up in capacity. Through the 1930s, the size of thermal plants increased. The dimensions and amount of equipment used within a facility grew.

By the mid-1930s, thermal cracking reached its zenith in scale and sophistication. At this time the world's largest thermal cracking unit, built by Indiana Standard in Texas city, Texas, had a capacity of 24,000 BPD. This represents a capacity over 270 times larger than the first Burton stills and over forty-two times larger than the early Tube-and-Tank units.

Fixed Bed Processes: Houdry Catalytic Cracking

At this time, forward-looking companies understood that the ability of a refiner to control the highest octane fuels could corner critical and specialized niche automotive and aviation fuel markets. Refiners looked on catalytic cracking as a way to more finely tune their products for these market segments.

By the mid-1930s, catalytic technology entered into petroleum refining. To a greater extent than thermal cracking, catalysis permitted the close control of the rate and direction of reaction. It minimized the formation of unwanted side reactions, such as carbon formation, and overall improved the yield and quality of fuel output.

Within the United States, catalytic cracking was carried out on petroleum vapors. In contrast to thermal cracking, catalytic cracking did not require the application of ultra-high pressures.

The first attempt at a commercial catalytic process was the Macafee Process. In this design, cracking took place within a circular vessel packed with aluminum chloride catalyst. Cracked gasoline vapor products exited the reactor through a series of chimney-like structures. The Gulf Refining Company built a working plant at Port Arthur, Texas, just after World War I. However, the rapid accumulation of carbon deposits on the inside of the reactor and the high cost of the catalyst precluded further development in this direction.

Further catalytic cracking efforts did not take place in earnest in this country until the early 1930s. Sun Oil undertook the first significant commercial effort in catalytic cracking beginning in 1932. At this time, Sun Oil, based in Marcus Hook, Pennsylvania, was a relatively small company. It operated a number of oil tankers and had at its disposal a growing pipeline network in the Northeast and increasingly the South and West. In addition to a refinery at Marcus Hook, it operated a large refinery at Toledo, Ohio. Sun established its reputation as a producer of a variety of high-quality fuels and related oil products. Having taken thermal cracking to its limit through the use of high pressures, Sun embraced a promising new method developed by Eugene Houdry, a French mechanical and automotive engineer.

Through the 1920s Houdry had experimented in France on a number of possible catalytic routes to higher octane fuel. Finding little success in France, he came to the United States to further develop his process. After initial attempts at commercialization under the sponsorship of Sacony-Vacuum Company (currently Mobil) in Paulsboro, New Jersey, failed, Houdry and his development company, Houdry Process Corporation, moved to Sun.

Over the next four years, Houdry, working closely with Sun's engineering team headed by Clarence Thayer, worked to build a commercial plant. The limitations imposed by a static catalyst bed design imposed a major obstacle, particularly in the formation of carbon deposits that fouled the catalyst mass and impeded a continuous system of production.

The commercialization of the Houdry Process involved borrowing and integrating mechanical designs from the automotive, electrical, and metallurgical industries. The Houdry Process consisted of a series of catalyst cases containing the cracking catalyst. Each case went through a succession of operations: cracking (which over time resulted in carbon deposits on the catalyst), preparation of the catalyst for regeneration (via the purging of oil vapors), regeneration of the spent catalyst (burning off of carbon deposits from the catalyst surface), preparations for the next cracking operation (i.e., purging the newly regenerated catalyst of combustion or flue gases), cracking, and so on. To approximate continuous operation, the process placed the catalyst cases on different phases of the cycle (via a staggered arrangement) at any one time. In this way, cracking, purging, and regenerations were carried on simultaneously in different cases.

Internal tube components were an important part of the Houdry Process. Tubes were used to distribute oil vapors over the catalyst during cracking and to receive and direct cracked vapors and combustion gases (after regeneration) to various parts of the system. Tubes also played a central role in heat control. Fluid-filled, heat control tubes were placed deep within the catalyst bed so that they tapped and transferred heat which built up throughout the mass.

The hot fluid moved through the tubes to a boiler into which heat energy was transferred. Steam generated here was transported back through the tubes to heat the catalyst for the cracking operation. Initially, the heat transfer fluid used was water or superheated steam. Because these fluids tended to cause tubes to crack, a more advanced design was developed that utilized molten salts, chemically and physically more stable under the rigorous operating conditions.

By the early 1940s, a Houdry plant capacity ranged from 7,000 to 15,000 barrels per day. Houdry's contribution to the U.S. energy industries extends beyond fuels. The Houdry Process was the first industrial technology in the United States to employ on a large scale the gas turbine system, adapted from European designs, and the heart of the energy recycling process. Capturing and turning into useful mechanical energy the heat generated during combustion in the regeneration cycle was especially critical. The Houdry Process paved the way for energy recycling technology, including the process commonly called cogeneration, in such industries as power generation and iron and steel production.

But there were many problems in the operation of the Houdry Process that could not be resolved. Even with its sophisticated regeneration system, carbon continued to form on the catalyst over a period of time. The heat transfer system was not as efficient as it needed to be. The process never achieved fully continuous operations, limiting the quantity of oil that could be processed and the quality of the gasoline produced. At its height (late 1930s, early 1940s) the process did not produce gasoline with an octane rating above 87. It never captured more than 10 percent of the total U.S. cracking capacity, although in the early 1940s it controlled over 90 percent of the total catalytic cracking market.

Moving-Bed Processes: The Thermofor and Air-Lift Systems

Sun attempted to resolve these problems by improving upon the fixed-bed process. The Sacony-Vacuum Company (formerly the Standard Oil company of New York and the future Mobil Oil) was the first to develop a different type of catalytic cracking process. While involved with Sun Oil in development of the fixed-bed process, Sacony early on understood the limitations of that technology. Beginning in 1932, Sacony began conceiving of the moving-bed concept.

In its development, it adapted two existing technologies. In the agricultural sector, the mechanics of grain elevators provided a model for how to move solids vertical distances and in closed-loop flow arrangements. Sacony engineers modified the elevator bucket systems traditionally used by the grain industry to carry hot catalyst from the bottom to top of vessels and between vessels.

Then too, Sacony modeled its regenerator vessel after a certain type of metallurgical furnace (known as the Thermofor kiln). The vessel consisted of a series of semi-independent burning zones. Distribution channels delivered compressed oxygen to each zone to fuel combustion. A series of baffles and ducts within each combustion compartment produced a uniform distribution of air through the catalyst. Flue gases emitted by the regeneration process collected in common headers located between the burning zones.

The so-called Thermofor moving-bed process borrowed two important techniques from Houdry's technology: a molten salt cooling system for the kiln section and gas turbine technology that generated power to pressurize more air for the regenerator. The catalyst was stored in an overhead hopper, from which it was fed into the catalyst-filled reactor. The catalyst then traveled down the vessel under the influence of gravity. In the commercial plants, oil, injected as a liquid spray near the top of the reactor, moved down along with the catalyst. During this time, the latter transferred its heat, obtained and stored during the previous regeneration cycle, to the oil. The system conserved on energy by thus recycling heat units through the catalyst which simultaneously vaporized and cracked the oil particles that descended with it.

Following cracking, the spent catalyst and oil descended to a disengager that separated the gasoline from the catalyst. The catalyst, with oil residue entrained on its surface, then moved through a purging section where superheated steam thermally removed oil remnants. The oil-free catalyst, still laden with carbon deposits, was then lifted by elevator from the bottom of the reactor to the top of the regenerator.

Regeneration was carried out as the catalyst fell through various burning zones. The flue gases were recycled by being directed to the turbo-compressors that the pressurized air used as fuel in the combustion process.

The first Thermofor cracking unit came on line in late 1942. By March of 1943, twenty Thermofor units had been completed or were under construction. The larger Thermofor plants could circulate 100-150 tons of catalyst per hour and could process up to 20,000 barrels of petroleum per day.

But problems persisted. The catalyst, moving at rapid rates, tended to disintegrate as it impacted the inside surface of equipment . Dust particles formed, clogging pipes and transfer lines and disrupting the smooth flow of operation. This difficulty in turn prevented uniform heat distribution through the system and affected the rate and extent of both cracking and regeneration. Both the volume and quality of fuel produced suffered.

An improved design undertaken by Sacony used high-velocity gases to replace the mechanical elevator systems as catalyst carriers. These so-called "air-lift" units improved upon the Thermofor process both in terms of economies and octane numbers. It was, however, only with the fluid cracking process that catalytic technology realized fully continuous production.

Fluid Catalytic Cracking

Fluid catalytic technology addressed two major shortcomings of previous moving-bed systems: the slowness with which catalyst traveled through the vessels and the inability to sustain the cracking process continuously over an indefinite period of time. The central problem facing the industry was how to move the catalyst around the production circuit at rapid rates and at the same time fully control the intensity and duration of cracking (and regeneration). Jersey Standard (Exxon), up to this point not a major player in advanced catalytic cracking, addressed these issues as it continued to improve upon more traditional cracking processes.

By the time Jersey Standard moved into fluid research in the late 1930s, it possessed both cracking (thermal) and catalytic expertise. As noted above, Jersey developed its most important cracking technology up to that point with its Tube-and-Tank process, a thermal approach. And beginning in 1927, the company formed a patent-sharing agreement with the German giant, I. G. Farben, for development of a high-pressure catalytic hydrogenation process. Jersey's early catalytic work resulted in a number of reforming practices, such as hydroforming (1938) and steam reforming (1942) which supplemented cracking processes.

By the late 1930s, Jersey, associated with a group of companies looking for improved catalytic processes (the Catalytic Research Associates), combined its past cracking and catalytic experience in developing a fully continuous catalytic cracking system.

Prior to coming upon the notion of fluidization as a basic principle of continuous catalytic cracking, Jersey experimented with a series of fixed-and moving-bed systems. A unique approach emerging out of these efforts involved the design of "slurry" systems, by which a pumping mechanism propelled catalyst particles and oil fluid together in concurrent fashion along a horizontal reactor.

While problems with the circulatory (i.e., pumping) system limited the usefulness of this approach, it led to the next major leap for fluid cracking. Warren K. Lewis, head of the Department of Chemical Engineering at MIT and consultant to Jersey, was the leading creative force behind fluid cracking. He led the initial experiments (at MIT) identifying the commercial viability of, and establishing the preconditions for, fluidization phenomena, including the existing of the so-called turbulent bed. He also directed the design of the first semi-commercial units.

Fluid cracking retained the moving bed concept of the catalyst transported regularly between the reactor and regenerator. And as with the air-lift systems, the fluid plant rejected mechanical carrying devices (elevators) in favor of standpipes through which the catalyst fluid traveled.

Fluid technology exceeded gas-lift technique by incorporating two innovative concepts, that is, under certain conditions of velocity flow and solid/vapor concentration: (1) a catalyst-gas mixture traveling around the plant behaves in just the same way as a circulating liquid; and (2) within vessels, rather than the catalyst and oil falling under gravity, they closely intermingle indefinitely in a dense turbulent but stable, well-defined and carefully (and indefinitely) controlled cracking "bed."

The fact that a flowing catalyst-vapor mixture acted just as a traditional liquid was a crucial point. It meant that the cracking plant was in essence a hydrodynamic system readily controlled over a range of velocities and throughput by simple adjustment of pressure gradients and such variables as the height of the catalyst (i.e., the head of pressure) in the standpipe and the velocity of upward moving gas which carried the catalyst from the bottom of the standpipe to processing vessels. An important control element also was the "aeration" of the moving catalyst at strategic points along the standpipe (and transfer and carrier lines) by use of jets of air to adjust pressure gradients as required.

At the heart of the process was the turbulent bed. As catalyst rose with the carrier gas up the standpipe and into the reactor, it tended to "slip back" and concentrate itself into a boiling but well-delineated mass. The boiling action served to keep the catalyst particles tumbling about. Rather than falling via gravity, the boiling action in effect served to counteract the force of gravity and so maintain the catalyst in an indefinitely suspended state. Particles simply moved from one part of the bed—the turbulent mass—to another, all the while undergoing cracking. This design applied as well during combustion in the regenerator.

The plant was able to operate continuously. The continual and controlled state of turbulence in the bed assured close intermixing between solids and vapors and an even distribution of thermal energy throughout the bed, and the "liquid" catalyst flowed smoothly and rapidly from one vessel to the next.

An early fluid cracking unit removed spent catalyst from reactors (to be directed to the regenerator) using an overhead cyclone system. A more efficient technique, the so-called down-flow design, followed. It altered operating and flow conditions so that spent catalyst concentrated in the bottom part of vessels, where they could be removed, resulting in greater ease of catalyst recovery, simplification of plant layout, and improvement in operating flexibility.

Fluid catalytic cracking rapidly overtook its competitors as both a source of fuel and of critical organic intermediates. Prior to 1942, the Houdry Process controlled 90 percent of the catalytic fuel market. But only three years later, in 1945, fluid cracking led all other catalytic cracking processes in market share (40 percent). At this time Thermofor technology stood at 31 percent, and Houdry at less than 30 percent.

After 1942, fluid cracking technology increasingly dominated U.S. petrochemical production. It manufactured high-tonnage fuels for both motor vehicles

A fluid catalytic cracking unit in Joliet, Illinois, converts heavy components of crude oils into high octane gasoline and distillates. (Corbis Corporation)

and aircraft for the wartime effort. The quality of the gasoline was unprecedented. Octane ratings of fluid-produced fuels exceeded 95, an unheard-of figure only a few years before, and critical for aviation gasoline. Fluid cracking technology played a central role the U.S. synthetic rubber program: its byproduct gases supplied the butylenes which were essential in the making of butadiene, the essential rubber intermediate.

RECENT DEVELOPMENTS IN PETROLEUM REFINING

Since 1945, the fluid catalytic cracking process has rapidly overtaken fuel production and has become the central technology in the U.S. petrochemicals industry. With fluid cracking, the scale of petrochemical operations grew enormously. For the first time, refiners could process virtually any volume of oil rapidly and efficiently.

Accordingly, technological change in refining technology has centered on alterations and improvements made to the fluid cracking process. These modifications have included improvements made to catalysts, materials of construction, interior linings, and a variety of mechanical details. Since 1945, the process has operated on progressively higher temperatures for both cracking and regeneration. It has also incorporate newer generations of catalysts.

By the early 1960s, fluid cracking had become the workhorse of the refining industry. It was the central process in the production of over 70 percent of all high-octane fuel. From early 1940s to mid-1960s, capacities of fluid units have grown from less than 20,000 BPD to between 100,000–200,000 BPD.

The flexibility of the process was manifested in its ability to economically process smaller volumes of feedstock. Between the 1950s and 1980s, refiners and engineering firms developed smaller, lower investment units which could be readily scaled up as required. Recently, such fluid crackers have been simplified to the point that cracking and regeneration take place within a single, vertical standpipe or riser tube. The capacities of such units often do not exceed 1,000 BPD.

By the mid-1990s, the technology was virtually the only catalytic cracking process in operation in the major refineries. The technology accounted for over 95 percent of all high-octane fuel within the United States. By 1997, there were approximately 350 fluid cracking facilities in operation worldwide, most located within the United States. Between 8 and 9 percent of the fluid units existing worldwide (25-30 units) are owned and operated by Exxon, the original innovator of fluid cracking.

In the late 1990s, the growth of fluid cracking as a major petroleum refining process was about 2 percent per year. Total world fresh feed capacity for the fluid process now stands at more than 11 million barrels/day. Worldwide, FCC makes 80 billion gallons of high-grade gasoline annually. This represents nearly half of total world gasoline production.

A major recent development for the technology has been its closer integration with the large petrochemical complex. Essential petrochemical activity has been relying more on fluid technology and less on thermal units for their intermediate feedstock. The big development for the 1990s is increasing integration of FCC with the large petrochemical plant.

In the postwar period, fluidization influenced U.S. manufacture in other areas as well. Most critically, it has been applied in combustion processes for the making of metallurgical materials and by the utilities for generating heat and electricity for industrial and residential use. Moreover, the technology is a "cleaner" method for producing energy and so is an important means by power-based companies to comply with stricter environmental regulations.

REFRIGERATORS AND FREEZERS

With 120 million household refrigerators and freezers in operation in the United States, their consumption of electrical energy is of major concern not only to the consumer, but also to the power generating utilities that have to provide the power. The government, charged by Congress with guarding against air pollution, protecting the Earth's ozone layer, and fighting global warming, has a keen interest in refrigerator energy consumption.

Vapor compression, absorption refrigeration (instead of electric power, uses heat as the source of energy), and thermoelectric refrigeration (the direct conversion of electrical energy to cooling effect), are the principal means of refrigeration. Of the three methods, vapor compression, often referred to as mechanical refrigeration, is the most energy efficient, approximately two times more efficient than absorption refrigeration, and four times more efficient than thermoelectric refrigeration. Vapor compression is by far the most popular means for refrigerating household refrigerators and freezers, although the other two technologies have unique advantages in some specific applications.

VAPOR COMPRESSION BASICS

Figure 1 shows the four basic elements of the vapor compression system: (1) the evaporator, where the refrigerant vaporizes, and thus absorbs heat from the surroundings; (2) the compressor, where the refrigerant vapor is compressed (typically in the ratio of ten to one); (3) the condenser, where the refrigerant vapor of high pressure and high temperature is condensed by rejecting the heat absorbed by the evaporator, together with the heat of compression, to the atmosphere; and (4) the expansion device, be it an expansion valve or a capillary tube, that allows the liquid refrigerant arriving from the condenser at high pressure and at room temperature, to enter the evaporator, and repeat the refrigeration cycle.

Figure 2, the pressure-enthalpy plot of the standard vapor compression cycle, traces the state of the refrigerant through the refrigeration system. (Enthalpy represents the energy of the refrigerant as

it circulates through the various components.) Note that the evaporator absorbs heat at low pressure, and the condenser rejects the heat absorbed by the evaporator and the work of compression, at high pressure. The curvature is the saturation curve of the refrigerant. It delineates the various *states* that the refrigerant passes through during the cycle, liquid to the left of the curve, two-phase mixture within the curve, *vapor* to the right of the curve.

The efficiency of any device is the ratio between what we are after to what we have to pay for it. In the case of a refrigerated appliance, we are after the refrigeration effect, (i.e., heat absorbed by the evaporator) and we pay for it with electric power that runs the compressor. In Figure 2, the evaporator absorbs more energy in the form of heat than the energy supplied to the *compressor* in the form of electricity. The ratio of the two is called the coefficient of performance (COP), a dimensionless number. Compressor efficiency is commonly expressed as the energy efficiency ratio (EER), the ratio of the refrigeration effect in Btu per lb of refrigerant, to the *energy input* to the compressor, in watt-hour per lb of refrigerant. The EER of a typical refrigerator compressor in the 1990s was about 5.5 Btu per watt-hour.

THE HISTORY OF VAPOR COMPRESSION

In 1748, William Cullen of the University of Glasgow in Scotland made the earliest demonstration of man-made cold when he evaporated ether in a partial vacuum. In 1824, Michael Faraday of the Royal Institute in London, found that ammonia vapor, when condensed by compression, would boil violently and become very cold when the pressure is removed. Only ten years later, in 1834, Jacob Perkins, an American living in London, patented the first closed vapor compression system that included a compressor, condenser, expansion device, and evaporator. This is the same basic system as in today's domestic refrigerator. He used ethyl ether as the refrigerant, and received British Patent 6662, dated 1834.

In 1844, John Gorrie, Florida, described in the Apalachicola Commercial Advertiser his new machine for making ice. The delays in ice delivery from the Boston lakes forced Gorrie to build his ice machine so that his hospital fever patients could be assured that ice would always be available.

In the early days ethyl ether and methyl ether were the refrigerants of choice. In 1869 the first ammonia system was introduced. Today ammonia is still a very common refrigerant not only in commercial vapor compression systems, but also in absorption refrigerators.

In 1915 Kelvinator marketed the first mechanical domestic refrigerator, followed shortly by Frigidaire. These models used belted compressors underneath wooden ice boxes that required frequent maintenance because of leaky shaft seals. In 1910 General Electric took out a license to build a sealed compressor that eliminated the need for shaft seals. The machine was originally invented in 1894 by Abby Audiffren, a French monk, who developed it for the purpose of cooling the monastery wine. After a major redesign it was introduced as the Monitor Top refrigerator in 1927, and was an instant success. Up to this time refrigerator cabinets were made principally of wood, with a great deal of carpentry, and not suitable for mass production. The Monitor Top had a steel cabinet, fabricated by punch presses and welding. The steel inner liner was attached to the outer shell by phenolic plastic breakerstrips. A more current production is the 27 cu ft refrigerator with through-the-door water and ice dispenser.

The *Monitor Top* used a toxic refrigerant, sulfur dioxide. In the late 1920s, Frigidaire Corporation, then a leading manufacturer of household refrigerators, asked the General Motors research laboratory to develop a refrigerant that is non-toxic and non-flammable. The result was a chlorofluorocarbon (CFC), namely dichlorodifluoromethane, commonly known as Refrigerant 12 of the Freon family. By the time of World War II, it completely replaced sulfur dioxide. In the 1980s, it was discovered that CFCs deplete the ozone layer surrounding the Earth, thus increasing the likelihood of skin cancer. In 1987 the United States joined other industrial nations in signing the

source: E. A. Vineyard, J. B. Horvay, and E. R. Schulak. "Experimental and Analytical Evaluation of a Ground-Coupled Refrigerator-Freezer." ASHRAE paper, p.2, presented in Toronto, Canada, on June 23, 1998.

"Montreal Protocol on Substances that Deplete the Ozone Layer." The phase-out of CFCs began on July 1, 1989, and by 1997, a hydrofluorcarbon, HFC134a, with zero ozone depletion potential, became the dominant refrigerant in the United States. The phase-out of CFCs in developing countries is on a slower schedule.

In the years after World War II many new customer-oriented features were introduced : plastic food liners, foam insulation, combination refrigerator-freezer, automatic defrosting, ice makers, and child-safe door closures. In the 1940s, the typical refrigerator was a single door cabinet, requiring periodic defrosting, with a storage volume of about 8 cu ft. By the 1990s, it developed into a 20 cu ft automatic defrosting two door combination refrigerator-freezer, with an ice maker.

ENERGY CONSIDERATIONS

The energy consumption of refrigerators and freezers is regulated by the Congress of the United States. The "National Appliance Energy Conservation Act of 1987" (NAECA) established an energy conservation standard "which prescribes a minimum level of energy efficiency or a maximum quantity of energy use". The Energy Standards were revised effective January 1, 1993, and again, effective July 2001. The first revision resulted in a cumulative 40 percent reduction in energy consumption when added to the initial standards. The result of the second revision in 2001 is an additional 30 percent reduction. A historical chart, Figure 3, shows actual and projected improvements in the use of electrical energy for refrigerator-freezers. In 1978 one manufacturer offered a 20 cu ft refrigerator-freezer that consumed 1,548 kWh per year. In 1997, the same manufacturer had a 22 cu ft refrigerator-freezer on the market that consumed 767 kWh per year. The 2001 target for the same product is 535 kWh per year. The latest mandatory energy reduction will add about $80 to the cost of the product, and result in an annual saving of $20 for the customer. Based on an annual production of 8.5 million refrigerators and freezers in the United States, this significant reduction of energy use will eliminate the need for building eight new power plants.

The energy consumption of a refrigerator is a function of two distinct elements: the heat that the evaporator needs to absorb to maintain the specified storage temperatures and the efficiency of the refrigeration system to reject that heat, and also the heat of compression, by the condenser. The heat load is determined by the storage volume of the appliance, the interior temperatures to be maintained, and the effectiveness of the insulation surrounding the storage space. The engineering challenge resides in reducing the heat load, and at the same time, improving the efficiency of the refrigeration system.

THE HEAT LOAD

Figure 4 shows the cabinet cross section of a typical automatic defrosting refrigerator. To defrost a refrigerator, forced convection heat transfer is needed between the evaporator and the load, thus the electric fan. The role of external heaters is to prevent the condensation of water vapor (sweating) on external cabinet surfaces. As the figure indicates, the heat flow through the walls of the cabinet represents 52 percent of the total heat load. Consequently, the thickness and thermal conductivity of the insulation has a major impact on the energy consumption of the appliance. Until the early 1960s the insulating material was glass fiber. Then the development of polyurethane insulation revolutionized the refrigeration industry. With an insulating value twice as good as glass fiber, wall thickness could be reduced by one-half, resulting in additional cubic feet of useful storage. In contrast to applying the glass fiber by hand, the assembly line for polyurethane foam is completely automated. The foam adds structural strength to the cabinet, allowing significant reduction in the thickness of the materials used on the inner and outer surfaces.

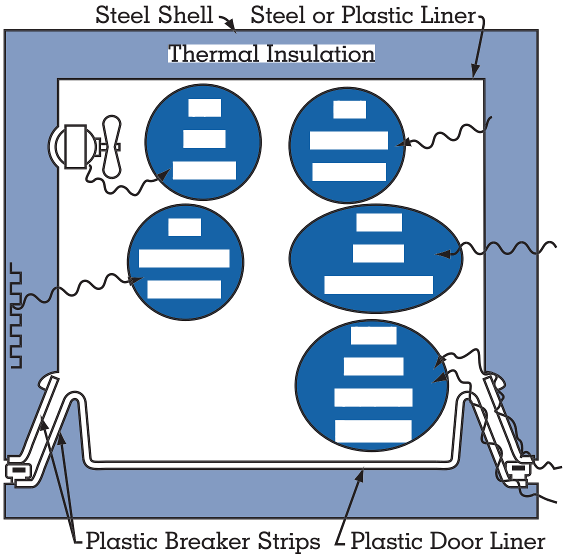

Figure 4.

SOURCE: ASHRAE Handbook. (1998). *Refrigeration.* Atlanta, GA: ASHRAE.

In the 1980s, with the discovery of the ozone depletion potential of CFC refrigerants, the R11 blowing agent used in polyurethane foam was destined for phase-out in the United States by 1996, just like refrigerant R12 of the refrigeration system. A frantic search began for environmentally acceptable substitutes and Table 1 lists some of the more promising candidates. Note that in addition to ozone depletion potential (ODP), a relatively recent environmental concern, global warming potential (GWP) (sometimes referred to as the “greenhouse effect”) is also listed. The numbers are all relative to the properties of CFC 11, the worst offender on the list. In their search for an alternative to R11, the United States and Western Europe went their separate ways. The American choice was hydrochlorofluorocarbon (HCFC) refrigerant R141b. Europe, with an annual production of some 17 million refrigerators and freezers, and under pressure from environmentalists,

Blowing Agent	*ODP*[1]	*GWP*[2]
CFC 11	1	1
HCFC 22	0,05	0,36
HCFC 123	0,02	0,01
HFC 134a	0	0,27
HCFC 141b	0,11	0,1
HCFC 142b	0,06	0,36
Pentane	**0**	**0,001**
Air	0	0
CO_2	0	0,00025

went to pentane.. While both substances have zero ODP, it is the difference in GWPs that tilted the Europeans toward pentane. As a matter of fact, R141b is scheduled to be phased out in the United States by January 2003, due to its residual ODP. Pentane is a hydrocarbon, like gasoline, and highly flammable. Due to the mandated safety measures, the conversion from R11 to pentane at the manufacturing sites is very extensive and expensive. Both foams, whether blown with R141b or with cyclopentane, have a higher thermal conductivity (poorer insulating value) than R11 blown foam. Consequently, these new formulations, require considerable redesign. For the energy consumption to remain the same, either the cabinet wall thickness needs to be increased or the efficiency of the refrigeration system needs to be improved.

To meet the 2001 U.S. energy standards and the 2003 phase-out of HCFCs, there is a great incentive to develop a significantly better thermal insulation. The most dramatic approach would use vacuum panels for insulating the cabinet. A number of U.S. and Japanese manufacturers have developed such panels and placed these kinds of refrigerators in homes. The panels consist of multilayer plastic envelopes filled with precipitated (fumed) silica. The claimed thermal conductivity is one-fourth that of polyurethane foam. The two major obstacles are cost and the maintenance of vacuum for twenty years.

THE REFRIGERATION SYSTEM

To meet the 1993 Energy Standards, the industry undertook , at considerable cost, the optimization of the various refrigeration system components. The most significant improvement was the increase in compressor efficiency, from an EER of about 4 to about 5.5. Other system improvements included more efficient fan motors, more effective heat transfer by the evaporator and the condenser, and less defrost energy. In the early 1980s, both the Whirlpool Corporation and White Consolidate Industries introduced electronic defrost controls. Heretofore, an electric timer initiated the defrost cycle, typically every twelve hours, whether the evaporator needed it or not. With the electronic control the defrost interval is more a function of frost accumulation than of time, and thus referred to as a “variable defrost control” or as “adaptive defrost.”It saves energy by being activated only when needed.

Further improvements in system efficiency will be difficult to achieve with evolutionary changes. Following are some of the more promising areas of development:

Rotary Compressor. Inherently a rotary compressor is more efficient than the current reciprocating compressor. (room air-conditioners have been using rotary compressors for decades.) Several manufacturers in the U.S. and Japan have produced refrigerators with rotary compressors, but experienced long-term quality problems.

Dual Evaporators. A typical refrigerator-freezer, with automatic defrost, has a single evaporator for refrigerating both compartments, at a pressure that is determined by the temperature of the freezer. With separate evaporators in each compartment, the compressor would alternate between the two evaporators in providing refrigeration. The fresh food compartment has a significantly higher temperature than the freezer compartment, so it would requier less pressure to refrigerate, resulting in energy savings.

Variable Speed Compressor. Every time the compressor cycles on during the first few minutes of running, the compressor works on building up the pressure difference between the evaporator and the condenser, and is extremely inefficient. By letting the compressor run all the time, and modulating its speed according to the refrigeration needs, these periods of inefficiency can be eliminated.

Sharp Corporation promotes its new refrigerator, which includes the first built-in LCD. (Corbis Corporation)

Sonic Compression. Sonic compression is appealing as a potential low-cost, high efficiency oil-free technology. It should work with a wide range of refrigerants, including hydrocarbons, fluorocarbons, and ammonia. Theoretical COP is comparable with current vapor compression refrigeration cycles. The initial prototypes have a target cooling capacity of 110 to 250 W.

ABSORPTION REFRIGERATION.

Absorption refrigeration is based on the great affinity between certain liquids and gases. For example, 1 cu ft of water is capable of absorbing 800 cu ft of ammonia gas. One might look at this process as compression of a sort. Starting out with a small volume of absorbent (water) and a large volume of refrigerant gas (ammonia), the process ends up with a small volume of liquid solution of the refrigerant in the absorbent. In comparison to the vapor compression system (Figure 1), the compressor is replaced by two components, the absorber and the generator (Figure 5). The condenser and the evaporator function just as in the vapor compression cycle. Upon entering the generator, the aqua-ammonia solution is heated, and the ammonia in the solution vaporizes first, due to it's lower boiling point. The ammonia vapor then enters the condenser as the water drains back to the absorber. The condensed liquid ammonia is allowed to expand into the evaporator. As it vaporizes it absorbs heat from the load, and then it is reabsorbed by the water in the absorber. The cycle is ready to repeat itself.

Vapor compression uses the highest form of energy, namely electrical energy. In absorption refrigeration, the energy input is any source of heat (e.g., electrical energy, bottled gas, kerosene, or solar energy).

The first practical absorption refrigerator was developed in 1850 by Edmund Carre of France, who

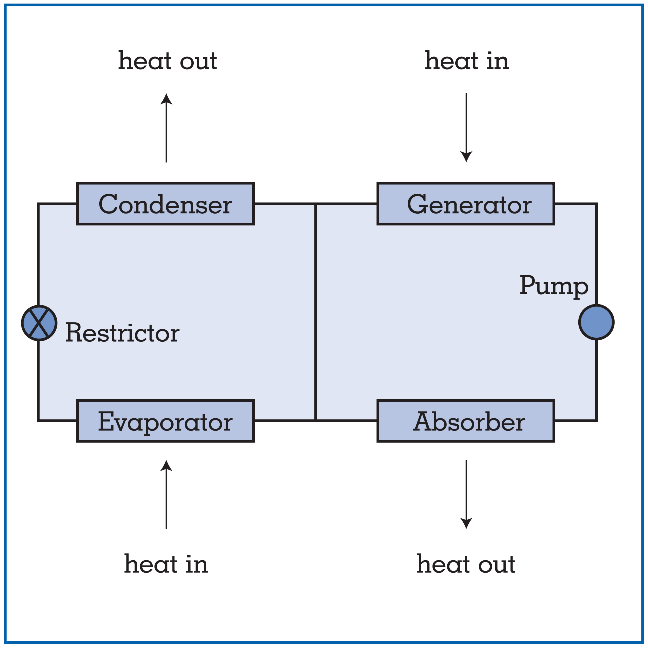

Figure 5.
Heat flow diagram of the absorption system.

was granted a U.S. patent in 1860. During the Civil War, the supply of ice from the North was cut off and Edmund's brother, Ferdinand Carre, shipped a 500 lb per day ice machine through the federal blockade to Augusta, Georgia, to be used in the convalescent hospital of the Confederate Army. Absorption refrigeration enjoyed it's heyday in the United States in the 1920s, with several manufacturers, like Servel and Norge, providing products. As larger refrigerators were demanded by the public, absorption refrigerators were unable to compete due to their inefficiency. The only remaining role for absorption refrigeration in the United States is in remote areas that are without electricity, and in boats and recreational vehicles that have bottled gas. There are many under-developed countries where absorption refrigeration is still the principal means of food preservation, due to lack of electricity.

THERMOELECTRIC REFRIGERATION

In 1821, Thomas Seebeck, an Estonian physician, discovered the existence of an electric current in a closed circuit consisting of unlike conductors, when the junctions between the conductors were at different temperatures. This discovery is the basis for thermocouples, used for all kinds of temperature measurements. In 1834, Jean Peltier, a French watchmaker, discovered the reverse of the "Seebeck Effect"; namely, if a direct current passes through a junction of two dissimilar metals in the appropriate direction, the junction will get cold. When thermocouples are put in series, one face of the assembly will get cold, the other hot.

The "Peltier Effect" was a laboratory curiosity until 1954, when Goldsmid and Douglass of England achieved a temperature difference of 47°F between the two junctions using a semiconductor, bismuth telluride, types negative and positive. It was predicted at that time that by the 1970s thermoelectric refrigeration would replace the vapor compression system in refrigerators and freezers. The 1966 Sears catalog offered a "Coldspot Thermo-electric Buffet Bar" that "chills foods and drinks to 40 degrees...." The buffet bar took advantage of an exciting feature of thermoelectric devices; namely, by reversing the electric current flow, the cold junctions will get hot, and the hot junctions cold. By the flick of a switch, the 2 cu ft compartment would change from a refrigerator to an oven. Due to its inefficiency, the thermoelectric refrigerator did not replace vapor compression.

The key to future advances in thermoelectric refrigeration is the discovery of a semiconductor more efficient than bismuth telluride. Until then, the only marketable applications are small portable refrigerators for cars and boats. They take advantage of the readily available direct current provided by the battery. Just plug it into the cigarette lighter and it begins to refrigerate.

REGULATION AND RATES FOR ELECTRICITY

Electric utilities have historically been franchise monopolies, vertically integrated from power production through transmission, distribution, and customer service with no competition from other electric utilities. However, in many parts of the country, electric and gas utilities do compete. Rates charged by these utilities were determined in a regulatory proceeding: Electric utilities proposed rates that compensated them for their expenses and allowed them to earn a reasonable return; state regulatory commissions reviewed and approved the proposals.

This historical relationship between electric utilities and their regulators is undergoing a dramatic change. Policymakers are restructuring and deregulating portions of the electric industry. Restructuring of the electric industry is consistent with the deregulation of other U.S. industries since the 1980s. The objective in "restructuring " is to increase efficiency, lower costs, increase customer choices, and lower the prices paid by consumers in restructured industries.

As in other industries, restructuring of the electric industry is a response to underlying conditions in the industry. Policymakers are responding to two phenomena. First, there is a disparity in retail electric prices among states and regions. For example, the average price of electricity in New England states such as New Hampshire (nearly 12 c/kWh) is almost three times as large as the price in low-cost states such as Idaho and Washington (approximately 4c/kWh). Second, advances in information technology will make it possible to perform complex real-time functions.

In restructured electric markets, the vertical electric monopoly will no longer be the sole provider of electricity. The generation, transmission, distribution, and customer service functions will be separated. The upstream generation function will be competitive, allowing new, any power producer to produce and sell electricityin any service territory. The transmission and distribution functions will continue to be regulated, but will be required to allow access to power suppliers and marketers. This separation or "unbundling" of the industry is necessary to provide nondiscriminatory access for all suppliers of electricity. Customers will have their choice of electric suppliers.

In these restructured electric markets, prices will be determined more by market forces and less by regulatory proceedings. To some, introducing competition will promote more efficient markets, providing the proper financial incentives for firms to enter or leave the industry. In this way, consumers will benefit from lower production costs and, hence, reduced electricity prices. To others, restructuring will increase electricity prices for some customers, sacrifice the current environmental and social benefits, and jeopardize system reliability of the status quo.

ADVANTAGES OF RESTRUCTURING

Consider a typical rate-making proceeding for a regulated utility. Electric utilities can recover all prudently incurred operating and maintenance costs plus an opportunity to earn a fair return on their investment. This process involves three steps: (1) determining the total amount of revenues (i.e., required revenues) that an electric utility needs; (2) allocating the total to individual customer groups (e.g., residential, commercial, and industrial customers); and (3) designing a rate structure for each customer group that allows the utility to recoup costs.

Required revenues are the sum of operation and maintenance expenses, depreciation, taxes, and a return on rate base. The rate base is the total amount of fixed capital used by the utility in producing, transmitting, and delivering electricity. The return on rate base is the weighted average cost of capital, including debt and equity sources.

Allocating required revenues to customer groups involves four steps: (1) categorizing customers into groups with similar characteristics (e.g., low-voltage customers); (2) functionalizing costs into those pertaining to production, transmission, distribution, and administration; (3) classifying functionally assigned costs into those attributable to the customer (e.g., metering costs), energy (e.g., amount of consumption), and capacity (e.g., instantaneous demand); and (4) allocating costs to customer groups. The result of this process is the allocation of all of a utility's revenue needs into customer groups. The number of groups depends on the characteristics of a utility's service territory.

Rates are then designed to recoup the revenues for each of the customer groups. Rates can be based on the amount of consumption or the type of service. Consumption-based rates are either flat, or increasing or decreasing in steps. Service-based rates depend on the type of service a utility offers its customer classes: firm rates, lifeline rates, interruptible rates, stanby rates, various incentive rates, or time-of-use rates.

The problems with this cost-of-service approach are the incentives and opportunities given to electric utilities. They are not the type of incentives that characterize an efficient market and that balance the additional risk of operating in an efficient market.

Industry restructuring advocates believe that a competitive market will create incentives to operate more efficiently and make better economic investments in utility plant and equipment. In contrast to a competitive market, cost-based ratemaking does not generally reward utilities with a higher return for making an especially good investment in plant and equipment, or penalize them for making an especially bad investment. The return that a utility earns on a highly successful investment is generally the same as its return on a less successful one. The opportunity to prosper—or, alternatively, to go bankrupt—is generally not part of this regulatory process.

In many cases, the regulators themselves distort the ratemaking process. Historically they have allowed or even encouraged utility investments that would not otherwise have been made in competitive markets.

Makers of public policy in the U.S. Department of Energy (DOE) and the Federal Energy Regulatory Commission (FERC) believe that industry restructuring will change these incentives and introduce more efficient practices and technologies in the industry. Proper pricing of electricity is one such change. Time-of-use (TOU) rates is one example. TOU rates vary over the course of a year: hour by hour, day by day, or season by season. They are theoretically appealing: Consumers who cause daily peaks bear the burden of paying higher costs during those periods. Likewise, consumers contributing to seasonal peaks—such as using air conditioners—bear the cost of building the capacity needed to meet the peaks. In practice, TOU pricing has proved effective in shaping load for electric utilities, reducing peak demand, and lowering production costs.

When initially adopted, TOU rates were based on projections of future costs by season, month, day, or hour. However, advances in metering and communications technology now afford utilities the ability to transmit prices to customers based on actual operating costs and to read meters in real time. This "real-time TOU pricing" is one of the most important aspects of many of the restructuring efforts to date. They can provide customers with direct access to the prices arising in competitive electric markets.

Under restructuring, customer exposure to market-based electric rates will broaden in other ways. Because deregulation allows customers to choose their own electric suppliers, potential suppliers are becoming more innovative in attracting customers. Although the Internet is in its infancy now, entrepreneurs are in the process of harnessing it for electricity sales. Some Internet companies are purchasing wholesale power from generating plants and reselling it to customers on the Net. Other companies are aggregators. They enlist customers on the Net and create buying pools from which they can extract lower prices from suppliers.

Restructuring will promote the introduction of other advanced technologies and practices as well. For example, the use of combined-cycle, gas turbine power plants are expected to proliferate under restructuring. These plants are generally more efficient and more environmentally benign than many fossil fuel plants currently in use.

DRAWBACKS OF RESTRUCTURING

Competition can promote efficiency and lower average prices for electricity. However, there is no guarantee that all customers will benefit equally from lower prices. Larger commercial and industrial customers generally have the wherewithal to obtain better rates in competitive markets than do smaller residential customers. Because of fewer options, low-income households are especially vulnerable to competitive markets for electricity.

Environmental and social benefits could also be jeopardized under restructuring. The elimination of integrated resource planning (IRP) is particularly of concern. In an IRP process, energy-efficiency programs and renewable-energy technologies "compete" with conventional generating plants for the resource investment expenditures of electric and gas utilities. The competition takes into account the environmental consequences of producing electricity from fossil fuels. At IRP's peak in the early 1990s, more than thirty-three states mandated the use of IRP processes. These mandates came from state legislation or from state regulatory commission orders.

As the electric industry undergoes reorganization, the retail price of electricity will be determined more and more in markets with the participation of multiple parties who do not themselves generate electricity. The "wires" portion of utilities that historically ran energy-efficiency programs argue that they are unfairly burdened by running these programs if their competitors are not also obligated to do so. Therefore, IRP processes are jeopardized in restructured electric markets. Without IRP, the environmental consequences of relying more on fossil fuels—and less on energy efficiency and renewables—are obvious.

Finally, a number of industry engineering experts and industry engineering organizations voiced concern that the electric grid may become less reliable after restructuring. The operation and maintenance of the North American electric grid depends on the coordinated interaction of more than a hundred control areas. The incentives to buy and sell power, retain adequate surplus capacity, and maintain the grid will change in a restructured electric industry. The reliability of the electric grid may suffer as a consequence.

RENEWABLE ENERGY

Renewable energy is energy that can be replenished on a time scale appropriate to human use. Solar energy for growing plants for food is renewable because light flows continuously from the sun, and plants can be reproduced on a time scale suitable for human needs. Coal is produced continually in some geologic formations, but the time scale is on the order of hundreds of thousands of years. Accordingly, coal is considered a nonrenewable energy.

The Department of Energy categorizes sources of nonrenewable energy production as fossil fuels, nuclear electric, and pumped hydroelectric. Sources of renewable energy are delineated as conventional hydroelectric, geothermal, biofuel, solar, and wind. Conventional hydroelectricity and energy from biofuels are considered mature sources of renewable energy; the remaining types are thought of as emerging. The chart in Figure 1 depicts energy production for 1997.

More electric energy is invested in pumping water for pumped storage hydroelectricity than is produced by the electric generators. Therefore, the net production of electricity from pumped hydro sources is slightly negative and does not appear on the chart in

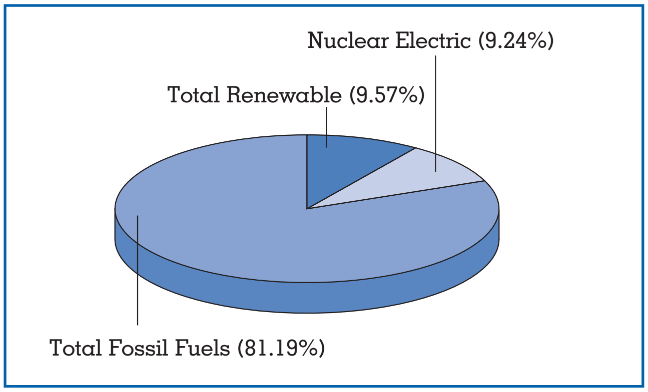

Figure 1.
Percentage of total energy production for 1997.

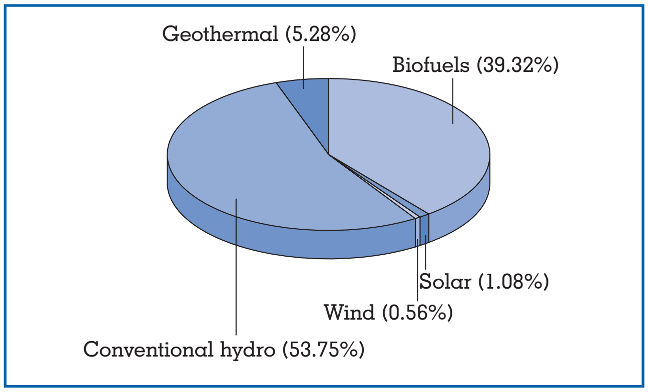

Figure 2.
Breakdown of energy production from renewable sources.
SOURCE: U.S. Energy Information Agency

Figure 1. A breakdown of the 9.57 percent contribution from renewable sources is shown in Figure 2. The great bulk of the energy produced from renewable sources is from biofuels and conventional hydroelectric systems, both of which are considered mature.

Nonrenewable energy such as coal, petroleum, and natural gas are vast but not inexhaustible. A nonrenewable resource can be preserved if it can be replaced with a renewable one. This is the prime attraction of renewable energy. Sometimes a renewable resource offers an environmental advantage. If a house heated by burning fuel oil could instead use a solar heating system, then products from burning that might contribute to environmental problems would not be released into the atmosphere. On the other hand, damming a river to make a reservoir for a hydroelectric power plant might inflict damage to the environs by destroying plant and animal habitat.

Most use of renewable energy involves the sun. Solar energy is converted to thermal energy for space heating, heating hot water for domestic use and, to some extent, for generating electricity. A photovoltaic cell, which functions like a battery, converts solar energy directly to electric energy. Biomass energy has its origin in plants grown with the help of solar radiation. Wind energy is due to unequal heating of Earth's surface by the sun. A hydroelectric plant converts the gravitational energy of water into electricity, but the mechanism that replenishes the water is powered by the sun. Roughly, 95 percent of all renewable energy is solar in origin. The remainder is from geothermal energy. Tidal energy, having its origin mainly in the gravitational force between Earth and Earth's moon, is used in some parts of the world (France, for example), but is yet to be exploited in the United States.

Figure 2 shows that biomass and hydroelectricity account for about 93 percent of renewable energy. Biomass includes wood, ethanol, and municipal solid waste. Wood pellets, manufactured from finely ground wood fiber, represent a growing market for biomass fuels for specially designed stoves and furnaces. Paper products, a biomass fuel, are the major component of municipal solid wastes. Disposal of these wastes is a major societal problem. Burning the wastes for their energy content was a popular option during the 1980s because of federal, state, and local policies promoting the construction of waste-to-energy facilities. Since then, environmental policies encouraging recycling and requiring costly pollution control have made the economics of operating a waste-to-energy facility far less favorable. Accordingly, the use of waste-to-energy facilities has declined. The technology for converting corn to ethanol is very well developed, but the degree to which ethanol becomes a substitute for gasoline will depend strongly on economics.

Solar and wind energy account for less than 2 percent of the use of renewable energy (see Figure 2). Nevertheless, there are some important developments. The greatest increase in wind energy is outside the United States; however, in 1997 the United States led the world for new wind generating systems by adding 1,620 megawatts of capacity. A power output of 1,620 megawatts is the equivalent of the power output of two large electric power plants. However, wind systems do not operate as continuously as large electric power plants, so in the long run they would not deliver nearly as much energy as two large electric power plants. Most wind energy projects are in California, but significant projects are in Texas and Minnesota.

When assessing ways to take advantage of solar energy, one should not necessarily think of sophisticated technological schemes such as roof-top collectors, photovoltaic cells, and wind-powered electric generators. Designing a house or a building to maximize the input of solar radiation during the heating season can produce significant savings in energy. If in the southern United States all the worn-out, dark-colored roofs were replaced with white ones, ten times more energy would be saved in air conditioning than is produced by all wind generators in the United States (Rosenfeld 1997).

The major facility for generating electricity from geothermal sources is at The Geysers in Northern California. Generation at The Geysers is declining both for economic reasons and because of reduced steam pressure. However, other facilities continue to produce steady quantities of electricity.

RESERVES AND RESOURCES

We need to know about the quantity and quality of oil and gas reserves because the prosperity of the world is dependent upon petroleum-based fuels. The debate about forthcoming oil shortages—as soon as 2004 or perhaps later in the twenty-first century—hinges on our understanding of petroleum reserves and future resources. Global catastrophic changes are predicted by some if a shortage occurs early in the twenty-first century; however, others are less concerned, because of new estimates of reserves and potential petroleum resources.

Our concepts of petroleum reserves and resources and their measurements are changing to reflect the uncertainty associated with these terms. Petroleum reserves have been largely calculated deterministically (i.e. single point estimates with the assumption of certainty). In the past decade, reserve and resource calculations have incorporated uncertainty into their estimates using probabilistic methodologies. One of the questions now being addressed are such as "how certain are you that the reserves you estimate are the actual reserves and what is the range of uncertainty associated with that estimate?" New techniques are required to address the critical question of how much petroleum we have and under what conditions it can be developed.

The goal of most industry and financial groups is to forecast future production rates, cash flow, net present values (NPV) and other measures designed to prudently manage financial and production aspects of the petroleum reserve. The determination of the appropriate category to which a reserve is assigned is a critically important decision. These groups emphasize the least risky category of reserves—proved (measured) reserves.—because industry and financial groups can determine the present value of a reserve from existing infrastructure, whereas other resources require additional investment and increased uncertainty regarding the ultimate asset value.

Revisions of original reserve estimates, that generally increase the earlier estimates, have caused several groups to undertake studies of these changes. Many such studies focus on the original underestimation of reserves and the supporting analysis of reserve growth. However, there are instances of original overestimation of reserves. U.S. Geological Survey (USGS) studies on reserve growth of the world's oil fields demonstrate the significant potential of reserve growth, a potential that may be greater than that of undiscovered resources. Close estimation of the true petroleum reserves is critically important to both producers and consumers of hydrocarbons, and opinions about estimates are numerous, conflicting, and often contentious. To understand the current flux of reserves and resources, definitions are provided followed by a discussion. Definitions given are those used in western literature. Countries of the former Soviet Union (FSU) use different reserve and resource definitions. Our analysis of databases in the Volga-Ural and West Siberian Basins shows that when FSU data are converted to our western definitions, similar uncertainties exist.

DEFINITIONS

There are many definitions of reserves and resources, and we need some historical perspective to understand the current debates.

U.S. Geological Survey/U.S. Bureau of Mines

In 1976 the USGS/U.S. Bureau of Mines (USBM) defined resources and reserves (Figure 1) as follows.

Resources: A concentration of naturally occurring solid, liquid, or gaseous materials in or on the Earth's crust in such form that economic extraction of a commodity is currently or potentially feasible.

Reserves: That portion of the identified resource from which a usable mineral and energy commodity can be economically and legally extracted at the time of determination. According to the American Geological Institute (AGI), by using this resource/reserve scheme, we can update the definition: an estimate within specified accuracy limits of the valuable metal or mineral content of known deposits that may be produced under current economic conditions and with present technology. The USGS and USBM do not distinguish between extractable and recoverable reserves and include only recoverable materials.

Securities and Exchange Commission

The critical linkage between financial and accounting considerations and reserve definitions requires an understanding of the definitions given in Securities and Exchange Commission Regulation (SEC) Regulation 4-10. The SEC was empowered to develop energy accounting standards for the United States by the Energy Policy and Conservation Act of 1975 (EPCA), which was passed largely in response to the 1973 oil embargo. This act required the establishment of a national energy database including financial information. The SEC's definitions may be inherently conservative or restrictive thereby causing initial conservative estimates of reserves. The SEC definitions largely focus on proved oil and gas reserves, but are divided into two subcategories: (1) proved developed oil and gas reserves and (2) proved undeveloped reserves.

From SEC Regulation 4-10, Section 210.4-10 and as used by the industry, proved oil and gas reserves are the estimated quantities of crude oil, natural gas, and natural gas liquids that geological and engineering data demonstrate with reasonable certainty to be recoverable in future years from known reservoirs under existing economic and operating conditions (i.e., prices and costs as of the date the estimate is made). It goes on to define proved reserves if economic producibility is supported by either actual production or conclusive formation test and include that portion delineated by drilling and defined by gas-oil and/or oil-water contacts, and immediately adjoining portions not yet drilled, but which can be reasonably judged as economically productive on the basis of available geological and engineering data. In the absence of information on fluid contacts, the lowest known structural occurrence of hydrocarbons controls the lower proved limit of the reservoir. Proved reserves do not include: oil that may become available from known reservoirs but is classified separately as "indicated additional reserves"; crude oil, natural gas, and natural gas liquids, the recovery of which is subject to reasonable doubt because of uncertainty as to geology, reservoir characteristics or economic factors; crude oil, natural gas, and natural gas liquids that may occur in undrilled prospects; and crude oil, natural gas, and natural gas liquids, that may be recovered from oil shales, coal, gilsonite, and other such sources.

Proved developed oil and gas reserves are reserves that can be expected to be recovered through existing wells with existing equipment and operating methods. Additional oil and gas expected to be obtained through the application of fluid injection or other improved recovery techniques for supplementing the natural forces and mechanisms of primary recovery

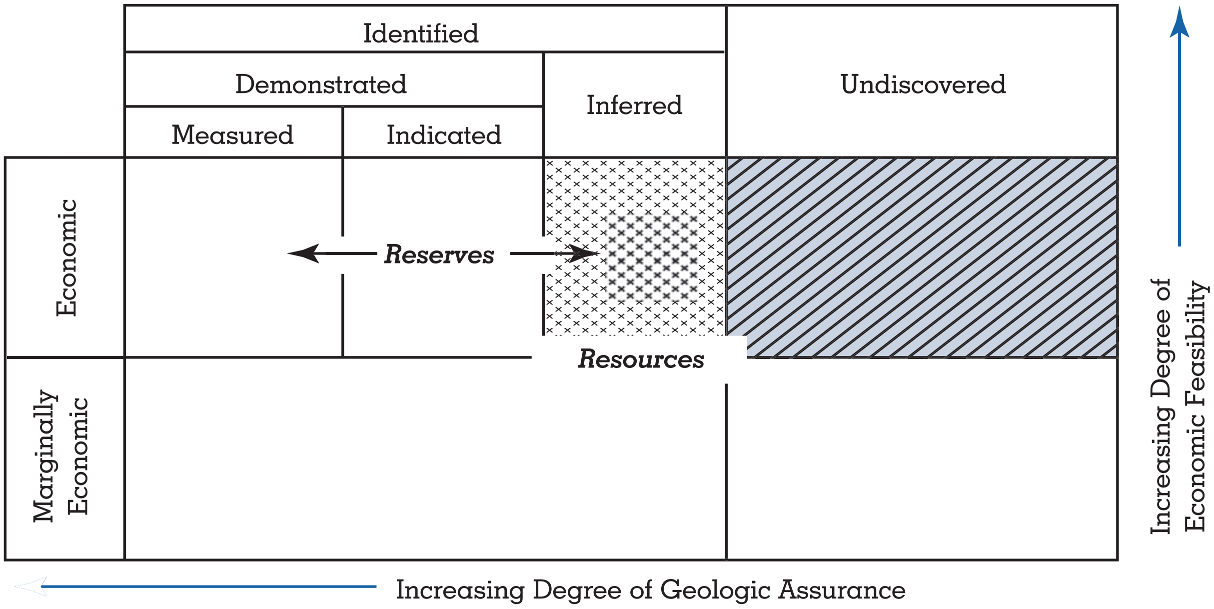

Figure 1.
Reserves vs. Resources Chart.
SOURCE: USGS/U.S. Bureau of Mines, 1976

should be included as "proved developed reserves" only after testing by a pilot project or after the operation of an installed program has confirmed through production response that increased recovery will be achieved.

Proved undeveloped oil and gas reserves are reserves that are expected to be recovered from new wells on undrilled acreage, or from existing wells where a relatively major expenditure is required for recompletion. Reserves on undrilled acreage shall be limited to those drilling units offsetting productive units that are reasonably certain of production when drilled. Proved reserves for other undrilled units can be claimed only where it can be demonstrated with certainty that there is continuity of production from the existing productive formation. Under no circumstances should estimates for proved undeveloped reserves be attributable to any acreage for which an application of fluid injection or other improved recovery technique is contemplated, unless such techniques have been proved effective by actual tests in the area and in the same reservoir.

The World Petroleum Congress/Society of Petroleum Engineers

In 1997, the World Petroleum Congress (WPC) and the Society of Petroleum Engineers (SPE) jointly published petroleum reserve definitions that added the element of probability to the deterministic definitions in common use. The WPC/SPE definitions build on the SEC definitions by including probabilistic estimates.

Reserves are those quantities of petroleum which are anticipated to be commercially recovered from known accumulations from a given date forward.

Proved reserves are those quantities of petroleum which, by analysis of geological and engineering data, can be estimated with reasonable certainty to be commercially recoverable, from a given date forward, from known reservoirs and under current economic conditions, operating methods, and government regulations. Proved reserves can be categorized as developed or undeveloped. If deterministic methods are used, the term reasonable certainty is intended to express a high degree of confidence that the quantities will be recovered. If probabilistic methods are used, there should be at least a 90 percent probability that the quantities actually recovered will equal or exceed the estimate.

Unproved reserves are based on geologic and/or engineering data similar to that used in estimates of proved reserves; but technical, contractual, economic, or regulatory uncertainties preclude such reserves being classified as proved. Unproved reserves may be further divided into two subcategories: probable reserves and possible reserves.

Probable reserves are those unproved reserves which analysis of geological and engineering data suggest are more likely than not to be recoverable. In this context, when probabilistic methods are used, there should be at least a 50 percent probability that the quantities actually recovered will equal or exceed the sum of estimated proved plus probable reserves.

Possible reserves are those unproved reserves which analysis of geological and engineering data suggests are less likely to be recoverable than probable reserves. In this context, when probabilistic methods are used, there should be at least a 10 percent probability that the quantities actually recovered will equal or exceed the sum of estimated proved plus probable plus possible reserves.

The reserves identified in the upper left part of Figure 1, measured reserves, have greater economic feasibility and greater geologic certainty than indicated or inferred reserves. Undiscovered resources have even greater uncertainty than the previous categories. Many industry groups use the terms proved, probable, possible and speculative that roughly correlate to USGS categories of measured, indicated, inferred, and undiscovered. Proved, probable and possible reserves are commonly called P1, P2, and P3 respectively (Figure 2) and considerable analysis has been applied to relationships among these reserve categories to estimate ultimate recoverable resources.

Technological advances, particularly 3-D seismic techniques and deepwater drilling technology, have revolutionized our ability to discover and develop petroleum reserves. Technology has accelerated the rate of discovery of new global petroleum resources throughout the 1990s. Deepwater offshore drilling technology (up to 3,000 m water depths) permit exploration of many areas that were previously inaccessible, such as offshore west Africa and offshore South America. This geographic expansion of petroleum resource development into offshore areas provides opportunities for many non-OPEC nations. The discovery of significant oil resources in the Western Hemisphere, particularly in deepwater areas of the south Atlantic Ocean and Gulf of Mexico, are important to the United States, which seeks oil from more widely distributed potential supply sources. Any regional optimism springing from this discovery is mitigated by the realization that future contributions from field growth, which according to the USGS are nearly as large as undiscovered petroleum resource potential, will come from the areas where fields are already discovered.

Natural gas is an underutilized resource worldwide relative to oil but will play an increased role in the twenty-first century. New technologies such as gas-to-liquids and large-scale liquefied natural gas projects will also dramatically alter the fossil fuel landscape.

DISCUSSION

The definitions above are an abbreviated version of those used in a very complex and financially significant exercise with the ultimate goal of estimating reserves and generating production forecasts in the petroleum industry. Deterministic estimates are derived largely from pore volume calculations to determine volumes of either oil or gas in-place (OIP, GIP). This volume when multiplied by a recovery factor gives a recoverable quantity of oil or natural gas liquids—commonly oil in standard barrels or natural gas in standard cubic feet at surface conditions. Many prefer to use barrels of oil equivalency (BOE) or total hydrocarbons for the sum of natural gas, natural gas liquids (NGL), and oil. For comparison purposes 6,000 cubic feet of gas is considered to be equivalent to one standard barrel on a British thermal unit (Btu) basis (42 U.S. gallons).

Accommodation of risk (or uncertainty) in reserve estimations is incorporated in economic decisions in several ways. One common method

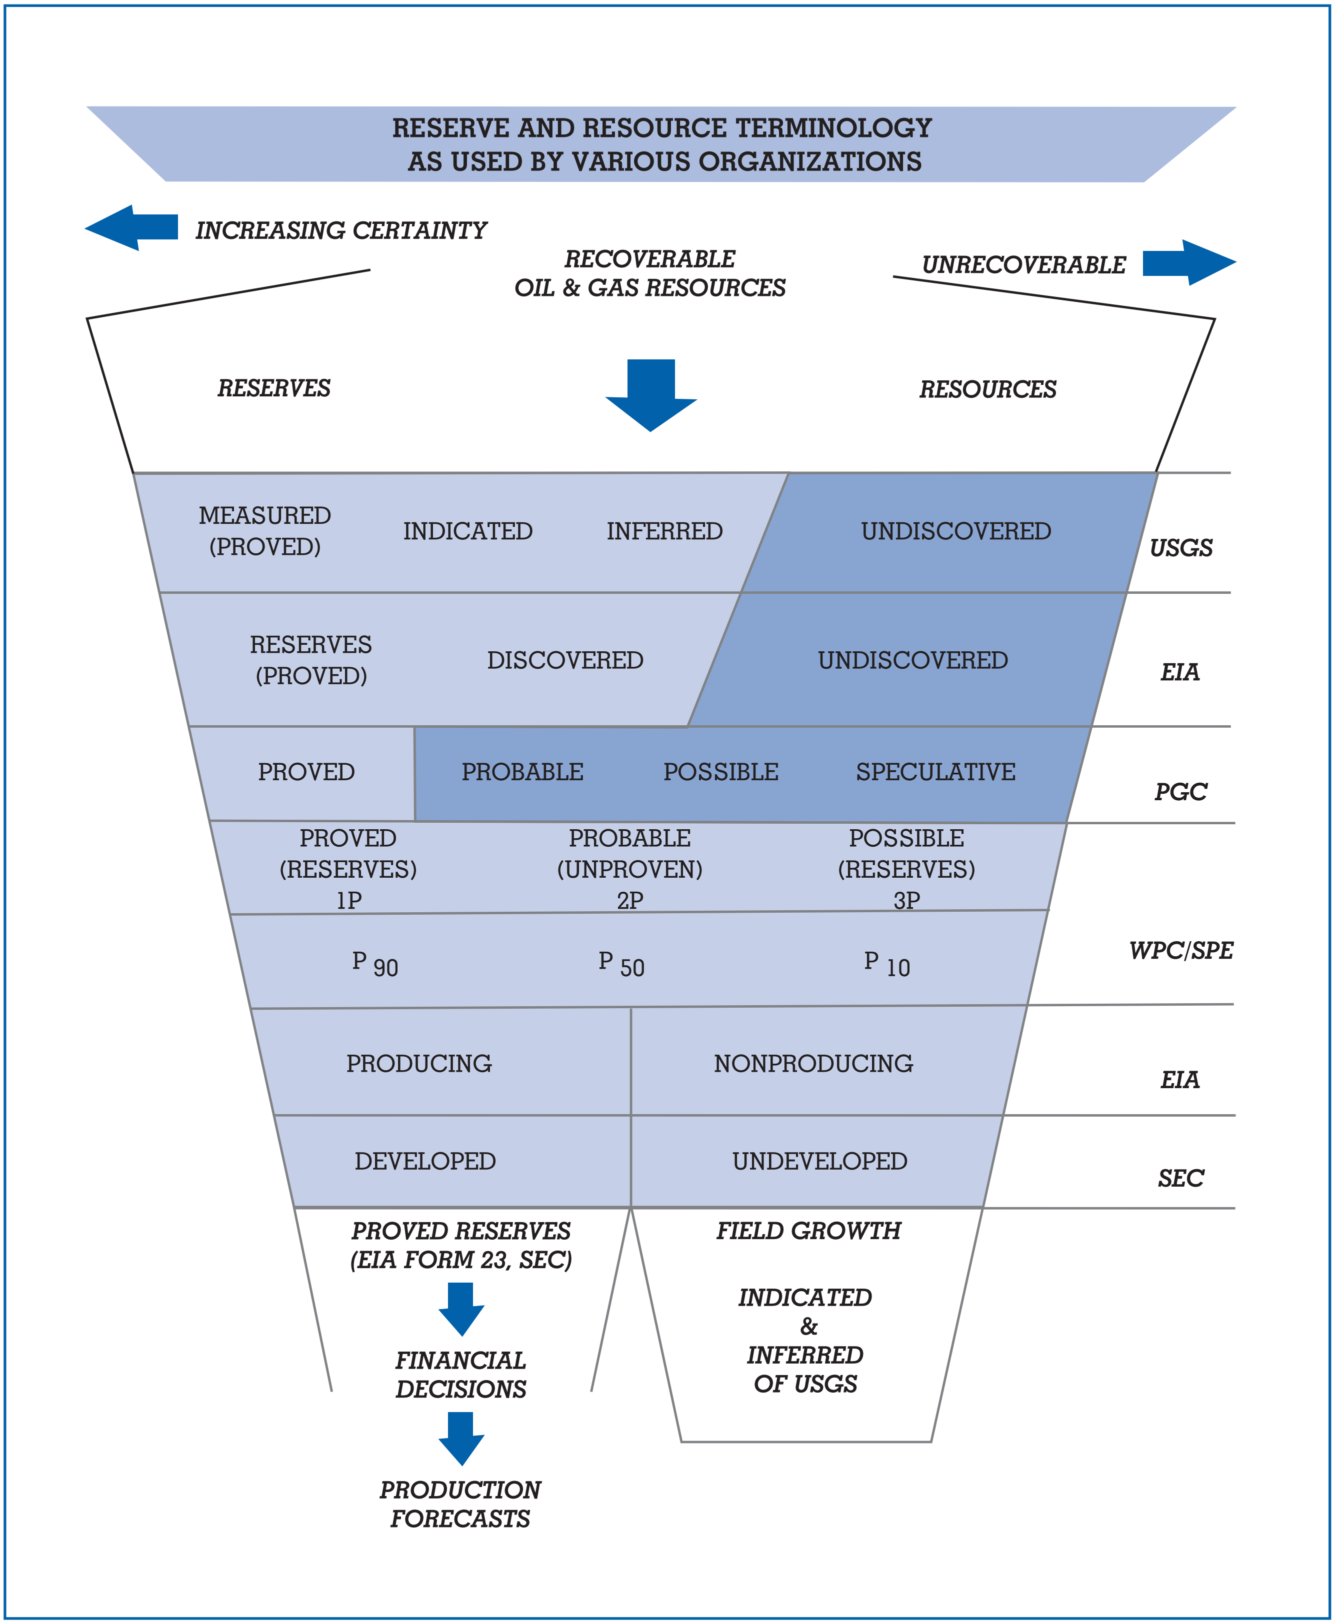

Figure 2.
Reserve and Resource Terminology.

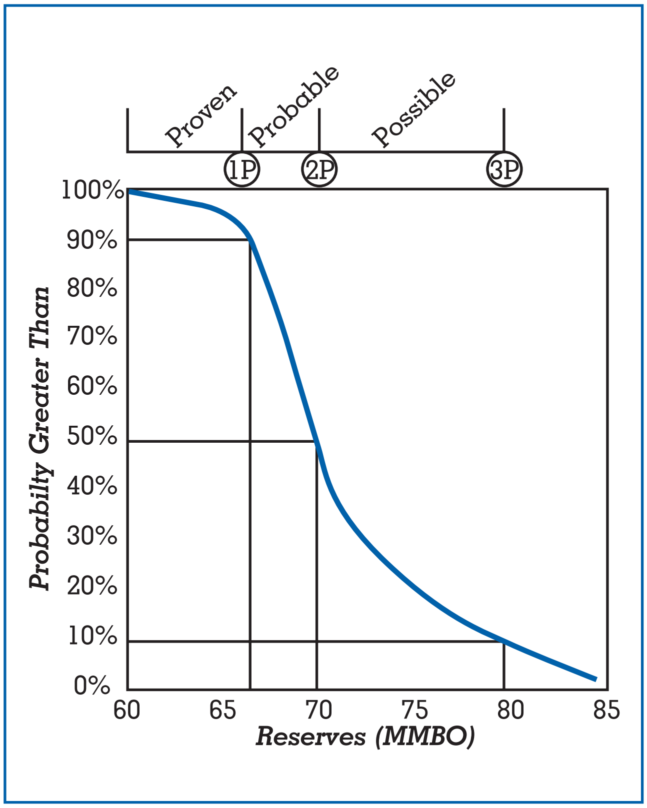

Figure 3.
Proven, Probable, and Possible Reserves and Associated Probabilities

As defined by the World Petroleum Congress/Society of Petroleum Engineers (modified from Grace, J. D. et al. (1993). "Comparative Reserves Definitions: U.S.A., Europe, and the Former Soviet Union." *Journal of Petroleum Technology* 45(9):866-872.

incorporates the expected value (EV) which is the probability-weighted average of all possible outcome values. This process is called "decision analysis"; however, the estimation or production forecast process has become so important that even more sophisticated analysis is commonly undertaken. In regions such as the North Sea, operating costs are high and critical infrastructure decisions are needed early in order to maximize the value of the reserve. Oil price, transportation costs, capital expense, operating expenditures, production rates, and closely estimated reserve volumes are the principal parameters used in developing an evaluation strategy. Reserve estimates can change quite dramatically. The United States is by far the most intensely developed petroleum region in the world with more than 3.5 million wells drilled and a long history of reserve estimation that shows substantial increases in ultimate recoverable reserve estimates. However, negative revisions also occur; either overestimation or underestimation of reserves can be costly. Petroleum reserve estimates are one of the parameters used in determining the EV of a field's reserves. In order to accommodate uncertainty in the various reserve categories, the reserve estimates are probability-weighted and used to determine the EV as shown in the following example and in Figure 3. Although a company may believe they have 3,525,000 barrels of recoverable oil, their probability-weighted reserve is only 31 percent of that figure or 1,093,750 barrels of recoverable oil. This procedure, repeated over and over in many fields throughout the world, has led to underestimation of ultimate recoverable reserve estimates. The subsequent upward revision of these initial conservative estimates is known as reserve growth or field growth. In the United States field growth accounts for twice the volume of future potential reserves of oil (i.e., 60 billion barrels) as undiscovered oil resources (i.e., 30 billion barrels) according to USGS 1995 estimates. In the world as a whole, field growth, based on analysis of the PetroConsultants datafile for a sixteen year period (1981–1996), accounts for nearly 500 billion barrels of oil for just those fields discovered since 1981.

Although, initially, deterministic or point value estimates of reserves were largely believed to be adequate, it is now clear that many factors complicate reserve estimation for recoverable oil or gas. Some complicating geologic and reservoir factors include: variations in reservoir architecture and quality (low complexity or high complexity), microscopic displacement efficiency, volumetric sweep efficiency (the effectiveness of hydrocarbon recovery from secondary and tertiary recovery processes), data quality and analysis. In the North Sea study, these variables are quantified and scored to improve field reserve estimates. In another study of North Sea fields, 65 percent of the responding countries used deterministic ultimate recovery estimates, whereas 53 percent used probablistic estimation methods. Inaccuracies of ultimate recovery and production forecasts were very expensive to those North Sea operators who either underestimated or overestimated facilities requirements. The conclusion that more unified and refined reserve definitions are needed is almost uni-

Reserve Category	*Total Company (boe)*	*Probability*	*Probability Weighted Reserve (boe)*
Proved producing	600,000	1.00	600,000
Proved developed non-producing (waiting on pipeline connection)	50,000	0.90	45,000
Proved behind pipe	125,000	0.75	93,750

versally supported. Appraisals at reservoir level are on a smaller scale than at field level. There are three basic ways to describe uncertainty in relation to reservoir and estimation models: fuzziness, incompleteness, and randomness. Fluctuations in the price of oil or natural gas affect the recoverability of the resource base and as prices increase, reserves increase as they become more economically viable. Advances in exploration and production technology also make recoverability more viable and enhance the amount of reserves that can be extracted from any given reservoir.

IMPLICATIONS

It is well known that reserve estimates made early in the development of a field are often wrong and that there's a 50 percent change in estimated ultimate recovery in many fields during the first ten years. In addition, the average field lifetime has been a decade longer than initially expected in the North Sea. If you believe in reserve growth, you would conclude that there will not be a petroleum crisis anytime soon. If, on the other hand, you believe that reserves have been overstated and you make negative revisions to reserve estimates, there will be a crisis soon. Current known petroleum reserves (proved + P50 probable) in the world are 1.44 trillion barrels of oil, 5,845 trillion cubic feet of gas, and 80 billion barrels of natural gas liquids based on 1996 PetroConsultants data. Depending upon the volume of undiscovered and field growth reserves added to these known reserves, you can develop either pessimisitic or optimistic scenarios.

In 1997, net U.S. petroleum imports of 8.9 million barrels of oil per day were worth $67 billion and exceeded U.S. petroleum production of 8.3 million barrels of oil per day. Concerns about oil shortages caused the United States to build a strategic petroleum reserve in 1977 that currently holds 563 million barrels of oil or about two months of net imported petroleum. Although domestic oil and gas production declined from 1970 to 1993, natural gas production has increased since the mid-1980s and energy equivalent production from natural gas exceeded domestic oil production in the late 1980s. Estimates in 1999 of per well oil production for the United States have fallen to 11.4 barrels a day, the lowest value in the last forty-five years. Considering this decline, the world's reserves and resources are critical to our future because the United States is the largest consumer of petroleum resources (~22% of world consumption). Increasingly, the United States relies on foreign oil supplies. Determining how much oil the world has and where it is located will continue to focus our attention on reserve estimation.

RESIDUAL FUELS

A residual fuel oil is any petroleum-based fuel which contains the undistilled residue from atmospheric or vacuum distillation of crude oil and may be called Bunker Fuel Oil, No. 6 Fuel Oil, or heavy Fuel Oil. When diluted with distillate to reduce viscosity, it may be called Marine Diesel Intermediate Fuel, No. 5 Fuel Oil, No. 4 Fuel Oil, or Light Fuel Oil) (Table 1). It is higher in viscosity than a distillate fuel, so it normally requires preheating for pumping and atomization. Asphaltenes, which are high molecular weight condensed aromatics in residual fuel, are difficult to burn completely, so combustion tends to give particulate emissions. Residual fuel usually contains organometallic compounds of vanadium, which leave an ash residue that may cause deposits and corrosion in boilers and engines because residual fuels are higher in sulfur and nitrogen than distillates. The emission of sulfur and nitrogen oxides during combustion is much greater. Carbon content is also higher than for distillate fuels or gas, so it emits more CO_2 than they do, but less than coal. Basically residual fuels are more difficult to handle and tend to pollute more than distillate or gaseous fuels, but less than solid fuels such as coal.The major advantage of residual fuel is that it is the cheapest liquid fuel available, in large part because it is a byproduct of the refining of gasoline and diesel fuel. As such, it sells for less per gallon than crude oil, the raw material from which it is made. Since heavy fuel prices are usually 50 percent to 75 percent of the price of crude, refiners try to minimize production of heavy fuel oil and maximize the production of higher-value gasoline and distillate fuels.

In order to use this low-priced fuel, consumers must make a significant investment in handling equipment. Heavier grades need preheat equipment to maintain 50°C (122°F) for pumping in the distribution system, and 135°C (275°F) for atomization in boilers or diesel engines. A relatively long residence time is needed in the boiler or engine to give complete burnout of the fuel asphaltenes, which tend to produce particulates. Thus, residual fuels are normally used only in relatively large installations.

Typical Residual Fuel Properties
SOURCE: ASTM T.P.T. Course Notes "Marine Fuels: Specifications, Testing, Purchase, and Use."

In the earliest days of refining, kerosene was the principal refinery product. All the crude heavier than kerosene was sold as residual fuel and used initially for industrial and commercial steam generation. Residual fuel soon began to displace coal in steamships and railroad locomotives because of its portability and relatively low ash content. In the 1920s, residual fuel underwent a drastic change in composition because of the installation of thermal cracking (a refinery process in which a heavy distillate or residual fraction of petroleum is subjected to high temperature, which causes large, high boiling molecules to crack into smaller ones which boil in the gasoline or heating oil range) to meet gasoline demand. Most heavy fuels contained large amounts of thermal tars and visbreaker products (products of a thermal racking process). Great care had to be taken when blending these fuels to avoid sediment formation due to incompatibility.

With the development of catalytic cracking in the 1930s and 1940s, residual fuel composition changed again. Vacuum distillation came into use to provide additional clean feed for catalytic cracking. Vacuum distillates, which had previously been part of residual fuel, were now converted to gasoline and heating oil in the catalytic cracker.

The residuum from vacuum distillation became, and still is, the basic component of residual fuel oil. It contains the heaviest fraction of the crude, including all the ash and asphaltenes. It is extremely high in viscosity and must be diluted with light distillate flux (a low viscosity distillate or residual fraction which is blended with a high viscosity residual fraction to yield a fuel in the desired viscosity range) to reach residual fuel viscosity. The lowest value distillates, usually cracked stocks, are used as flux. In some cases the vacuum residuum is visbroken to reduce its viscosity so that it requires less distillate flux.

By the end of World War II the use of residual fuel oil in the United States had reached about 1.2 million barrels per day. The bulk of this use was in industrial/commercial boilers, railroad locomotives, and steamships. Shortly thereafter, railroad use declined rapidly as diesel engines, which used distillate fuel, replaced steam locomotives. In the 1950s and 1960s residual fuel oil use for marine and industrial applications, as well as for electric power generation, con-

tinued to grow. During this period, the use of fuel oil for marine propulsion gradually shifted from steamships to low and medium speed diesel engines, which were gradually displacing steam turbine propulsion because they were more efficient.

By 1973 about 1.4 million barrels per day of residual fuel oil were used for electric power generation in the United States. This accounted for 16.8 percent of U.S. electricity generation, mostly in areas where cheap, foreign heavy fuel could be delivered by tanker. That same year, another 1.4 million barrels per day of heavy fuel oil were used in the United States for industrial and commercial applications. Worldwide during 1973 about 2.6 million barrels per day of residual fuel oil were used in marine diesel engines, and another 1.1 million barrels per day were used for steamship propulsion.

After the energy crisis of the 1970s, the price of heavy fuel oil rose dramatically and demand dropped drastically. By 1983, heavy fuel oil for electric power generation in the United States fell to 650 thousand barrels per day, providing just 6.2 percent of the total generated. Industrial/commercial demand fell almost as far, to 770 thousand barrels per day. Worldwide demand for marine diesel fuel had dropped to 1.4 million barrels per day and steamship demand to 245 thousand barrels per day. Since 1983, the demand in each of these sectors except marine diesel fuel has continued to decrease. Diesel engines, which are more efficient than steam turbine systems, have become the dominant means of ship propulsion. By 1997, the demand for marine diesel fuel was back to about 2.4 million barrels per day. It is forecast to stay at about that level or slightly higher.

Refiners have coped with this decrease in demand for residual fuel oil by making as little as possible and by shifting their production to heavier grades. They no longer make lighter grades, such as No. 4 or No. 5 fuels, except by special arrangement. Consumers who previously used these grades now use No. 6 fuel oil or gas. Similarly, most marine diesel fuel oil is now supplied as IF 180 (180 Cst @ 50°C) or IF 380 (380 Cst @ 50°C). Prior to 1973, many marine diesel engines were operated on lighter grades. Switching from IF 60, which is roughly 29 percent distillate and 71 percent bunker fuel (the residual fuel burned in boilers on steamships), to IF 380, which is 2 percent distillate and 98 percent bunker fuel, would increase bunker fuel consumption by 38 percent and reduce distillate consumption by 93 percent. Such switches have been beneficial to both refiners and consumers since the energy crisis. Refiners supply more residual and less distillate to a given consumer, and the consumer pays a lower price for the heavier grade of fuel. In most cases, the diesel engine operates properly on the heavier fuel.

While some refiners have reduced residual fuel production by supplying heavier grades, others have eliminated residual fuel completely by installing cokers or hydrocrackers. These are process units that convert residua to gasoline or distillate. They are very expensive to install and operate, but can be justified when there is an oversupply of residual fuel.

RISK ASSESSMENT AND MANAGEMENT

By their very nature, operations in the energy industry are characterized by high risk. Operating an oil well, a power plant, or petrochemical plant is considerably more complex and costly than running most other operations. Losses may be infrequent, yet when they occur they could be substantial. The risks involved in these kinds of operations can be classified under two categories—technical (engineering) risk and financial (price) risk. This article focuses on Financial Risk.

PRICE RISK

The price risk can be defined and understood in alternative ways. One can view the risk as the probable fluctuation of the price around its expected level (i.e., the mean). The larger the deviation around the mean the larger is the perceived price risk. The volatility around the mean can be measured by standard deviation and be used as a quantitative measure for price risk. At the same time, in the industry it is common to define "risk" referring only to a price movement that would have an adverse effect on the profitability. Thus, one would talk about an "upward potential and downside risk."

ENERGY PRICE DYNAMICS

Unpredictable movements in the price level are uncommon in energy markets. The magnitudes of these price shocks can be substantial: 1973 and 1979 oil price shocks, electricity price swings in June 1998, and 2000 oil price increases exemplify the potential magnitudes of these price fluctuations. Energy price dynamics usually consist of three components: deterministic part, seasonal and cyclical influences, and noise. In a market situation with no demand or supply shocks, the only uncertainty observed in the market will be due to noise. A number of variables, such as import policies, policy changes of industry organizations (e.g., OPEC); unexpected weather and atmospheric conditions, tax and regulatory policy changes, legal, environmental, and economic problems, and political and currency crises can affect the demand/supply for energy products and thus lead to large price swings.

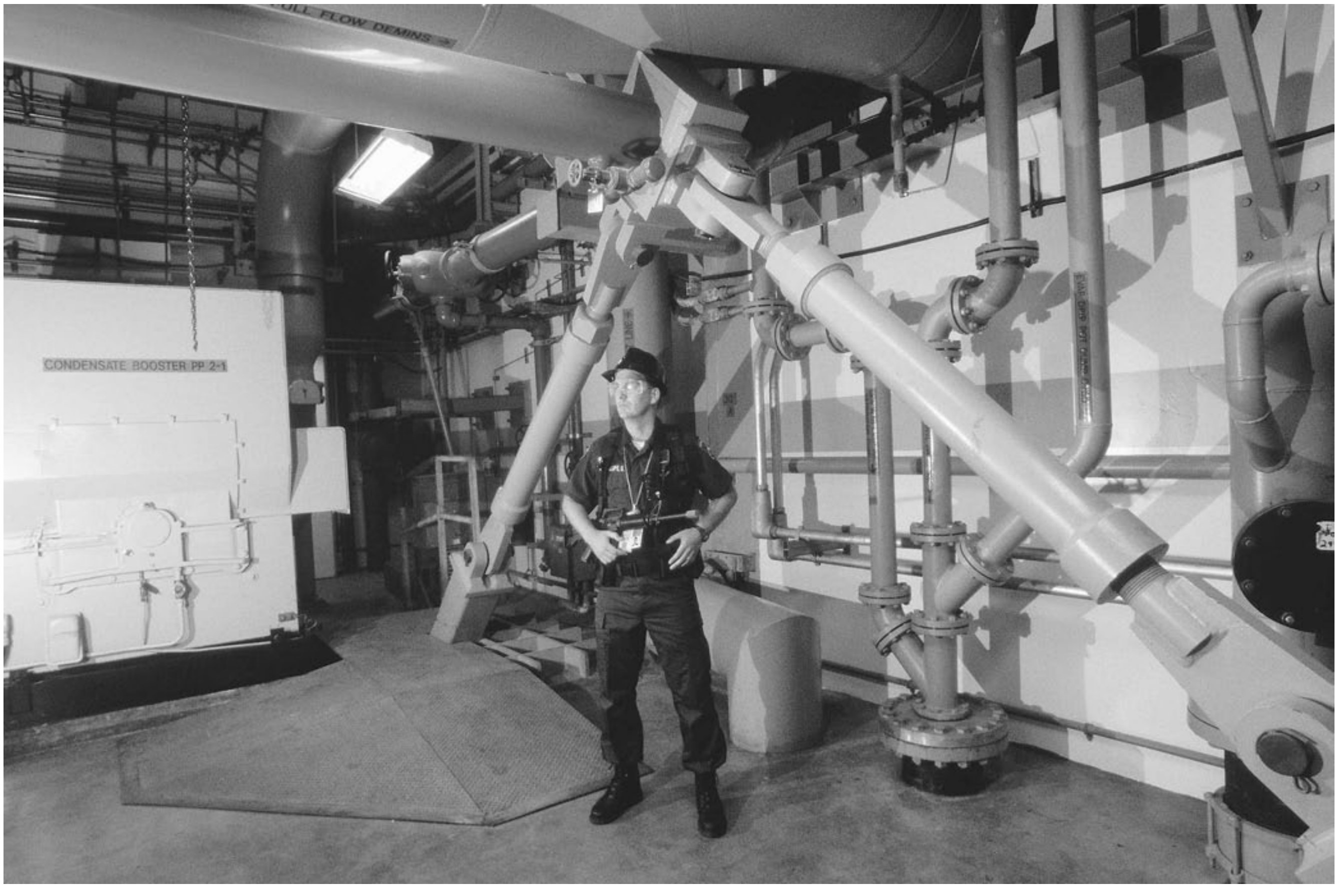
DIVERSIFIABLE AND NONDIVERSIFIABLE RISK

Market-wide (governmental, political, legal, environmental, or economic) events may affect individual firms in the energy industry differently. The magnitude of the individual impact will be determined by the co-movement of the market and individual firms (systematic risk). At the micro level, companies are not only exposed to price and systematic risk, but also to firm-level, nonsystematic risk factors. At the market level, these individual firm-level risks can be reduced or diversified, making it possible to focus on price management only. But at the individual firm level, risk managers also have to address a number of engineering risk factors, such as windstorms that may damage offshore platforms, explosions or fire in the well, and vapor cloud explosions.

MANAGING RISK

Beause energy firms face a variety of potential risk factors that may lead to substantial price fluctuations, risk managers in energy industries combine traditional insurance strategies with financial instruments and hedging policies to manage the risk. The standard financial hedging instruments that are employed are futures and options contracts traded on several energy products, such as crude oil, heating oil, gasoline, natural gas, and electricity.

Energy companies' property/casualty insurance programs typically address a wide spectrum of exposures, such as political risk, earthquake, and workers' compensation. Traditional insurance contracts have been used in energy markets for years against property damage and casualty, for reducing coastal hurricane liability and similar cost reduction purposes. Due to the many great risks that energy companies face, they commonly have to reduce some of the total



The seismic braces seen here in the Diablo Canyon Nuclear Power Plant reduce the risks associated with an area prone to earthquakes. (Corbis Corporation)

risk so that they can afford the insurance to undertake a project.

A recent financial concept that is becoming popular is reinsurance, a transaction whereby one insurance company agrees to indemnify another insurance company against all or part of the loss that the latter sustains under a policy or policies that it has issued. For this service, the ceding company pays the reinsurer a premium. The purpose of reinsurance is the same as that of insurance (i.e., to spread risk). With financial reinsurance in place, energy companies can use traditional excess insurance to address their higher levels of coverage. The combined risk management strategy uses a financial instrument in combination with an insurance policy. This improves the ability of energy companies to fund their own losses during periods of high prices and profits, yet in unfavorable market conditions, the companies can tap an arranged insurance capacity to decrease their financial vulnerability. This strategy is attractive for energy companies because it limits the probability of having to pay for losses to cases where the insurance is actually needed.

There are several other financial risk management tools used in energy markets. For example, option-trading strategies are employed to avoid the adverse effects of price movements. Companies can also protect themselves from volatile (or stable) prices by trading various option strategies. They can trade on the cost of processing products by buying and selling contracts on the raw and processed goods. Recent contributions to risk management in energy industries comprise instruments and strategies such as bidding hedges and weather swaps. A bidding hedge is used to protect against the financial exposures in a competitive bid to construct an energy facility (e.g., currency risks, interest rate, and price risks). Weather swaps allow companies to exchange a series of variable cash flows for a series of fixed cash flows dependent on an index based on weather statistics. One common application of this class of instruments is the temperature swap that attracts many energy companies' interest whose products are sensitive to weather conditions and temperature (e.g., heating oil).

Recent trends in energy finance can be outlined as follows: The focus of main energy sources is turning away from coal and other high CO_x emitting sources to natural gas. Investment in crude oil is slowing. Nuclear power plants remain unpopular due to high operational risk and high waste clean-up costs. On the other hand, investments in the electricity sector are growing at a rapid rate; they have increased from $500 million in 1988 to over $10 billion in 1997.

ROCKET PROPELLANTS

Rocket propellant is a mixture of combustible substances that is burned inside the combustion chamber of a rocket engine. Burning is the chemical process of decomposition and oxidation of the propellant. The resulting highly heated and compressed gas (propulsive mass) is ejected from a combustion chamber and facilitates propulsion—movement of the aggregate attached to the rocket engine. In physical terms, combustion converts chemical energy into kinetic energy.

Rocket propellants possess unique properties, such as a capability to self-sustain the burning process, generate thermal energy, and simultaneously produce propulsive mass. Some types of propellants are even able to self-ignite (initiate burning without outside power input). Unlike most other combustible chemicals, rocket propellants can burn in vacuum. This is because a propellant consists of two integral components: a fuel that burns and produces propulsive mass and an oxidizer that facilitates and sustains oxidation. In this respect, rocket propellants are more like explosives than like automobile and aviation fuels used that require atmospheric air for oxidation. The major difference between explosives and rocket propellants is the gas expansion rate which is much slower in propellants and makes it possible to contain and control the process of burning inside the rocket engine. Most modern rockets use solid and liquid propellants.

SOLID PROPELLANTS

A solid propellant is a mechanical (heterogeneous) or a chemical (homogeneous, or colloidal) mixture of solid-state fuel and oxidizer-rich chemicals. Specially-formed charges of solid propellant (grains) are placed in the combustion chamber of the solid rocket motor (SRM) at a production facility. Once assembled, the engine does not require additional maintenance, making it simple, reliable and easy to use.

The earliest known rocket engines used gunpowder as a solid propellant. Composed of 75 percent potassium nitrate, 10 percent sulfur, and 15 percent charcoal, gunpowder was probably invented in China in the tenth century. One of the first references to rockets can be found in Chinese chronicles from 1232. Rockets began to appear in Europe in thirteenth century. A century later, they were used for various purposes, mostly for fireworks, in France and Italy. The term "rocket," which became common in fifteenth or sixteenth century, originated from the Italian word *rocchetta* (spindle), a reference to the shape of early rockets. In seventeenth and eighteenth centuries, rockets spread all around Europe. In the nineteenth century they were widely used in Great Britain, Russia, France, Austria,

The space shuttle *Challenger* lifting off. (NASA)

Germany and other European countries as a weapon: an auxiliary light-weight artillery. During the same period, British rockets were brought to the American continent. Solid rocket motors evolved with the introduction of smokeless gunpowder, a far more energy-efficient propellant. Unlike the black gunpowder that was a mechanical mixture, smokeless gunpowder was a complex compound developed chemically from cellulose. Rockets of this type first appeared in the early twentieth century but were not widespread until the 1940s. Unguided short-range barrage missiles with smokeless gunpowder propellant were used extensively in World War II by the Soviet Union, United States and Germany. Germans built the first long-range solid propellant missile, called *Rheinbote*. A composite solid propellant developed in the United States in 1941 facilitated a real revolution in solid rocket technology in the 1950s and1960s. It allowed the production of very large and powerful solid propellant engines that became suitable for long-range ballistic missiles and space launch systems.

Modern composite solid propellant is a mechanical mixture of the powder-like chemicals and a binding resin. The propellant used for the Space Shuttle solid rocket boosters (SRBs) is a typical example of such mixture:

- Ammonium perchlorate (oxidizer), 69.93%
- Aluminum powder (fuel), 16.00%
- Rubber-based polymer, called PBAN (binder), 12.04%
- Epoxy-based curing agent, 1.96%
- Iron oxide powder (burning rate catalyst), 0.07%

After these components are mixed, the propellant looks like a thick syrup. It is poured into the engine's casing, where it cures and solidifies. During solidification process, the propellant glues itself to the walls of the casing and special tools are used to produce a cylindrical or star-shaped channel in the center of the grain. Due to changing area of the burning surface as propellant is consumed, the channel's diameter and shape determine the initial thrust and how it changes during the burn time. Since the burning starts inside the channel, the propellant itself shields the engine's casing from the hot gases until the very last seconds of the burn time. This is the most common configuration, but other shapes of the propellant grains can be used, if necessary.

In its final state, the composite solid propellant looks like a gray rubbery material and must be flexible enough to resist stress and vibration. Even small imperfections of the propellant surface, such as air bubbles, caverns and cracks, are very dangerous. Imperfections may cause a sudden radical increase of internal pressure (due to increase of the burning surface area) and rupture the engine's casing, leading to a catastrophic explosion. Integrity of the engine's body is especially important for very large solid rocket motors, which are assembled from separate sections. In 1986, loss of the engine's casing integrity caused a national tragedy: hot gases leaked through a faulty joint between two sections of the SRB and destroyed the Space Shuttle *Challenger*, killing seven astronauts. Production of the large solid propellant engines require a substantial amount of time, high precision equipment, and a tightly controlled environment. As a result, the modern powerful solid rocket motors are as expensive as the much more complex liquid propellant engines.

Ammonium perchlorate (oxidizer)	69.93%
Aluminum powder (fuel)	16%
Rubber-based polymer, called PBAN (binder)	12.04%
Epoxy-based curing agent	1.96%
Iron oxide powder (burning rate catalyst)	0.07%

Table 1.
Energy Efficiency of Modern Rocket Propellants

LIQUID PROPELLANTS

A liquid propellant consists of two liquid chemicals, fuel and oxidizer, which are delivered from separate tanks into the combustion chamber of a liquid propellant rocket engine (LPRE).

The use of a liquid propellant, namely liquid oxygen and liquid hydrogen, was proposed by the Russian space pioneer Konstantin Tsiolkovsky in 1903. He hypothesized that in addition to supplying more energy than gunpowder, such propellant would also supply water and oxygen to the crew of the future spacecraft. Space proponents from other countries independently came to the same conclusion. One of them was the American physics professor Robert Goddard, who built and launched the world's first liquid propellant rocket in 1926. LPRE technology received a major boost in the 1940s, when German engineers under Wernher von Braun developed the first operational long-range ballistic missile, *A-4* (better known as the *V-2*).

Despite the variety of liquid propellants, all of them can be divided into two major categories: storable and cryogenic. Physical properties of the storable propellants are very attractive from a technological standpoint. They have high density, do not boil under normal temperature, and degrade slowly. That makes it possible to keep the propellant inside a rocket for long periods, which is especially important for military applications and lengthy space missions. Among numerous possible combinations, the derivatives of nitric acid and hydrazine are the most widely used storable propellants today. Such propellants are self-igniting (hypergolic): the rocket engine fires as soon as the propellant components are mixed in a combustion chamber. An added advantage is that no electrical ignition mechanism is required. A typical example of a hypergolic propellant is a propellant for the Russian space launch vehicle Proton. It contains 73 percent of nitrogen tetroxide (NT) as an oxidizer, and 27 percent of unsymmetrical dimethyl hydrazine (UDMH) as a fuel.

Convenient physical properties cannot overshadow the extremely dangerous nature of storable propellants. Practically all of them are highly toxic, corrosive toward many materials, and cause severe burns on human skin. The history of the world rocketry reveals numerous cases of injures and deaths among rocket service personnel due to mishandling of these deadly chemicals. The most tragic of such accidents happened in the Soviet Union on October 24, 1960, when a ballistic missile filled with storable propellant exploded while being serviced by a ground crew. About a hundred people were fatally burned, or suffocated in toxic fumes. The founder of the Soviet space program, Dr. Sergei Korolev, called storable propellants "the devil's venom."

PROPELLANT	***SPECIFIC IMPULSE AT SEA LEVEL***	***COMMENTS***
Composite solid propellant	270 seconds	Used for modern solid propellant engines in military missiles, space launch vehicles and spacecraft. Pollutes environment by toxic exhaust.
Nitrogen Tetroxide + UDMH (liquid storable)	296 seconds	The best modern storable propellant. Widely used in military missiles, space launch vehicles and spacecraft. Both components are toxic before burning and pollute environment by toxic exhaust.
LOX + Kerosene (cryogenic, non-storable)	311 seconds	Widely used in space launch vehicles. Non-toxic, environmentally clean.
LOX + Liquid Hydrogen (cryogenic, non-storable)	388 seconds	The best modern cryogenic propellant. Used in the most advanced space launch vehicles. Non-toxic, environmentally clean.
Liquid Fluorite + Liquid Hydrogen (cryogenic, non-storable)	411 seconds	Not Used. Oxidizer is very toxic before burning and pollutes environment by toxic exhaust.

Table 2
Specific impulses of Rocket Propellants.

At first glance, the physical properties of the cryogenic propellants seem far less suitable for rocket technology since they consist of volatile liquified gases, such as liquid oxygen (LOX). Due to extremely low temperature (-183° Celsius for LOX), cryogenic propellant components require special care and complex equipment. These components are constantly boiling and evaporating under normal conditions and cannot be stored for a long time. After the cryogenic rocket is fueled and prepared for launch, it must constantly be fed by new portions of propellant to compensate for evaporation losses. This feeding can only be stopped just seconds before the takeoff. In spite of these disadvantages, cryogenic propellants provide superior energy characteristics. Liquified gases represent pure chemical elements that fully participate in a process of oxidation. For example, nitrogen tetroxide contains only 70 percent of oxygen compared to 100 percent for LOX. Thus, the energy output of complete oxidation is greater than in the case of the complex chemical compounds. Cryogenic components cost much less to produce than solid composite and liquid storable propellants. Natural resources of oxygen is also unlimited: the Earth's atmosphere. Yet the complexity of the cryogenic rocket hardware makes this technology very expensive.

Liquid oxygen is the most common cryogenic material today and the oldest liquid oxidizer in the rocket technology: it was used for the first liquid propellant rocket of Robert Goddard. It remains unsurpassed in its combination of effectiveness, low cost, and environmental "friendliness." Although liquid oxygen can be used with a variety of storable fuels (alcohol, kerosene, hydrazine, etc.), the best result is achieved with another cryogenic component, liquid hydrogen (LH_2). This combination is the most energy-efficient propellant of today's rocket technology. Yet it is probably one of the most difficult propellants to use. The major problem with liquid hydrogen is its low density (only 7% of water density). Thus, LH_2 occupies large volume and requires fuel tanks to be so spacious and heavy that it sometimes makes the use of LH_2 prohibitive. Rocket engineers are trying to resolve this problem by various methods. For example, the introduction of the new lightweight alloys decreased the mass of the Space Shuttle External

Tank (containing LOX/LH_2 propellant) by 13 percent, and NASA is willing to make it 26 percent lighter. Another solution is the "hydrogen slush," which is liquid hydrogen hyper cooled almost to the point of solidification (–259° Celsius compared to –252° Celsius for "normal" LH_2). Due to 15 percent greater density, hydrogen slush occupies lesser volume and has lower evaporation losses.

Although modern chemistry allows development of even more effective rocket propellants, energy efficiency is not the only consideration factor. For example, fluorine and its derivatives are better oxidizers than oxygen, but their extreme toxicity make them environmentally dangerous. The same concerns prevent the use of beryllium hydride—an excellent fuel that combines high density with the energy efficiency comparable to liquid hydrogen.

An increasing number of space launches worldwide makes environmental and economic problems more acute even with the existing technology. Most modern space launch vehicles use solid and storable propellants that pollute air, water and soil by toxic exhausts and by the remains of unburned propellant inside the ejected stages. One possible solution is replacement of the toxic propellants with the less expensive non-toxic components on the existing launch vehicles. Russian engineers, for example, proposed the use of liquid methane (or another natural gas) in combination with liquid oxygen. This new propellant would completely eliminate pollution and allow a lower cost per launch. At the same time its energy-efficiency would be second only to the liquid hydrogen/liquid oxygen propellant.

Apart from its chemical content and physical properties, the performance of a rocket propellant depends on engine design. Assuming that such design is optimal for a particular propellant, it is possible to compare various propellants using the energy-efficiency criteria of rocket engines, the specific impulse. Greater specific impulse indicates better propellant. Table 2 shows specific impulses of several typical propellants achievable by the best modern rocket engines.

S

SAKHAROV, ANDREI DMITRIEVICH (1921–1989)

Andrei Sakharov was a Soviet physicist who became, in the words of the Nobel Peace Prize Committee, "a spokesman for the conscience of mankind." He made many important contributions to our understanding of plasma physics, particle physics, and cosmology. He also designed nuclear weapons for two decades, becoming "the father of the Soviet hydrogen bomb" in the 1950s. After recognizing the dangers of nuclear weapons tests, he championed the 1963 U.S.-Soviet test ban treaty and other antinuclear initiatives.

From the 1960s onward, at great personal risk, Sakharov severely criticized the Soviet regime and ardently defended human rights against it. He won the Nobel Peace Prize in 1975.

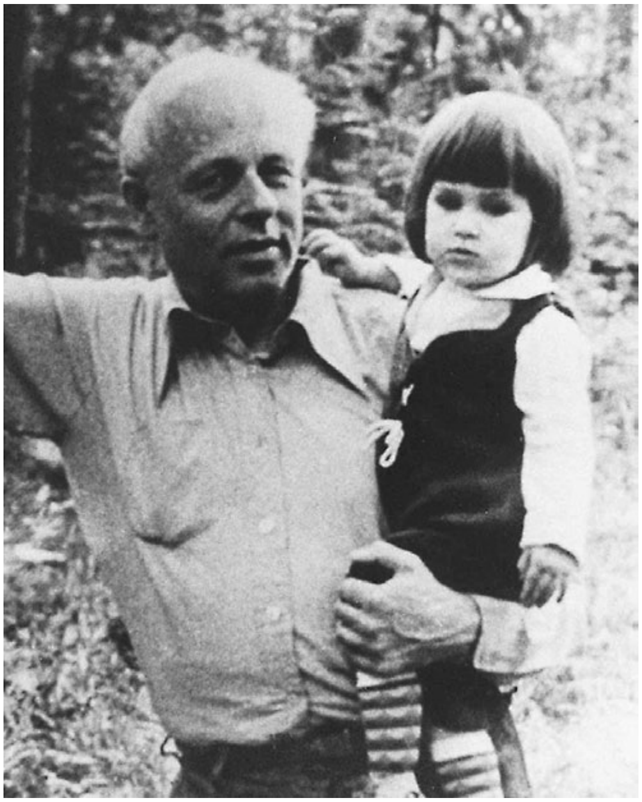
Andrei Sakharov was born in Moscow, Russia, to a family of the intelligentsia on May 21, 1921. His father, Dmitri, taught college physics and wrote textbooks and popular science books. Sakharov studied at home until the seventh grade. Dmitri, a man of warmth and culture, was his first physics teacher.

In 1938 Sakharov entered the Physics Department of Moscow State University. When World War II began, his academic prowess exempted him from military service. He and the remaining students and teachers were evacuated to Ashkhabad in Soviet Central Asia. Sakharov graduated with honors in 1942, with the war at its height, but joined a factory rather than continue school. While doing routine laboratory work at a munitions factory in Ulyanovsk on the Volga River, his engineering talent showed through a number of inventions. He also met Klavdia Vikhireva, a laboratory technician. They married in 1943.

Sakharov returned to Moscow in early 1945, as a graduate student at FIAN, the Physical Institute of the USSR Academy of Sciences. Igor Tamm, head of FIAN's Theoretical Physics Department, influenced him greatly. In 1947, Sakharov received his Ph.D. for work on particle physics.

In June 1948 Tamm was commissioned to help Yakov Zeldovich and his research team, which for two years had studied the feasibility of a thermonuclear, or hydrogen, bomb. Tamm and several of his students, including Sakharov, formed a special auxiliary group at FIAN to work on an H-bomb proposal. Sakharov suggested a radically new scheme for the bomb, and Vitaly Ginzburg added a key idea concerning thermonuclear explosive material. The U.S.-Soviet arms race took off. In the spring of 1950, Tamm and Sakharov moved to the Installation, a secret city in the central Volga region of the USSR. They worked on Sakharov's scheme and successfully tested the first prototype Soviet H-bomb on August 12, 1953.

Also in 1950 Sakharov and Tamm proposed an idea for a controlled thermonuclear fusion reactor, the TOKAMAK (acronym for the Russian phrase for "toroidal chamber with magnetic coil"), which achieved the highest ratio of output power to input power of any fusion device of the twentieth century. This reactor grew out of interest in a controlled nuclear fusion reaction, since 1950. Sakharov first considered electrostatic confinement, but soon came to the idea of magnetic confinement. Tamm joined the effort with his work on particle motion in a magnetic field, including cyclotron motion, drifts, and magnetic surfaces. Sakharov and Tamm realized that



Andrei Sakharov with his granddaughter Anya, in the 1970s. (Library of Congress)

destructive drifts could be avoided either with current-carrying rings in the plasma or with an induction current directly in the plasma. The latter is essentially the TOKAMAK concept.

At the Installation, Sakharov worked with many colleagues, in particular Yakov Zeldovich and David Frank-Kamenetskii. Sakharov made key contributions to the Soviets' first full-fledged H-bomb, tested in 1955. He also made many contributions to basic physics, perhaps the most important being his thesis that the universe is composed of matter (rather than all matter having been annihilated against antimatter) is likely to be related to charge-parity (CP) noninvariance.

Sakharov received many honors. He was elected as a full member of the Soviet Academy of Sciences in 1953 (at only age thirty-two); he was awarded three Hero of Socialist Labor Medals; he received a Stalin Prize; and he was given a country cottage. Sakharov's anti-Soviet activism cost him these rewards.

In May 1968 he completed the essay "Reflections on Progress, Peaceful Coexistence, and Intellectual Freedom." It proposed Soviet cooperation with the West, which the Soviets flatly rejected. The manuscript circulated in several typewritten copies known as *samizdat* ("self-print" in Russian) and was widely read outside the USSR. Sakharov was summarily banned from military-related research.

Also in May 1968, Sakharov accepted an offer to return to FIAN to work on academic topics. He combined work on fundamental theoretical physics with increased political activism, developing contacts to the emerging human rights movement. His wife, Klavdia, died of cancer in March 1969. In 1970 Sakharov and Soviet dissidents Valery Chalidze and Andrei Tverdokhlebov founded the Moscow Human Rights Committee. In the movement he met Elena Bonner, who became his companion-in-arms. They married in 1972.

Although Sakharov won the 1975 Nobel Peace Prize, and was the only Soviet ever to win it, he was barred from leaving Russia to receive it. The Nobel Committee's official citation praised Sakharov for his "fearless personal commitment in upholding the fundamental principles for peace…. Uncompromisingly and with unflagging strength Sakharov has fought against the abuse of power and all forms of violation of human dignity, and he has fought no less courageously for the idea of government based on the rule of law."

The Soviet regime persecuted Sakharov for his activism on behalf of dissidents and those seeking to emigrate. After he spoke out against the Soviet invasion of Afghanistan in 1979, he was picked up by the KGB and exiled to Gorky, under house arrest. There was no trial. In 1986 he was released by Premier Mikhail Gorbachev and returned to Moscow.

Sakharov made his first trip outside the Soviet Union in late 1988. In 1989 he was elected to the Congress of People's Deputies, the supreme legislative body of the Soviet Union. He died on December 14, 1989.

SAVERY, THOMAS (1650–1715)

In the study of seventeenth-century life, mystery often pervades the lives and deaths of even the most famous people and Thomas Savery is no exception. There is no record of his birth in local registers, but it is believed that he was born near Plymouth in Shilston, England, around 1650. There is no known portrait of him available today, although there was purportedly a drawing of him in a reprint of *A Miner's Friend*, published in 1827. After 1700 he became known as Captain Savery, with little evidence as to why, although he had done service as a military engineer, working as a Trench Master in 1696. According to folklore, many who were placed in charge during that era were likely to be called "Captain."

What *is* known is that Savery is sometimes left out of listings of the great mechanical inventors, even though he played a decidedly major role in the invention of the first steam engine. In fact, he was called "the most prolific inventor of his day" by the very book that set out to give proper due to the oft-neglected Thomas Newcomen as the steam engine's true inventor—*The Steam Engine of Thomas Newcomen* (Rolt and Allen, 1997).

Savery's career was hardly preordained, although he came from a family of prosperous merchants in Totnes, who acquired the manors of Shilston and Spriddlescombe in the parish of Modbury in the early seventeenth century. Savery's family was well known in the West Country and he may have been a merchant in Exeter for a period of time. At the age of twenty-three, he was protected by a writ from Charles II forbidding the local politicians to molest him. The writ in 1673 cited Savery's "many losses, particularly in the last Dutch wars," while serving as a freeman for the Merchant Adventurers Company.

Continuing a career that began in military engineering, his first patent was granted on July 25, 1698, for his historic work entitled "Raising water by the impellent force of fire." He called it "The Miner's Friend." Captain Savery's most important contribution was to evaluate the advances and frustrations of more than a century of experiments with steam power and create important innovation by combining steam with the effects of atmospheric pressure. His inventiveness was stimulated by his keen knowledge of copper and tin mining operations.

The principle of his pump was that steam was passed from a boiler into a closed receiver filled with water where its pressure forced the water through a nonreturn valve and up an ascending delivery pipe. When all the water was expelled, the steam supply was shut off and a new supply of cold water was poured over the outside walls of the receiver. This cooled the receiver and condensed the steam within. A vacuum was therefore created in the receiver, forcing water up a suction pipe, though a second nonreturn valve by atmospheric pressure. When the receiver was refilled the cooling water was shut off, steam turned on, and the cycle was repeated.

In subsequent years, Savery made important improvements that benefited future steam inventions. In June 1699 he demonstrated to the Royal Society a pump with two receivers, each with a separate, hand-controlled steam supply. This ensured improved continuity of operation, allowing one receiver to operate in its vacuum stage and the other under steam pressure. In 1701, he added two more critical steps: a second boiler, avoiding the need to shut down the fire and pump, between stages; and he replaced the two interconnected steam cocks with a single valve, run with a manually operated long lever. This may have been the inspiration for the modern slide valve and his inventiveness created, in effect, the world's first feed-water heater.

Savery appeared to be the first to take the huge step out of the lab and into the practical workshop. His equipment was made of brass and beaten copper, using firebrick furnaces. It was said that Salisbury Court (extending from Fleet Street to the river Thames) was the site of the world's first steam pump factory, although there is evidence that Savery abandoned his project in 1705. The limitations of his progress became known, literally under fire.

When tested, his engines generated too much heat and steam pressure for the technology of the times. Soldering would melt or machine joints would split. In order to solve the need for pumping water from mines, the necessary system of pumps would be far too costly and dangerous. In light of the dangers, both historians and scientists might find it intriguing that Savery never saw fit to add a safety valve, invented around that time.

In one of the more amusing assessments of this danger, Steven Switzer commented in *Hydrostatics and Hydraulics* (1729) about the steam power, "How useful it is, in gardens and fountain works ... in the garden of that noble peer, the Duke of Chandos, where the engine was placed under a delightful banqueting house, and the water was being forced up into a cistern on top, used to play a fountain in a delightful manner." Rival steam inventors derisively chided that the guests might forego the delight of the water fountain, had they known exactly what pressures were building under their feet.

Savery's work at the turn of the century preceded Newcomen's radically different and more successful engine in 1712. It also followed on the heels of noteworthy early experimenters, such as Giambattista della Porta in Italy in the early 1600s, Salomon de Caus in England in the 1620s, David Ramsay of Scotland in 1631, Edward Somerset of England in 1663, Sir Samuel Morland in 1667, Otto von Guericke of Magdeburg in 1672, and Denis Papin in the 1690s.

Savery's name and work remained in the public eye, followed by many scientists and inventors during the eighteenth century. The most important was Englishman Thomas Newcomen, who is believed to have known Savery and also to have seen his engines at work. Although Newcomen created a very different engine to solve the needs of the mines, the similarities were sufficient and Savery had earned his patent first. As a result, Newcomen and Savery entered into a joint patent agreement, whereby each shared the benefits of the other's work, while saving themselves the expense of a costly battle over separate patents.

The practical, if limited, use of Savery's incrementally successful efforts were permanently inscribed in history, as highly important advancements of his time.

SCIENTIFIC AND TECHNICAL UNDERSTANDING OF ENERGY

The word "energy" entered English and other European languages in the sixteenth century from Aristotle's writings, and was restricted to meanings close to his until the nineteenth century. The total entry for "Energy" in the first edition (1771) of the *Encyclopaedia Britannica* is as follows: "A term of Greek origin signifying the powers, virtues or efficacy of a thing. It is also used figuratively, to denote emphasis of speech." These meanings survive; Swift's energetic pronouncement in 1720 that "Many words deserve to be thrown out of our language, and not a few antiquated to be restored, on account of their *energy* and sound" still rings a bell. But they are no longer dominant. Stronger by far is the scientific meaning, fixed between 1849 and 1855 by two men, William Thomson (the future Lord Kelvin) and W. J. Macquorn Rankine, professors, respectively, of natural philosophy and engineering at the University of Glasgow in Scotland.

Though Rankine and Thomson gave the term "energy" its modern scientific meaning, they did not originate the concept. The idea that through every change in nature some entity stays fixed arose in a complex engagement of many people, culminating between 1842 and 1847 in the writings of four men: Robert Mayer, James Prescott Joule, Hermann Helmholtz, and Ludvig Colding. The later choice of a word, easy as it may seem, is no mere detail. In the 1840s the lack of a word for the concept struggling to be born was a heavy impediment. The two nearest "Kraft" in German, and "force" in English—were riddled with ambiguity. With "energy" everything fell into place.

Three issues are involved in the coming-into-being of both concept and term: (1) the eighteenth-century debate on Leibniz's notion of *vis viva* ("living force"), (2) the unfolding eighteenth- and nineteenth-century understanding of steam engines, and (3) the search after 1830 for correlations among "physical forces." Concept must come first, with (3) treated before (2). On force as a term, compare (1) and (3) with Newton's definition. For the Newtonian, a force is a push or a pull, which, unless balanced by another, makes objects to which it is applied accelerate. "Living force" was not that at all: It corresponded to the quantity that we, under Thomson's tutelage, know as kinetic energy. As for forces being correlated, force in that context bore a sense not unlike the modern physicist's four "forces of nature," gravity, electromagnetism, and the two nuclear ones. It referred to the active principle in some class of phenomena, vital force, chemical force, the forces of electricity, magnetism, heat, and so on. To correlate these—to unify them under some overarching scheme—was as much the longed-for grail in 1830 as Grand Unification would be for physicists after 1975.

CORRELATION OF FORCES AND CONSERVATION OF ENERGY

Sometime around 1800 there came over the European mind a shadow of unease about Newtonian science. Beauty, life, and mystery were all expiring in a desert of atoms and forces and soulless mechanisms—so the poets held, but not only they. Science also, many people felt, must seek higher themes, broader principles, deeper foundations—symmetries, connections, structures, polarities, beyond, across, and above particular findings. Elusive, obscure, sometimes merely obscurantist, remarkably this inchoate longing actualized itself in a few decades in a succession of luminous discoveries, and flowed forward into the idea of energy.

In Germany it took shape in a much-praised, much-derided movement, interminable in discourse about Urprinciples and life forces, spearheaded by Lorenz Oken and Friedrich Schelling under the name *Naturphilosophie*, turgid indeed, but source of a powerful new credo. Nature is one, and so must all the sciences be; the true philosopher is one who connects. Thus in 1820 Hans Christian Oersted joined magnetism to electricity with his amazing discovery that an electric current deflects a magnet. Readers of Oersted baffled by strange talk of "polarities" and the "electric conflict" should know that it stems from Schelling: Oersted was a Naturphilosoph. But there were other voices. Similar hopes expressed in a more down-to-earth English tone mark John Herschel's *Preliminary Discourse on the Study of Natural Philosophy* (1830), Mary Somerville's *Connexion of the Physical Sciences* (1839), and W. R. Grove's *On the Correlation of Physical Forces* (1843). Fluent in German and Hanoverian in descent, Herschel has special interest because his "natural philosophy" had so resolutely English a cast, remote from Naturphilosophie. His master was Bacon, yet Herschel sought connection. So above all did the man whose first published paper (1816) was on the composition of caustic lime from Tuscany, and his last (1859) on effects of pressure on the melting point of ice, the profoundly English Michael Faraday.

From worldviews about the connectedness of everything to the correlation of specific "forces" to enunciating the law of energy was a long journey requiring two almost antithetical principles: great boldness in speculation and great exactness in measurement. Two eras may be identified: an era of correlation from the discovery of electrochemistry in 1800 through much of Faraday's career, and the era of energy beginning in the late 1840s. The two are connected: Without correlation there might have been no energy, and with energy new light was thrown on correlations, but they are not the same. In the great correlations of Oersted and Faraday, the discovery, when finally made, often embodied a surprise. An electric current exerts a magnetic force, as

Oersted had expected, but it is a transverse force. A magnet generates an electric current, as Faraday had hoped, but it must be a moving magnet, and the current is transient. A magnetic field affects light traversing glass, as Faraday had surmised, but its action is a twisting one far from his first guess. Not number but vision was the key, an openness to the unexpected. Energy is different. To say that energy of one kind has been transformed into energy of another kind makes sense only if the two are numerically equal.

Between Faraday and Joule, the man after whom very properly the unit of energy, the joule, is named, lay an instructive contrast. Both master experimenters with a feeling for theory, they stood at opposite conceptual poles: geometry versus number. For Faraday, discovery was relational. His ideas about fields of force reveal him, though untrained, as a geometer of high order. His experiments disclose the same spatial sense; number he left mainly to others. "Permeability" and "susceptibility," the terms quantifying his work on magnetism are from Thomson; the quantity characterizing his magnetooptical effect is (after the French physicist Marcel Verdet) Verdet's constant. For Joule, number was supreme. His whole thinking on energy originated in the hope that electric motors run from batteries would outperform steam engines. His best experiments yielded numbers, the electrical and mechanical equivalents of heat. His neatest theoretical idea was to compute one number, the extraordinarily high velocity gas molecules must have if pressure is to be attributed to their impacts on the walls of the container.

The doctrine of energy came in the 1840s to the most diverse minds: to Mayer, physician on a Dutch ship, off Java in 1842; to Joule, brewer turned physicist, at Manchester in 1843; to Colding, engineer and student of Oersted's, at Copenhagen in 1843; to Helmholtz, surgeon in the Prussian Army, at Potsdam in 1847. In a famous text, "Energy Conservation as an Example of Simultaneous Discovery" (1959), Thomas Kuhn listed eight others, including Faraday and Grove, directly concerned with interconvertibility of forces, and several more peripherally so, arguing that all in some sense had a common aim. Against this it is necessary to reemphasize the distinction between correlation and quantification (Faraday, the geometrist, found more "correlations" than any energist) and the desperate confusion about force. In exchanges in 1856 with the young James Clerk Maxwell, Faraday discussed "conservation of force"—meaning what? Not conservation of energy but his geometric intuition of a quite different law, conservation of *flux*, the mathematical result discovered in 1828 by M. V. Ostrogradsky, afterward Teutonized as Gauss's theorem. In 1856, energy—so natural to the twenty-five-year-old Maxwell—was utterly foreign to the sixty-four-year-old master from another age.

Physicists regard energy, and the laws governing it, as among the most basic principles of their science. It may seem odd that of the four founders two were doctors, one an engineer, and one only, Joule (and he only inexactly), could have been called then a physicist. The surprise lessens when we recognize that much of the impetus of discovery came from the steam engine, to which one key lay in that potent term coined and quantified in 1782 by James Watt, "horsepower." Seen in one light, horses and human beings are engines.

WORK, DUTY, POWER, AND THE STEAM ENGINE

The steam engine was invented early in the eighteenth century for pumping water out of mines. Later Watt applied it to machinery, and others to trains and ships, but the first use was in mines, especially the deep tin and copper mines of Cornwall, in southwestern England. Crucial always, to use the eighteenth-century term, was the *duty* of the engine: the amount of water raised through consuming a given quantity of fuel: so many foot-pounds of water per bushel of coal. To the mineowner it was simple. Formerly, pumping had been done by horses harnessed to a rotary mill. Now (making allowance for amortization of investment), which was cheaper: oats for the horses or coal for the engine? The answer was often nicely balanced, depending on how close the metals mine was to a coal mine.

Improving the duty meant using fuel more efficiently, but to rationalize that easy truth was the work of more than a century. Theoretically, it depended, among other things, on the recognition in 1758 by Adam Black—Watt's mentor at Glasgow—of a distinction between heat and temperature, and the recognition by nineteenth-century chemists of an absolute zero of temperature. On the practical side lay a series of brilliant inventions, beginning in 1710 with Thomas Newcomen's first "atmospheric" engine, preceded (and impeded) by a patent of 1698 by Thomas Savery. Eventually two kinds of efficiency were distinguished, thermal and thermodynamic. Thermal efficiency means avoiding unnecessary loss, heat going up the chimney, or heat dissipated in the walls of the cylinder. Thermodynamic efficiency, more subtly, engages a strange fundamental limit. Even in an ideal engine with no losses, not all the heat can be converted into work.

Both Savery's and Newcomen's engines worked by repeatedly filling a space with steam and condensing the steam to create a vacuum. Savery's sucked water straight up into the evacuated vessel; Newcomen's was a beam engine with a pump on one side and a driving cylinder on the other, running typically at ten to fifteen strokes a minute. The horsepower of the earliest of which anything is known was about 5.5. Comprehensively ingenious as this engine was, the vital difference between it and Savery's lay in one point: how the vacuum was created. Savery poured cold water over the outside, which meant that next time hot steam entered, much of it was spent reheating the cylinder. Newcomen sprayed water directly into the steam. The higher thermal efficiency and increased speed of operation made the difference between a useless and a profoundly useful machine.

Newcomen engines continued to operate, especially in collieries, almost to the end of the eighteenth century. Yet they, too, were wasteful. The way was open for a great advance, James Watt's invention in 1768 of the separate "condenser." Next to the driving cylinder stood another cylinder, exhausted and permanently cold. When the moment for the downstroke came, a valve opened, the steam rushed over and condensed; the valve then closed and the cycle was repeated. The driving cylinder stayed permanently hot.

Watt and Matthew Boulton, his business partner, were obsessed with numbers. Testing Clydesdale dray horses, the strongest in Britain, Watt fixed their lifting power (times 1.33) at 33,000 ft-lbs per minute. Thus was horsepower defined. Comparing his first engines with the best Newcomen ones, he found his to have four times higher duty. His next leap was to make the engine double acting and subject to "expansive working." Double action meant admitting steam alternately above and below the piston in a cylinder closed at both ends; for an engine of given size it more than doubled the power. Expansive working was one of those casual-seeming ideas that totally reorder a problem. Steam expands. This being so, it dawned on Watt that the duty might be raised by cutting off the flow into the cylinder early—say, a third of the way through the stroke. Like something for nothing, the steam continued to push without using fuel. Where was the effort coming from? The answer, not obvious at the time, is that as steam expands, it cools. Not pressure alone, but pressure and temperature together enter the lore of engines.

Behind the final clarifying insight provided in 1824 by Sadi Carnot, son of the French engineer-mathematician and revolutionary politician Lazare Carnot, lay three decades of invention by working engineers. One, too little remembered, was a young employee of Boulton and Watt, James Southern. Sometime in the 1790s he devised the indicator diagram to optimize engine performance under expansive working. In this wonderfully clever instrument a pressure gauge (the "indicator") was mounted on the cylinder, and a pen attached by one arm to it and another to the piston rod drew a continuous closed curve of pressure versus volume for engines in actual operation. The area of the curve gave the work (force times distance) done by the engine over each cycle; optimization lay in adjusting the steam cutoff and other factors to maximize this against fuel consumption. Known to most purchasers only by the presence of a mysterious sealed-off port on top of the cylinder—and exorbitant patent royalties for improved engine performance—the indicator was a jealously guarded industrial secret. The engineer John Farey, historian of the steam engine, had heard whispers of it for years before first seeing one in operation in Russia in 1819. To it as background to Carnot must be added three further points: (1) the invention in 1781 by one of Watt's Cornish rivals, J. C. Hornblower, of compounding (two stages of expansion successively in small and large cylinders); (2) the use of high-pressure steam; and (3) the recognition, especially by Robert Stirling, inventor in 1816 of the "Stirling cycle" hot air engine, that the working substance in engines need not be steam. Of these, high pressure had the greatest immediate impact, especially in steam traction.

Because Watt, who had an innate distaste for explosions, insisted on low pressures, his engines had huge cylinders and were quite unsuitable to vehicles. No such craven fears afflicted Richard Trevithick in Cornwall or Oliver Evans in Pennsylvania, each of whom in around 1800 began building high-pressure engines, locomotive and stationary, as a little later did another Cornish engineer, Arthur Woolf. Soon a curious fact emerged. Not only were high-pressure engines more compact, they were often more efficient. Woolf's stationary engines in particular, combining high pressure with compounding, performed outstandingly and were widely exported to France. Their success set Carnot thinking. The higher duty comes not from pressure itself but because high-pressure steam is hotter. There is an analogy with hydraulics. The output of a waterwheel depends on how far the water falls in distance: the output of a heat engine depends on how far the working substance falls in temperature. The ideal would be to use the total drop from the temperature of burning coal—about 1,500°C (2,700°F)—to room temperature. Judged by this standard, even high-pressure steam is woefully short; water at 6 atmospheres (a high pressure then) boils at 160°C (321°F).

Carnot had in effect distinguished thermal and thermodynamic inefficiencies, the latter being a failure to make use of the full available drop in temperature. He clarified this by a thought experiment. In real engines, worked expansively, the entering steam was hotter than the cylinder, and the expanded steam cooler, with a constant wasteful shuttling of heat between the two. Ideally, transfer should be isothermal—that is, with only infinitesimal temperature differences. The thought experiment—put ten years later (1834) into the language of indicator diagrams by the French mining engineer Émil Clapeyron—comprised four successive operations on a fixed substance. In two it received or gave up heat isothermally; in the other two it did or received work with no heat transfer. Neither Carnot nor Clapeyron could quantify thermodynamic efficiency; Thomson in 1848 could. He saw that the Carnot cycle would define a temperature scale (now known as the Kelvin scale) identical with the one chemists had deduced from gas laws. For an ideal engine working between temperatures T_1 (cold) and T_2 (hot) measured from absolute zero, the thermodynamic efficiency is $(T_2 - T_1)/T_2$. No engine can surpass that.

Nothing in nature is lost; that was the message of the 1840s. Chemical, mechanical, and electrical processes are quantifiable, exact, obey a strict law of energy. Equally exact are the amounts of heat these processes generate. But the reverse does not hold. The history of steam was one long struggle against loss; not even Carnot's engine can extract all the energy the fuel has to give. This was the conceptual paradox three men, Thomson and Rankine in Scotland, and Rudolf Clausius in Germany, faced in 1849–1850 in creating the new science of thermodynamics. Out of it has arisen a verbal paradox. For physicists conservation of energy is a fact, the first law of thermodynamics. For ordinary people (including off-duty physicists), to conserve energy is a moral imperative.

Heat as energy is somehow an energy unlike all the rest. Defining how takes a second law, a law so special that Clausius and Thomson found two opposite ways of framing it. To Clausius the issue was the age-old one of perpetual motion. With two Carnot engines coupled in opposition, the rule forbidding perpetual motion translated into a rule about heat. His second law of thermodynamics was that heat cannot flow without work uphill from a cold body to a hot body. Refrigerators need power to stay cold. Thomson's guide was Joseph Fourier's great treatise on heat *Théorie analytique de la chaleur* (1827), and the fact that unequally heated bodies, left to themselves, come always to equilibrium. His version was that work has to be expended to maintain bodies above the temperature of their surroundings. Animals need food to stay warm.

In a paper with the doom-laden title "On a Universal Tendency in Nature to a Dissipation of Mechanical Energy," Thomson in 1852 laid out the new law's dire consequences. How oddly did the 1850s bring two clashing scientific faiths: Darwin's, that evolution makes everything better and better; and Thomson's, that thermodynamics makes everything worse and worse. Thirteen years later Clausius rephrased it in the aphorism "The energy of the world is constant, the entropy of the world strives toward a maximum." After Maxwell in 1870 had invented his delightful (but imaginary) demon to defeat entropy, and Ludwig Boltzmann in 1877 had related it formally to molecular disorder through the equation which we now, following Max Planck, write $S = k \log W$, the gloom only increased. With it came a deep physics problem, first studied by Maxwell in his earliest account of the demon but first published by Thomson in 1874, the "reversibility paradox." The second law is a consequence of molecular collisions, which obey the laws of ordinary dynamics—laws reversible in time. Why then is entropy not also reversible? How can reversible laws have irreversible effects? The argument is sometimes inverted in hope of explaining another, even deeper mystery, the arrow of time. Why can one move forward and backward in space but only forward in time? The case is not proven. Most of the supposed explanations conceal within their assumptions the very arrow they seek to explain.

In the history of heat engines from Newcomen's on, engineering intuition is gradually advancing scientific knowledge. The first engines strictly designed from thermodynamic principles were Rudolf Diesel's, patented in 1892. With a compression ratio of fifty to one, and a temperature drop on reexpansion of 1,200°C (~2,160°F), his were among the most efficient ever built, converting 34 percent of the chemical energy of the fuel into mechanical work.

SOLIDIFICATION OF THE VOCABULARY OF ENERGY

Two concepts entangling mass and velocity made chaos in eighteenth-century dynamics, Newton's *vis motrix* mv and Leibniz's *vis viva* mv^2 (now written ½ mv^2, as first proposed by Gaspard Coriolis in 1829). It was a battle of concepts but also a battle of terms. Then casually in 1807 Thomas Young in his *Course of Lectures on Natural Philosophy and the Mechanical Arts*, dropped this remark: "The term energy may be applied with great propriety to the product of the mass or weight of a body times the number expressing the square of its velocity." Proper or not, *energy* might have fallen still born in science had not John Farey also, with due praise of Young, twice used it in 1827 in his *History of the Steam Engine* for *vis viva*. There, dormant, the word lay, four uses in two books, until 1849, when Thomson in last-minute doubt added this footnote to his second paper on Carnot's theorem, "An Account of Carnot's Theory on the Motive Power of Heat": "When thermal agency is spent in conducting heat through a solid what becomes of the mechanical effect it might produce? Nothing can be lost in the operation of nature—no energy can be destroyed. What then is produced in place of the mechanical effect that is lost?"

In that superb instance of Thomson's genius for producing "science-forming" ideas (the phrase is Maxwell's), thermodynamics is crystallized and energy is given almost its modern meaning. His next paper, "On the Quantities of Mechanical Energy Contained in a Fluid in Different States as to Temperature and Density" (1851), elevated energy to the title and contained the first attempt to define it within the new framework of thought. The next after was the sad one on dissipation. The torch then passed to Rankine, who in two exceptionally able papers, "On the General Law of the Transformation of Energy" (1853) and "Outlines of the Science of Energetics" (1855), completed the main work. The first introduced the term (not the concept) "conservation of energy," together with "actual or sensible energy" for *vis viva*, and "potential or latent energy" for energy of configuration. "Potential energy" has stuck; "actual energy" was renamed "kinetic energy" by Thomson and P. G. Tait in their *Treatise on Natural Philosophy* (1867); their definition (vol. 1, sec. 213) nicely explains the Coriolis factor: "The *Vis Viva or Kinetic Energy* of a moving body is proportional to the mass and the square of the velocity, conjointly. If we adopt the same units for mass and velocity as before there is particular advantage in defining kinetic energy as half the product of the mass and the square of the velocity."

A paper in French by Thomson, "Mémoire sur l'energie mécanique du système solaire" (1854), was the first use in a language other than English; but it was Clausius who by adapting the German *Energie* to the new scientific sense assured its future. He met much opposition from Mayer and some from Helmholtz, both of whom favored Kraft. Mayer indeed held fiercely that Kraft or force in the sense "forces of nature" had conceptual priority, so that Newton's use of "force" should be disowned. More was at stake here than words. The dispute goes back to the three meanings of "force." For Mayer, conservation and correlation were two sides of the same coin, and the single word "Kraft" preserved the connection. For advocates of "energy," "Kraft/force" in this general sense was a vague term with no quantitative significance. "Energy" was so precise, explicit, and quantitative a concept that it required a term to itself.

Beyond the expressions "conservation of energy" and "potential energy," and the notion and name of a science of energetics (revived in the 1890s by Wilhelm

Ostwald), Rankine gave far more in concept and term than he receives credit for. He supplied the first theory of the steam engine, the important term "adiabatic" to denote processes in which work is done with no transfer of heat, and—by a curious accident—the name "thermodynamics" for the science. In 1849 Thomson, seeking a generic name for machines that convert heat into work, had used "thermo-dynamic engine." Rankine followed suit, introducing in 1853 the vital concept of a thermo-dynamic function. Then in 1854 he submitted to the Philosophical Transactions of the Royal Society a long paper, "On the Geometrical Representation of the Expansive Action of Heat and the Theory of Thermo-Dynamic Engines." Papers there carried a running head, author's name to the left, title to the right. Faced with Rankine's lengthy title, the compositor set "Mr. Macquorn Rankine" on the left and "On Thermo-Dynamics" on the right. So apt did this seem that "thermodynamics" (without the hyphen) quickly became the secure name of the science. Later critics, unaware of its roots, have accused the inventors of thermodynamics of muddled thinking about dynamics; in fact, this and the history of Rankine's function provide one more instance of the power and subtlety of words. The "thermo-dynamic function" is what we, after Clausius who rediscovered it and gave it in 1865 its modern name, call entropy. In its original setting as the mathematical function proper to the efficient functioning of engines, Rankine's name was a good one. In the long view, however, Clausius's name for it, formed by analogy with energy, was better, even though the etymological reading he based it on (energy = work content, entropy = transformation content) was false. It was shorter and catchier but, more important, stressed both the parallel and the difference between the two laws of thermo-dynamics.

In 1861, at the Manchester meeting of the British Association for the Advancement of Science, two engineers, Charles Bright and Latimer Clark, read a paper "On the Formation of Standards of Electrical Quantity and Resistance," which had an influence on science and everyday life out of all proportion to the thirteen lines it takes in the Association Report. Its aim was simple. As practical telegraphers, Bright and Clark wished to attain internationally agreed definitions, values, and names for working quantities in their field. Their proposal led to the setting up under Thomson of a famous British Association committee to determine—from energy principles—an absolute unit of electrical resistance. Another, and fascinating, topic was Clark's suggestion made verbally at Manchester that units should be named after eminent scientists. He proposed "volt," "ohm," and "ampere" for units of potential, resistance, and current, though on ampere there was dispute, for Thomson's committee preferred to name the unit of current for the German electrician Weber.

International blessing and the setting of many names came at the Paris Congress of Electricians in 1881, but with no choice yet for units of energy and power. A year later C. William Siemens, the Anglicized younger brother of Ernst Werner von Siemens, was president of the British Association. In his address reported in the British Association report in 1882 he proposed "watt" and "joule"—the one "in honour of that master mind in mechanical science, James Watt … who first had a clear physical conception of power and gave a rational method of measuring it," the other "after the man who has done so much to develop the dynamical theory of heat." According to the *Athenaeum* in 1882, Siemens's suggestions were "unanimously approved" by the Physics Section of the British Association a few days later. Joule, who was sixty-four at the time and had another seven years to live, seems to have been the only man so commemorated during his lifetime.

QUANTIZATION, E = MC^2 AND EINSTEIN

Accompanying the new nineteenth-century vista on heat were insights into its relation to matter and radiation that opened a fresh crisis. Gases, according to the "kinetic" theory, comprise large numbers of rapidly moving colliding molecules. As remade by Clausius and Maxwell in the 1850s it was an attractive—indeed, a correct—picture; then something went horribly wrong. From the Newtonian mechanics of colliding bodies, Maxwell deduced a statistical theorem—later called the equipartition theorem—flatly contrary to experiment. Two numbers, 1.408 for the measured value of a certain ratio, 1.333 for its calculated value, failed to agree. So upset was he that in a lecture at Oxford in 1860 he said that this one discrepancy "overturned the whole theory." That was too extreme, for the kinetic theory, and the wider science of statistical mechanics, continued to flourish and bring new discoveries, but there was truth in it. Equipartition of energy ran on, an ever-worsening riddle, until finally in 1900 Max Planck, by focusing not on molecules but on radiation, found the answer. Energy is discontinuous. It comes in quantized packets $E = h\nu$, where h is a constant ("Planck's constant") and n the frequency of radiation. Expressed in joule-seconds, h has the exceedingly small value $6.67\text{x}10^{-34}$. Quantum effects are chiefly manifested at or below the atomic level.

The forty years from equipartition to Planck deserve more thought than they ordinarily get. The theorem itself is one hard to match for sheer mathematical surprise. It concerns statistical averages within dynamical systems. As first put by Maxwell, it had two parts: (1) if two or more sets of distinct molecules constantly collide, the mean translational energies of the individual ones in each set will be equal, (2) if the collisions produce rotation, the mean translational *and rotational* energies will also be equal. This is equipartition. Mathematically, the result seemed impregnable; the snag was this. Gases have two specific heats, one at constant pressure, the other at constant volume. Calculating their ratio C_p/C_v from the new formula was easy; by 1859 the value was already well known experimentally, having been central to both acoustics and Carnot's theory. Data and hypothesis were excellent; only the outcome was wrong.

Worse was to come. Boltzmann in 1872 made the same weird statistical equality hold for *every* mode in a dynamical system. It must, for example, apply to any internal motions that molecules might have. Assuming, as most physicists did by then, that the sharp lines seen in the spectra of chemical elements originate in just such internal motions, any calculation now of C_p/C_v would yield a figure even lower than 1.333. Worse yet, as Maxwell shatteringly remarked to one student, equipartition must apply to solids and liquids as well as gases: "Boltzmann has proved too much."

Why, given the scope of the calamity, was insight so long coming? The answer is that the evidence as it stood was all negative. Progress requires, data sufficiently rich and cohesive to give shape to theoretical musings. Hints came in 1887 when the Russian physicist V. A. Michelson began applying equipartition to a new and different branch of physical inquiry, the radiation emitted from a heated "black body"; but even there, the data were too sparse. Only through an elaborate interplay of measurement and speculation could a crisis so profound be settled.

Gradually it was, as Wilhelm Wien and others determined the form of the radiation, and Planck guessed and calculated his way to the new law. Found, it was like a magic key. Einstein with dazzling originality applied it to the photoelectric effect. Bohr, after Rutherford's discovery of the nucleus, used it to unlock the secrets of the atom. The worry about gases evaporated, for quantization limits which modes of energy affect specific heats. As for that later worry of Maxwell's about solids, trouble became triumph, a meeting ground between theory and experiment. Among many advances in the art of experimentation after 1870, one especially was cryogenics. One by one all the gases were liquefied, culminating with hydrogen in 1898 and helium in 1908, respectively at 19.2 K and 4.2 K above absolute zero. Hence came accurate measurements near zero of the specific heats of solids, started by James Dewar. They fell off rapidly with temperature. It was Einstein in 1907 who first saw why—because the modes of vibrational energy in solids are quantized. More exact calculations by Peter Debye, and by Max Born and Theodore von Kármán, both in 1912, made C at low temperatures vary as T^3. It was a result at once beautifully confirmed by F. A. Lindemann (Lord Cherwell) in experiments with Walther Nernst in Berlin.

From Planck's h to Bohr's atom to the austere reorganization of thought required in the 1920s to create quantum mechanics is a drama in itself. Crucial to its denouement was Heisenberg's "uncertainty principle," a natural limit first on knowing simultaneously the position x and momentum p of a body ($\Delta x \, \Delta p \sim h$) and second, no less profound, on energy. The energy E of a dynamical system can never be known exactly: measured over a time interval Δt it has an uncertainty $\Delta E \sim h/\Delta t$. But whether quantum uncertainty is an epistemological truth (a limit on knowledge) or an ontological one (a limit in nature) is an endless, uncertain debate.

If the $E = h\nu$ of quantum theory is one beguilingly simple later advance in the concept of energy, the supremely famous mass-energy law $E = mc^2$ is another. This and its import for nuclear energy are usually credited solely to Einstein. The truth is more interesting.

It begins with J. J. Thomson in 1881 calculating the motion of an electric charge on Maxwell's electromagnetic theory, a theme Maxwell had barely touched. To the charge's ordinary mass Thomson found it necessary to add an "electromagnetic mass" connected with electrical energy stored in the surrounding field. It was like a ship moving through water—some of the water is dragged along, adding to the ship's apparent mass. Had the calculation been perfect, Thomson would have found $E = mc^2$, as Einstein and others did years later. As it was, Thomson's formula yields after a trivial conversion the near-miss $E = \frac{3}{4} mc^2$.

After Thomson nothing particular transpired, until a number of people, of whom Joseph Larmor in 1895 was perhaps first, entertained what historians now call the "electromagnetic worldview." Instead of basing electromagnetism on dynamics, as many had tried, could one base dynamics on electromagnetism? How far this thought would have gone is unclear had it not been for another even greater leap of Thomson's, this time experimental: his discovery of the electron. In 1897, by combining measurements of two kinds, he proved that cathode rays must consist of rapidly moving charged objects with a mass roughly one one-thousandth of the hydrogen atom's. Here was revolution—the first subatomic particle. Hardly less revolutionary was his conjecture that its mass was *all* electromagnetic. A shadow ship plowing through an electromagnetic sea: That was Thomson's vision of the electron.

The argument then took two forms: one electromagnetic, the other based on radioactivity. The first was tied to a prediction of Maxwell's in 1865, proved experimentally in 1900 by Petr Lebedev, that light and other electromagnetic radiations exert pressure. This was the line Einstein would follow, but it was Henri Poincaré who, in 1900 at a widely publicized meeting in honor of H. A. Lorentz, first got the point. The Maxwell pressure corresponds to a momentum, given by the density of electromagnetic energy in space divided by the velocity c of light. Momentum is mass times velocity. Unite the two and it is natural to think that a volume of space containing radiant energy E has associated with it a mass $m = E/c^2$. Meanwhile, as if from nowhere, had come radioactivity—in Rutherford's phrase, "a Tom Tiddler's ground" where anything might turn up. In 1903 Pierre Curie and his student Albert Laborde discovered that a speck of radium placed in a calorimeter emitted a continuous flux of heat sufficient to maintain it at 1.5°C above the surroundings. Their data translated into a power output of 100W/kg. Where was the power coming from? Was this finally an illimitable source of energy, nature's own perpetual-motion machine? It was here that Einstein, in a concise phrase, carried the argument to its limit. In his own derivation of $E = mc^2$ in 1905, five years after Poincaré's observation, he remarked that any body emitting radiation should lose weight.

The events of World War II, and that side of Einstein that made credit for scientific ideas in his universe a thing more blessed to receive than to give, have created a belief that atomic energy somehow began with him. In truth the student of early twentieth-century literature notices how soon after radioactivity there arose among people who knew nothing of $E = mc^2$ or Einstein a conviction that here was a mighty new source of energy. Geologists hailed it with relief, for as the Irish physicist John Joly demonstrated in 1903, it provided an escape from Kelvin's devastating thermodynamic limit on the age of Earth. But not only they, and not always with relief. In Jack London's nightmare futurist vision *The Iron Heel*, published in 1908, atomic gloom permeates the plot. No less interesting is this, from a 1907 work London may have read that remains among the most illuminating popularizations of the events of that era, R. K. Duncan's *The New Knowledge*: "March, 1903, … was a date to which, in all probability, the men of the future will after refer as the veritable beginning of the larger powers and energies that they will control. It was in March, 1903, that Curie and Laborde announced the heat-emitting power of radium. The fact was simple of demonstration and unquestionable. They discovered that a radium compound continuously emits heat without combustion, or change in its molecular structure.… It is all just as surprising as though Curie had discovered a red-hot stove which required no fuel to maintain it on heat." But there *was* fuel: the fuel was mass.

The highest (and most puzzling) of Einstein's offerings is not $E = mc^2$, where his claim is short, but the spectacular reinterpretation of gravitational energy in the new theory he advanced in 1915 under the name general relativity. Owing much to a brilliant paper of 1908 by his former teacher Hermann Minkowski, this, of course, is not the popular fable that everything is relative. It is a theory of relations in which two paired quantities—mass-energy and space-time—are each joined through the velocity of light mass-energy via $E = mc^2$, space-time via a theorem akin to Pythagoras's where time multiplied by c enters as a fourth dimension, not additively but by subtraction $-(ct)^2$. When in this context Einstein came to develop a theory of gravity to replace Newton's, he met two surprises, both due ultimately to the curious—indeed deeply mysterious—fact that in gravitation, unlike any other force of nature, mass enters in two ways. Newton's law of acceleration $F = ma$ makes it the receptacle of inertia; his law of gravity $F = GMm/r^2$ makes it the origin of the force. If, therefore, as with electromagnetism, the energy is disseminated through space, it will have the extraordinary effect of making gravitation a source for itself. Consider Earth. Its mass is 6×10^{21} tons; the mass of the gravitational field around it, computed from $E = mc^2$, though tiny by comparison, has the by-human-standards enormous value of 4×10^{10} tons. It, too, exerts an attraction. For denser bodies this "mass of the field" is far greater. Because of it any relativistic theory of gravitation has to be nonlinear.

Even deeper, drawn from his much-discussed but too little understood "falling elevator" argument, was Einstein's substituting for Newton's equivalence between two kinds of mass an equivalence between two kinds of acceleration. How innocent it seems and how stunning was the transformation it led to. The theory could be rewritten in terms not of mass-energy variables but of space-time variables. Gravitation could be represented as warping space-time—in just the right nonlinear way. For this one form, energy had been transmuted into geometry. But was the geometrization limited to gravity, or might it extend to energy of every kind, beginning with electromagnetic? That great failed vision of the geometrization of physics would charm and frustrate Einstein and many others for the next forty years, and it retains its appeal.

Looking back over more than a century since energy began as concept and term, it is impossible not to be struck both by the magnitude of the advance and the strenuousness of the puzzles that remain. In the design of engines, the practice of quantum mechanics, the understanding of elementary particles, the application of relativity, detailed prescriptions and laws exist that work perfectly over the range of need. Beyond lies doubt. To physicists with their conviction that beauty and simplicity are the keys to theory, it is distressing that two of the most beautifully simple conceptions proposed in physics, J. J. Thomson's that all mass is electromagnetic, Einstein's that all energy is geometric, both manifestly verging on truth, have both failed, with nothing either as simple or as beautiful arising since to take their place. Then there are issues such as quantum uncertainty and the problems of dissipation, reversibility, and the arrow of time, where to a certain depth everything is clear, but deeper (and the depth seems inescapable), everything is murky and obscure—questions upon which physicists and philosophers, such as Milton's theologians, sit apart in high debate and find no end in wandering mazes lost.

SEEBECK, THOMAS JOHANN (1770–1831)

Thomas Johann Seebeck, German physician, physicist, and chemist, was born April 9, 1770, in the Hanseatic town of Revel (now Tallinn Estonia). Seebeck studied medicine in Berlin and Goettingen, where in 1802 he took a physician's doctor degree. He lived in Jena (Thuringia) between 1802 and 1810 as an independent scholar not practicing medicine. In the Jena period Seebeck met poet Johann Wolfgang Goethe, who carried on his own studies on chromatics. From 1806 untill 1818 Seebeck consulted and informed Goethe about his optical observations. He discovered entoptical colors in 1813. These are color figures which originate inside glass volume after cooling. The phenomenon of entoptical colors was broadly documented by Goethe in his treatises on theory of colors. Seebeck became a member of the Academy of Sciences in Berlin in 1814. After stays in Bayreuth and Nuernberg (Bavaria) he moved to Berlin in 1818. Goethe hoped that Seebeck, in the prestigious position of an academician, would help to lend respectability to his theory of colors. Instead, the contact between the two men loosened in the 1820s, as Seebeck seems to have distanced himself cautiously from Goethe's theory. In Berlin Seebeck devoted most of his time to experiments measuring the influence of heat on magnetism and electricity. Seebeck died December 10, 1831, in Berlin.

Seebeck's outstanding scientific achievement was the discovery of one of the three classical thermoelectric effects, which are the Seebeck, the Peltier, and the Thomson effects. Seebeck's discovery was the first, dating from 1822–1823, followed by that of Jean-Charles-Athanase Peltier in 1832 and that of William Thomson in 1854. Seebeck observed that an electric current in a closed circuit comprised different metallic components if he heated the junctions of the components to different temperatures. He noted that the effect increases linearly with the applied temperature difference and that it crucially depends on the choice of materials. Seebeck tested most of the available metallic materials for thermoelectricity. His studies were further systematized by the French physicist

Antoine-Cesar Becquerel (1788–1878). It has become common after Becquerel to classify materials according to their so-called thermoelectric power. The difference in thermoelectric power of the applied materials determines the strength of thermoelectricity. Since the Seebeck effect can only be observed if two dissimilar conductors are employed, one obtains therewith only access to differences of values of thermoelectric power. Absolute values can be ascertained through the Thomson effect, which states that in a single homogeneous material heat develops (or is absorbed) in case electric current flows parallel (or antiparallel) to a temperature gradient. The strength of this effect is expressed by the Thomson coefficient, which is a temperature-dependent quantity varying from material to material. The absolute value of the thermoelectric power of a material is given by the temperature integral of the Thomson coefficient multiplied by the inverse temperature.

Seebeck understood that his effect might be used for precision measurements of temperature differences, and indeed it is exploited for this purpose in modern thermoelements. The basic device in these thermoelements is an electric circuit comprising two metallic components of different thermoelectric power, a thermocouple. The temperature difference to which the thermocouple is exposed is measured through the voltage built up in the circuit, according to Seebeck. Thermoelements with various combinations of materials for their thermocouples are used in the temperature range from –200°C to 3,000°C. their simplicity and robustness makethem an almost universal element in the fields of temperature recording and temperature regulation. In addition to their higher precision as compared to conventional thermometers, these thermoelements have the additional advantage that they can be introduced into apertures fitting to the thinnest technologically realizable wires. Thermoelements also have a much smaller heat capacity than conventional thermometers (e.g. mercury thermometers) and therefore interfere much less with the body to be measured.

Another application of the Seebeck effect is to be found in detectors of small quantities of heat radiation. These sensitive detectors comprise a thermopile, a pile of thermocouples (small pieces of two different metals connected in V form and put into series). Half of the junctions of the thermopile are shielded within the detector, whereas the other half are exposed to external heat radiation which is recorded through a voltmeter in the thermopile circuit.

SEISMIC ENERGY

Seismic energy is energy in the form of elastic waves that are propagated through the earth's interior or along its surface, or have the form of standing waves (free oscillations) in the planet as a whole. The source of seismic waves may be either natural—an earthquake—or artificial, for example, a chemical or nuclear explosion, or a weight dropped on the earth's surface. The energy source, whatever it is, imposes a strain—a change in shape and volume—on the surrounding earth material, which resists the strain because of its elastic properties. As the strained material tries to recover its original shape and volume, oscillations are produced, which are transferred to material slightly farther away from the source. In this way, seismic waves are produced that spread out from the source in all directions. In detail, the mechanics of seismic sources can be quite complex.

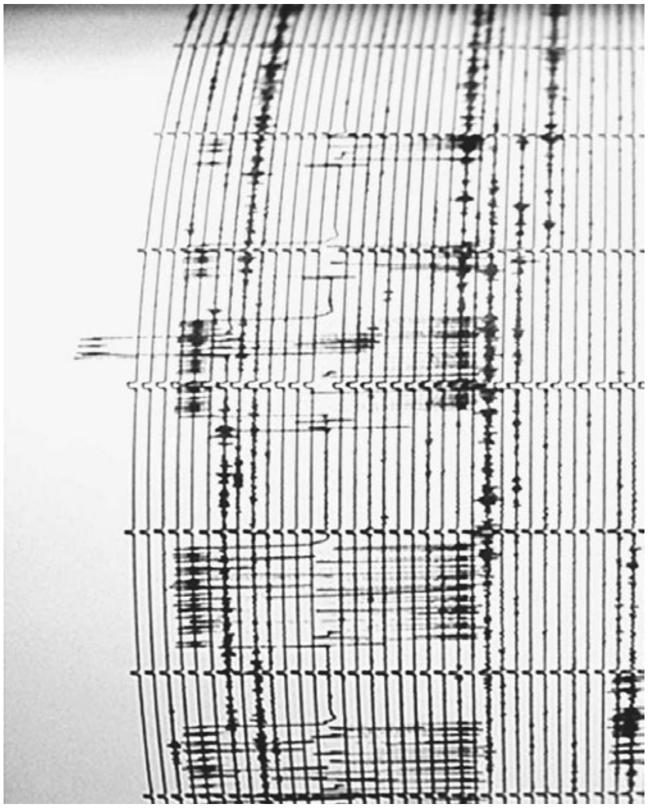
Several types of seismic waves are recognized. Longitudinal waves, also called compressional waves or P waves, consist of oscillations back and forth in the direction of wave propagation. Transverse waves, also called shear waves or S waves, consist of oscillations at right angles to the direction of wave propagation. Because S waves depend upon the rigidity of materials for their existence, they cannot propagate through a fluid medium. L waves, so-called from their long wavelengths, propagate along the free surface of the earth, or within layers near the surface. They are called surface waves, in contrast to the body waves (P and S waves) that travel through the interior body of the earth. Free oscillations of the earth, which exist in several modes, are standing seismic waves produced by very large earthquakes.

EARTHQUAKES

Although earthquakes may be caused by natural events such as rockfalls or the movement of magma in volcanic regions, most are caused by a sudden release of energy at a fault. Before being released in the forms of heat and seismic waves, this energy was stored as elastic strain—that is, recoverable distortions of the size or shape of a volume of rock. Strain develops in response to tectonic forces acting in the lithosphere, the relatively rigid uppermost 100 kilometers (60 miles) or so of the earth. This may be likened to the energy stored in a stretched rubber band, which then is released when the band snaps. The ultimate source of the tectonic forces, and therefore of the energy released by earthquakes, is to be sought in the heat of the deeper portions of the earth. This heat is thought to be a combination of heat produced by natural radioactivity, of residual heat from the earth's accretion, and of heat generated by the separation of iron into the earth's core.

At some point during the accumulation of strain, a certain volume of rock suddenly lurches back toward its original, unstrained condition. The level of stress, which has accumulated along with the strain, decreases rapidly, the rock slips a certain distance along a fracture plane (fault), and seismic waves propagate away from the source region. At sufficiently large distances, the source appears to be a single point within the earth, called the hypocenter (or focus) of the earthquake. The epicenter is a point on the earth's surface located directly above the hypocenter.

The total energy of the earthquake is partitioned into heat and seismic-wave energy. The latter has been estimated to account for only one-sixth to one-quarter of the total energy for tectonic earthquakes, and much less—perhaps only 1 percent—for rockfalls and explosions. The energy of the seismic waves is responsible for the destruction wrought by large earthquakes, either directly through ground shaking, or indirectly by inducing ground failure. The size of a tectonic earthquake is a function of the area of the fault that has slipped, the average amount of slip, and the rigidity of the rock in the vicinity of the fault. The product of these three factors is called the moment of the earthquake, and is related to the more familiar concept of earthquake magnitude.



Seismograph recording seismic activity of Volcano Island, Philippines. (Corbis Corporation)

Earthquake magnitude is a term coined in the 1930s by Charles Richter, a seismologist at the California Institute of Technology. Richter based his original magnitude scale on the amplitudes of seismic waves as recorded on a common type of seismograph then in use in southern California, after correction for the distance to the epicenter. Subsequently, many other methods of measuring earthquake magnitude were developed, not all of which gave results that closely coincided with those of Richter's original method. Today the method that gives the most consistent results across the entire range of magnitudes is based on the earthquake moment, which can be found by analyzing the wavelengths and amplitudes of the seismic waves. Moment is then converted into a magnitude number, known as moment magnitude. On this scale, the very largest earthquakes have magnitudes about 9.5, while the smallest have values of magnitude that are negative. In principle, seismic-wave energy and earthquake moment are directly proportional: $E = AM_0$. In this equation E is energy, M_0 is moment, and A is a constant with an approximate value of

Workers conduct seismic explosions in search of oil and gas deposits on private islands in Bob Marshall Wilderness Area, Montana. (Corbis Corporation)

5×10^{-5} if E and M_0 are expressed in the same units. For example, the moment magnitude of the great Alaska earthquake of 1964 has been estimated at 9.2. This corresponds to a seismic moment of nearly 10^{23} joules, or seismic-wave energy of 5×10^{18} joules. The energy generated by this one earthquake was ten times greater than the amount of seismic-wave energy generated in the entire earth in an average year, which is estimated to be 5×10^{17} joules. That is why high-magnitude earthquakes are the most destructive of natural phenomena. Each whole step on the moment magnitude scale corresponds to an increase of about thirty-two times in seismic-wave energy. Seismologists cannot yet predict when an earthquake of a given size will occur on a given segment of a given fault, but many years of observation have revealed that the frequency of occurrence of earthquakes decreases by about a factor of ten for every whole step increase in magnitude. Thus, in a typical year southern California might experience about a hundred earthquakes in the magnitude range 3 to 4, about ten in the range 4 to 5, and perhaps one of magnitude 5 or greater.

USE OF SEISMIC ENERGY

Since about the beginning of the twentieth century, seismologists have made use of natural seismic waves to investigate the internal structure of the earth. Because of changes in the density and elasticity of earth materials with depth and, to a lesser extent, horizontally, seismic waves are refracted, reflected, and dispersed in fairly complex ways as they propagate through and around the earth. Analysis of free oscillations also provides valuable information about the state of the earth's interior. It is primarily through these techniques that we know that the earth is subdivided into a crust, mantle, outer core, and inner core, as well as details about each of these internal regions.

Artificially generated seismic waves also may be used to explore below the earth's surface, for either scientific or commercial purposes. Seismic energy produced by explosions, weight drops, vibrators, or, at sea, by electrical sparkers and air guns is used extensively to explore for geologic structures that may contain petroleum. The most common method makes use of P waves that are recorded as they arrive back at the earth's surface after having been reflected from boundaries separating rocks of differing properties. Intensive computer-assisted processing converts the raw data so collected into a detailed picture of the subsurface region. Similar techniques are used on a smaller scale in civil engineering projects to find the depth to bedrock beneath soil cover, to investigate the quality of the bedrock, or to find the depth to a groundwater aquifer.

SHIPS

From the earliest times, ships and boats were propelled by human power and wind power. In the nineteenth century very large and efficient sailing ships (many 70 to 100 m long) were transporting passengers and cargo to ports all over the world. In the Western world most of the cargoes were carried by sailing ships until the 1890s. By the middle of the nineteenth century, with the development of reliable steam engines, the designers of ships began to use coal-burning steam power plants to propel ships, using paddle wheels and then propellers. Other power plants were developed in the late nineteenth century and during the twentieth century, including steam turbines, spark-ignition engines, diesel engines, gas turbines, and nuclear power plants. These ship power plants were developed from their land-based counterparts to operate in the severe ocean environment. A relatively new power source, the fuel cell, is being developed to provide electrical power for underwater vessels and also is being evaluated for future applications in surface ships.

High-speed ships and large-displacement slower ships can have power requirements of 30,000 to 75,000 kW (approximately 40,000 to 100,000 hp) for propulsion. Some nuclear-powered aircraft carriers have power plants that develop 200,000 kW. In addition to the power required to propel the vessel, some energy and power have to be provided for various ship services, such as heating, lighting, and cooling; this is often described as the "hotel load." Power also is required to refrigerate the cargo in some vessels and to pump oil in tankers.

SHIP RESISTANCE

Experiments by William Froude in the nineteenth century indicated that ship resistance has two main components: frictional, and wave-making resistance or drag. Frictional resistance is caused by the movement of the underwater hull (wetted surface area) through the viscous fluid, water. Wave-making drag is the component of resistance resulting from the energy expended on the waves generated by the moving ship. Short, bluff ships have less wetted surface area than long, slender ships for the same displacement and therefore have lower frictional drag. The long, slender ships, however, tend to generate smaller waves and thus have lower wave-making drag at high ship speeds, where wave-making drag predominates. Placing bulbous bows on large commercial ships such as tankers has been shown to reduce wave-making drag. In addition to frictional and wave-making drag, there is form drag induced by the complex fluid flow around the hull near the stern of many ships, and there is also the wind resistance of the structure of the ship above the sea surface.

Information on ship resistance has been determined from large numbers of tests on scale models of ships and from full-size ships, and compilations of these experimental results have been published. For a new and innovative hull form the usual procedure is to construct a scale model of the ship and then to conduct resistance tests in a special test facility (towing tank). Alternatively, analytical methods can provide estimates of ship resistance for a range of different hull shapes. Computer programs have been written based on these theoretical analyses and have been used with success for many ship designs, including racing sailboats.

Methods for reducing wave-making drag are often introduced for ships that operate at high speed. Lifting the hull partly or completely out of the water by using hydrodynamic lift or air pressure has been investigated for high-speed ship designs. Fast but short-range ferries have been built on these principles using planing hulls, air-cushion designs, and hydrofoil configurations. In air cushion and surface-effect ships, 15 to 30 percent of the total power has to be supplied to the fans that provide the air pressure to lift the hulls.

Another concern is the ability of a ship to operate in storms. The pounding of waves on the hull increases the resistance; this can cause structural damage, and the violent ship motions can harm the passengers, cargo, and crew of the ship. Some designers have proposed special configurations that can maintain the ship speed in storms.

PROPULSORS

Propellers are the predominant propulsive devices driving ships, although water jets are now used in some high-speed ships. An experimental installation in a small ship of a magnetohydrodynamic propulsor has been tested, but it achieved rather low propulsive efficiency. Fish-like propulsion also has been examined for possible application to ships and underwater vehicles.

In the middle of the nineteenth century some ship designers began to replace paddle wheels with propellers (or screws). A propeller has a series of identical blades placed around a hub that is driven by the engine. W. J. M. Rankine presented a theoretical model of the ideal propeller in his classic paper "On the Mechanical Principles of the Action of Propellers" (1865). He demonstrated that the efficiency of an ideal frictionless propeller to produce a specified thrust was improved as the propeller diameter was increased. There are, of course, practical limitations to the propeller diameter, depending on the ship geometry and to some extent on the fabrication capabilities of the propeller manufacturers. Designers have developed the shapes of the propeller blades to achieve good efficiency.

Methods for defining the details of the geometry of the propeller and its blading to achieve high efficiency are well established and are continuously being improved. Digital computer programs have been developed that are widely used to provide the design and analysis of propulsors. These programs were originally used to design conventional propellers, and the methods have been extended to apply to propellers in ducts and also to the pumps for waterjets.

To produce thrust it is necessary to apply torque to the propeller; this results in a swirling flow downstream of the propeller from the reaction of this torque acting on the water. The swirling flow is not used to produce thrust and is therefore a source of energy loss. Several methods have been developed to raise the propulsive efficiency by canceling or removing this swirling flow. Stationary blades (stators) upstream or downstream of the propeller have been installed in a few propellers for this purpose, and counterrotating screws have been used. An additional device downstream of the propeller that rotates freely, called a Grim wheel or a vane wheel, has been used in some applications. The inner portion of the vane wheel absorbs the swirling energy from the propeller wake while the outer portion acts as an additional propeller and produces thrust.

In the 1930s ducts or nozzles surrounding highly loaded propellers were introduced. Experiments had shown that propeller efficiency was improved, and many of these devices (often referred to as Kort nozzles) have been used in tugs and fishing boats. Theoretical analysis of ducted propellers has shown that the efficiency can be improved compared to conventional propellers when some of the thrust is produced by the fluid flow around the nozzle.

The designer is expected to develop a propeller design to minimize the power required by the power

Table 1.
Representative Ship and Power Data for Various Ship Types

plant to propel the ship at the design speed. At this speed the effective power, P_e, is the product of ship resistance and ship speed and would be determined by model tests, correlations of experimental results, or computed using theoretical predictions, discussed earlier. The shaft power developed by the engine, P_s, is the power required to drive the propeller through the transmission and shafting. The propulsive efficiency or propulsive coefficient (PC) is the ratio of effective power to shaft power: $PC = P_e/P_s$. The propulsive coefficient is usually between 60 and 75 percent for most ship designs.

The propulsor, in a steady situation, has to provide the thrust equivalent to the resistance of the ship. The prediction of this balance between ship resistance and propeller thrust is a complex process because the water flow in the stern region of the ship interacts with the flow through the propeller. The ship resistance may be modified by the action of the propeller, while the propeller efficiency usually is influenced by the disturbed flow regime near the stern of the ship.

The phenomenon of propeller cavitation often occurs at high ship speed and on highly loaded propellers. It provides a very serious limitation to propeller performance because it can damage the propeller and ship components near it. In addition, the efficiency may be reduced and the phenomenon can cause noise and vibration. Cavitation occurs when the local pressure of the water on the blade surface is reduced below the vapor pressure of the water passing over the blade surface. The high velocity of the water passing over regions of the propeller blades creates this reduction in pressure. The water boils when the local pressure becomes very low, and pockets of water vapor are formed at the blade surface. These vapor pockets and their subsequent collapse cause the problems associated with cavitation. Modern methods of propeller design have allowed designers to predict the onset of cavitation and to define the performance limitations.

WATERJETS

Waterjets have been developed for application to high-speed ships. The waterjet has an inlet usually on the side or bottom of the ship in the region of the stern, which allows water to flow into a water pump. The pressure of the water is raised in the pump, and the water is expelled as a jet to produce the desired thrust. The direction of the jet flow can be controlled to provide maneuvering forces, eliminating the need for rudders. The propulsive coefficient of modern waterjets usually is lower than propellers for the same application, but they have been used where severe cavitation would occur in conventional propellers.

SHIP POWER PLANTS

Most ships are powered by thermal power plants, including diesel engines, gas turbines, and nuclear systems. Merchant ships usually have diesel engines, while gas turbines or a combination of diesel engines and gas turbines often power naval vessels. Some of the larger ships in the U.S. Navy have nuclear power plants.

Large, low-speed diesel engines are remarkably efficient and convert about 45 percent of the energy of the fuel-air reaction into power. In addition, the cooling water and engine exhaust can be used to generate steam to provide heat and power for the ship. The steam has been used in some designs to generate power through steam turbines.

Improvements also have been made to the gas turbine for naval applications. An intercooled recuperative (ICR) gas turbine has been designed to improve the fuel consumption of naval power plants. The engine has a recuperator to take the heat that would otherwise be wasted in the exhaust and transfers it to the air entering the combustor. The new engine is expected to save about 30 percent of the fuel consumed, compared to the simple gas turbine. The ICR engine is, however, larger and more expensive than the simple gas turbine.

In the early steam ships the paddle wheels and propellers were directly connected to reciprocating steam engines. The large low-speed diesel engines of today are able to operate efficiently at the low propeller speeds and usually are directly connected by shafts to the propellers. Other ship power plants, such as steam turbines, gas turbines, and medium-speed diesel engines, operate most efficiently at higher rotational speeds than propellers. Speed converters have to be provided to reduce the rotational speed from the high engine speed to the low propeller speed. Mechanical reduction gearboxes are generally used to provide this conversion. Electric drives, consisting of high-speed electric generators driven by steam turbines coupled to low-speed electric motors, were used during World War II, when there was a shortage of gearboxes. A modern version of electric drive sometimes is used in cruise ships and also is being evaluated for the U.S. Navy.

Submarines, submersibles, and other underwater vehicles have a difficult operational problem, namely the absence of atmospheric oxygen, which is necessary for all thermal engines except nuclear power plants. At about the beginning of the twentieth century rechargeable batteries were developed, and these batteries, coupled to electric motors and propellers, were used to propel submarines under the sea. Spark ignition engines and later diesel engines provided the power for operation at the surface and to recharge the batteries. Since 1985, stored oxygen has been used in some thermal power plants and in fuel cells for experimental underwater vehicles. Nuclear power plants, which do not require oxygen for power generation, were introduced in 1954 to power U.S. military submarines. Other nations also have developed nuclear power for naval submarines.

ENVIRONMENTAL PROBLEMS

Two of the main environmental concerns are the atmospheric pollutants generated by ship's engines, and the possibility of damaging oil spills from accidents and ship operations.

Commercial ships have traditionally used the least expensive and therefore the most polluting oil fuels. Large diesel engines can now operate successfully with the lowest grade of fuel oils, and these fuels have a relatively high sulfur content. As a result the harmful SO_x by-products are released to the atmosphere. In addition, the combustion process in diesel engines produces harmful NOX pollutants. International, national, and local restrictions have encouraged engine manufacturers to develop remedial methods to reduce pollution.

The reduction of SO_x is best achieved by reducing the sulfur content of the fuel oil. Ship engineers are required to replace high-sulfur fuel with expensive higher-grade oil fuel as their ships approach coastlines where strict pollution restrictions apply.

Higher-grade fuels also reduce NO_x production in diesel engines, but more stringent methods are required to satisfy pollution regulations in some areas (e.g., California). Experiments conducted on diesel engines indicate that the concentration of NO_x in the exhaust gases increases as the engine power is reduced as ships approach coasts and harbors. Two approaches have been evaluated to improve the situation. First, changes to the combustion process have been tried by such measures as recirculating some of the exhaust and by the addition of water to the fuel to form an emulsion. Tests on engines have shown that about a 25 percent reduction in NO_x can be attained with such methods. The second approach has involved attempts to clean up the exhaust by catalytic reactions. Catalytic converters, as used in automobiles, have not been successful up to now, because diesel engines operate with too much oxygen in the exhaust products. An alternative approach using ammonia vapor as the catalyst has been shown to reduce the NO_x in the exhaust by more than 80 percent. This has been termed the selective catalytic reduction (SCR) method; it relies on the excess oxygen in the exhaust products to react with the ammonia and the NO_x to produce harmless water vapor and nitrogen. Careful measurement of the pollutants in the exhaust gases ahead of the ammonia injector has to be provided so the optimum quantity of ammonia can be injected.

In the last 30 years of the twentieth century, there were very damaging oil spills from the grounding of tankers filled with crude oil. In addition, there have been many smaller accidents, as well as routine operations, that have resulted in significant amounts of oil being released to the environment.

The International Maritime Organization (IMO) has issued a series of rules to tanker designers in an attempt to minimize the outflow of oil after accidental side or bottom damage. New tankers are required to have double hulls or other structural innovations to minimize tanker spills.

When cargo ships and fishing boats are involved in accidents, there are various measures that have to be carried out to limit the flow of fuel oil into the water. Accidents in harbors and close to shore are treated with great care. Oil booms would be placed around the vessel to prevent the spread of oil, and skimmers would be brought to the area to collect the oil released to the environment. In extreme cases the fuel oil cargo may be burned when the oil could not be pumped out or when a stranded vessel could not be refloated.

Routine operations of many ships have resulted in oil pollution. Cleaning up minor spills on deck and in the engine room is now treated very carefully. Fuel-oil and crude-oil tanks are cleaned from time to time. In the past the polluted oil-water mixture was dumped overboard, but now it must be pumped ashore for treatment.

SIEMENS, ERNST WERNER VON (1816–1892)

Werner Siemens, German inventor, engineer, and entrepreneur was born on December 13, 1816, in Lenthe near Hanover, Lower Saxony, as the fourth child of fourteen children. His father was a tenant farmer. Siemens's education was first undertaken by his grandmother Deichmann, and it continued under a series of home tutors. In 1823 the family moved to Mecklenburg where the father took over the running of the estate of Menzendorf. From Easter 1832 until Easter 1834, Siemens attended the Katharineum, a gymnasium (secondary school) in the Hanseatic town of Lübeck, which he left without final examination. Because his interests were mathematics and natural sciences, rather than classical languages, he took some private lessons in mathematics to improve his education.

The family's precarious financial situation prompted Siemens to choose a military career as a way to advance his education in mathematics, physics and chemistry. In 1835 after basic training at the Artillery Corps in Magdeburg, he moved to Berlin where he stayed for three years as an officer candidate and a student of the Prussian Artillery School. There he was able to study under the guidance of the physicist Gustav Magnus. The death of both parents in 1840 put Siemens, as the oldest son, in charge of his nine surviving siblings. He took his brother Wilhelm to Magdeburg, where he continued his service in an artillery regiment. Passing a term of confinement in fortress, because of assisting a duel, Siemens smuggled in chemicals and experimented with galvanoplasty, a procedure discovered by Moriz Hermann Jacobi. He successfully developed a galvanic method of gold and silver plating. His brother Wilhelm went to England, patented and sold the discovery. From Siemens's electrochemical interests originated also a method of production of ozone and of electrolytic production of clean copper.

TELEGRAPHY

Siemens met the precision engineer Johann Georg Halske at Magnus's Institute of Physics in 1846. Together the two men founded "Siemens & Halske Telegraph Construction Co" in 1847 to exploit the new technology of electric telegraphy, which had been established three years earlier with the first public telegraph line of Samuel Morse. Siemens improved the dial-telegraph, invented the method for a seamless insulation of copper wire with gutta-percha, and discovered the multiple telegraphic use of copper conductors. The first long-line telegraph line, which was 660 km long and laid by Siemens & Halske between Berlin and Frankfurt was inaugurated on March 28, 1849, the day at which the first German national parliament in Frankfurt passed a constitution. His industrial career ensured, Siemens retired from the army. In 1851 Siemens & Halske commenced installation of a telegraph line between Moscow and St. Petersburg. For the Russian project Siemens put his brother Carl in charge. In 1855 the telegraph network for European Russia was installed, and through a Polish line a crucial link with Western Europe was established.

To compete worldwide, Siemens founded several industry subsidiary companies: in St. Petersburg, in London, in France, and in Vienna. In these endeavors, Siemens placced great trust in family members. After cousin Johann Georg helped to establish the company financially, Siemens incorporated other relatives: brother Friedrich and nephew Georg, later the first director of Deutsche Bank. In 1868 Siemens Brothers Co. of London started a cooperation with the Indo-European Telegraph Co. to lay mainly overhead cables through Southern Russia and Persia, effectively joining London and Calcutta. An improved printer telegraph with a punched tape synchronized with current pulses of an inductor with a double T armature operated from 1870 on this line.

Between 1874 and 1880 Siemens Brothers laid transatlantic cables using their own cable-steamer *Faraday*.

ELECTRIC GENERATORS AND MACHINES

The only source of electric energy available until the 1830s was in the form of galvanic elements. The situation changed in 1831 with the discovery of the law of electromagnetic induction by Michael Faraday. The law states that an electric current is generated in a conducting circuit if the latter is exposed to a fluctuating magnetic field. As a consequence of Faraday's discovery, numerous engineers—among them Siemens—designed and improved electric generators. The basic idea behind the first generators was to move wire coils into and out of the magnetic field of a permanent magnet, thereby generating an electric current in the coils according to the induction law. A hand-turned generator with magnets revolving around coils was constructed as early as 1832 in Paris. A year later, the reversed principle to rotate the coils in a fixed field of a permanent magnet was realized in a generator constructed in London. Around 1850, industrial production of electric generators was set up in several European countries. In 1856, Siemens developed a double T armature, cylinder magnet constructed on the basis of Faraday's law of induction to provide a source of electricity for telegraphs cheaper than Zinc galvanic batteries. Though more powerful than galvanic elements, the first generators did not yet provide sufficient electric energy for heavy mechanical work. The limitation was imposed through the rather modest size of the available permanent magnets. To overcome this shortcoming Siemens proposed in 1866, almost simultaneously and independently of some others (Soren Hjorth, Anyos Jedlik, Alfred Vaarley, and Charles Wheatstone) to substitute an electromagnetic effective magnet for the permanent magnet. Siemens is credited with having worked out the principle underlying the new type of generator: a rotating coil inside a stationary coil, both forming a single circuit connected to the external consumer circuit. By starting the rotation of the movable coil, a weak current is induced through a residual magnetic field delivered from the iron armature of the apparatus. The current in the stationary coil causes an increase of the magnetic field, which in turn gives rise to an increased current output from the rotating coil. A self-enhancing process of current generation is so initiated. Siemens called this scheme of a self-excited generator the "dynamo electrical principle." Its formulation, presented to the Academy of Science on January 17, 1867, and subsequent demonstration of the electric light from the dynamo-machine moved through a steam-machine at the factory side in Markgrafenstrasse, Berlin, laid the groundwork for the modern technology of electric generators. This discovery is considered Siemens's most important contribution to science and engineering.

Siemens constructed the first electric railway shown at the Berlin Trade Fair of 1879 and the first electrically-operated lift in 1880, and the first electric trams began operating in Berlin in 1881. Siemens received many honors for his work: an 1860 honorary doctorate from the University of Berlin, an 1873 membership in the Royal Academy of Science, and an 1888 knighthood from Emperor Friedrich III. Siemens died in Berlin, Charlottenburg, on December 6, 1892.

SMEATON, JOHN (1724–1792)

John Smeaton was one of the first great British civil engineers, the first to use the title "Civil Engineer" (seeing himself as a professional ranking alongside doctors and lawyers), and the first to achieve distinction as an engineering scientist.

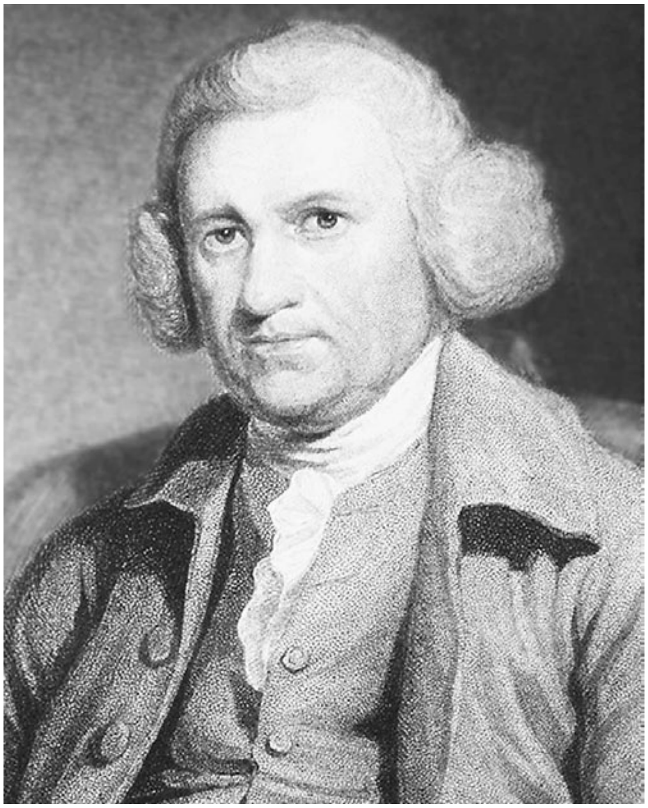
Smeaton was born on June, 8, 1724 at Austhorpe Lodge, near Leeds. He was the son of a successful Leeds lawyer, and from an early age Smeaton developed an interest in mechanics (which his father indulged by providing a workshop), building a working model of a steam engine being erected at a nearby colliery (coal mine). It was the desire of Smeaton's father that his son should succeed him, and at the age of sixteen Smeaton was employed in his father's office. In an attempt to wean him from his mechanical pursuits and partly to give him a good legal education, Smeaton was sent to London. In London, Smeaton's desire to pursue a mechanical career was not suppressed, and his father finally agreed to finance his training as a philosophical instrument maker, to make instruments or apparatus for study of natural philosophy or the physical sciences. The young Smeaton did not however, live the life of a workman, but attended meetings of the Royal Society and was often in the company of educated people. He was soon able to set up as a mathematical instrument maker (making instruments used by draftsmen, navigators, or land surveyors) in London, and at the age of twenty-six presented a paper before the Royal Society on improvements in the marine compass. More papers quickly followed, and in 1753 he was elected a fellow.

In 1759 Smeaton presented to the Royal Society a paper entitled "An Experimental Enquiry concerning the natural Power of Water and Wind to turn mills, and other machines, depending on a circular motion." This paper was the result of a series of experiments carried out in 1752 and 1753, Smeaton having delayed its publication until he had put his deductions into practice. At the time there was a lively debate as to the merits of undershot and overshot waterwheels, but little published data to substantiate various claims. Smeaton's solution to this problem depended solely on experiments made with working model waterwheels. He wanted to compare the "power" of the water delivered to the wheel with the useful "effect" produced by the wheel.

Smeaton's elegant experimental technique enabled him to deal with both hydraulic and mechanical friction losses, allowing him to calculate water velocity at the wheel and thereby determine an "effective" or "virtual" head. Smeaton's experimental apparatus was a brilliant device that enabled him to measure the efficiency of the waterwheel, alone rather than the overall efficiency of the experiment. Smeaton was able to conclusively show that a water-wheel when driven by the weight of water alone, is about twice as efficient as when driven by the impulse of water. This demonstration ensured that British mills, wherever possible, from then on would be fitted with overshot or breastshot waterwheels, rather than undershot.

Smeaton also turned his attention to windmills, but with inconclusive results. This may have been because there was no clear-cut issue to be resolved as was the case with the waterwheel regarding which form was the best type. However, he did produce useful guidelines on the construction of windmills. Smeaton was careful to distinguish the circumstances in which a model test rig differs from the full-size machine, cautioning, "otherwise a model is more apt to lead us from the truth than towards it." Smeaton's experiments demonstrated that work done by a prime mover was a good measure of its performance. In 1765, seeing a need for a practical measure, he fixed the power of a horse working an eight-hour day as 22,000/ft. lb/min.

Britain in the mid-eighteenth century experienced rapid expansion in the number and scale of public works. This enabled Smeaton, in 1753, to give up instrument-making and become a consulting civil engineer, building both wind and water mills, canals, bridges and, from 1756 to 1759, the Eddystone lighthouse. In preparing his designs, Smeaton adopted a scientific approach. It was his practice to prepare a report and have the work carried out by a resident engineer.



John Smeaton. (Library of Congress)

In 1766 Smeaton designed an atmospheric steam-pumping engine for the New River Company; however, when the engine was set to work, its performance was less than Smeaton had expected. Realizing his knowledge of steam engines was deficient, he approached the problem in the same manner as he did his study of water and wind power—by deciding to carry out a systematic, practical study. His first action was to have drawn up a list of all steam engines working in the district around Newcastle. Of these, fifteen were chosen and a set of engine tests made. Smeaton was the first to gather such comprehensive data, from which he calculated for each engine the "great product per minute" or power, and "effect per minute of one bushel of coal per hour" or performance.

Smeaton constructed on the grounds of his house, a small experimental atmospheric engine with a ten-inch cylinder. Beginning in 1770 he made some 130 tests over two years. All relevant measurements were made, including temperature, pressure—both internal and barometric, evaporation of water per bushel of coal, etc. Smeaton's method of testing was to adjust the engine to good performance and take measurements, then alter one of the parameters and take further measurements. By this means he was able to optimize valve timing, piston loading, and size of injector nozzle. He also carried out experiments to test the evaporative powers of various types of coal.

From the knowledge gained, Smeaton drew up a table for the proportions of parts for Newcomen-type engines. Although Smeaton's experiments added nothing to the invention of the Newcomen engine, establishing proper proportions for engines enabled him to built more efficient and powerful engines. The great leap forward in the operation of atmospheric steam engines came with Watt's separate condenser.

Smeaton was a born mechanic and incessant experimentor, but a man of simple tastes and wants. He limited his professional engagements in order to devote a certain portion of his time to scientific investigations. One of Smeaton's rules was not to trust deductions drawn from theory when there was an opportunity for actual experiment. In 1771 Smeaton founded a club for engineers, which later came to be call the "Smeatonian Society."

In 1756 Smeaton married Ann Jenkinson, the daughter of a merchant tailor and freeman of the city of York. They had two daughters. Ann Smeaton fell ill and died in 1784. Smeaton continued working until 1791, when he retired to Austhorpe Lodge to prepare for publication descriptions of his various engineering works. While walking in his gardens he suffered a stroke and died six weeks later, on October 28, 1792, in his sixty-ninth year.

SOLAR ENERGY

Energy from the sun is abundant and renewable. It is also the principal factor that has enabled and shaped life on our planet. The sun is directly or indirectly responsible for nearly all the energy on earth, except for radioactive decay heat from the earth's core, ocean tides associated with the gravitational attraction of Earth's moon, and the energy available from nuclear fission and fusion. Located approximately ninety-three million miles from Earth, the sun, an average-size star, belongs to the class of dwarf yellow stars whose members are more numerous than those of any other class. The energy radiated into outer space by the sun (solar radiation) is fueled by a fusion reaction in the sun's central core where the temperature is estimated to be about 10 million degrees. At this temperature the corresponding motion of matter is so violent that all atoms and molecules are reduced to fast-moving atomic nuclei and stripped electrons collectively known as a plasma. The nuclei collide frequently and energetically, producing fusion reactions of the type that occur in thermonuclear explosions.

While about two-thirds of the elements found on earth have been shown to be present in the sun, the most abundant element is hydrogen, constituting about 80 percent of the sun's mass (approximately two trillion trillion million kilograms). When hydrogen nuclei (i.e., protons) collide in the sun's core, they may fuse and create helium nuclei with four nucleons (two protons and two neutrons). Roughly 20 percent of the sun's mass is in the form of helium. Also created in each fusion reaction are two neutrinos, high-energy particles having no net electrical charge, which escape into outer space, and high-energy gamma radiation that interacts strongly with the sun's matter surrounding its core. As this radiation streams outward from the core, it collides with and transfers energy to nuclei and electrons, and heats the mass of the sun so that it achieves a surface temperature of several thousand degrees

Celsius. The energy distribution of the radiation emitted by this surface is fairly close to that of a classical "black body" (i.e., a perfect emitter of radiation) at a temperature of 5,500°C, with much of the energy radiated in the visible portion of the electromagnetic spectrum. Energy is also emitted in the infrared, ultraviolet and x-ray portions of the spectrum (Figure 1).

The sun radiates energy uniformly in all directions, and at a distance of ninety-three million miles, Earth's disk intercepts only four parts in ten billion of the total energy radiated by the sun. Nevertheless, this very small fraction is what sustains life on Earth and, on an annual basis, is more than ten thousand times larger than all the energy currently used by Earth's human inhabitants. Total human energy use is less than 0.01 percent of the 1.5 billion billion kilowatt-hours (kWh) of energy per year the sun delivers to Earth. A kilowatt hour is one thousand watt hours and is the energy unit shown on your electric bill. A one-hundred-watt light bulb left on for ten hours will use one kWh of electric energy.

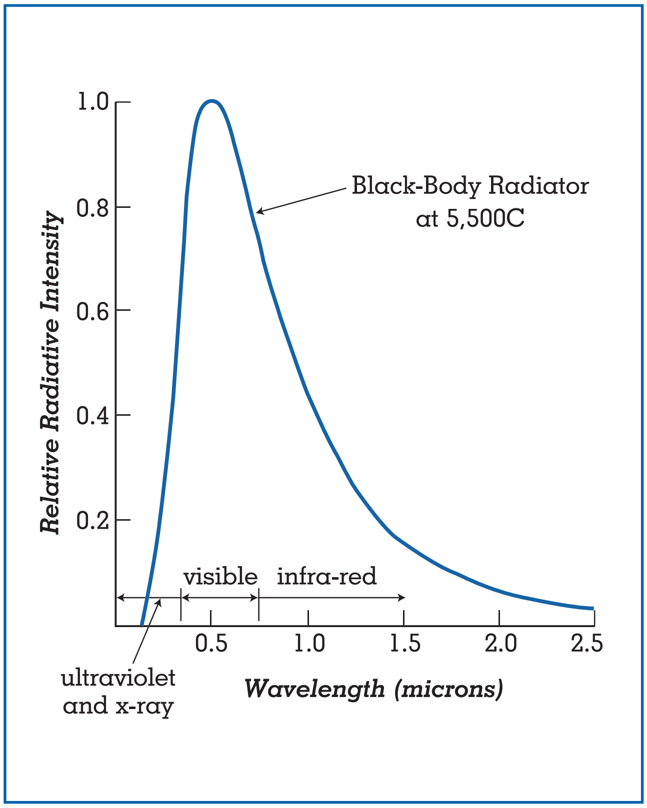

Figure 1.
Relative radiative intensity as a function of wavelength.

AVAILABILITY OF SOLAR ENERGY

While the amount of energy radiated by the sun does vary slightly due to sunspot activity, this variation is negligible compared to the energy released by the sun's basic radiative process. As a result, the amount of energy received at the outer boundary of Earth's atmosphere is called the Solar Constant because it varies so little. This number, averaged over Earth's orbit around the sun, is 1,367 watts per square meter (W/m^2) on a surface perpendicular to the sun's rays. If, on average, Earth were closer to the sun than ninety-three million miles, this number would be larger; if it were farther from the sun, it would be smaller. In fact, Earth's orbit about the sun is not circular, but elliptical. As a result, the Solar Constant increases and decreases by about 3 percent from its average value at various times during the year. In the northern hemisphere the highest value is in the winter and the lowest is in the summer.

A non-negligible fraction of the solar radiation incident on the earth is lost by reflection from the top of the atmosphere and tops of clouds back into outer space. For the radiation penetrating the earth's atmosphere, some of the incident energy is lost due to scattering or absorption by air molecules, clouds, dust and aerosols. The radiation that reaches the earth's surface directly with negligible direction change and scattering in the atmosphere is called "direct" or "beam" radiation. The scattered radiation that reaches the earth's surface is called "diffuse" radiation. Some of the radiation may reach a receiver after reflection from the ground, and is called "albedo." The total radiation received by a surface can have all three components, which is called "global radiation."

The amount of solar radiation that reaches any point on the ground is extremely variable. As it passes through the atmosphere, 25 to 50 percent of the incident energy is lost due to reflection, scattering or absorption. Even on a cloud-free day about 30 percent is lost, and only 70 percent of 1,367 W/m^2, or 960 W/m^2, is available at the earth's surface. One must also take into account the earth's rotation and the resultant day-night (diurnal) cycle. If the sun shines 50 percent of the time (twelve hours per day, every day) on a one square meter surface, that surface receives no more than (960 W/m^2) × (12 hours/day) × (365 days/year) =

4,200 kWh of solar energy per year. Since, on average, the sun actually shines less than twelve hours per day at any location, the maximum solar radiation a site can receive is closer to 2,600 kWh per square meter per year. To put this number into perspective, the average person on earth uses about 18,000 kWh of all forms of energy each year.

HISTORY

For centuries the idea of using the sun's heat and light has stimulated human imagination and inventiveness. The ancient Greeks, Romans, and Chinese used passive solar architectural techniques to heat, cool, and provide light to some of their buildings. For example, in 100 C.E., Pliny the Younger built a summer home in northern Italy that incorporated thin sheets of transparent mica as windows in one room. The room got warmer than the others and saved on short supplies of wood. To conserve firewood, the Romans heated their public baths by running the water over black tiles exposed to the sun. By the sixth century, sunrooms on private houses and public building were so common that the Justinian Code introduced "sun rights" to ensure access to the sun.

In more recent times, Joseph Priestly used concentrated sunlight to heat mercuric oxide and collected the resulting gas, thus discovering oxygen. In 1872, a solar distillation plant was built in Chile that provided six thousand gallons of fresh water from salt water daily for a mining operation. In 1878, at an exhibition in Paris, concentrated sunlight was used to create steam for a small steam engine that ran a printing press.

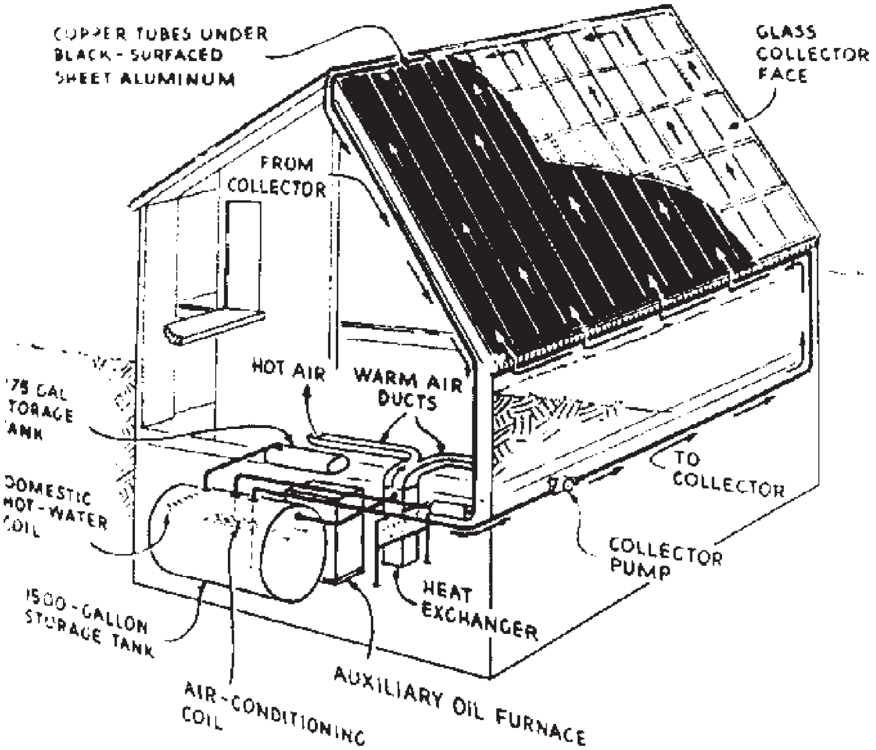
Many further solar energy developments and demonstrations took place in the first half of the twentieth century. However, only one solar technology survived the commercial competition with cheap fossil fuels. That exception was solar water heaters that were widely used in Japan, Israel, Australia and Florida, where electricity was expensive and before low-cost natural gas became available.

Also, passive solar, or climate responsive, buildings were in such demand by 1947 as a result of energy shortages during World War II, that the Libbey-Owens-Ford Glass Company published a book entitled *Your Solar House*, which profiled forty-nine solar architects. In the mid-1950s, architect Frank Bridgers designed the world's first commercial office building using passive design and solar water heating. This solar system has since been operating continuously, and is now in the U.S. National Historic Register as the world's first solar-heated office building.

It was the oil embargo of 1973 that refocused attention on use of solar energy, when the cost of fossil fuels (coal, oil and natural gas) increased dramatically and people began to appreciate that fossil fuels were a depletable resource. More recently, concerns about energy security (the dependence on other countries for one's energy supply), and the local and global environmental impacts of fossil fuel use, have led to the growing realization that we cannot project today's energy system, largely dependent on fossil fuels, into the long-term future. In the years following the oil embargo, much thought and effort has gone into rethinking and developing new energy options. As a result, a growing number of people in all parts of the world believe that renewable (i.e., non- depletable) energy in its various forms (all derived directly or indirectly from solar energy except for geothermal and tidal energy) will be the basis for a new sustainable energy system that will evolve in the twenty-first century.

USING SOLAR ENERGY

Solar energy can be used in many direct and indirect ways. It can be used directly to provide heat and electricity. Indirectly, non-uniform heating of Earth's surface by the sun results in the movement of large masses of air (i.e., wind). The energy associated with the wind's motion, its kinetic energy, can be tapped by special turbines designed for that purpose. Winds also create ocean waves, and techniques for tapping the kinetic energy in waves are under active development. Hydropower is another indirect form of solar energy, in that the sun's radiant energy heats water at Earth's surface, water evaporates, and it eventually returns to Earth as rainfall. This rainfall creates the river flows on which hydropower depends. In addition, sunlight is essential to photosynthesis, the process by which plants synthesize complex organic materials from carbon dioxide, water and inorganic salts. The solar energy used to drive this process is captured in the resulting biomass material and can be released by burning the biomass, gasifying it to produce hydrogen and other combustible gases, or converting it to liquid fuels for use in transportation and other applications.



A 1958 diagram of sun-heated home designed by the Massachusetts Institute of Technology showing air ducts and tanks. (Library of Congress)

In principle, energy can also be extracted from the kinetic energy of large currents of water circulating beneath the ocean's surface. These currents are also driven by the sun's energy, much as are wind currents, but in this case it is a slower-moving, much more dense fluid. Research into practical use of this energy resource is in its very earliest stages, but is looking increasingly promising.

Finally, there are renewable sources of energy that are not direct or indirect forms of solar energy. These include geothermal energy in the form of hot water or steam derived from reservoirs below the surface of Earth (hydrothermal energy), hot dry rock, and extremely hot liquid rock (magma). These resources derive their energy content from the large amount of heat generated by radioactive decay of elements in Earth's core. Energy can also be tapped from tidal flows resulting from Earth's gravitational interaction with the moon.

SOLAR HEATING AND COOLING

Solar heating and cooling systems are classified either as passive or active. Passive systems make coordinated use of traditional building elements such as insulation, south-facing glass, and massive floors and walls to naturally provide for the heating, cooling and lighting needs of the occupants. They do not require pumps to circulate liquids through pipes, or fans to circulate air through ducts. Careful design is the key. Active solar heating and cooling systems circulate liquids or air through pipes or other channels to move the necessary heat to where it can be used, and utilize other components to collect, store and control the energy from the solar energy source. Systems that combine both passive and active features are called hybrid systems. Solar heating systems are used primarily for hot water heating, interior space heating, and industrial and agricultur-

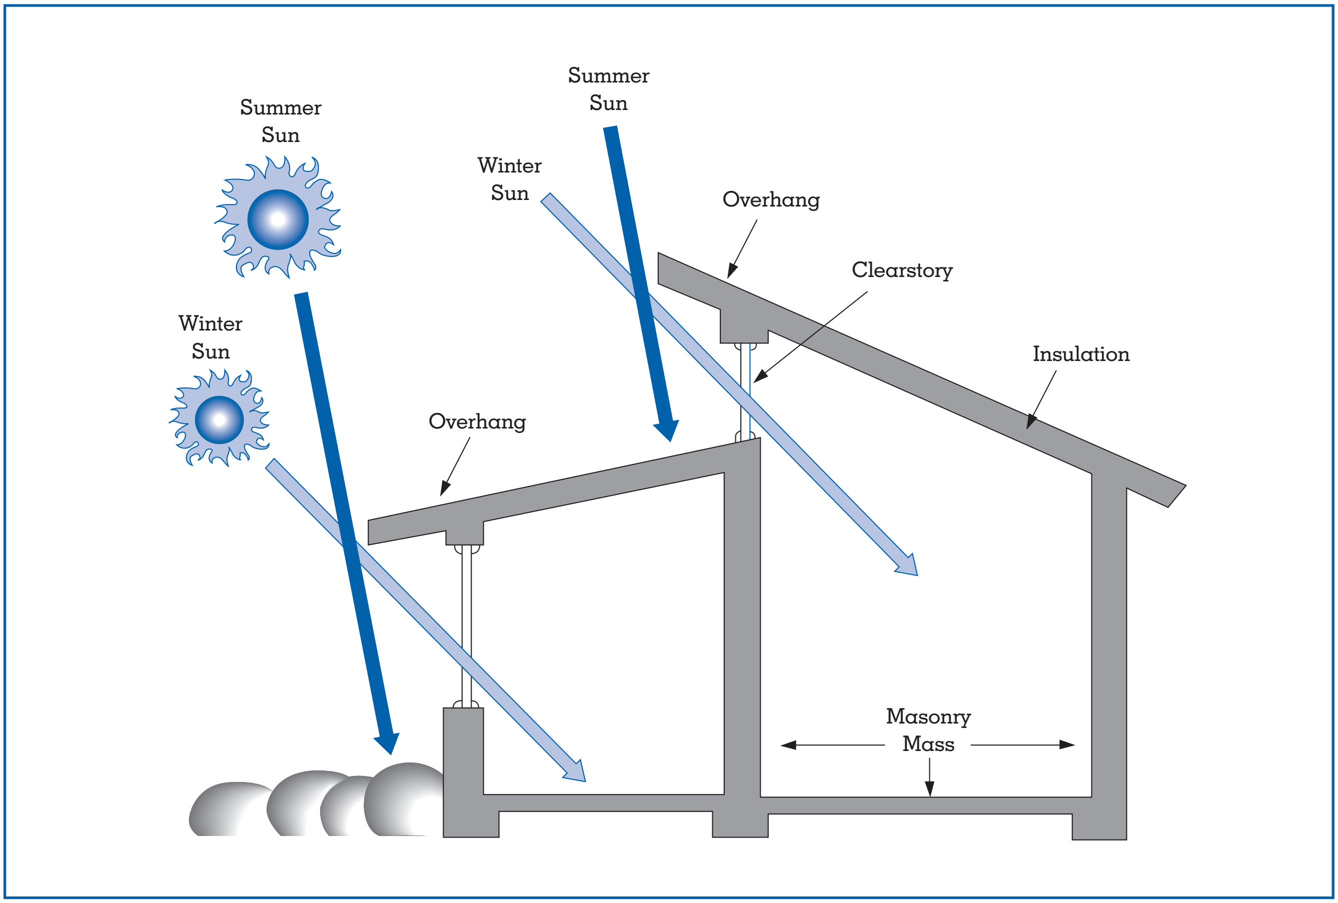


Figure 2.
Direct Gain.

al process heat applications. Solar cooling systems use solar heat to energize heat-driven refrigeration systems or to recycle dessicant-cooling systems. They are most often combined with solar hot water and space heating systems to provide year-round use of the solar energy system.

PASSIVE SYSTEMS

There are several types of passive system designs: direct gain, thermal storage, solar greenhouse, roof pond, and convective loop. The simplest is the direct gain design (Figure 2), which in the northern hemisphere is an expanse of south-facing glass (usually double glazed). The energy in the sunlight entering directly through the windows is absorbed, converted to heat, and stored in the thermal mass of the floors and walls. A thermal storage wall system consists of a massive sunlight-absorbing wall behind south-facing double glazing. The wall may contain water or masonry to store the energy during the day and release it during the night. Another type of passive system is the solar greenhouse (or sunspace), which combines direct gain in the greenhouse and a thermal storage wall between the greenhouse and the rest of the house. Solar energy provides the heat for the greenhouse and a good share of the energy for heating the living space in the house.

A fourth type of passive solar heating and cooling system is the roof pond, in which containers of water are used to collect and store the sun's energy. Movable insulating panels are used to control the gain and loss of heat. In winter, the insulation is opened during the day to allow collection of the sun's heat; at night the insulation is closed to minimize loss of heat that is to be released to the house. In summer, the insulation is closed during the day to block the sun, and opened to the sky at night to provide radiative cooling.

Solar collector panels. (Digital Stock)

The fifth type of passive system is the natural convective loop, in which the collector is placed below the living space and the hot air that is created rises to provide heat where it is needed. This same principle is used in passive solar hot water heating systems known as thermosiphons. The storage tank is placed above the collector. Water is heated in the collector, becomes less dense, and rises (convects) into the storage tank. Colder water in the storage tank is displaced and moves down to the collector where it is heated to continue the cycle.

More than one million residences and twenty thousand commercial buildings across the United States now employ passive solar design.

ACTIVE SYSTEMS

An active solar heating and cooling system consists of a solar energy collector (flat plate or concentrating), a storage component to supply heat when the sun is not shining, a heat distribution system, controls, and a back-up energy source to supply heat when the sun is not shining and the storage system is depleted.

The simplest type of active solar collector, the flat-plate collector, is a plate with a black surface under glass that absorbs visible solar radiation, heats up, and reradiates in the infrared portion of the electromagnetic spectrum. Because the glass is transparent to visible but not to infrared radiation, the plate gets increasingly hotter until thermal losses equal the solar heat gain. This is the same process that occurs in a car on a sunny day, and in the atmosphere, where gases such as carbon dioxide and methane play the role of the glass. It is called the greenhouse effect. Careful design can limit these losses and produce moderately high temperatures at the plate—as much as 160°F (71°C). The plate transfers its heat to circulating air or water, which can then be used for space heating or for producing hot water for use in homes, businesses or swimming pools.

Higher temperatures—up to 350°F (177°C)—can be achieved in evacuated tube collectors that encase both the cylindrical absorber surface and the tubes carrying the circulating fluid in a larger tube containing a vacuum which serves as highly efficient insulation. Still another high-temperature system is the parabolic-trough collector that uses curved reflecting surfaces to focus sunlight on a receiver tube placed along the focal line of the curved surface. Such concentrating systems use only direct sunlight, and can achieve temperatures as high as 750°F (400°C), but do require tracking of the sun.

Water heating accounts for approximately 25 percent of the total energy used in a typical single-family home. An estimated 1.5 million residential and commercial solar water-heating systems have been installed in the U.S. In Tokyo—there are nearly that many buildings with solar water heating. Large numbers of solar water heaters have also been installed in Greece, Israel, and other countries. More than 300,000 swimming pools are heated by solar energy in the United States.

SOLAR THERMAL POWER SYSTEMS

A solar thermal power system, increasingly referred to as concentrating solar power, to differentiate it from solar heating of residential/commercial air and water, tracks the sun and concentrates direct sunlight to create heat that is transferred to water to create steam, which is then used to generate electricity. There are three types of solar thermal power systems: troughs that concentrate sunlight along the focal axes of parabolic collectors (the most mature form of solar thermal power technology), power towers with a central receiver surrounded by a field of concentrating mirrors, and dish-engine systems that use radar-type reflecting dishes to focus sunlight on a heat-driven engine placed at the dish's focal point. Solar ponds are also a form of solar thermal power technology that does not require tracking.

Trough Systems

Trough systems currently account for more than 90 percent of the world's solar electric capacity. They use parabolic reflectors in long trough configurations to focus and concentrate sunlight (up to one hundred times) on oil-filled glass tubes placed along the trough's focal line. The dark oil absorbs the solar radiation, gets hot (up to 750°F (400°C)), and transfers its heat to water, creating steam that is fed into a conventional turbine-generator. Troughs are modular and can be grouped together to create large amounts of heat or power. Troughs operating in the Mojave Desert in the United States have been feeding up to 354 MW of electrical energy reliably into the Southern California power grid since the early 1990s, usually with minimal maintenance. While not currently cost competitive with fossil fuel-powered sources of electricity (trough electricity costs are about 12 cents per kWh), construction of the trough systems was encouraged by generous power purchase agreements for renewable electricity issued by the State of California, and Federal tax incentives.

Power Towers

Power towers, also known as central receivers, have a large field of mirrors, called heliostats, surrounding a fixed receiver mounted on a tall tower. Each of the heliostats independently tracks the sun and focuses sunlight on the receiver where it heats a fluid (water or air) to a very high temperature (1,200°F (650°C)). The fluid is then allowed to expand through a turbine connected to an electric generator. Another version heats a nitrate salt to 1,050°F (565°C), which provides a means for storage of thermal energy for use even when the sun is not shining. The heat stored in this salt, which becomes molten at these elevated temperatures, is then transferred to water to produce steam that drives a turbine-generator. Ten megawatt electrical power towers have been built and tested in the United States, one using water as the material to be heated in the receiver, and one using nitrate salt. A smaller unit that heats air has also been operated at the Platforma Solar test site in Almeria, Spain. While there are no commercial power tower units operating today, technical feasibility has been established and, in commercial production, electricity production costs are projected to be well below ten cents per kWh. At such costs, power towers will begin to compete with more traditional fossil fuel-powered generating systems. It is believed that power towers will be practical in sizes up to 200 MW (electrical).

Dish-Engine Systems

A dish-engine system uses a dish-shaped parabolic reflector, or a collection of smaller mirrors in the shape of a dish, to focus the sun's rays onto a receiv-

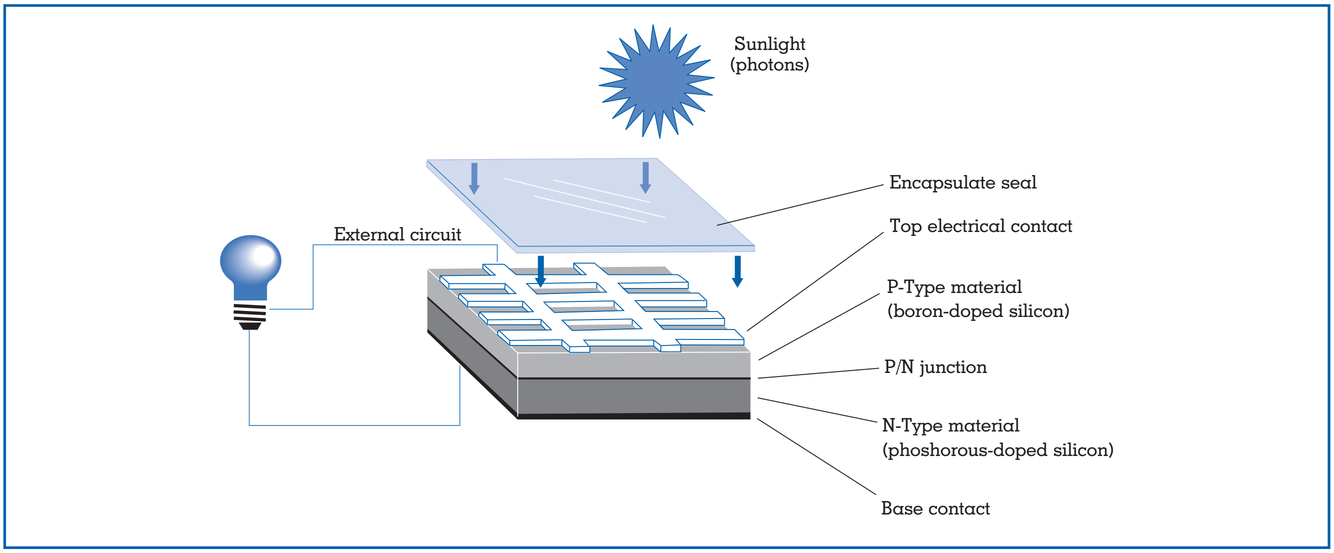

Figure 3.
Basic PV cell construction.

er mounted above the dish at its focal point. Two-axis tracking is used to maximize solar energy capture, and most often a Stirling engine (a sealed engine that can be driven by any source of external heat) is mounted on the receiver. Such systems are not yet commercial, but have been tested in sizes ranging from 5 to 50 kW (electrical). Conversion efficiencies of up to 29 percent have been achieved. Dish-engine systems are also modular, and can be used individually or in large assemblies.

Power-tower and dish-engine systems have higher concentration ratios than troughs, and therefore the potential to achieve higher efficiencies and lower costs for converting heat to electricity. All three systems can be hybridized (i.e., backed up by a fossil fuel system for supplying the heat), an important feature that allows the system to produce power whenever it is needed and not just when the sun is shining (dispatchability).

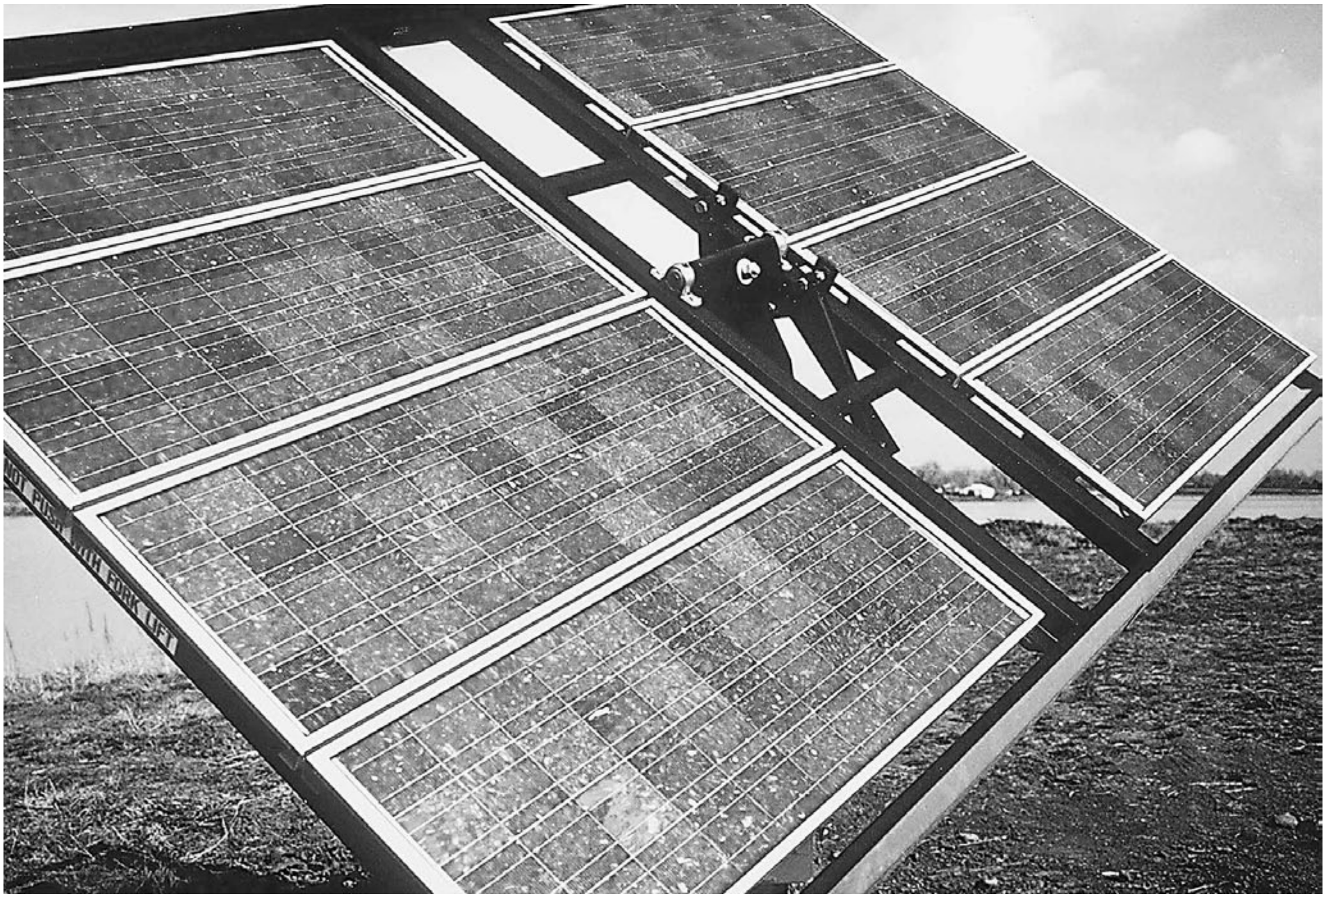
Solar Ponds

A solar pond does not concentrate solar radiation, but collects solar energy in the pond's water by absorbing both the direct and diffuse components of sunlight. Solar ponds contain salt in high concentrations near the bottom, with decreasing concentrations closer to the surface. This variation in concentration, known as a salt-density gradient, suppresses the natural tendency of hot water to rise, thus allowing the heated water to remain in the bottom layers of the pond while the surface layers stay relatively cool. Temperature differences between the bottom and top layers are sufficient to drive an organic Rankine-cycle engine that uses a volatile organic substance as the working fluid instead of steam. Temperatures of 90°C are routinely achieved in the pond bottom, and solar ponds are sufficiently large to provide some degree of energy storage.

The largest solar pond in the United States is a tenth of an acre experimental facility in El Paso, Texas, which has been operating reliably since 1986. The pond runs a 70 kW (electrical) turbine-generator and a 5,000 gallon per day desalination unit, while also providing process heat to an adjacent food processing plant. The potential of solar ponds to provide fresh water, process heat and electricity, especially for island communities and coastal desert regions, appears promising, but has not been fully investigated.

PHOTOVOLTAICS

Photovoltaics (photo for light, voltaic for electricity), often abbreviated as PV, is the direct conversion of sunlight to electricity. Considered by many to be the most promising of the renewable electric technologies in the long term, it is an attractive alternative to conventional sources of electricity for many reasons: it is silent and non-polluting, requires no special



Two huge solar energy panels track a photovoltaic system at the National Renewable Energy Lab in Golden, Colorado. (U.S. Department of Energy)

training to operate, is modular and versatile, has no moving parts, and is highly reliable and largely maintenance-free. It can be installed almost anywhere, uses both direct and diffuse radiation, and can be incorporated into a variety of building products (roofing tiles and shingles, facades, overhangs, awnings, windows, atriums).

The photoelectric effect (the creation of an electrical current when light shines on a photosensitive material connected in an electrical circuit) was first observed in 1839 by the French scientist Edward Becquerel. More than one hundred years went by before researchers in the United States Bell Laboratories developed the first modern PV cell in 1954. Four years later, PV was used to power a satellite in space and has provided reliable electric power for space exploration ever since.

The 1960s brought the first terrestrial applications for PV. At that time the technology was very expensive, with PV collectors, called modules, costing upwards of $1,000 per peak watt. The term "peak watts" is used to characterize the power output of a PV module when incident solar radiation is at its peak. Nevertheless, PV was a preferred choice in remote locations where no other form of power production was feasible. Over the past three decades, steady advances in technology and manufacturing have brought the price of modules down more than 200-fold, to $4 per peak watt. Further reductions in module cost to $1 to $2 per peak watt are expected within the next decade.

A photovoltaic cell (often called a solar cell) consists of layers of semiconductor materials with different electronic properties. In most of today's solar cells the semiconductor is silicon, an abundant element in the earth's crust. By doping (i.e., chemically introducing impurity elements) most of the silicon with boron to give it a positive or p-type electrical character, and doping a thin layer on the front of the cell with phosphorus to give it a negative or n-type character, a transition region between the two types

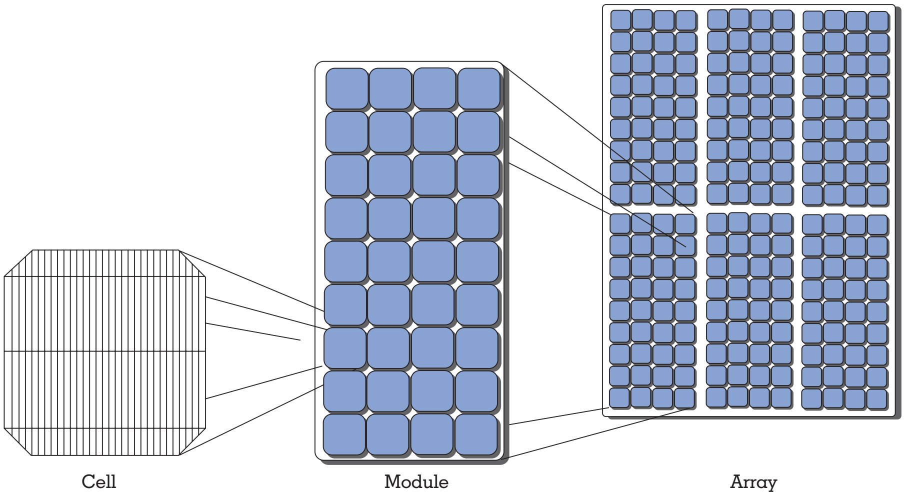


Figure 4.
PV cell, module, and array.

of doped silicon is formed that contains an electric field. This transition region is called a junction.Light consists of energy packets called photons. When light is incident on the cell, some of the photons are absorbed in the region of the junction and energy is transferred to the semiconductor, freeing electrons in the silicon. If the photons have enough energy, the electrons will be able to overcome the opposing electric field at the junction and move freely through the silicon and into an external circuit. As these electrons stimulate current flow in the external circuit, their energy can be converted into useful work (Figure 3).

Photovoltaic systems for specific applications are produced by connecting individual modules in series and parallel to provide the desired voltage and current (Figure 4). Each module is constructed of individual solar cells also connected in series and parallel. Modules are typically available in ratings from a few peak watts to 250 peak watts.

Commercially available PV systems most often include modules made from single-crystal or polycrystalline silicon or from thin layers of amorphous (non-crystalline) silicon. The thin-film modules use considerably less semiconductor material but have lower efficiencies for converting sunlight to direct-current electricity. Cells and modules made from other thin-film PV materials such as copper-indium-diselenide and cadmium telluride are under active development and are beginning to enter the market. Most experts consider thin-film technology to be the future of the PV industry because of the reduced material requirements, the reduced energy required to manufacture thin film devices, and the ability to manufacture thin films on a mass-production basis.

Amorphous silicon modules experience a conversion efficiency loss of about 10 percent when initially exposed to sunlight, but then stabilize at the reduced figure. The mechanism for this reduction is being actively investigated, but is still not well understood. Individual modules made with other PV materials do not exhibit such loss of conversion efficiency, but combinations of modules in arrays do exhibit systematic reductions in power output over their lifetimes. Estimated at about 1 percent per year on average, based on data to date, these reductions are most likely associated with deteriorating electrical connections and non-module electrical components.

Complete PV systems require other components in addition to the PV modules. This “balance-of-system” generally includes a support structure for the modules to orient them properly to the sun, an inverter to convert direct-current electricity to alternating-current electricity, a storage system for electrical energy (usually batteries), an electronic charge regulator to prevent damage to the batteries by protecting against overcharging by the PV array and excessive discharge by the electrical load, and related wiring and safety features (Figure 5).

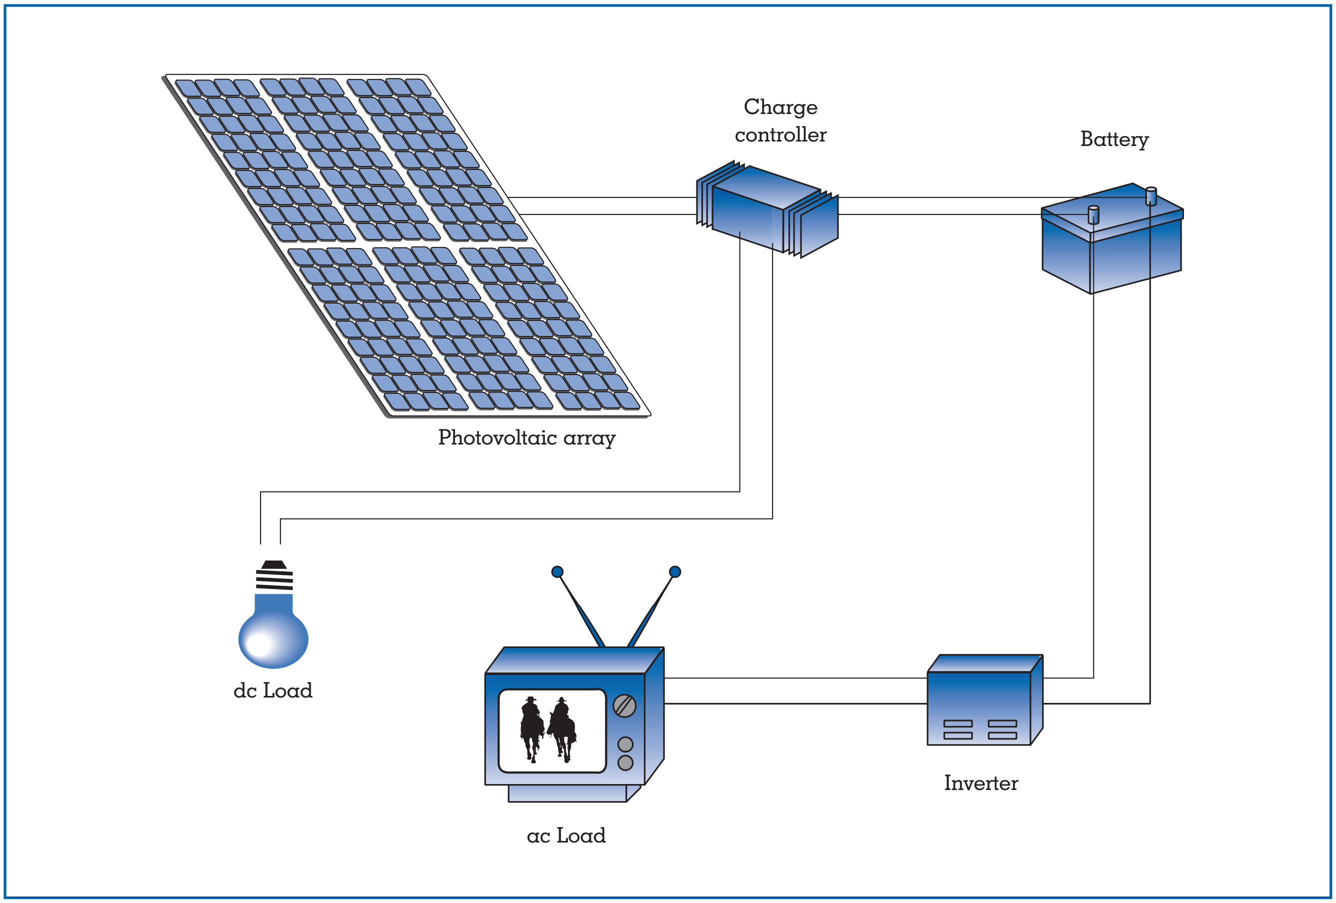

Figure 5.
Components of a typical off-grid PV system.

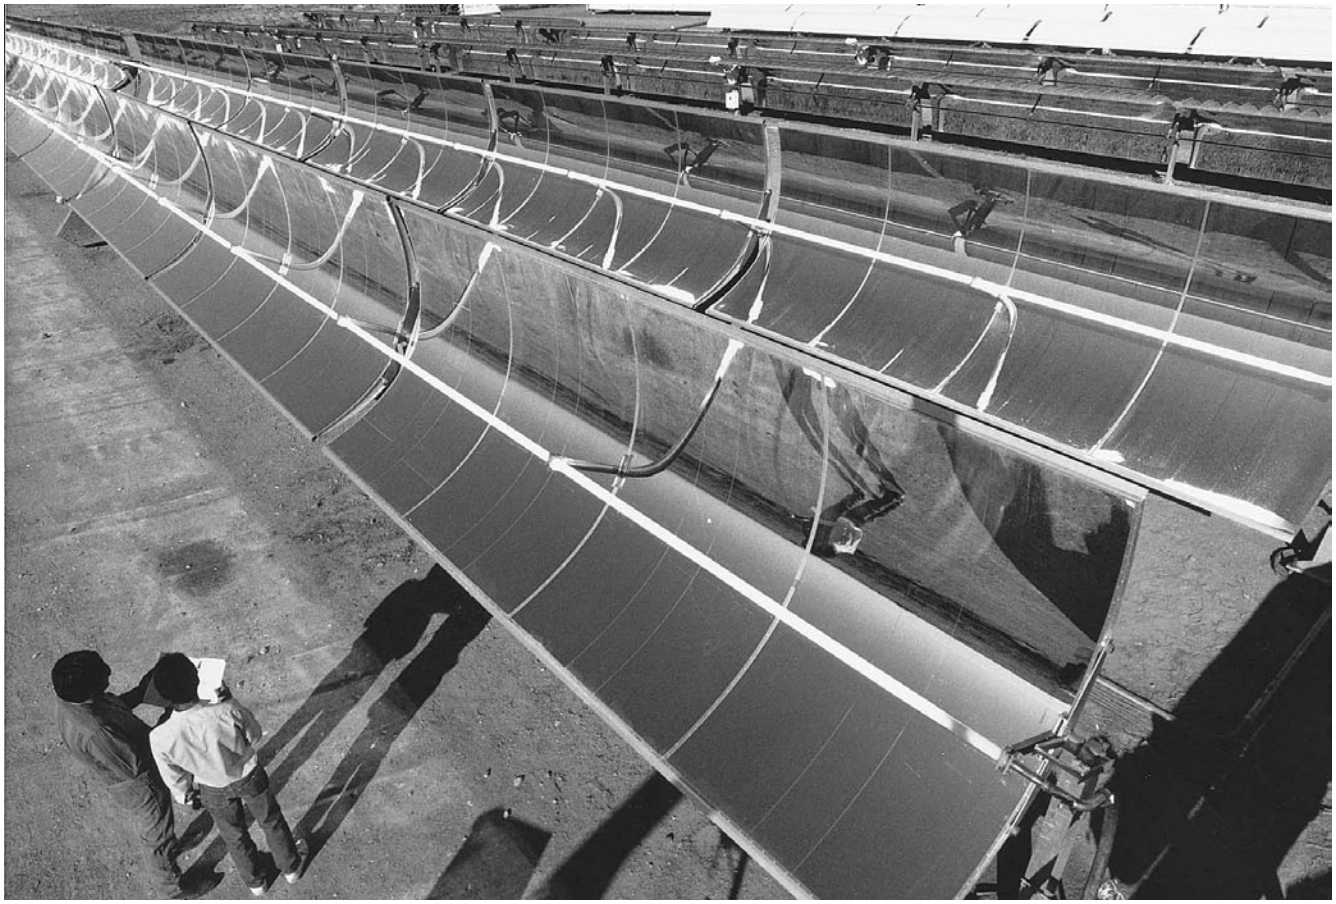
The output of a solar cell can be increased significantly by concentrating the incident sunlight onto a small area. Commercially available concentrator systems use low-cost lenses, mirrors or troughs in conjunction with tracking systems to focus sunlight on a small, high efficiency but expensive solar cell. One-axis trackers follow the sun during the day; two-axis trackers track daily and yearly variations in the sun's position. The higher cost of the cell and the associated tracking equipment, and the inability to use diffuse radiation, are offset by the higher conversion efficiencies achieved.

The cost of PV electricity is largely determined by four factors: cost of the PV modules, the efficiency of converting sunlight to electricity, the balance-of-system costs, and the lifetime of the systems. There are many combinations of these factors that provide about the same cost of electricity. Modules are now available that are designed to last at least thirty years.

Another scheme that has been proposed for use of photovoltaics is the solar satellite power system. Such a system would place large individual PV arrays (up to ten megawatts peak power) in synchronous orbit around the earth, and beam the collected and converted solar energy through the atmosphere in the form of microwaves to large receiving antennas on earth. The microwave generators would be powered by the PV electricity. The microwave energy collected at the surface would then be converted back to electricity for broad distribution. While of some interest, there are major issues associated with cost, environmental impact, and energy security.

PHOTOVOLTAIC APPLICATIONS

By its very nature PV can be used wherever electricity is needed and sunlight is available. For many years PV systems have been the preferred power sources for



Researchers at Sandia National Labs use a trough of parabolic mirrors to focus sunlight on a long glass tube in order to detoxify water. (U.S. Department of Energy)

buildings or other facilities in remote areas not served by the utility grid. As the cost of PV systems continues to decline, there is growing consensus that distributed PV systems on buildings that are grid-connected may be the first application to reach widespread commercialization. Typical off-grid applications for PV today include communications (microwave repeaters, emergency call boxes), cathodic protection (pipelines, bridges), lighting (billboards, highway signs, security lighting, parking lots), monitoring equipment (meteorological information, water quality, pipeline systems), warning signals (navigational beacons, railroad signs, power plant stacks), and remote loads (village power, parks and campgrounds, water pumping and irrigation, vacation cabins). On-grid applications include support for utility transmission and distribution (T&D) systems, where the benefits derive from avoiding or deferring T&D system investments, and from improving the quality of electrical service.

More than 200,000 homes in the U.S. currently use some type of PV technology, and more than 10,000 U.S. homes are powered entirely by PV. A large number of homes in Japan, where consumer electricity rates are three times higher than in the U.S., have roof-integrated PV systems. Half a million PV systems have been installed in developing countries by the World Bank. More than 10,000 have been installed in Sri Lanka, 60,000 in Indonesia, 150,000 in Kenya, 85,000 in Zimbabwe, 40,000 in Mexico, and 100,000 in China. Global use of PV is expected to grow rapidly in the coming decades.

OTHER DIRECT APPLICATIONS OF SOLAR ENERGY

In addition to the applications already discussed, solar energy can also be used for solar cooking (use of a reflecting surface to focus sunlight on pots used for food preparation), distillation (use of solar heat to evaporate and desalinate seawater), purification (use of concentrated ultraviolet radiation to kill organisms in contaminated water), and agriculture (use of solar heat to dry crops and grains, space and water heating, heating of commercial greenhouses, and use of PV electricity to power water pumping and other remote facilities). Many other applications will also become feasible as PV costs continue to decline.

Production of PV modules is still relatively small, but has been growing at a steady and significant rate. Global production in 1998 reached 150 megawatts peak. As costs come down and new manufacturing facilities are placed in operation, this number will grow rapidly.

SOLAR ENERGY'S POTENTIAL AND PROBLEMS

The amount of solar energy available on earth is many times greater than all the energy collectively used by people around the world. When one takes into account all the various forms in which solar energy is directly or indirectly available, along with energy available from geothermal and nuclear sources, it becomes clear that there is no global shortage of energy. The only shortage is that of low-cost energy. In principle there is no reason that solar energy in its various forms could not supply all the world's energy. To give but one example, all the electricity used by the United States (a little more than 3 trillion kWh) could be generated by commercially available PV modules covering half of a 100 mile by 100 mile area in the Nevada desert.

Greater use of solar and other forms of renewable energy is increasingly seen as the long-term response to growing demand for electricity and transportation fuels in developed and developing countries. For example, electricity derived from renewable resources can be used to electrolyze water and create hydrogen, which can then be used in fuel cells to provide electricity or power electric vehicles. As a result of the issues raised by the oil embargo of 1973, and increasing awareness of the local and global environmental damage associated with use of fossil fuels, many people now believe that the world must undergo a transition to a clean and sustainable energy system during the twenty-first century. There is great hope that renewable energy will be the basis for that new, sustainable system.

This is not to suggest that widespread use of solar energy is not facing major barriers. For many applications, today's high cost of solar energy systems is an important limitation. Nevertheless, significant progress has been and will continue to be made in improving system performance and reducing associated energy costs. A particular challenge to solar energy research and development efforts is that incident solar energy is not highly concentrated and is intermittent. The former necessitates use of concentrator systems, or large collection areas that can have impacts on ecosystems due to land use and disturbances during the construction stage of large-scale power plants. Centralized, multi-megawatt power facilities can also result in significant visual impacts.

The fact that solar energy is an intermittent energy resource means that energy storage systems (e.g., batteries, ultracapacitors, flywheels, and even hydrogen) will be required if solar energy is to be utilized widely. In addition, a variety of toxic chemicals are used in the manufacture of PV cells; however, studies of the risks associated with their manufacture and disposal indicate little threat to surroundings and the environment.

CONCLUSIONS

Solar energy offers a clean, sustainable alternative to continued use of fossil fuels. In its various forms it is already providing useful amounts of energy on a global basis, and will provide steadily increasing amounts in the twenty-first century, especially as developing countries require more energy to improve their economies.

In February 1979 the Carter Administration released a 30-federal agency study entitled *Domestic Policy Review of Solar Energy*. This study found that, with increasing oil prices and "comprehensive and aggressive initiatives at the Federal, State and local levels," renewable energy sources "could provide about 20 percent of the nation's energy by the year 2000." This did not occur, as oil prices actually dropped in the 1980s, Federal funding for renewables was reduced, and, for a period of time, energy issues largely disappeared from public view. Today, renewable energy sources supply about 12 percent of U.S. electricity and 8 percent of total U.S. energy consumption.

Continuing research and development efforts by the public and private sectors have significantly reduced the costs of solar energy, and further significant reductions are expected. Together with growing public concern about global climate change, it is anticipated that the 21st century will see widespread deployment of solar energy and other renewable energy systems, in both developing and developed countries.

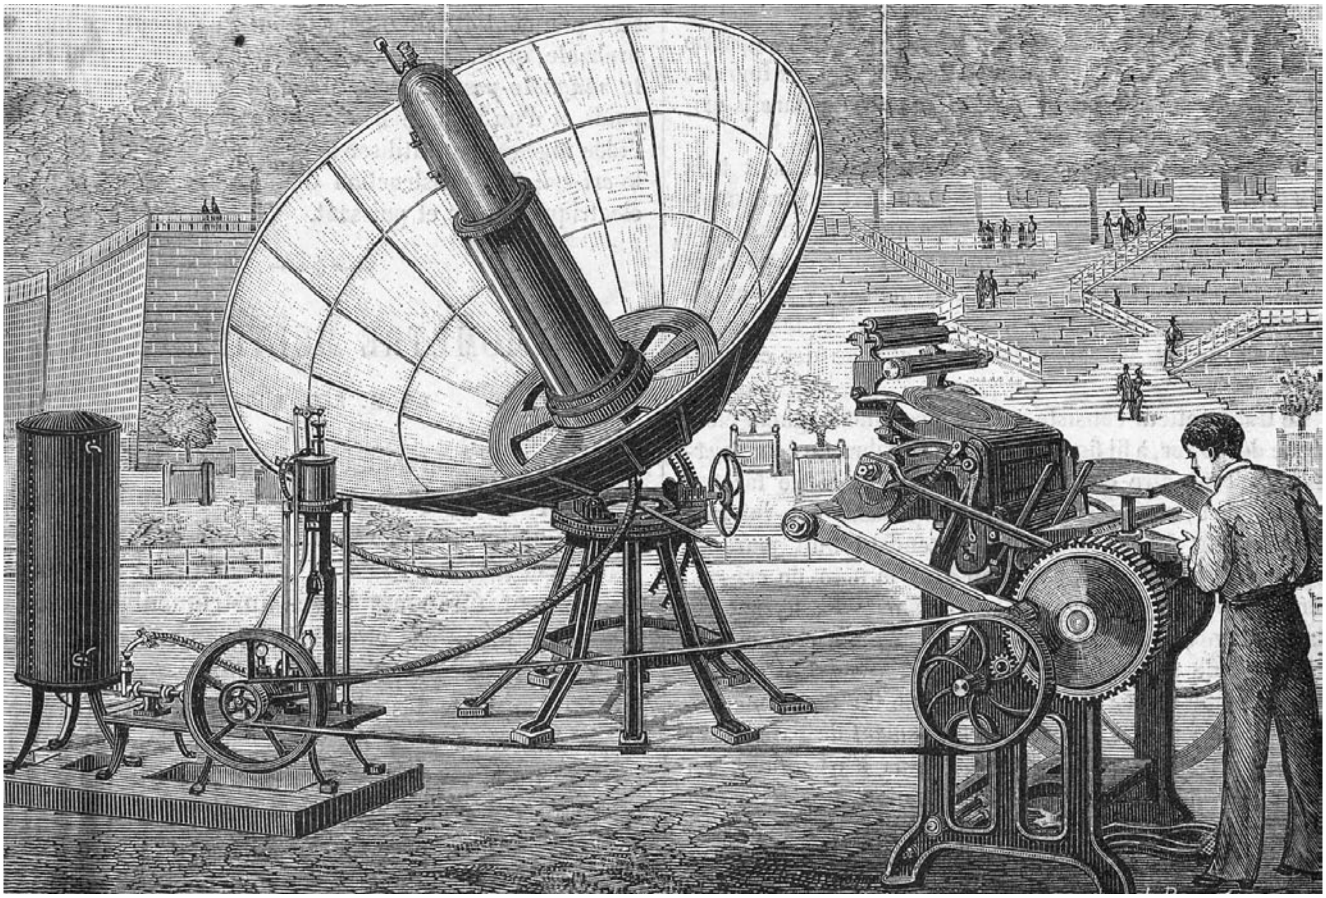
SOLAR ENERGY, HISTORICAL EVOLUTION OF THE USE OF

Every ninety-five minutes an object the size of a bus circles Earth. It represents an unparalleled achievement in space observation technology and is called the Hubble Space Telescope (HST). Since its deployment in 1990, the HST has brought images to the astronomy community that traditionally had been reserved for expensive long-range space missions by unmanned craft. One of the essential technological developments that make the HST such an attractive investment is its use of one "natural resource" found in space, the sun. The HST utilizes photovoltaic technology to capture the sun's rays and convert them directly into electricity. This procedure is commonly referred to active solar generation.

Active solar generation is nothing new to the space industry. Photovoltaics have been used to power satellites since the late 1950s and are an essential element to the new international space station. Closer to home, active solar technologies are used on houses and buildings to generate heat, hot water, and electricity. Spacecraft use of the sun is indeed a technological marvel. However, strategic use of the sun for heating and cooling is not a new discovery. In fact, 2,400 years ago the Greek philosopher Socrates observed:

> Now in houses with a south aspect, the sun's rays penetrate into the porticos in winter, but in the sum-



The operation of a solar-powered printing press. Experiment conducting in the Garden of Tuileries, Paris, on Aug 6, 1882, for the festival of "L'Union Francaises of Jeuenesse." (Corbis Corporation)

> mer, the path of the sun is right over our heads and above the roof, so that there is shade. If then this is the best arrangement, we should build the south side loftier to get the winter sun and the north side lower to keep out the winter winds. (Xenophon, 1994, chap. 2, sec. 8)

Socrates has described the strategic placement of a home to best utilize the rotation of Earth, to receive maximum sunlight during the winter and minimal sunlight in summer. The strategic utilization of the seasonal course of the sun in home design is called passive solar architecture. Passive solar use is best described as the greenhouse effect. This simple phenomenon is illustrated by the experience of returning to your car on a sunny, cool day and finding it heated. Hubble and Socrates represent opposite ends of the solar historical spectrum. However, solar technologies have historically been met with mixed results. While the technology has consistently proved itself to be useful and environmentally friendly, it has often been pushed into the shadows by cheaper, less environmentally friendly energy technologies.

Historically the most common problems associated with solar technologies are efficiency and economics compared to competing energy technologies. During the Industrial Revolution coal was relatively cheap and, for the most part, readily available in most of the world. These facts, which still hold true today, make coal a powerful competitor against alternative power technologies. However, solar technologies have been able to survive in niche markets long enough to increase efficiency and lower costs. Although sunlight is free and also readily available, solar technologies have experienced little success in large-scale applications. Solar technologies also have been able to take advantage of advances in silicon technology. An initial niche market for solar technology was the colonies of Europe.

EARLY APPLICATIONS: SOLAR THERMAL

One of the earliest forays in the use of solar technologies for power generation was in 1861. French engineer Auguste Mouchout utilized solar thermal technology by focusing the sun's rays to create steam, which in turn was used to power engines. Mouchout's design incorporated a water-filled cauldron surrounded by a polished metal dish that focused the sun's rays on the cauldron, creating steam. Mouchout was granted the first solar patent for an elementary one-half horsepower steam engine powered by a solar reflective dish. Several of Mouchout's solar motors were deployed in Algeria, then a French protectorate, where coal was expensive due to transportation costs. One-half horsepower may not seem like much, but it was a considerable advance in alternative power generating. At the time, the major source of energy was man and draft animals, the steam engine was in its infancy, and water power was not very portable. Mouchout was able to expand his design to a larger scale, but the project was abandoned due to new innovations in coal transportation that made coal a more efficient investment.

Solar thermal technology survived Mouchout and was further developed by Swiss-born engineer John Ericsson. In 1870 Ericsson created a variation of Mouchout's design that used a trough instead of a dish to reflect the Sun's rays. Ericsson's basic design would later become the standard for modern-day parabolic troughs. He allegedly refined his design to the point where it would be able to compete actively with conventional generation techniques of the time but he died without leaving any plans or blueprints.

Englishman William Adams designed another interesting variation of Mouchout's work in 1878. Adams's design used mirrors that could be moved to track sunlight and focus the rays on a stationary cauldron. In theory, a larger number of mirrors would generate increased heat levels and greater steam output for larger engines. Adams was able to power a two-and-a-half-horsepower engine during daylight hours and viewed his invention as an alternative fuel source in tropical countries. Although Adams was more interested in proving that it could be done than in developing the technology, his basic design would become the prototype for contemporary large-scale centralized solar plants called "power towers" that are currently in operation in the United States and other countries.

CONTEMPORARY USES: SOLAR THERMAL

Solar thermal technology varied little in design from 1870 to 1970. Advances were made in the materials, such as lower-boiling-point fluids and higher-efficiency motors, but the basic design of using mirrors to focus sunlight remained the same. The aforementioned introductory ventures in the use of solar technology provided the intellectual foundation for growth and extensive technological development of solar use in the twentieth century. These pioneers helped to establish solar as a viable alternative to conventional power generation. However, many of the same barriers resurfaced, preventing widespread implementation. Many of the previously mentioned designs survived by gaining support within environmental communities as environmentally friendly alternatives to fossil fuels, as well as a safer alternative to nuclear power. In addition, solar technologies were able to establish themselves within new niche markets and to gain further interest during the oil crisis of the 1970s.

As previously mentioned, both Ericsson's and Adams's original designs were upgraded and implemented as modern solar power generating facilities. Contemporary versions of the solar trough and power tower were constructed during the 1980s in the Mojave Desert of California by LUZ International Ltd. Currently the corporate successor of LUZ, which went bankrupt in 1991, partly due to dependence on a federal subsidy (tax credits) not renewed in 1991, has nine solar thermal plants in California and has generated more energy from solar thermal than any other company in the world.

EARLY APPLICATIONS: PHOTOVOLTAICS

Use of solar panels or photovoltaics (PVs) is another popular way to generate solar electricity. The space program is perhaps the most recognized user of PVs and is responsible for most of the advancements in PVs. Many people are familiar with PVs through small applications such as calculators and perhaps solar water heaters, but early forays in PV experimentation were little more than noted side observations in non-PV experiments.

In 1839 Alexandre-Edmund Becquerel, a French experimental physicist, did the earliest recorded experiments with the photovoltaic effect. Becquerel discovered the photovoltaic effect while experimenting with an electrolytic cell made up of two metal

Buckminster Fuller stands in front of a solar-powered geodesic dome house. (AP/Wide World Photos)

electrodes placed in an electricity-conducting solution. When exposed to sunlight, the generation increased. Between 1873 and 1883 several scientists observed the photoconductivity of selenium. American inventor Charles Fritts described the first experimental selenium solar cells in 1883. Notable scientists such Albert Einstein and Wilhelm Hallwachs conducted many experiments with various elements to explore it further. In 1921 Einstein won the Nobel Prize in Physics for his theories explaining the photoelectric effect.

Many elements were found to experience the photoelectric effect. Germanium, copper, selenium, and cuprous oxide comprised many of the early experimental cells. In 1953 Bell Laboratories scientists Calvin Fuller and Gerald Pearson were conducting

Parabolic solar energy concentrating dishes sit in a row at the power station at White Cliffs, Australia. The plant, operated by Solar Research Corp. of Melbourne, is Australia's first experimental solar station. (Corbis Corporation)

experiments that brought the silicon transistor from theory to working device. When they exposed their transistors to lamplight, they produced a significant amount of electricity. Their colleague Darryl Chaplin was looking for better ways to provide power for electrical equipment in remote locations. After a year of refinements Bell Laboratories presented the first working silicon solar cell, which would later become the core of contemporary PV applications.

CONTEMPORARY USE: PHOTOVOLTAICS

The utility industry has experimented with large-scale central station PV plants but concluded that in most cases they are not cost-effective due to their perceived low efficiency and high capital costs. However, PV has proven useful in niche markets within the utility system as remote power stations, peak generation applications, and in a distributed generation scheme. Distributed generation is the inverse of central generation. Instead of constructing large generating facilities energy has to be sent to consumers, energy is generated where it is used. Highway signs are a good example of distributed generation. They use solar panels and batteries on the signs to collect and store the power used to illuminate the signs at night. Because very energy-efficient LED lighting replaced incandescent bulbs, these signs could be powered much more economically by PVs than by traditional gasoline-powered generators. Perhaps the most prolific use of PVs is in the space program. The sun, the only natural energy source available in space, is the logical choice for powering space vehicles. Photovolttaics are safer and longer-lasting energy sources than nuclear power is.

An instance where large-scale grid-connected PV generation has occurred is the Sacramento Municipal Utility District (SMUD). SMUD built several dozen "solar buildings" and placed PV systems directly on their clients' homes. SMUD purchased one megawatt of distributed PV systems each year until the year 2000.

SMUD's approach introduced another distributed application concept for PV, called building integrated photovoltaics or BIPV. Currently Japan has one of the largest BIPV programs, started in 1996. The simplest application of BIPV is the installation of solar panels directly on a building. While this method is perhaps the easiest, it does not reflect the best use of PV technology. The best potential for the growth of PV is for PV to double as building materials. Examples include exterior insulation cover, roofing shingles, windows, and skylights that incorporate solar cells. Incorporating PV into construction materials is very complex and requires joint cooperation among traditionally separate entities of the building sector. Although no actual products exist, many of the major manufacturers began experimenting with prototypes in the late 1990s and hope to introduce cost-effective products on the market by 2005. Additional uses for PV include desalinization of seawater for fresh water, solar water heaters, and solar ovens.

IMPLEMENTATION AND BARRIERS

Solar energy is used worldwide in many applications, from niche markets in developed countries to primary village power in rural and developing communities. Its attractiveness can be attributed to several factors:

- Solar power works well in small facilities, and it may be comparatively cost-effective when all factors (transmission, fuel transportation costs, service life, etc.) are taken into consideration. In many instances solar energy is the *only* viable energy option in the region.
- Solar distributed energy systems provide security and flexibility during peak use and outages associated with environmental disasters. In addition, programs that allow consumers to sell surplus energy they generate back to the utility, called “net metering,” will make residential solar technologies more attractive.
- Solar power is environmentally friendly and will help mitigate global environmental concerns associated with climate change.

These claims have been the primary call to arms for many solar advocates and industries since the 1970s, but solar technologies have not enjoyed widespread use except within niche markets, especially among developed countries. According to a U.S. Department of Energy report by the Energy Information Administration, solar technologies have only experienced modest sector growth domestically because domestic solar thermal technologies face stiff competition from fossil-fueled energy generation. PV growth faces similar challenges, since deregulation is likely to lower the cost of electric power from natural gas and coal.

Because of the wide range of ideological leanings of various administrations, direct subsidies and federally funded research and development have fluctuated wildly since the late 1970s. In 1980 the United States spent $260 million on solar research and development, but then the amount fell to $38 million by 1990. Between 1990 and 1994 support doubled, reaching $78 million.

Because of the problems associated with nuclear power and burning fossil fuels, solar technologies may again be viewed as a viable alternative. However, solar technology faces several challenges

First. the energy expended in the production of PV panels is considerable. Second, solar cells become less efficient over time (degradation is slow, but eventually they lose most of their conductivity). Third, contemporary solar cells use mercury in their construction and present toxic waste disposal problems. Finally, solar technologies are part-time power sources. Solar thermal technology requires full, direct sunlight, and PVs do not work at night (although batteries and supplementary generating applications such as wind power can be combined to provide full-time generation).

The need for long-term clean power will be a controversial but necessary issue in the twenty-first century. The debate will focus on the deregulation of the power industry and the needs of consumers, coupled with what is best for the environment. For certain applications, solar technology has proven to be efficient and reliable. The question remains whether solar will be wholly embraced as energy options for a sustainable future in a climate of cheap fossil fuels and less than enthusiastic public support.

SPACECRAFT ENERGY SYSTEMS

Energy systems in space technology are devices that convert one kind of energy into another to ensure the functioning of automated and piloted satellites, interplanetary probes, and other kinds of spacecraft. Multiple functions of any spacecraft require two distinctly different energy sources: propulsion for launch and maneuvers, and electricity supply to power the onboard equipment.

PROPULSION SYSTEMS

Propulsion generates kinetic energy to facilitate motion of spacecraft. Although propulsion is provided by various types of devices, the most common propulsion system of modern space technology is a rocket engine, a device that propels a rocket by a force of reaction. In its simplest form, the rocket engine could be described as a container (combustion chamber) with an opening at one end (exhaust). Burning of combustible chemicals inside the container generates a large amount of a compressed gas—a propulsive mass—that is ejected through the exhaust. According to the laws of mechanics, the force of pressure that ejects the gas creates the reaction force, called thrust, that pushes the container in the direction opposite to the exhaust. The International System of Measurements designates thrust in a unit of force called a newton (N= 0.098 kg[f] = 0.216 lb[f]), while more often it is measured in tons, kilograms, or pounds. The thrust is greater if a bell-shaped nozzle is installed at the engine's exhaust. The nozzle's specially designed profile (the so-called Laval nozzle) creates a strong pressure differential at the exhaust. This differential facilitates expansion of the ejected gas with a substantially higher ejection velocity, thus releasing greater kinetic energy.

The energy efficiency of a rocket engine is determined by specific impulse, commonly measured in seconds (although scientifically correct designations are N s/kg, or m/s). Specific impulse is the time in which a rocket engine consumes the amount of propellant equal to the engine's thrust. For example, compare two engines with an equal thrust of 100 kg each. If the first engine consumed 100 kg of propellant in 20 seconds, and the second one consumed the same amount in 30 seconds, the second engine generated greater kinetic energy per kilogram of propellant—it worked longer. Thus the higher specific impulse indicates the more efficient engine.

The most common chemical rocket engines use gaseous propulsive mass produced through the burning of special chemicals called propellants. Thermal energy released in this process accelerates and ejects the propulsive mass, converting itself into kinetic energy of motion. Solid and liquid propellant motors are the two major types of chemical rocket engines. The solid rocket motor (SRM) burns propellant that consists of fuel and oxidizer mixed together in a solid-state compound. Solid propellant is stored inside a combustion chamber of the SRM, making the engine relatively simple and reliable due to a lack of moving parts (see Figure 1). However, because of lower specific impulse and difficulty controlling the final speed, since the SRM usually cannot be shut down and restarted until all propellant is consumed,

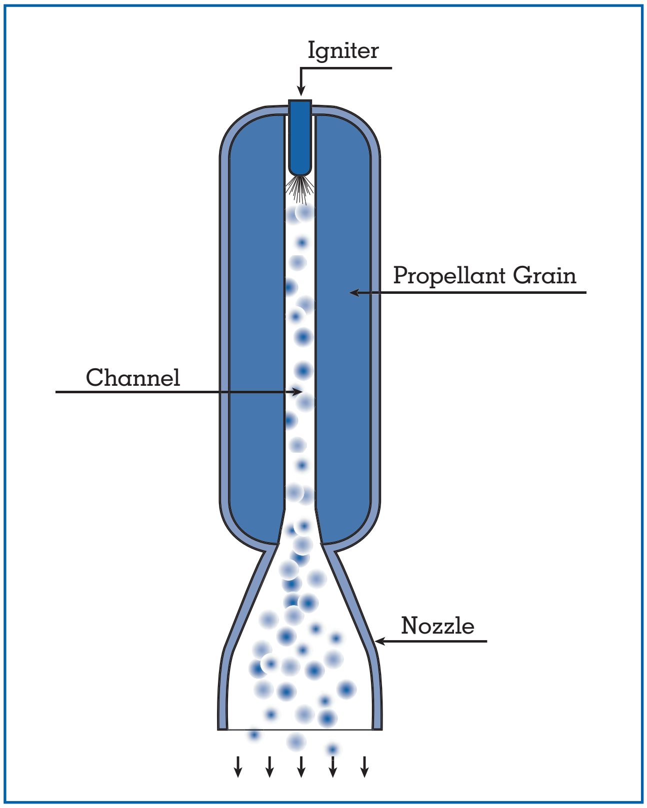

Figure 1.
Solid rocket motor.

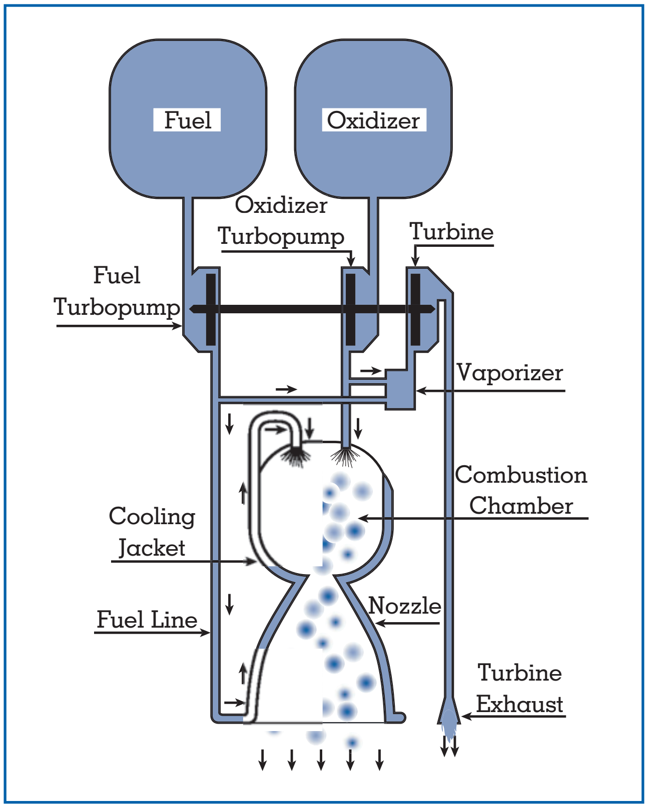

Figure 2.
Liquid propellant rocket engine.

the solid rocket is primarily for short duration but powerful impulse.

A liquid propellant rocket engine (LPRE) generates propulsive mass through burning of two liquid chemicals—fuel and oxidizer—which are pumped into a combustion chamber from separate tanks. LRPE has a very complex design: It contains numerous components with a large number of moving parts. The combustion chamber and nozzle have intricate structures that allow them to withstand high internal pressure while being lightweight. One of the propellant components is driven between the thin double walls of the chamber and nozzle to cool them and prevent hot exhaust from burning through (see Figure 2). LPRE complexity is compensated by advantages of better energy efficiency (higher specific impulse); precision control over burn time, thrust and final speed; and the possibility to restart the engine.

There are two major types of liquid propellants: a storable propellant (that does not boil under a normal temperature) and a cryogenic propellant (a liquefied gas under very low temperature). Storable propellant engines are simpler and more reliable. They are useful for spacecraft that require multiple propulsion impulses and a long stay in space. Although more complex and demanding, cryogenic engines are regarded as best for launch vehicles due to their superior energy efficiency.

In each space mission, the maximum amount of energy is used for spacecraft launching. This is because the spacecraft had to be accelerated to a velocity of 28,500 km/h (17,700 miles/h) in fewer than 10 minutes, while overcoming forces of gravity and atmospheric drag. Due to the enormous energy requirements for this task, propellant accounts for up to 92 percent of the total mass of modern launch vehicles, leaving no more than 4 percent for the useful payload (the rest is the “dry mass” of a rocket). That dictates the importance of energy efficiency—better engines allow for the launching of heavier payloads with less propellant. Although the overall efficiency of a launch vehicle depends on many fac-

Space Shuttle USA	I - 2 solid boosters II - liquid cryogenic	2,040 tons (4,500,000 lb)	29,500 kg+ orbiter 94,000 kg (65,000 + 207,000 lb)	1.45%	The world's only operational reusable launch vehicle (RLV). Purpose-built. Operational since 1981.
Venture Star (project) USA	Single Stage-to-Orbit liquid cryogenic	993.6 tons (2,186,000 lb)	20,500 kg + RLV 117,000 kg (45,100 + 257,000 lb)	2.06%	Future US reusable launch vehicle (RLV). Under development. Expected to start operations in 2005.

Table 1.
Space Launch Vehicles (SLVs)

tors, it could be roughly estimated by a simple percentage ratio between the rocket's maximum payload mass (PM) and of its total mass at launch (LM). The greater percentage would indicate a more efficient launch vehicle (see Table 1).

Energy efficiency is one of the major factors that determines the launch vehicle layout and choice of engines. Currently, about 98 percent of all spacecraft worldwide are launched by liquid-propellant rockets. While the purpose-built launchers mostly use cryogenic engines to ensure the best performance, many current space rockets utilize storable propellants. This is because the majority were developed from military ballistic missiles. Although not ideal from the energy efficiency standpoint, such conversion is less expensive than developing a brand-new launch vehicle. Solid-propellant engines are primarily used as auxiliary boosters for some liquid propellant rockets. Only a few purely solid-propellant space launch vehicles exist today in the world because they are capable of placing fewer than 1,000 kg (2,200 lb) into low orbit, while liquid-propellant rockets can launch much more—up to 29,500 kg (64,900 lb).

Some unique launchers were even more powerful. Such was *Saturn V*—a gigantic rocket capable of launching a payload of 140,000 kg (308,000 lb) that allowed American astronauts to land on the moon. Russian *N-1* and *Energia* rockets were capable of launching 95,000 kg (209,000 lb) and 105,000 kg (231,000 lb), respectively. All these launch vehicles are not in use anymore due to their enormous cost. These giants were created for specific national prestige goals, such as manned lunar expedition, and for launching of the expected massive civilian and military payloads. The shifts in political and economic priorities in the space programs of the United States and Russia have left these rockets without any feasible payload assignments. At the same time, the cost of the launch vehicles' preservation along with their production and maintenance facilities for possible future use was proven to be prohibitive and unjustifiable economically.

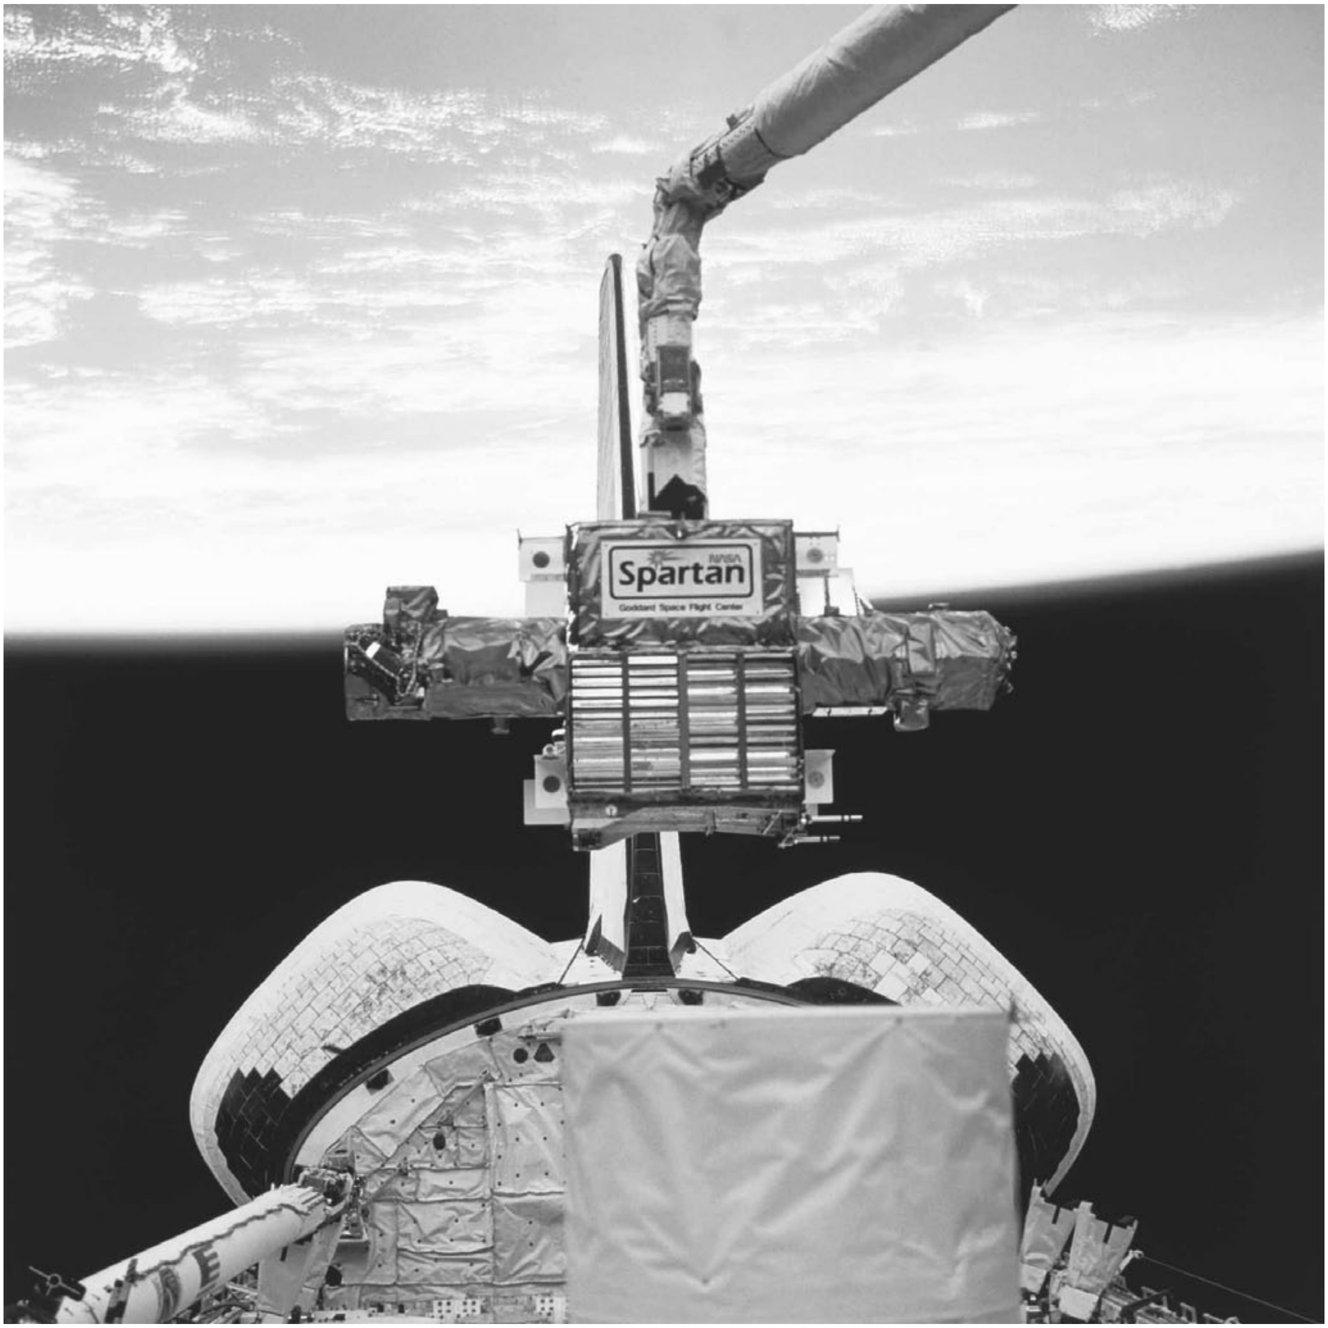
Space launchers usually consist of several stages, which are the individual rockets stacked together. This is another method to increase efficiency—the stages are ejected as soon as their propellant is spent, and a rocket does not have to carry empty tanks. The number of stages also depends on engines' effectiveness. Liquid-propellant rockets usually consist of two to three stages, while solid ones have to have three to five stages.

Rocket engines are also used for maneuvers in space. Some operations, such as a onetime transfer of a satellite from lower to higher orbit, could be performed by a solid-propellant engine. Yet many complex maneuvers, such as rendezvous and docking with another spacecraft, require multiple engine firings and variable power impulses. Hence modern spacecraft are equipped with an assortment of attitude control engines that usually use liquid storable propellant.

A good illustration of how all these engines work together in a single system is the American Space Shuttle. Two very large solid rocket boosters (SRBs) represent the first stage of the launch vehicle. The SRBs are the most powerful rocket engines in existence: Each produces more than 1,500 tons (15.3 MN, or 3,310,000 lb) of thrust for 122 seconds. The second stage consists of a large external tank with cryogenic propellant (liquid hydrogen and liquid oxygen) and three Space Shuttle main engines (SSMEs) mounted on the orbiter. Each SSME produces more than 170 tons (1.73 MN, or 375,000 lb) of thrust at sea level. At launch, SRBs and SSMEs ignite just a few seconds apart and are used to break through the most dense layers of atmosphere. After a separation of the SRBs at the altitude of about 40 km (25 mi), the Space Shuttle continues its acceleration with the SSMEs only. Just before the Space Shuttle reaches orbital velocity (520 seconds after launch), the SSMEs are shut down and the external tank is ejected. Now two smaller engines of the orbital maneuvering system (OMS) aboard the orbiter provide the final acceleration. The OMS engines are also used for orbital maneuvers and for deceleration before the spacecraft reentry. Unlike the SSMEs, they utilize storable liquid propellant, and each produces thrust of 3 tons (30.6 kN, or 6,700 lb). Very fine Space Shuttle orbital maneuvering is performed by the reaction control system (RCS), which consists of 44 small liquid-propellant engines assembled in three arrays.

The immense advantages to humanity of modern space technology come at a hefty price. High risks and environmental hazards of rocketry, uniqueness of spacecraft equipment, and the necessity for specialized launching facilities make space technology very expensive. Today the average cost to launch just 1 kg (2.2 lb) of a payload in orbit could be as high as $10,000. Because of that, only six countries—the United States, Russia, China, Japan, India, and Israel—and the France-dominated European Space Agency (ESA) maintain independent space launching capabilities.

One of the seemingly obvious ways to cut down the cost is a reusable launch vehicle, such as the Space Shuttle. NASA hoped that the enormous cost of the Space Shuttle development would have been compensated by the expected tenfold reduction in the price of putting a payload in orbit. Unfortunately, that goal was not achieved. Despite the Shuttle's unique capabilities, the cost of its payload delivery



The Space Shuttle *Discovery*'s robotic arm deploys the SPARTAN-201 satellite. (Corbis-Bettmann)

appeared to be at least two times higher than that of expendable rockets. The Shuttle's maintenance after each mission turned out to be much more expensive than had been expected. As a reusable spacecraft, the orbiter has to spend energy carrying into space additional massive components that are not essential for payload deployment, such as the main engines, wings, and heat protection. Thus the Shuttle's efficiency factor is two times lower than of the best expendable launchers. The very large size of the orbiter and the necessity to accommodate a crew even for routine satellite launches substantially increase the overall cost of Space Shuttle operations. Projected high expenses recently forced Russia and

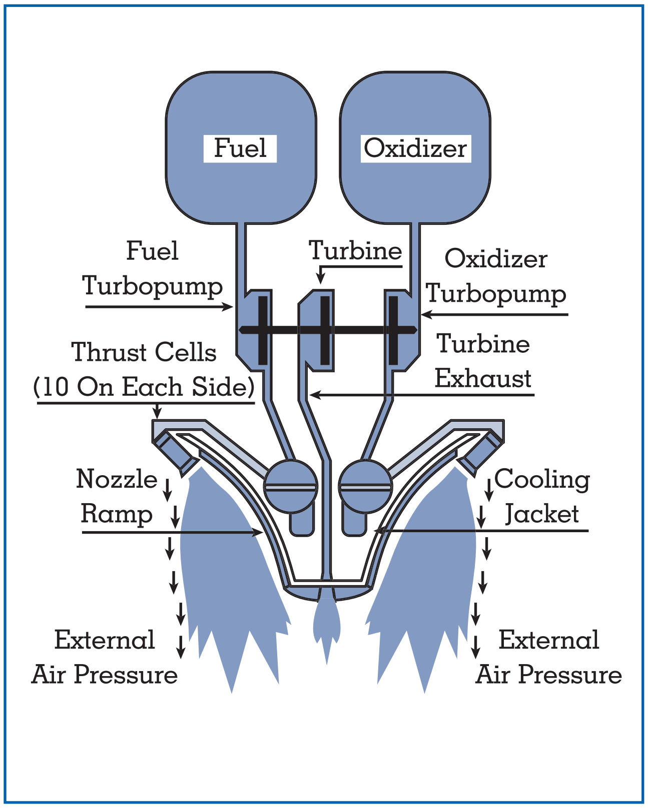


Figure 3.
Aerospike rocket engine.

the ESA to abandon their own nearly completed space shuttle programs.

The numerous projects of the reusable launch vehicles that have appeared from the mid-1980s through the 1990s are intended to overcome the Space Shuttle drawbacks. Some vehicles are designed as conventional rockets that would use parachutes, helicopter rotors, or rocket engines for landing. Others retain the airplane configuration but are planned to be more compact. Regardless of configuration, almost all these projects rely on new types of rocket engines that have yet to be developed.

The most advanced among today's projects is the future American reusable launch system known as *Venture Star*. It utilizes two new concepts that are expected to boost efficiency and cut down the cost of a payload. The first is the single stage-to-orbit concept—the launch vehicle carries the entire propellant load and does not have any expendable parts. The latter is planned to be achieved by a revolutionary rocket engine design called *Aerospike*. The bell-shaped nozzle of a conventional rocket engine controls the expansion of exhaust gases and influences the engine's thrust and efficiency. Since the optimal gas expansion is different at various altitudes, the lower and upper stages of conventional rockets have engines with nozzles of different shapes. In *Aerospike*, an array of combustion chambers fire along the curved central body, called a ramp or a spike. The spike plays the role of an inner wall of a nozzle, while the outer wall is formed by the pressure of the incoming air flow. Changes in atmospheric pressure upon the vehicle's ascent immediately change the exhaust expansion, allowing the engine to perform optimally at any altitude (see Figure 3). The vehicle will take off vertically but land like an airplane, using its lifting body configuration. The *Venture Star* is planned to be about 30 percent smaller than the Space Shuttle. The *Venture Star*'s payload will be 20,500 kg (45,100 lb), compared of the Shuttle's 29,500 kg (64,900 lb). If successful, the *Venture Star* is to make its first flight in the first decade of the twenty-first century. Meanwhile, NASA prepares to fly a scaled-down technology demonstrator, *X-33*, which will test the *Venture Star* design.

Another method to increase efficiency is to launch a rocket eastward close to Earth's equatorial plane. It would be additionally accelerated by Earth's rotation, achieving greater payload capability without any extra energy consumption. Small rockets could be launched from an airplane, which makes building expensive launching facilities unnecessary. This concept is currently utilized by the American Pegasus launch system. Larger rockets could take off from floating launchers, such as the San Marco platform, which had been used by Italy for the American Scout rockets in the 1960s. The end of the Cold War allowed the use of existing military technology for this purpose. For example, the Russian Navy successfully launched a small satellite by a ballistic missile from a submerged strategic submarine in 1998. The largest floating launch platform was built in 1998 in Norway for the Sea Launch international consortium. It operates from the United States, making commercial launches of heavy rockets jointly built by Russia and Ukraine.

In their quest for energy efficiency, some designers are seeking radically new methods of launching spacecraft. For example, leaving the energy source on the ground instead of being carried by a spacecraft would make the launching more efficient. One such method is firing a satellite from a large cannon—something that revives a space travel idea from Jules Verne's science fiction classic *From the Earth to the Moon* (1865). In his joint experiments with the U.S. Navy in the late 1960s, the Canadian ballistics expert Gerald V. Bull proved that small satellites could indeed survive tremendous shock and acceleration in a cannon barrel and achieve orbital velocity. Instead of conventional cannons, very long chemical accelerators with numerous combustion chambers along the barrel are considered. In this case, the pressure of expanding gas would not decrease, but continuously be built behind a projectile, providing it with greater velocity. Among variations of that concept are electromagnetic accelerators, where the force of chemical explosion is replaced by electromagnetic energy. A typical example is a coil gun, which accelerates a projectile by magnetic fields created in sequence by electric coils wrapped around a barrel. Unlike cannons, electromagnetic accelerators promise a smoother rate of acceleration and better control over the projectile's velocity. They also are much "friendlier" to the environment in terms of lack of excessive noise and chemical exhaust pollution. Although attractive, such launchers would require consumption of enormous amounts of electricity, as well as construction of large and expensive facilities. Experiments with chemical and electromagnetic accelerators have been under way in the United States, Russia, and some other countries for many years.

The choice of exotic propulsion systems is even broader in open space, where the lack of gravity and atmospheric drag allows a wide selection of low-thrust but economical engines. For example, thermal energy produced by a controlled chain reaction in a nuclear reactor can heat a propulsive mass to a higher extent than in chemical rocket engines. Higher temperature means greater ejection velocity and higher specific impulse. This concept of a nuclear rocket engine was thoroughly researched in the United States and the USSR from the 1960s to the 1980s, and working prototypes were ground-tested in both countries. For instance, the American NERVA (nuclear engine for rocket vehicle application) engine used liquid hydrogen as a propulsive mass and had a sea-level thrust of 29.4 tons (300 kN, or 64,680 lb). Figure 4 shows a principal design of the nuclear rocket engine with a solid-state reactor.

The heating elements in modern nuclear reactors are made of solid radioactive materials, but theoretically they could exist in a colloidal (semiliquid) or gaseous state. That would allow a radical increase in propulsive mass temperature and ejection velocity. Research has shown that the colloidal and gaseous-state nuclear reactors would respectively produce specific impulses from 20 percent to 50 percent higher than the solid-state reactor. Some very advanced concepts of gaseous-state reactors promise even greater efficiency.

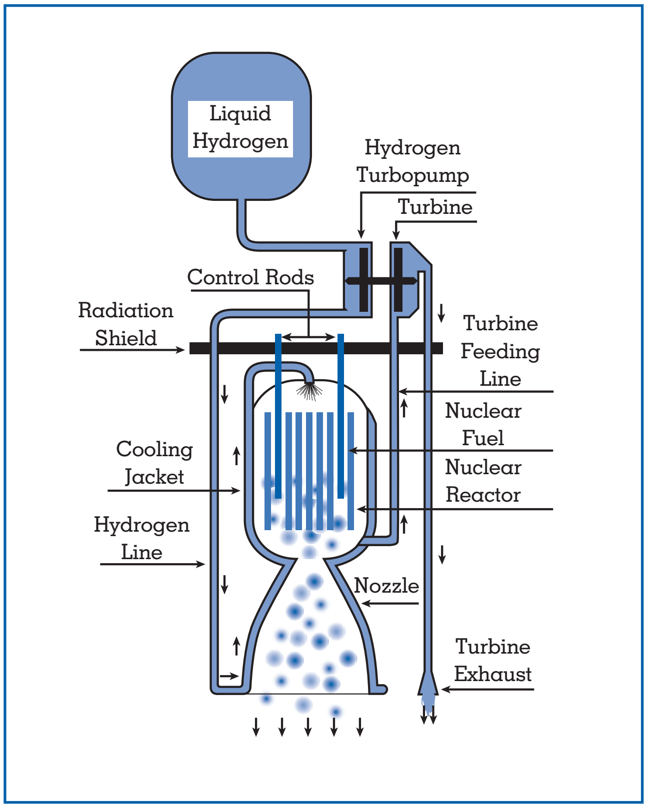

Figure 4.
Nuclear rocket engine.

Another attractive idea is to use electric power for propulsion. Having many design variations, the electric rocket engines (ERE) could roughly be divided into three groups:

- thermal electric engines, which eject propulsive mass heated by the electricity;
- magneto-hydrodynamic (plasmic) engines, which convert propulsive mass into plasma and accelerate it by a magnetic field;
- ion engines, where an ionized propulsive mass is ejected by an electrostatic field.

Type	*Maximum Thrust*	*Continuous Firing Time*	*Specific Impulse*	*Comments*
Chemical Solid Propellant Rocket Engines	up to 1,500,000 kg	dozens of seconds	270 seconds	Widely used in launch vehicles and spacecraft as auxiliary boosters and, sometimes, for main propulsion.
Chemical Liquid Propellant Rocket Engines	up to 800,000 kg	dozens of minutes	388 seconds	Main type of propulsion system of modern space technology.
Nuclear Solid State Rocket Engines	up to 30,000 kg	dozens of minutes	700 - 900 seconds	Under development. Prototypes were ground tested in the 1960s - 1980s.
Electric Rocket Engines	up to 0.15 kg	thousands of hours	1,200 - 25,000 seconds	Under development. Used to stabilize some satellites and as a main propulsion of a planetary probe.

Table 2.
Space Propulsion Systems

Experiments showed that the EREs can utilize a variety of chemical elements for propellant: from metals (cesium, rubidium, mercury) to gases (hydrogen, argon, xenon). The main advantage of these engines is in unsurpassed efficiency. They produce very low thrust but can continuously work for thousands of hours, consuming very little propellant due to their unparalleled specific impulse. In open space, slow but steady acceleration eventually produces the same result as a powerful but short-duration impulse—the spacecraft achieves a desired velocity. It is just a matter of time. Yet the low power and high electricity consumption so far remain the main difficulties in the ERE development.

The first experiments with the thermal electric engine were conducted in Russia in 1929 by its inventor, Valentin P. Glushko, who later became a world-famous authority in rocket propulsion. For more than forty years, the United States and Russia have devoted many resources to research and development of various kinds of EREs. First tested in space by the Russians in 1964, these engines have found some limited applications in modern space technology. For more than two decades Russian weather and communication satellites have regularly used electric rocket engines for orbital stabilization. The first spacecraft to employ ERE for main propulsion was the American asteroid exploration probe *Deep Space 1*, launched in 1998. The performance of its ion engine is illustrated by the fact that after 2.5 months of continuous work it increased the spacecraft velocity by 2,415 km/h while consuming only 11.5 kg (25.3 lb) of propellant (xenon).

Table 2 compares some of the modern propulsion systems.

POWER SUPPLY SYSTEMS

Power supply systems provide electricity to feed the onboard spacecraft equipment and can be classified by the primary energy sources: chemical, solar, and nuclear.

Dry cells (batteries) and fuel cells are the main chemical electricity sources. Dry cells consist of two electrodes, made of different metals, placed into a solid electrolyte. The latter facilitates an oxidation process and a flow of electrons between electrodes, directly converting chemical energy into electricity. Various metal combinations in electrodes determine different characteristics of the dry cells. For example, nickel-cadmium cells have low output but can work for several years. On the other hand, silver-zinc cells are more powerful but with a much shorter life span. Therefore, the use of a particular type of dry cell is determined by the spacecraft mission profile. Usually these are the short missions with low electricity consumption. Dry cells are simple and reliable, since they lack moving parts. Their major drawbacks are the bulk and deterioration of current stability during the life span.

In fuel cells, electricity is generated by the same chemical process of oxidation between liquid fuel and oxidizer in the presence of a catalytic agent and electrolyte. While various chemical solutions could be utilized, the most common fuel cells use the oxygen/hydrogen combination. The oxygen/hydrogen fuel cell consists of a chamber with three compartments separated by electrodes (nickel plates with tiny holes and a catalytic agent). The middle chamber is filled with electrolyte. Oxygen and hydrogen (fuel) are pumped into the side chambers. As a result of a chemical reaction, the cell produces electricity, heat, and water. Fuel cells provide 75 percent higher output than the best dry cells, and their electric current does not deteriorate with time. At the same time they are much bulkier and more complex in design, with numerous moving parts. Their life time is limited by the supply of fuel and oxidizer onboard a spacecraft. Fuel cells usually are used for short-duration missions with high electricity consumption. They were installed aboard the American *Gemini* and *Apollo* manned spacecraft and later—on the Space Shuttle.

Solar energy systems utilize an unlimited natural source of energy—the sun. Solar arrays directly convert visual light into electricity. Such devices are the most widely used sources of electric power in modern space technology. They consist of a large number of specially developed semiconducting platters (cells) that develop electrical current when exposed to light. Silicon semiconducting cells are most common, while the newest and more expensive gallium and cadmium cells are more efficient. The cells are connected and assembled in arrays on the body of the spacecraft, or on specially deployed external panels. The panels are usually made of a number of hinged plates that are stacked during the launch and open after the spacecraft reaches orbit. However, in the late 1980s a new type of panel—based on a thin, flexible film—was introduced, making solar arrays lighter in weight and easier to store and deploy.

Solar array efficiency depends on its orientation to the sun. The best result is achieved if the array faces the sun at an angle of 90° to 85°. Precise orientation can be achieved either through the rotation of the whole spacecraft, or the rotation of the solar arrays only. To ensure constant electricity flow regardless of changes in spacecraft orientation, solar arrays charge a secondary power source—the rechargeable booster batteries—which in turn power the spacecraft equipment.

Large solar arrays can produce high power, since the total electrical output depends on the overall area of panels. The capability to work for several years with stable current makes solar panels more effective than chemical sources for long-duration space missions. Spacecraft power supplies could be upgraded if solar arrays are enlarged, or replaced in flight. Such operations were performed by cosmonauts and astronauts aboard the Russian *Salyut* and *Mir* space stations and the American Hubble Space Telescope. At the same time, the solar arrays and related equipment are bulky and massive. Large solar arrays are susceptible to erosion by space radiation, micrometeorites, and damage from space debris. Large solar arrays also have limited applications for low-flying satellites (due to increase in atmospheric drag) and for deep space probes, since their efficiency diminishes at greater distances from the sun. To solve the latter problem, NASA recently pioneered a new concept—the refractive solar concentrator array. The solar panel in this case contains a layer of tiny lenses that concentrate solar light on the cells and compensate for energy losses in distant space. The first spacecraft to test this new design was *Deep Space 1.*

Modern nuclear electric systems are represented by two different types of devices: radioisotope generators and nuclear reactors. Radioisotope generators utilize the natural decay of radioactive materials, which could last for several years. The simplest among radioisotope generators—the so-called nuclear battery—develops electricity in electrodes directly exposed to isotope radiation. This is a low output but very compact device that could be used as an auxiliary power supply. Unlike nuclear batteries, thermal radioisotope generators produce electricity from the heat emitted by the isotope via static thermal converters of two major types. The most common are the radioisotope thermoelectric generators (RTGs), where electricity appears in arrays of semiconductors heated at one end and cooled at the other. RTGs have been intensively studied in the United States and Russia for almost four decades and have reached a high level of sophistication and reliability. The early models were flight-tested by both countries in the mid-1960s. Since then, the United States has used RTGs on more than two dozen military and scientific space missions, mostly for deep-

Type	*Prime Energy Source*	*Advantages*	*Disadvantages*	*Comments*
Dry Cells	Chemical.	-Simplicity.	-Low output; -Short life-span; -Bulk; -Current deterioration.	In use for short duration space missions. Various designs provide different life-span and output.
Fuel Cells	Chemical.	-High output; -Stable current; -Water supply as a sub-product.	-Complex design; -Bulk; -Life-span is limited by onboard fuel supply.	Used in some piloted spacecraft for short duration missions.
Solar Arrays	Visual solar radiation.	-Long life-span; -High output; -Stable current.	-Require precision Sun orientation; -Bulk; -Require booster batteries for electricity storage; -Ineffective in low-flying and deep space spacecraft.	The most widely used power supply system in modern spacecraft.
Atomic Batteries	Radioisotope decay.	-Long life-span; -Stable current; -Simplicity; -Compactness.	-Very low output; -Emit harmful radiation; -High cost.	Used as auxiliary power sources in some spacecraft.
Radioisotope Generators	Thermal from radioisotope decay.	-Long life-span; -Stable current; -Compactness.	-Low output; -Require additional devices to produce electricity; -Emit harmful radiation; -High cost.	Used for some long-duration missions, mostly deep-space probes.
Nuclear Reactors	Thermal from nuclear chain reaction.	-High output; -Long life-span; -Stable current; -Compactness.	-Complex design; -Require additional devices to produce electricity; -Emit harmful radiation; -High cost.	Used for some space missions with high power consumption. May produce radioactive pollution of the environment in case of disintegration at launch, or de-orbiting.
Solar Concentrators	Thermal from visual solar radiation.	-High output; -Long life-span; -Stable current.	-Complex design; -Require additional devices for electricity production and storage; -Bulk; -Require precision Sun orientation.	Not used. Considered as prime power supply systems for large space stations.

Table 3.
Power Supply Systems

space and planetary probes. Automated scientific stations installed by astronauts on the moon, *Viking* landers on Mars, *Pioneer* missions to Jupiter and Saturn, and *Voyager* explorations of the outer planets of the solar system all owe their many years of uninterrupted power supplies to radioisotope generators. The *Cassini* probe, launched toward Saturn in 1997, was the latest spacecraft equipped with RTGs. However, since the 1980s closer attention has been paid to the development of the more complex thermionic generators, since they are considered more efficient than RTGs. In thermionic converters electricity is developed in a chain of metal electrodes enclosed in a sealed container and exposed to a high temperature. The electrodes are placed very close to each other (up to 0.01 mm), with a special dielectric solution between them.

Radioisotope generators cannot produce high output, but their main advantages are compactness, self-containment, and unsurpassed durability. The lack of moving parts makes them highly reliable. At the same time, radioisotope generators are expensive and require protection of the onboard electronic equipment and ground personnel from harmful radiation. The use of radioisotope generators is justifiable in small, long-duration, and low-power-consumption spacecraft.

Unlike radioisotope generators, nuclear reactors utilize the much more intense process of nuclear chain reaction. Since this process is controlled in the reactor, the energy output could be regulated depending on the system's requirements. It actually could produce twice its nominal power, if necessary. Nuclear reactors can provide greater electrical output than radioisotope generators using the same types of thermal converters. This output is comparable to that of fuel cells and solar arrays, while nuclear reactors are more durable and compact.

Reactor-based electrical systems were studied in the United States and the USSR for many years. After testing in space of its first nuclear reactor, SNAP-10A, in 1965, the United States concentrated mostly on developing RTGs. On the contrary, the Russian engineers put more effort into researching nuclear reactors. The Soviet Union was the first nation to start regular use of spaceborne nuclear reactors, called Buk, with thermoelectric converters. That system powered the military ocean radar surveillance and targeting satellite US-A ("US" stands for universal satellite), better known in the West as RORSAT. The satellite's size limitations, low orbit, and radar's high power consumption made the nuclear reactor the only possible energy source. A total of thirty-one such satellites were launched from 1970 to 1987. At the end of their life span, the satellites eject the reactors to a higher "storage" orbit, were they will exist for several hundred years. By the time of their natural reentry, the nuclear material should decay beyond the danger of atmospheric contamination. Unfortunately, that did not always work: Three times the reactors accidentally reentered along with satellites and caused air and water pollution in Canada and the Pacific. Later the USSR developed a series of more advanced reactors with thermionic converters and successfully flight-tested them in 1987. In 1992 one of those reactors, Topaz 2, was purchased by the United States to study its possible military application.

Future spacecraft probably will require much more power than today. This problem could be solved by dynamic thermal converters, in which a high-temperature gas spins the electrical generator's turbine. Obviously, such a generator would depend on a supply of the gas-producing material onboard a spacecraft. In this respect most effective would be a closed-cycle generator, where the used gas is not discharged into space, but continuously recycled through a special radiator. Theoretically, dynamic converters can produce 45 percent higher output than static ones. As a source of thermal energy, dynamic generators may use nuclear reactors, or solar concentrators—large parabolic mirrors that produce a high temperature zone in a focal point. Unlike solar arrays, the mirrors are less susceptible to erosion and theoretically could work for a longer time. Solar concentrators have been studied in the United States and Russia but have never been used in space flight.

Table 3 compares various spacecraft power supply systems.

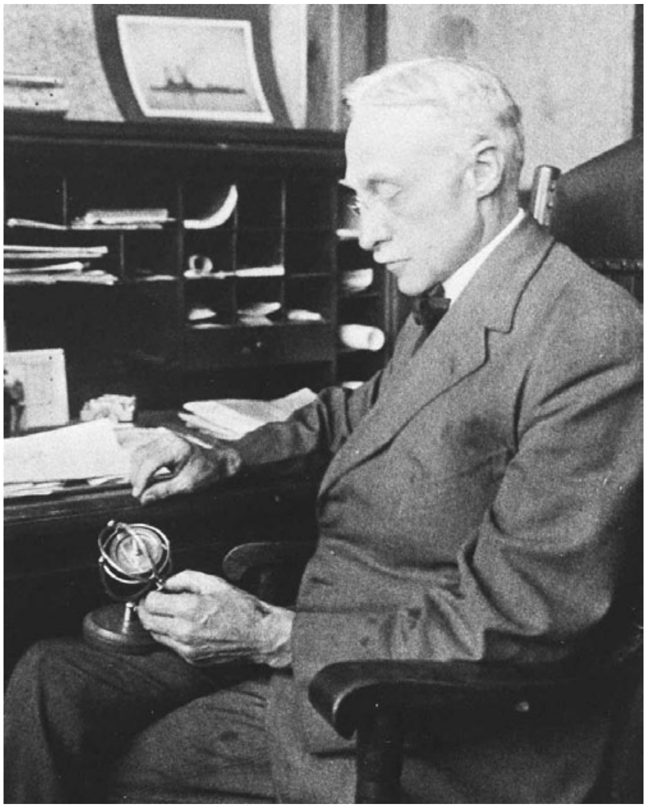
SPERRY, ELMER AMBROSE (1860–1930)

Elmer Ambrose Sperry was born near Cortland, New York, on October 12, 1860. Sperry, whose mostly absent father was a farmer and itinerant worker and whose mother died hours after his birth, was raised by his aunt Helen until she married, as well as by his paternal grandparents. The young Sperry often studied the many water-driven mills, a steam-driven mill, and the railway station in Blodgett Mills. Later, he also became a familiar presence at the mills, factories, blacksmithy, machine shop, printing press, foundry, railway yard, and pottery of the larger Cortland.



Elmer Ambrose Sperry. (Library of Congress)

A turning point for Sperry was his attendance at the Philadelphia Centennial exposition in 1876. Sperry was particularly fascinated by the Machinery Hall, observing for hours, for example, a Jacquard loom incorporating an early version of card punch automatic control.

The YMCA greatly influenced Sperry, who avidly read the latest scientific magazines, including the *Official Gazette of the U.S. Patent Office*, in its periodical room. The organization also sponsored lectures given by professors at the Cortland Normal School, which Sperry attended, as well as lectures by leaders in many fields, including Alexander Graham Bell. While growing up, he was active in the Baptist church in Cortland. After moving to Chicago in 1882, Sperry became heavily involved at the First Baptist Church where Zula Goodman, whom he later married, played the organ. That marriage, beginning June 28, 1887, was long and happy and produced three sons and a daughter.

In 1883, Sperry began his first business, the Sperry Electric Light, Motor, and Car Brake Company. This company, which pursued dynamo-driven arc lighting during a time of the rapid development of incandescent lighting and alternating current, folded in 1887. Out of the ashes of the former company, Sperry formed the Sperry Electric Company, whose principal assets were Sperry's arc-light patents. His attention, however, was divided between this company and the Elmer A. Sperry Company, a research and development enterprise formed in 1888 and almost entirely owned by Sperry, in which he was freed from engineering and business matters. It was the Elmer A. Sperry Company that allowed him to develop and patent his ideas, with the aid of about thirty workmen in the shop. Sperry developed a series of labor-saving devices, including a highly successful electric locomotive for mine haulage (introduced in 1891), to ease miners' work and increase mine productivity. Sperry also created the Sperry Electric Mining Machine Company (1889; sold in 1892) and the Sperry Electric Railway Company (1892). In addition, a separate company was developed (reorganized in 1900 as Goodman

Manufacturing Company and in which Sperry acquired a large block of stock) that bought mining industry patents, as well as manufacturing several products Sperry's company had originally manufactured. Throughout his life, Sperry stayed involved in policy decisions and technical consulting as a vice president of the Goodman Company, which became a good source of income for Sperry to apply to his future invention projects.

Sperry's method of invention was to examine a field, determine market need, and focus on creating an innovative device to meet that need. He was amazingly visually oriented rather than mathematically inclined. When an invention was patented and ready to market, its patents were often used as the principal capital assets of a specially formed company. Sperry then relegated management of its manufacture and sales to others, freeing him to concentrate on the next invention. Sperry invented his streetcar during the early 1890s, assigning the resulting patents to General Electric in 1895. With its invention, Sperry combined his in-depth grasp of both mechanical and electrical engineering. By 1898, he had developed a superior electric car. Running on a battery he created, it could drive a reputed 87 miles per charge, compared to around 30 miles for other electric cars. The jigs and tools to turn out "Sperry Electric Carriages" in lots of 100 were being readied; instead, in 1900, the American Bicycle Company acquired some of the key patents related to Sperry's electric car, using these to protect its own lines of steam, petroleum, and electric automobiles. Heartened by his success with the battery, Sperry then focused on electrochemistry, spurred in part by the harnessing of electrical power at Niagara Falls in 1895, which made electric power cheaply available. By 1904, Sperry and Clinton P. Townsend had refined an electrolysis process to the point where Elon Huntington Hooker decided to purchase the patents for the process—the beginning of the Hooker Electrochemical Company of Niagara Falls, which became a major U.S. chemical manufacturer.

Sperry turned his attention to the American Can Company's huge amount of scrap metal remaining after round can tops were pressed from square sheets. He and his colleagues refined American Can's electrolytic detinning process to deal with this scrap so that absolutely pure tin powder resulted. In 1907 and 1908, Sperry was involved in patent interference cases concerning this detinning process. The outcome was that the Goldschmidt Detinning Company, formed by American Can in 1908 using the detinning process pioneered by the German Goldschmidt company, bought Sperry's patents, and in 1909 sold the rights to these patents to same Goldschmidt company in Germany (attesting to their value). Meanwhile Sperry's interest since 1907 had been moving into the nascent and promising area of gyroscopic technology.

After attempting unsuccessfully to convince the automobile industry of the safety value of his car gyrostabilizer, Sperry continued his concentration, begun in late 1907, on a gyrostabilizer for ships, seeking to improve the one developed by Ernst Otto Schlick in Germany. By May 1908, Sperry had completed his invention and filed a patent application, marking the beginning of Sperry's most famous period—as inventor of an *active* (as opposed to Schlick's *passive*) ship gyrostabilizer. It was active in that an actuator (later called a sensor), consisting of a pendulum that, upon sensing small rolls of the ship, activated the switches or valves or other means that controlled the motor; the motor then stimulated the much less sensitive gyro to overcome its greater inertia (compared to the pendulum) and begin precession *before* the gyro actually began to feel the torque of the ship's roll. The pendulum system incorporated a feedback control mechanism, one of many Sperry had developed, and would continue to develop, as essential components of his inventions—making Sperry a pioneer in the area that came to be known as cybernetics.

By 1911, Sperry had in addition invented and developed a gyrocompass that was installed for testing on one of the U.S. Navy's state-of-the-art Dreadnoughts. After refining its design, Sperry fulfilled his company's Navy contract by installing the gyrocompass on three more of the Navy's Dreadnoughts and by June 1912 on two submarines. One refinement was a mechanical analog computer that automatically corrected compass errors.

Between 1909 and 1912, aircraft invention was burgeoning, but lack of adequate stabilization resulted in many lost lives. Sperry, his brilliant son Lawrence (who would die in 1924 in a crash while flying across the English Channel), and Sperry's hand-picked engineers developed an airplane automatic stabilizer, redesigned it into the main component of an automatically controlled missile during World War I, and after the war transformed it again into an automatic pilot system. During the war, when the Sperry Gyroscope Company (formed in 1910) became almost exclusively devoted to wartime development, several other inventions, such as a superior high-intensity searchlight, were introduced. Also introduced and installed on several Navy battleships was a highly effective improved gunfire control system, whose basic component was the gyrocompass.

Following the war, the gyrocompass was adapted for merchant-marine vessels, providing unmatched ease of use and maintenance, far outstripping the magnetic compass in navigational economies and safety. By 1932, the Sperry gyrocompass had been installed on more than 1,000 merchant-marine ships. The gyrostabilizer had also been installed on a few huge ocean liners. Another major achievement during this time was the automatic pilot developed for ships, incorporating the most sophisticated guidance and control mechanisms Sperry had yet invented. Nicknamed "Metal Mike," the gyropilot was installed in around 400 merchant-marine ships worldwide by 1932. In addition, Sperry developed and marketed a helm indicator and course recorder that proved valuable adjuncts to the gyropilot and gyrocompass.

Sperry's output continued undiminished until his wife died on March 11, 1930, after which his health declined until he died on June 16, 1930.

Sperry applied for his first patent—a dynamo-electric machine—when he was twenty. His final patent application—for a variable pitch propeller—was submitted in 1930, shortly after his death. In total, 355 of his over 400 patent applications matured as actual granted patents.

STEAM ENGINES

A steam engine is a device that converts a portion of the heat energy absorbed by a liquid, after it has vaporized, into mechanical work.

For a classic reciprocating steam engine, pressurized steam from a boiler is admitted into cylinder, driving a piston attached to a connecting rod and crankshaft. Steam admission is typically cut off in midstroke. This cutoff steam continues to expand against the piston until the stroke ends, converting more heat energy into work.

The most efficient performance is achieved when the engine expands steam to achieve the greatest absolute difference between steam admission and exhaust temperatures. *Superheaters* are devices in the boiler that raise the temperature of steam above that of the water from which it was generated. Efficiency is improved because this added temperature, or superheat, permits greater expansion (and thus temperature drop) before the steam begins condensing and is exhausted. Further efficiency gains can be realized by exhausting the steam not to the atmosphere but rather to a separate apparatus called a *condenser*. This is a sealed chamber cooled by air or water. As entering steam cools, it condenses, and its volume is greatly reduced, producing a partial vacuum. Exhausting into this partial vacuum permits yet further expansion and temperature drop.

Steam *turbines*, which generate more than 80 percent of the world's electric power, differ from steam engines in that steam drives blades and not pistons. Steam turbines expand pressurized steam through nozzles that accelerate the steam at the expense of heat energy and pressure. Work is created by transferring a portion of steam velocity to blades, buckets, or nozzles affixed to a rotor to move at high speeds. Steam turbines are relatively compact in relation to steam engines. Turbines are generally operated at higher pressure, resulting in greater output for the size. Their rotary nature also permits continuous admission, expansion, and exhaust so that power production is uninterrupted. Steam engines, by contrast, only develop maximum output during the period before cutoff and none at all during the exhaust period.

Steam power was a cornerstone of the Industrial Revolution. Steam freed humans from limits imposed by natural energy sources as muscle, water, wind, and sun. Human and beast-of-burden muscle power was limited. Most humans turning a crank affixed to an electric generator cannot sustain enough effort to illuminate a 150-watt lightbulb for more than a few minutes. Water was a fairly reliable energy source, but only obtainable along rivers capable of sustaining suitable dams. Windmills were also an early energy source. Although effective, they lacked a means of storing energy, and were only useful for jobs that could be profitably performed intermittently, such as grinding grain.

Starting in eighteenth-century England, steam engines suddenly made concentrated power available on demand anywhere. Earliest uses included pumping water from iron and coal mines, driving iron mill furnaces and hammers, and, a bit later, propelling locomotives to and from the mines. In a synergistic relationship, steam engines made iron and coal affordable, which in turn lowered the cost of building and operating steam engines. Previously costly iron products soon became affordable to all, and engine-driven industry and transportation spread rapidly across the globe.

PREDECESSORS OF THE MODERN STEAM ENGINE

In 1606 Gioavanni Battista della Porta of Naples performed two experiments that formed the basis for steam engines. He proved that steam could develop pressure by expelling water from a sealed container. In the next experiment a steam-filled flask was immersed neck down in water. As the cooling steam condensed, water flowed upward into the flask, proving that a vacuum had been created.

By 1698 Captain Thomas Savery exploited these principles with a patented steam pump. Alternately admitting pressurized steam into a vessel forced water upward through a one-way (check) valve, while the vacuum created by cooling the vessel drew water from below through a second valve. French inventor Denis Papin demonstrated the first steam-driven piston in 1690. His experiment consisted of a cylinder with a closed bottom and a piston. A weight attached to a cord passing over two pulleys applied upward force on the piston. Flame beneath the cylinder heated a small quantity of water, creating steam pressure to raise the piston. Condensation followed removal of heat, and the difference in air pressure on the piston top and the vacuum below caused the piston to descend, raising the weight. By 1705 Thomas Newcomen introduced his pumping engine to England. It built upon the work of Papin but was made practical by use of a separate boiler. The Newcomen engine consisted of a vertical cylinder with a piston attached to a counterweighted crossbeam. A piston pump to drain mines was attached to the crossbeam. The combined efforts of low-pressure steam and counterweight forced the piston upward, to the cylinder top. Spraying cold water into the cylinder condensed the steam, which created a partial vacuum, returning the piston to the bottom.

Both the Newcomen and the Papin pumps derived most of their power from this atmospheric force rather than from steam pressure. Newcomen engines consumed perhaps 32 pounds of coal each hour per horsepower developed, about 1 percent of the energy that burning coal emits.

MODERN STEAM ENGINES

Scottish doctor Joseph Black discovered in 1765 that applying heat to water would steadily raise temperature until reaching the boiling point, where no further temperature increase occurred. However, boiling did not commence immediately but only after a relatively large additional hidden; or latent heat was added. Learning of this discovery, Scottish instrumentmaker James Watt realized that the cold water spray in the Newcomen cylinder wastefully removed latent heat. Maintaining the cylinder at steam temperature would conserve heat and reduce energy consumption. Watt conceived of the condenser, a separate vessel cooled by water immersion and connected to the cylinder through an automatic valve. Steam entering the vessel rapidly condensed, and the vacuum created was applied to the piston, as in the Newcomen engine. Early Watt cylinders were open at the top, like the Newcomen engine. Later, Watt created the double-acting engine by enclosing both cylinder ends and connecting them to the boiler and condenser with automatic valves. Air no longer wastefully cooled the cylinder, and steam rather than air pressure pushed the piston in both directions.

While Watt engines admitted steam throughout the full stroke, he did patent the idea of cutoff to allow the steam to work expansively and more efficiently. Higher pressures were needed to exploit expansion, and it fell to other inventors, notably Richard Trevithick of Wales and Oliver Evans of the United States, to make this leap. Their design eliminated the pull by a vacuum and introduced a push by high pressure. Further efficiency gains occur by superheating the steam, heating it to a greater temperature than by which it was generated. This added temperature permits greater expansion and work to occur before the steam condenses. Watts's use of separate boiler, engine, and condenser, double-acting engines, and insulation all resulted in the first modern steam engine. He tripled efficiency over the Newcomen engine, reaching about 3 percent efficiency overall.

In 1781 Jonathan Hornblower invented the compound engine, but conflicting patent rights prevented development. Arthur Woolf revived the idea in 1804 and invented a valve mechanism often associated with compounding. The compound engine partially expands steam in one cylinder and then further expands it in one or more succeeding cylinders, each expansion being termed a stage. Compound expansion reduces temperature swings in each cylinder, improving efficiency since less energy is lost reheating metal on each piston stroke. While simple engines with condensers reached 10 to 15 percent efficiency on superheated steam, compounds with up to four stages readily reach 20 percent and in a few cases as much as 27 percent.

Reciprocating steam engine development reached its pinnacle with the development of the uniflow engine. Invented by T. J. Todd of England in 1885 and refined some twenty years later by German engineer Johann Stumpf, the uniflow features a single-inlet valve, and exhaust ports at the end of the stroke. Steam is cut off relatively quickly and allowed to expand; at the end of the stroke, the piston exposes the exhaust port. As the piston returns and covers the port, the piston it recompresses the steam remaining in the cylinder back to the admission pressure. This recompression heats the steam in much the same fashion as it cooled off while expanding; consequently little energy is lost reheating the metal. Uniflow engines are more simple and economical to build than compounds and generally approach compounds in efficiency; at least a few examples may have surpassed compounds, with one engine reportedly testing at 29 percent efficiency. Uniflow engines never became prevalent due to rapid concurrent development of the steam turbine.

Steam engine development preceded understanding of the principles governing their operation. Steam engines were widely used in locomotives, automobiles, ships, mills and factories. It was not until 1859, when the Rankine cycle (named after Scottish engineer and physicist William John Macquorn Rankine) was postulated, that steam engine design finally received a sound theoretical footing.

STEAM TURBINES

Curiously, although practical steam turbines are a more recent development than piston steam engines, two of the earliest steam devices were turbines. The earliest generally recognized steam-powered mechanism was the aeolipile, built by Hero of Alexandria in the first century C.E. It was essentially a pan-shaped boiler connected to a hollow rotating shaft on which was mounted a hollow sphere. Jets of steam exiting the sphere through two tangentially placed nozzles spun the device. The action was similar to a modern rotating lawn sprinkler. The Branca engine of 1629 consisted of a boiler fancifully shaped into a human head and torso. Steam exiting a nozzle placed at the mouth impinged upon a paddle wheel. Although efficiency and performance were very low, cog wheels provided sufficient torque for a small mortar and pestle to powder drugs.

Modern steam turbines can reach efficiencies of 40 percent. About 90 percent of newly installed electrical generating capacity is driven by steam turbines due to high efficiency and large capacity. The impulse turbine is the most basic modern turbine. An impulse stage consists of one or more stationary steam nozzles mounted in the casing and a rotating wheel with curved blades mounted along its periphery. Steam expanding through the nozzles exchanges pressure and temperature for great speed. Directing this steam against curved blades transfers momentum to the wheel. The Branca engine was an early impulse turbine. Reaction turbines exploit Newton's third law: "For every action there is an equal and opposite reaction." While Hero's aeolipile lacks blades like a modern turbine, recoil from steam did rotate the sphere, making it a reaction turbine.

The allure of producing rotary motion without intermediary crankshafts and connecting rods attracted efforts of engineers to little success until the 1880s, when two entirely different designs appeared in England and Sweden. In 1884 Charles Algernon Parsons patented the first practical reaction turbine. Unlike Hero's turbine, which had two jets, Parson's turbine had blades mounted around the periphery of fourteen pairs of rotating disks mounted on a single shaft. The area between blades was designed similarly to nozzles; steam passing through these spaces expanded and accelerated, imparting thrust to the rotating disk. Succeeding blade sets became larger, permitting steam to expand farther in each stage and is analogous to compounding in reciprocating engines. Fixed blades between the disks smoothly redirected steam to the following rotating blades. Large turbine sets can employ many more stages of expansion than reciprocating steam engines, since each stage adds only a small amount of friction, while additional cylinders soon add enough friction to offset any efficiency gains. The final stages in these machines can often effectively extract energy from steam at pressures below atmospheric. This aggressive use of compounding leads to significantly more efficient operation than for reciprocating steam engines.

Parsons adopted this multistage design to reduce turbine operating speeds to a useful level. His initial turbine was developed to produce electricity onboard ships and had an output of about 7 kW. In 1888 he designed the first steam turbine generating unit for public utility service. By the time of his death in 1931, his company manufactured turbines generating more than 50,000 kW.

In 1894 the success of his electrical generating plants led Parsons to undertake development of the first marine turbine, with the goal of building the fastest ship afloat. The prototype vessel *Turbinia* was 100 feet long. Initial trials with a single turbine directly connected to a propeller were unsatisfactory, as the turbine speed was too high for efficient operation. In 1896 the single turbine was replaced by three separate turbines, with steam flowing from the high-pressure turbine element to the intermediate element and then the low-pressure turbine element. Each turbine shaft was fitted with three propellers and she made 34½ knots, a new world's record.

In 1888 Carl G. P. de Laval invented his impulse turbine, which was based on the Pelton water wheel. Steam was accelerated to nearly the speed of sound through a nozzle or a series of nozzles. Directing the steam toward curved vanes mounted upon a disk resulted in high rotating speeds. Conceptually this is identical to Branca's turbine, but August Camille Edmond Rateau of Paris learned that wasp-waisted nozzles greatly enhanced velocity, making turbines feasible. Noticing that excessive rotating speeds were a weakness of de Laval turbines, Rateau patented a multistage impulse turbine in 1896. His machine was essentially a series of de Laval turbines. Breaking expansion into stages resulted in smaller pressure drops across each set of vanes and lower velocity for the same mechanical output. Over the years many variants of turbine arrangements have been tried and adopted. Efficiency has more than doubled since the turn of the twentieth century, and output has risen enormously. The first Parsons turbines of 1884 were perhaps 10 hp. By 1900, when the demand for electric power was growing tremendously, the largest steam turbine-generator unit produced about 1,250 kW, but advances over the next twenty years increased capacity to more than 60,000 kW. This output far exceeded what even the largest steam engines could provide, and paved the way for central generating plants with millions of turbine horsepower to be the principal electric power generators of the twentieth century.

The steady march of improvements in performance of steam turbines can be largely attributed to exploiting higher steam pressures and steam temperatures. Steam generator pressures and temperatures increased from about 175 psi and 440°F (227°C) in 1903 to 450 psi and 650°F (343°C) in 1921 and 1,200 psi and 950°F (510°C) by 1940. Since the late 1950s steam pressures of more than 3,500 psi and 1,150°F (621°C) have become available and at least one unit has reached 5,300 psi and 1,210°F (654°C). Nationwide, average plant efficiency climbed steadily, with an average of 29 percent in the late 1930s, 35.5 percent in the late 1940s, and 38.5 percent in the late 1950s. Efficiency improved little in the following decades as boiler and turbine operating temperatures and pressures had reached the limits of available material strength and durability.

By the turn of the twentieth century, reciprocating steam engines had become common items in everyday life. Transportation was dominated by steam-powered ships, locomotives, and boats. Steam was the preferred method of driving the earliest automobiles, with more steamers on U.S. roads than internal-combustion engines until about 1906. Portable and self-propelled steam engines provided power to drive agricultural and lumbering machinery on site. Most factories, shops, and mills had a steam engine that drove machinery by way of overhead shafts and leather belts. The sound of the mill steam whistle signaling the shift change set the routine in many communities. Within a few years this personal relationship with steam receded. Internal-combustion engines largely supplanted small steam engines where self-contained power was necessary, while electric motors became dominant in stationary applications.

Except for a few countries that still use steam engine locomotives, reciprocating steam engines have passed into history. They are used only rarely, more often than not as a hobby. Steam turbines, on the other hand, have continually increased in importance, as they are used to generate most of our electricity. All nuclear power plants generate steam to drive turbines, and some geothermal installations use the earth's heat similarly. Although steam turbines are still common on oceangoing ships, they are being replaced by large diesel and gas turbine installations due to high intrinsic efficiency, low first cost, and more economical labor and maintenance requirements.

Even when large diesels and gas turbines take over as prime movers, steam turbines still often have a vital role. A process called bottom cycling or combined cycling can team the steam turbine with an internal-combustion engine, which is inherently efficient due to its high temperature operation. Exhaust gases from these operating cycles are often sufficiently hot enough to operate a boiler and steam turbine. Since the steam system is driven by heat that would otherwise be discarded, overall system efficiency soars. Such bottom cycling plants, which are gaining favor in new generating facilities in the United States, are now 50 percent efficient and are likely to close in on 60 percent in the near future.

STEPHENSON, GEORGE (1781–1848)

Many successful people are inspired by their parents and George Stephenson was no exception. In modern day vernacular, his father had one of the "coolest jobs in town" in the small village of Wylam, on the River Tyne, eight miles west of Newcastle, England, where George was born. Robert Stephenson raised his family in a primitive dwelling while serving as the pumping engine fireman at the local colliery, keeping the mines free of water. The company's coal wagon passed very close to the family's front door, helping George make up for his lack of formal education with up close and very personal attentiveness.

When George was eight yeas old, the mine's pumping engine broke down and work temporarily ceased, forcing his father to move the family in search of work. With the impact of engines permanently etched in his mind, the young boy began to make clay models in great detail, simulating his father's machines. Unknowingly, he was destined to study engines for the rest of his life. Defying parental wishes to take up farming, at age thirteen he joined his brother James as a picker in another mine. Working his way up the ladder at the Black Callerton mine, George began driving an engine and by seventeen he earned the position of assistant engine fireman—higher than any post his father had ever attained.

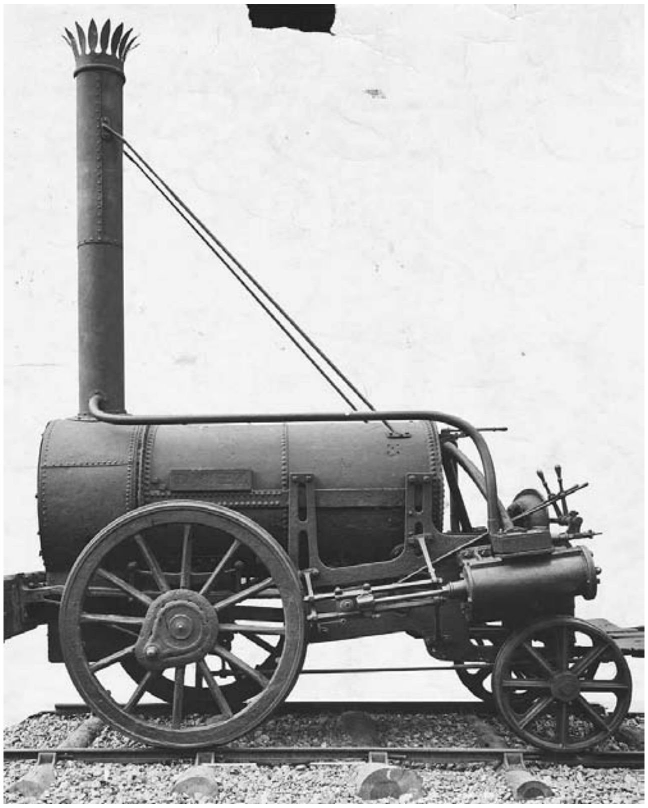
He was eventually promoted to engineman—or plugman—which required intricate engine knowledge and skills. He quickly learned to devote all his free time to the study and care of his engines, tearing down and rebuilding them to better understand their inner workings.

He became interested in stories about James Watt and Matthew Boulton but faced a significant hurdle: at the age of eighteen, he was still unable to read. He began reading lessons with a young schoolmaster, Robin Cowens, and then, to further his knowledge of engineering, was tutored in math by Andrew Robertson, a Scottish mathematician.

George earned the prestigious position of brakesman at the Dolly Pit colliery, responsible for the engine used for hauling coal out of the mines. He was married in 1802. During that year he made an unsuccessful attempt to build a perpetual motion machine. But he did gain respect in the community as an accomplished clock-mender.

In 1808, his career breakthrough came at the Killingworth High Pit, where he and two other brakesman contracted with management to work on a royalty basis, rather than a fixed weekly wage. The risk was offset by his ability to create mechanical engineering efficiencies, considered one of Stephenson's greatest strengths. Opportunity knocked in the form of a pumping engine built by John Smeaton that had been a complete failure during a period of twelve months. Approaching the investors, Stephenson made an audacious claim that he could have the engine running within a week. In fact, he did so in only three days of breakdown and reconstruction, acquiring great local renown and the true launching of his career as a self-taught "doctor of engines." Proving his flexibility, he drained an entire quarry with a unique miniature pump that he invented.

George continued his adult education with John Wigham, focusing on the areas of math and physics. In addition, he befriended an engineer, John Steele, who had apprenticed under Richard Trevithick in the building of a successful locomotive engine during 1803 to 1804.



Side view of George Stephenson's locomotive, "The Rocket." (Corbis Corporation)

Stephenson applied theories developed by others, including Ralph Allen's work on self-acting inclines, in which empty coal wagons were pulled up a track, powered by full wagons moving downhill. Other inventions included a winding-engine and new design for pumping engines, before turning his attention to the self-propelled steam engine.

In the early nineteenth century, hardly anyone imagined that passenger transportation would evolve, concentrating instead on the need to transport coal. Most of the inventiveness applied before Stephenson was to reduce track friction, allowing horses to pull more load. There were even experiments in the seventeenth century by Sir Humphrey Mackworth to build a wind-powered land-ship, which were disappointing due to the inevitable limits of nature. The first successful steam locomotive was built by French engineer Cugnot in 1763. Designed for war, its top speed was a paltry two and one-half miles per hour, with endurance of only fifteen minutes. There were numerous failures for the rest of the century, hampered by persistent attempts to operate them on roads.

It is noteworthy that William Murdock achieved significant progress in the 1780s, despite discouraging remarks by James Watt and his partner, Matthew Bolton, who thought that steam locomotion was impractical. This chiding among rivals was common and it seemed that personal credibility was sometimes as important as genius. When Trevithick did his brilliant work with locomotives, his eccentricities and irascibility deterred his acceptance, as did his unbusinesslike and unprofessional nature. Stephenson's predecessors who did earn credibility, however, were William Hedley and aide, Timothy Hackworth, at coal mines in the Newcastle area.

George Stephenson was not truly the inventor of railways or steam locomotives. But, like Thomas Newcomen and his work with the first practical atmospheric steam engine, George and his son, Robert, were the first to use concentrated imagination to turn existing work and theory into fully functional locomotive engines on rails. The Stephensons made the greatest contribution toward the building of the British railway system.

George Stephenson's first engine, named the Blucher, took ten months to complete, and first operated on the Killingworth Railway on July 25, 1814. His most notable achievement was building the Liverpool to Manchester railway, that featured thirty miles of track and sixty-three bridges. The most famous locomotive ever built—"The Rocket"—was actually designed and made by his son, Robert, although its most serious fault was reconfigured by George, who approved all concepts of design and manufacture.

Despite their growing reputation, there was great resistance at times to the Stephensons' locomotive building, most notably among farmers. Although the noise that scared animals was largely reduced, there was an economic concern to farmers—if steam trains and carriages succeeded, there would be less demand for horses and less demand to grow oats to feed them. But technological progress prevailed, even if it was often settled in court.

In addition to George's acclaimed work with locomotives, he and his son Robert designed numerous contraptions such as a scarecrow with wind-aided arms, a sundial, an oil light that burned underwater, and an automatic cradle rocker. While George Stephenson derived immediate satisfaction from his mechanical accomplishments, there is some evidence that he resented or disdained the public acclaim through his rejection of invitations to join the Royal Society or to accept Knighthood. Despite his brilliance, his relative late education kept him from feeling socially accepted. This may have started with a grudge as early as 1815, when he lost out in a patent dispute with a more privileged rival over a safety lamp that George invented.

Nonetheless, Stephenson realized that he had a great impact on society and finished his career as a traveling consultant in engineering. He was known to dine with kings, such as the King of Belgium, and richly earned his permanent place in the annals of industrial history.

STIRLING, ROBERT (1790–1878)

Robert Stirling was born on October 25, 1790, in the parish of Methvin, Perthshire, Scotland. Stirling, the son of a farmer, received a classical education followed by studies in divinity at the universities of Edinburgh and Glasgow. The Church of Scotland, after examining his knowledge of Hebrew, Greek, divinity, and church history, licensed Stirling to preach the Gospel in March 1816. Shortly after, Stirling accepted the patronage of the Duke of Portland, who proposed Stirling as a suitable candidate for the vacant post of assistant minister at Kilmarnock. Stirling was ordained on September 19, 1816.

Just eight days after his ordination, Stirling applied for a patent for "Improvements for diminishing the consumption of fuel." He had evidently carried out his experiments while he was a student at Edinburgh, but why a student of divinity should have developed an interest in fuel economy, and gone to the expense of applying for a patent to protect his invention, is something of a mystery. Stirling's patent was in several parts. The first part was for a method of diminishing the quantity of fuel used in furnaces for melting glass, while still producing the high degree of heat required. The second was for a heat exchanger suitable for use in breweries and factories where economies could be made by transferring heat from one fluid or vapor to another. The third was for an engine for moving machinery.

Stirling's engine consisted of an externally heated, hot-air engine fitted with what he termed an "economiser." The economiser absorbed and released heat to and from the enclosed air, which was shifted alternately between hot and cold spaces, with the resulting pressure changes communicated to a power piston. Stirling was the first to design an engine with a working cycle that depended on recovering waste heat for efficient operation.

Stirling's patent was based on practical experiments and a working knowledge of radiant heat. Stirling may have been influenced by the works of John Leslie, Professor of Mathematics at Edinburgh, who in 1804 published the results of his investigations into the nature of radiant heat. The general layout of Stirling's engine embodies Leslie's experiments with spaced radiation screens to reduce the transmission of heat. In a second work published in 1813, Leslie argued that heat was transmitted as a series of vibrations, and if heat were applied to one end of a cylinder of metal, then a regular descending graduation of temperature would soon be established along the whole length. Stirling seems to have perceived that here was a process that might be made reversible. If heat were transmitted in a series of vibrating layers, and if the heat source were itself moved along the layers, heat could be discharged into bands of heat at decreasing temperatures. That is to say, as the heated mass touched each layer, the temperature of the heated mass would fall. If the mass of air were to be passed back over the bands of heat, then it would regain its former temperature. This was how Stirling described the workings of his economiser, although he took care to dispel any idea of perpetual motion by pointing out the losses.

Stirling's transfer to Kilmarnock did not put a stop to his experimenting. Here he meet Thomas Morton, an inventor and manufacturer who supplied him with a workshop. Morton also built telescopes and observatories and was influential in developing Stirling's interest in constructing optical and scientific instruments. In 1818 Stirling erected an engine of his own design to drain water from a local stone quarry. This engine performed its duty well until, as a result of carelessness of the engine-man, it overheated and was rendered useless.

James Stirling, who was ten years younger than his brother Robert, initially studied for the church, taking a classical education at Edinburgh and Saint Andrews University. The pull of mechanics proved stronger than religion, and he took up an apprenticeship with Claud Girdwood and Co., of Glasgow, machine makers and iron founders. In 1824 he suggested his brother use compressed air for his engine rather than air at atmospheric pressure, and by 1827 James was influential enough to have built an experimental twenty horse-powerengine fitted with a sheet iron economiser, in which too much faith was placed, resulting in the engine failing for want of effective cooling. This engine embodied a number of improvements in the economiser, which were patented in 1827 in the joint names of Robert and James Stirling. James left Girdwood's in 1830 to become manager of the Dundee Foundry, Dundee.

At Dundee the brothers continued experimenting, directing their efforts into improving the efficiency of both cooling apparatus and economiser. The results of these experiments were patented in 1840 (the year Robert was awarded a Doctor of Divinity), and in 1843 a forty-five horsepower engine was set up to power the whole of the foundry, which it did until 1847. The trial engine successfully vindicated the Stirling brothers' claims for improved fuel efficiency, but ultimately failed as a practical engine because the available material—cast iron—could not withstand the high temperatures required for efficient operation. The development of the Stirling engine was effectively halted until improvements in metallurgy were made.

In 1837 James married Susan Hunter, the daughter of a Saint Andrews Professor; they had no children. James left Dundee in 1845 to become a successful consulting engineer in Edinburgh, where he died at the age of seventy-five. In 1819 Robert had married Jane Rankine, the daughter of a Kilmarnock merchant. They had two daughters and five sons. Robert had moved to the parish of Galston in 1823, and he remained a respected minister until his death at the age of eighty-eight, although some of his parishioners felt he devoted too much time to his mechanical pursuits.

Such was Robert Stirling's interest in science and engineering that of his sons, four became leading railway engineers in Britain and South America, and one became a church minister. His son-in-law became the general manager of an iron works. Stirling never sought to benefit from his invention; indeed, he did little to prevent infringements of his patents. Stirling's 1816 patent foresaw all possible applications of what came to be called the regenerative process, a term coined by John Ericsson, who never accepted the priority of Stirling's patent. However, Ernst Warner von Siemens, who profitably developed the regenerative furnace for smelting metals, did acknowledge Stirling as the originator.

STIRLING ENGINES

The principle that makes Stirling engines possible is quite simple. When air is heated it expands, and when it is cooled it contracts. Stirling engines work by cyclically heating and cooling air (or perhaps another gas such as helium) inside a leak tight container and using the pressure changes to drive a piston. The heating and cooling process works like this: One part of the engine is kept hot while another part is kept cold. A mechanism then moves the air back and forth between the hot side and the cold side. When the air is moved to the hot side, it expands and pushes up on the piston, and when the air is moved back to the cold side, it contracts and pulls down on the piston.

While Stirling engines are conceptually quite simple, understanding how any particular engine design works is often quite difficult because there are hundreds of different mechanical configurations that can achieve the Stirling cycle. Figure 1 shows a schematic of a transparent educational demonstration engine that runs on the top of a cup of hot coffee. This engine uses a piece of foam similar to what would be used as a filter for a window air conditioning unit to "displace" the air between the hot side and the cold side. This foam displacer is carefully mounted so it does not touch the walls of the cylinder. Figure 2 shows how this particular engine achieves the Stirling cycle. In this engine, the air flows through and around the displacer from the hot side then back to the cold side, producing a power pulse during both the hot and cold portion of the cycle. Stirling engines can be mechanically quite simple since they have no valves, and no sparkplugs. This can result in extremely high reliability as there are fewer parts to fail.

It is worthwhile to compare Stirling engines to other more familiar engines and note their similarities as well as their differences. Stirling engines are a type of heat engine. They turn heat into mechanical work and in this sense they perform the same function as other well known heat engines such as gasoline, diesel, and steam engines. Like steam engines, Stirling engines are external combustion engines, since the heat is supplied to the engine from a source outside the cylinder instead of being supplied by a fuel burning inside the cylinder. Because the heat in a Stirling engine comes from outside of the engine, Stirling engines can be designed that will run on any heat source from fossil fuel heat, to geothermal heat, to sunshine. Unlike steam engines, Stirling engines do not use a boiler that might explode if not carefully monitored.

When operating on sunshine, or geothermal heat, Stirling engines obviously produce no pollution at all, but they can be exceedingly low emissions engines even when burning gasoline, diesel, or home heating oil. Unlike gasoline or diesel engines that have many thousands of start stop cycles of combustion each minute, burners in Stirling engines burn fuel continuously. It's much easier to make a continuous combustion engine burn very cleanly than one that has to start and stop. An excellent demonstration of this principle is to strike a match, let it burn for a few seconds, then blow it out. Most of the smoke is produced during the starting and stopping phases of combustion.

A BRIEF HISTORY

In the early days of the industrial revolution, steam engine explosions were a real problem. Metal fatigue

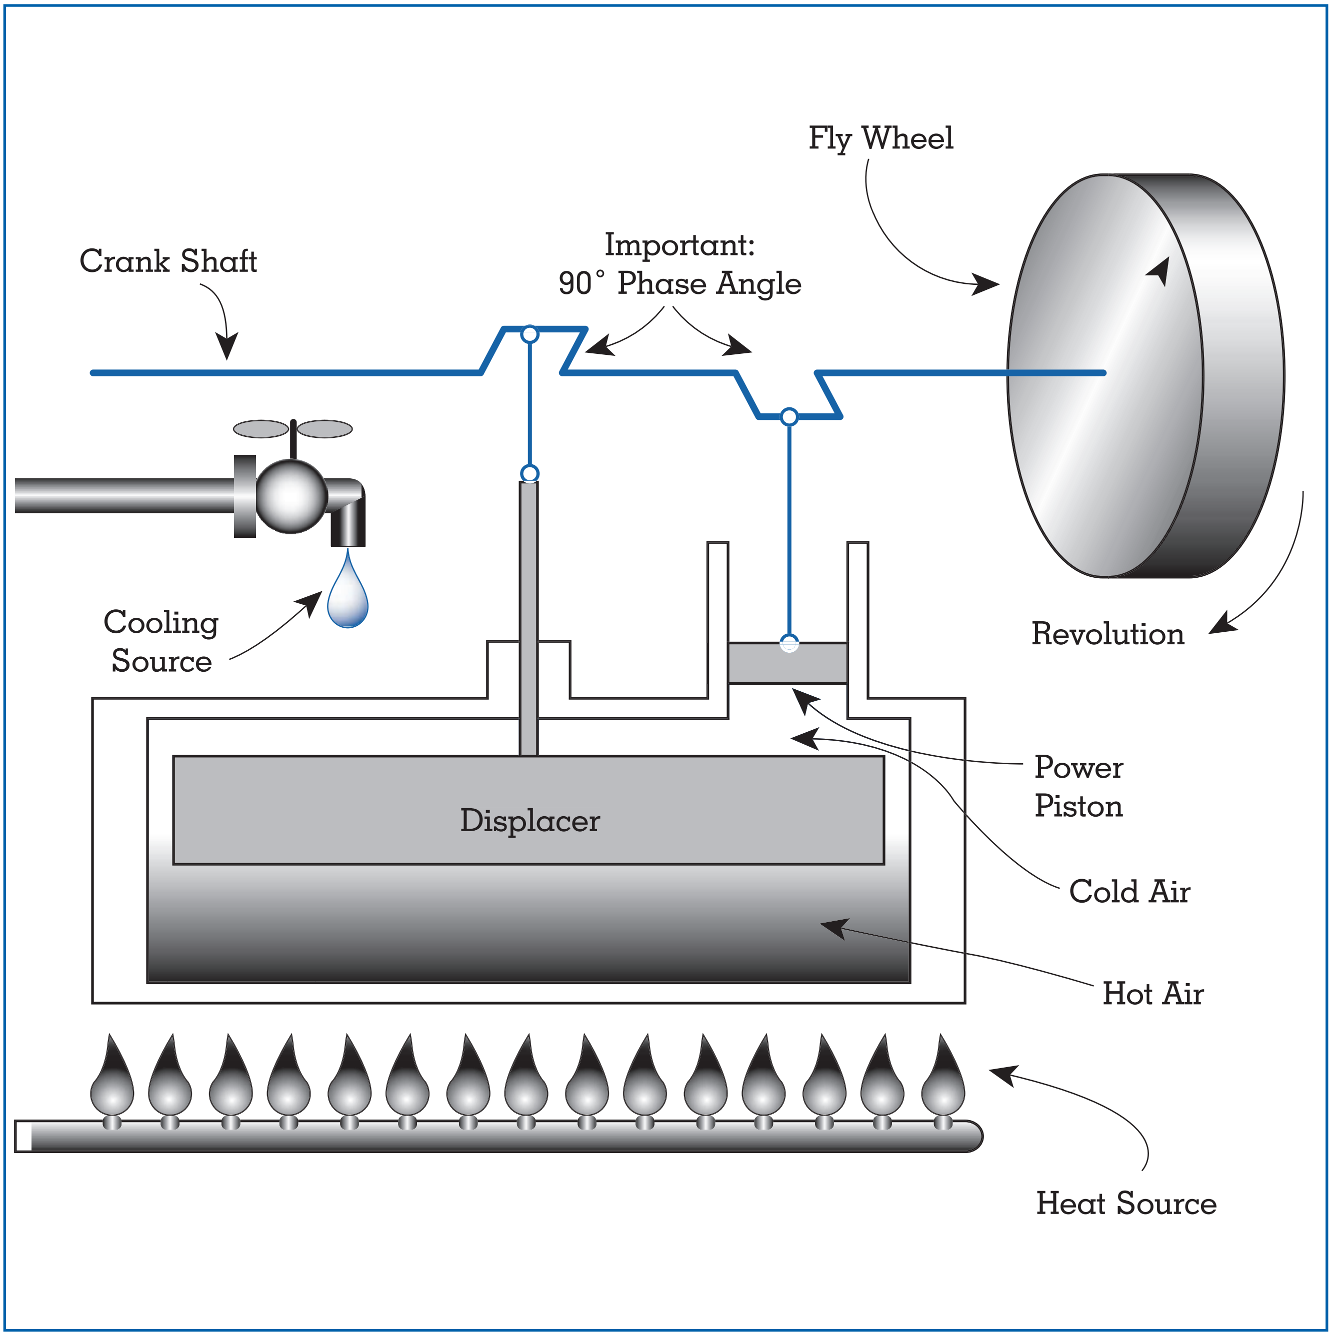

Figure 1.
Key to Stirling Engine. The air flows both through and around the porous displacer. The displacer looks like a piston but it is not.

was not well understood, and the steam engines of the day would often explode, killing and injuring people nearby. In 1816 the Reverend Robert Stirling, a minister of the Church of Scotland, invented what he called "A New Type of Hot Air Engine with Economiser" as a safe and economical alternative to steam. His engines couldn't explode, used less fuel, and put out more power than the steam engines of the day.

The engines designed by Stirling and those who followed him were very innovative engines, but there was a problem with the material that was used to build them. In a Stirling engine, the hot side of the

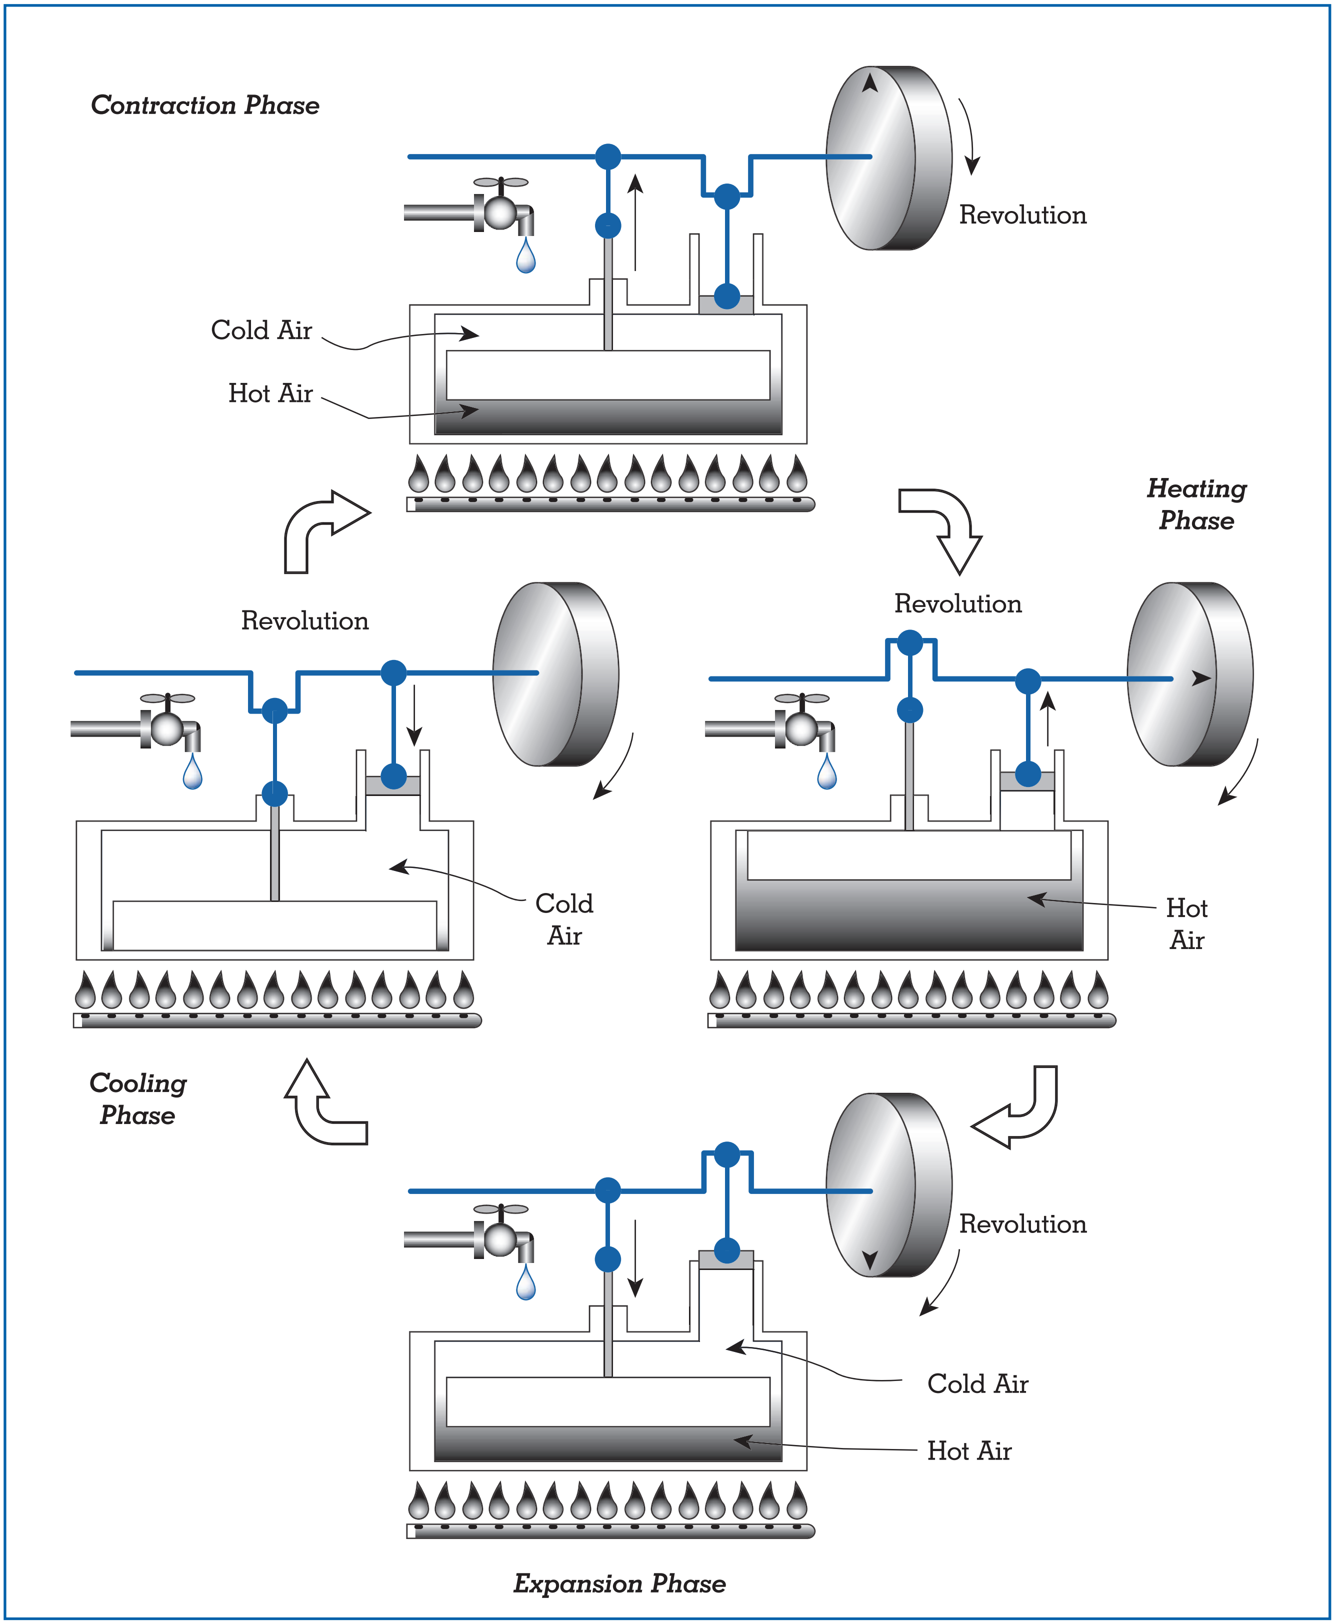

Figure 2.
Four phases of the Stirling engine power cycle.

engine heats up to the average temperature of the flame used to heat it and remains at that temperature. There is no time for the cylinder head to cool off briefly between power pulses. When Stirling built his first engines, cast iron was the only readily available material, and when the hot side of a cast iron Stirling engine was heated to almost red hot, it would oxidize fairly quickly. The result was that quite often a hole would burn through the hot side causing the engine to quit. In spite of the difficulties with materials, tens of thousands of Stirling engines were used to power water pumps, run small machines, and turn fans, from the time of their invention up until about 1915.

As electricity became more widely available in the early 1900s, and as gasoline became readily available as a fuel for automobiles, electric motors and gasoline engines began to replace Stirling engines.

REGENERATION

Robert Stirling's most important invention was probably a feature of his engines that he called an "economiser." Stirling realized that heat engines usually get their power from the force of an expanding gas that pushes up on a piston. The steam engines that he observed dumped all of their waste heat into the environment through their exhaust and the heat was lost forever. Stirling engines changed all that. Robert Stirling invented what he called an "economiser" that saved some heat from one cycle and used it again to preheat the air for the next cycle.

It worked like this: After the hot air had expanded and pushed the piston as far as the connecting rod would allow, the air still had quite a bit of heat energy left in it. Stirling's engines stored some of this waste heat by making the air flow through economiser tubes that absorbed some of the heat from the air. This precooled air was then moved to the cold part of the engine where it cooled very quickly and as it cooled it contracted, pulling down on the piston. Next the air was mechanically moved back through the preheating economiser tubes to the hot side of the engine where it was heated even further, expanding and pushing up on the piston. This type of heat storage is used in many industrial processes and today is called "regeneration." Stirling engines do not have to have regenerators to work, but well designed engines will run faster and put out more power if they have a regenerator.

CONTINUED INTEREST

In spite of the fact that the world offers many competing sources of power there are some very good reasons why interest in Stirling engines has remained strong among scientists, engineers, and public policy makers. Stirling engines can be made to run on any heat source. Every imaginable heat source from fossil fuel heat to solar energy heat can and has been used to power a Stirling engine.

Stirling engines also have the maximum theoretical possible efficiency because their power cycle (their theoretical pressure volume diagram) matches the Carnot cycle. The Carnot cycle, first described by the French physicist Sadi Carnot, determines the maximum theoretical efficiency of any heat engine operating between a hot and a cold reservoir. The Carnot efficiency formula is

$$(T(\text{hot})-T(\text{cold}))/T(\text{hot})$$

T(hot) is the temperature on the hot side of the engine. T(cold) is the temperature on the cold side of the engine. These temperatures must be measured in absolute degrees (Kelvin or Rankine).

STIRLING APPLICATIONS

Stirling engines make sense in applications that take advantage of their best features while avoiding their drawbacks. Unfortunately, there have been some extremely dedicated research efforts that apparently overlooked the critical importance of matching the right technology to the right application.

In the 1970s and 1980s a huge amount of research was done on Stirling engines for automobiles by companies such as General Motors, Ford, and Philips Electronics. The difficulty was that Stirling engines have several intrinsic characteristics that make building a good automobile Stirling engine quite difficult. Stirling engines like to run at a constant power setting, which is perfect for pumping water, but is a real challenge for the stop and go driving of an automobile.

Automobile engines need to be able to change power levels very quickly as a driver accelerates from a stop to highway speed. It is easy to design a Stirling engine power control mechanism that will change power levels efficiently, by simply turning up or down the burner. But this is a relatively slow method of changing power levels and probably is not a good way to add the power necessary to accelerate across an intersection. It's also easy to design a simple Stirling engine control device that can change power levels quickly but allows the engine to continue to consume fuel at the full power rate even while producing low amounts of power. However it seems to be quite difficult to design a power control mechanism that can change power levels both quickly and efficiently. A few research Stirling engines have done this, but they all used very complex mechanical methods for achieving their goal.

Stirling engines do not develop power immediately after the heat source is turned on. It can take a minute or longer for the hot side of the engine to get up to operating temperature and make full power available. Automobile drivers are used to having full power available almost instantly after they start their engines.

In spite of these difficulties, there are some automobile Stirling applications that make sense. Hybrid electric cars that include both batteries and a Stirling engine generator would probably be an extremely effective power system. The batteries would give the car the instant acceleration that drivers are used to, while a silent and clean running Stirling engine would give drivers the freedom to make long trips away from battery charging stations. On long trips, the hybrid car could burn either gasoline or diesel, depending on which fuel was cheaper.

To generate electricity for homes and businesses, research Stirling generators fueled by either solar energy or natural gas have been tested. They run on solar power when the sun is shining and automatically convert to clean burning natural gas at night or when the weather is cloudy.

There are no explosions inside Stirling engines, so they can be designed to be extremely quiet. The Swedish defense contractor Kockums has produced Stirling engine powered submarines for the Swedish navy that are said to be the quietest submarines in the world.

Aircraft engines operate in an environment that gets increasingly colder as the aircraft climbs to altitude, so Stirling aircraft engines, unlike any other type of aircraft engine may derive some performance benefit from climbing to altitude. The communities near airports would benefit from the extremely quiet operation that is possible. Stirling engines make sense where these conditions are met:

1. There is a premium on quiet.
2. There is a very good cooling source available.
3. Relatively slow revolutions are desired.
4. Multiple fuel capacity is desired.
5. The engine can run at a constant power output.
6. The engine does not need to change power levels quickly.
7. A warm-up period of several minutes is acceptable.

LOW TEMPERATURE DIFFERENCE ENGINES

In 1983, Ivo Kolin, a professor at the University of Zagreb in Croatia, demonstrated the first Stirling engine that would run on a heat source cooler than boiling water. After he published his work, James Senft, a mathematics professor at the University of Wisconsin, River Falls built improved engines that would run on increasingly small temperature differences, culminating in an elegant and delicate Stirling engine that would run on a temperature difference smaller than 1°F.

These delicate engines provide value as educational tools, but they immediately inspire curiosity into the possibility of generating power from one of the many sources of low temperature waste heat (less than 100°C) that are available. A quick look at the Carnot formula shows that an engine operating with a hot side at 100°C and a cold side at 23°C will have a maximum Carnot efficiency of [((373 K–296 K)/373 K) × 100] about 21 percent. If an engine could be built that achieved 25 percent of the possible 21 percent Carnot efficiency it would have about 5 percent overall Carnot efficiency.

That figure seems quite low until one realizes that calculating Carnot efficiency for an engine that uses a free heat source might not make much sense. For this type of engine it would probably be more worthwhile to first consider what types of engines can be built, then use dollars per watt as the appropriate figure of merit.

Stirling engines that run on low temperature differences tend to be rather large for the amount of power they put out. However, this may not be a significant drawback since these engines can be largely manufactured from lightweight and cheap materials such as plastics. These engines could be used for applications such as irrigation and remote water pumping.

CRYOCOOLERS

It isn't immediately obvious, but Stirling engines are a reversible device. If one end is heated while the other end is cooled, they will produce mechanical work. But if mechanical work is input into the engine by connecting an electric motor to the power output shaft, one end will get hot and the other end will get cold. In a correctly designed Stirling cooler, the cold end will get extremely cold. Stirling coolers have been built for research use that will cool to below 10 K. Cigarette pack sized Stirling coolers have been produced in large numbers for cooling infrared chips down to 80 K. These micro Stirling coolers have been used in high end night vision devices, antiaircraft missile tracking systems, and even some satellite infrared cameras.

STORAGE

Energy storage is having energy in reserve for future needs. While it takes millions of years to create huge energy stores in the form of coal, oil, natural gas, and uranium, humans are able to quickly manufacture energy stores such as batteries, and to build dams to store the gravitational energy of water. Although batteries and dams are very useful and important storage systems, the amount stored is very small compared to natural stores. These natural energy stores are large,

Solar panels on a house roof in Soldier's Grove, Wisconsin. (Corbis Corporation) but finite, and it is important to realize that they will not last forever.

The food a person eats is a personal energy store banking on photosynthesis. In photosynthesis, gaseous carbon dioxide, liquid water, and solar energy interact to produce solid carbohydrates, such as sugar and starch, and gaseous oxygen.

$$\text{carbon dioxide} + \text{oxygen} + \text{solar energy} \rightarrow \text{carbohydrates} + \text{oxygen}$$

Solar energy for photosynthesis is converted and stored in the molecular bonds of carbohydrate molecules. When the process is reversed by combining carbohydrates with oxygen, stored energy is released. We literally see and feel the results when wood is burned to produce heat. A flame is not produced when carbohydrates and oxygen interact in the human body, but the process is similar and appropriately called "burning." The energy we derive from food for performing our daily activities comes from burning carbohydrates.

About 80 percent of the electric energy used in the United States is derived from stored energy in coal. The stored energy has its origin in photosynthesis. Coal is the end product of the accumulation of plant matter in an oxygen-deficient environment where burning is thwarted. Formation takes millions of years. Proven reserves of coal in the United States are upwards of 500 billion tons, a reserve so great that even if coal continues to be burned at a rate of over one billion tons per year, the reserves will last for hundreds of years.

Stores of petroleum, from which gasoline is derived, are vital to industry and the transportation sector. Stores of natural gas are important to industry and the residential and commercial sectors. Both petroleum and natural gas result from the decay of animal and plant life in an oxygen-deficient environment. Solar radiation is the source of the energy stored in the molecules making up all the fossil fuels (i.e., coal, petroleum, and natural gas). The energy is released when petroleum and natural gas are burned. Economic considerations figure prominently in determining proven reserves of petroleum and natural gas. To be proven, a reserve must provide an economically competitive product. There may be a substantial quantity of an energy product in the ground, but if it cannot be recovered and sold at a profit, it is not proven. There are substantive quantities of energy stored as oil in shale deposits in the western United States, but, to date, extracting them are not economical. Proven reserves of oil and natural gas for the United States are around thirty-five billion barrels and 250 trillion cubic feet, respectively. Consumption rates of about three billion barrels per year and twenty trillion cubic feet per year suggest that they will be depleted in the early part of the twenty-first century. But economic conditions can change and new proven reserves will emerge.

An early Energizer watch battery, held against shirt cuff button for size comparison. (Corbis Corporation)

For several decades, the United States has relied on foreign sources of petroleum energy. The availability of petroleum from foreign sources is subject to political instability and changes in the economies in these countries. To guard against losses in petroleum supplies, the United States has established the Strategic Petroleum Reserve. The reserve is an emergency supply of crude oil stored in huge underground salt caverns along the coastline of the Gulf of Mexico. Upwards of one billion barrels of petroleum are stored in six sites along the coasts of Texas and Louisiana.

A battery stores electric energy. Although the concentration of energy is small compared, for example to gasoline, we see a myriad of uses of batteries in radios, cellular phones, flashlights, computers, watches, and so on. The public's demand for these portable products is ever increasing, and scientists strive to develop lighter and better batteries.

An electric power plant generates huge amounts of electric energy, but it does this only on demand by consumers because there is no economical way to store electric energy. Electric power plants are massive units that are difficult to shut down and expensive to start up. At night when consumer demand is low, electric utilities are willing to reduce the cost of electric energy in order to keep the plants operating. During the night, it is often economical to use electricity to run pumps that move water to an elevated position. Then when demand for electricity is high, the water is released to run turbogenerators at a lower level. Such a system is called a pumped storage unit. There are fourteen of these in the United States, each having an electrical output of more than 240 megawatts, which is comparable to a large electric power plant.

A nuclear power plant converts energy stored in uranium and plutonium. Uranium occurs naturally; plutonium is made through nuclear transmutations. The nucleus of a uranium atom consists of protons and neutrons that are bound together by a nuclear force. The stored energy in a uranium nucleus is associated with nuclear forces holding the nucleus together. Energy is released in a nuclear reactor by nuclear (fission) reactions initiated by interaction of neutrons with uranium nuclei. Typically, a single reaction produces two other nuclei and three neutrons. Schematically

$$\mathrm{n} + \mathrm{U} \rightarrow \mathrm{X} + \mathrm{Y} + 3\mathrm{n}.$$

Importantly, the neutrons and protons in the reacting products (n + U) are rearranged into lower energy configurations in the reaction products (X + Y + 3n), and stored energy is released. A single nuclear fission reaction releases upwards of 10,000,000 times more energy than a chemical reaction in the burning of coal. Whereas a coal-burning electric power plant producing 1,000 megawatts of electric power must burn some 10,000 tons of coal per day, a nuclear power plant producing comparable power will need an initial loading of around a hundred tons of uranium of which about twenty-five tons are changed each year.

Water freezes and ice melts at 0°C (32°F). Melting requires 334 kilojoules (kJ) of energy for each kilogram (kg) of ice turned to water. The 334 kJ of energy are stored in the one kg of water. The 334 kj of energy must be removed from the one kg of water in order to convert the water back to ice. If heat is added to water at temperatures between the freezing point (0°C) and boiling point (100°C), the temperature of the water increases 1°C for every 4200 J added to a kilogram of water. The 4,200 kJ/kg °C is called "the specific heat" of water. The specific heat is a property of all materials. Importantly, the specific heat is substantially larger for water than for nearly all other substances in nature. Heat transferred to a substance to increase the temperature is called "sensible heat." The energy added stays within the substance making the substance a reservoir of thermal energy. Because of its high specific heat, water is a superb coolant for an automobile engine or steam turbine. Fortunately, water is cheap and usually available. In a climate where the coolant in an automobile engine might freeze, antifreezes keep this from happening by lowering the freezing point of the coolant.

Solar energy systems are very popular among many for environmental reasons, and people are even willing to pay more for this "clean" energy. The biggest problem with these sources is that the time when energy is available does not necessarily match when it is needed. One way that solar system designers address this problem is by incorporating a thermal storage system. A solar-heated house or commercial building must have a thermal energy store to provide heat at night or on days when clouds block solar radiation. Solar heating systems using roof-top collectors often use water or rocks to store thermal energy. Some solar houses employ large, south-facing windows to maximize the amount of solar energy entering the house. The solar energy may warm a brick or concrete wall or floor so that it becomes a thermal energy store that provides heat when needed at night.

STORAGE TECHNOLOGY

MOTIVATION

Electric utilities are expected to provide uninterrupted service. To fulfill this expectation, utilities use a range of energy storage technology so that electricity can be produced in the most economical and efficient manner. Gasoline refined from crude oil is drawn from an underground storage tank when a driver replenishes the fuel in an automobile. Imagine the difficulty meeting the demands of the drivers if the crude oil had to be refined at the time of the replenishment. The task is imposing because consumer demand varies throughout the day and throughout the year. The same is true for utilities providing electricity to consumers.

A large electric power plant produces electricity on consumer demand, and the utility must be prepared to meet demands that vary throughout the day, the week, and the year. The demand is divided roughly into three parts termed baseload, part time, and peak. Base load demand is met with large units having slow response. Usually these works are fueled by fossil fuels, such as coal and natural gas, or uranium. In some cases the electricity may come from a large hydroelectric plant. Generation of baseload electricity is the most economical of the three types. If demand were constant, only baseload electricity would be needed and the cost of electricity to consumers would be minimized. The demand labeled part time is generally provided by the large plants used for baseload. Because of the difficulty of having to start and stop large systems, electricity produced in the part time mode is some two to three times more expensive than baseload electricity. Peak demands requiring fast response are met with oil- and gas-fired turbo-generators, hydroelectricity, pumped-storage hydroelectric systems, purchases from other utilities and, in a few cases, wind-powered generators and solar-powered systems. Peak electricity may cost three to four times more than baseload electricity. Apart from the generating capacity needed to meet peak demands, the distribution system of transmission lines and associated equipment must be able to handle the electric power. Economically, it is in the interest of both the electric utility and the consumer to make an effort to “flatten out” the demand curve. To do this, a utility sometimes encourages consumers to do chores requiring electricity at night by offering a cheaper night rate. It is also in the economic interest of both consumers and utilities if the utilities can produce electric energy during the off-peak times, store the energy in some form, and then convert the stored energy to electric energy during times of greater need. In addition to using pumped storage hydroelectric systems or flywheels for this scheme, there are serious efforts for developing energy storage technology using compressed air, superconducting magnets, and batteries.

EVALUATING ENERGY STORAGE SYSTEMS: ENERGY DENSITY

Every source of energy has a certain mass and occupies a certain amount of space, and both mass and volume are important practical considerations. Clearly, some energy storage systems will be rejected simply because their physical size and cost are impractical. Accordingly, developers of energy storage systems need to know the energy density, measured in kilowatt-hours per kilogram (kWh/kg) or in kilowatt-hours per cubic meter (kWh/m^3). Determining the energy densities for a pumped hydroelectric storage system, which is a practical scheme in many areas of the United States, is straightforward and provides a basis of comparison for other energy storage technologies.

A pumped hydroelectric system makes use of the potential energy of an elevated mass of water. The potential energy (E) of a mass (m) of water elevated a height (H) is $E = mgH$, where g is the acceleration due to gravity. Dividing both sides of this equation by the mass produces $E/m = gH$, which is the energy density in kWh/kg. For water elevated a height of 100 meters, the energy density is about 1000 kWh/kg.

To measure the energy density in kWh/m^3, we relate the mass (m) to mass density (ρ) and volume (V) by $m = \rho V$. The potential energy may then be written as $E = \rho VgH$. Dividing both sides of $E = rVgH$ by the volume produces $E/V = \rho gH$, which is the energy density in kWh/m^3. For H = 100 m the energy density of water is about 0.3 kWh/m^3. Because pumped storage technology is workable, the energy density provides a benchmark for evaluating other energy storage systems.

COMPRESSED AIR ENERGY STORAGE (CAES)

Compressed air can be stored in a container until it is released to turn the blades of a fan or turbine. To determine the energy density of the compressed air, one has to make thermodynamic assumptions about the process. For reasonable assumptions, the energy density is about 2 kWh/m^3, or about 10 times the energy density of water in a pumped storage hydroelectric system. Compressed air energy storage is very attractive from energy density considerations. On the other hand, the volume required for significant amounts of energy is quite large. For example, storing a million kilowatt-hours of energy requires a volume of about 500,000 cubic meters. For comparison, a box 50 meters wide and 100 meters long (roughly the size of the playing area of a football field) and 100 meters high has a volume of 500,000 cubic meters. At this time, there are two operational compressed air energy storage facilities in the world, and both use natural underground reservoirs for the compressed air.

The compressed air energy storage unit operated by the Alabama Electric Cooperative in McIntosh, Alabama utilizes a 19-million cubic foot underground cavern. Air is released during peak periods, heated with natural gas, and expanded through a turbogenerator to produce 110 megawatts of electric power. There is sufficient energy stored to deliver power for 26 hours. A compressed air energy storage system in Huntoff, Germany employs 300,000 cubic meters of space in an underground cavity in a natural salt deposit. Electric generators in the system produce 300 megawatts and there is sufficient energy stored to operate the generators for 2 hours. The Electric Power Research Institute (EPRI) has estimated that more than 85 percent of the United States has geological characteristics that could accommodate an underground CAES reservoir. If the disparity in costs between baseline and part-time/peak load increases, the use of more underground CAES reservoirs is likely.

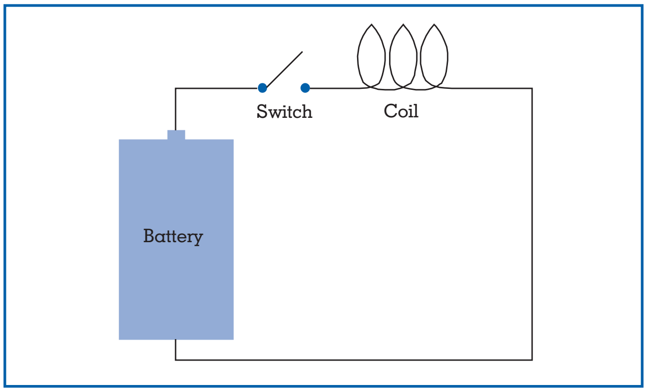

Figure 1.
An elementary electric circuit.

SUPERCONDUCTOR MAGNETIC ENERGY STORAGE (SMES)

Electric utilities can anticipate peak demands and be prepared to meet them. On the other hand, there are short-term fluctuations in the power levels that a utility cannot anticipate but must handle quickly. Superconducting magnetic energy storage (SMES) is a technology that has potential for meeting both anticipated peak demands and those requiring quick response.

Imagine an electric circuit consisting of a battery, a switch, and a coil of wire (Figure 1). There is no electric current in the coil when the switch is open. When the switch is closed, a current is initiated and a magnetic field is produced in the region around the wire. This is an example of the Oersted effect. As long as the magnetic field is changing, voltage is induced in the coil according to an example of Faraday's law. The induced voltage provides opposition to the current established by the battery, this opposition is the essence of Lenz's law. Eventually the current will stabilize at a constant value and a constant magnetic field is established. Electric forces provided by the battery do work to establish the magnetic field and this work gives rise to energy stored in the magnetic field. The energy can be recovered when the switch is opened and the current eventually falls to zero. The amount of energy stored in the magnetic field depends on the electric current and a property of the coil called the inductance. Inductance depends on the construction of the coil and the medium in which the coil is placed. Formally, the magnetic energy is given by $E = (1/2) LI^2$, where L and I represent the inductance and the electric current. For any coil, it would appear that any amount of magnetic energy could be stored by producing a sufficiently large current. However, the wire from which the coil is made has electric resistance, and the combination of current and resistance produces heat. Accordingly, the battery must continually do work and expend energy in order to maintain the current. For ordinary materials, there is a practical limit to the current that can be maintained. Despite the practical limitations imposed by heat considerations, there are many practical applications utilizing energy stored in the magnetic field of a current-carrying coil.

The electrical resistance of most conductors, metals in particular, decreases as the temperature of the conductor decreases. For some pure metals and compounds of the metals, the resistance decreases with temperature as usual, but at some critical temperature the resistance drops identically to zero. The resistance remains zero as long as the material is maintained at a temperature below the critical temperature. Such a material is termed a superconductor and the zero resistance state is termed superconductivity. Mercury, first observed to be a superconductor by Heike Kamerlingh Onnes in 1908, has a critical temperature of 4.2 K (room temperature is approximately 300 K). Since Onnes's discovery several other superconductors have been identified but until 1986 the material with the highest critical temperature, 23 K, was a compound of niobium and germanium (Nb_3Ge). In spite of requiring a very low temperature, several very important technologies involving large magnetic fields evolved, including magnetic resonance imaging for medical diagnostic purposes, and superconducting magnets for particle accelerators and nuclear fusion research. Technology for magnetic energy storage never advanced significantly because of the economics involved in producing the low temperatures required for the superconducting state of existing materials.

The optimism about inexpensive superconductivity was stimulated by two notable discoveries. In 1986 Alex Muller and Georg Bednorz discovered a new class of superconductors, ceramic in form, having a critical temperature of 35 K. In 1987 Paul Chu produced a compound that became superconducting at 94 K. While 94 K is still a very low temperature, it is easily and inexpensively attainable with liquid nitrogen (77 K). Materials with critical temperatures as high as 135 K have been found and there is speculation that someday a material may be discovered that is superconducting at room temperature. Because the critical temperatures of these superconductors are considerably higher than that of their metallic counterparts, the phenomenon has been labeled "high-temperature superconductivity" or HTS.

Although no heat is produced by current in a superconductor, the current cannot be made arbitrarily large because the superconducting state vanishes for a well-defined critical current. Because magnetic energy is proportional to the square of the current, research on HTS for magnetic energy storage focuses on developing materials with high critical current. The technology has proceeded to the development stage. For example, a superconducting magnetic energy storage system for quick response to voltage fluctuations has been field tested at Carolina Power and Light. Energy is drawn from the magnetic storage system and fed to the electrical system during moments when power drops because of faults in the electrical system.

BATTERY STORAGE

When a battery, such as the lead-acid type used in automobiles, is charged with an electric generator, an electric current stimulates chemical reactions that store energy. When a device, such as a light bulb, is connected to the battery's terminals, the chemical reactions reverse and produce an electric current in the bulb. The energy stored by a battery is relatively low. For example, a lead-acid battery has an energy density of about 0.05 kWh/kg. Nevertheless, batteries are extremely useful and they play an increasingly important role in a variety of energy storage applications for electric utilities.

In the electric power industry, batteries are used in conjunction with other ways of generating electricity. For example, a home may employ photovoltaic cells or a wind turbine for electricity. However, photovoltaic cells cannot operate without sunlight and wind turbines cannot produce electricity without wind. Batteries charged by photovoltaic cells or wind turbines in off-use times or by the electric utility at hand can provide electricity when the local system is inoperative. The electric power delivered in this mode tends to be in the range of 1 to 4 kilowatts. Batteries have been used for this purpose since the 1970s.

Electricity is delivered to a home or industry at a nominal voltage and frequency. For a home, the voltage is nominally 230 volts, which is reduced to 115 volts for most appliances, and the frequency is 60 hertz. For a variety of reasons, either (or both) the voltage and frequency may change. For example, if the demand during a peak period is excessive, the voltage level may drop. Voltage fluctuations are fairly common and sometimes abrupt. Brief fluctuations sometimes cause computers, for example, to "crash." Avoiding system crashes is important because they are costly and reduce productivity. Although the technology of quality power storage systems that can quickly correct voltage fluctuations is not widespread, there is interest in them and development is proceeding. These systems would likely be designed for a commercial establishment, an industrial complex, or a village, and would have power capability between 30 and 100 kilowatts.

A typical large coal-burning or nuclear-fueled electric power plant is capable of delivering about 1,000 megawatts of electric power, and an average home during peak usage needs about 3 kilowatts of electric power. Some 330,000 homes could be served if all the power from a large plant went to homes during peak usage. Because the power involved is significant, changes in demand during peak periods can be significant, and a utility must be prepared to meet them. One way of doing this is with storage batteries. The technology is complicated by having to change the alternating current (a.c.) voltage produced by a generator to direct current (d.c.) for charging the batteries and then changing d.c. voltage from the batteries to a.c. to meet peak demands. Nevertheless, the technology exists. The power delivered by these battery storage systems tend to be on the order of megawatts. In 1997, more than 70 megawatts of capacity was installed in ten states across the United States.

Type	*Energy* (kWh/kg)	*Power* (kW/kg)
Lead acid	0.050	0.200
Nickel cadmium	0.053	0.160
Nickel metal hydride	0.070	0.175
Sodium sulfur	0.085	0.115
Lithium iron sulfide	0.095	0.104
Zinc bromine	0.075	0.045
Long-term goal of the U.S. Advanced Battery Consortium	0.2	0.4

Table 1.
Status of Battery Technology in 1999

The low energy density of batteries is a major deterrent to more widespread use in the electric utility sector. Although progress in developing better batteries has been slow and discouraging, research continues. The status of battery development at the time of this writing is presented in Table 1. A battery subscribing to the long-term goal of the United States Advanced Battery Consortium would still have an energy density about 70 times less than that of gasoline (about 15 kWh/kg).

COOL THERMAL ENERGY STORAGE

Electric power usage peaks in summer in most areas mainly because of demand for air conditioning. If consumers could satisfy their air conditioning needs without operating energy intensive conventional systems, then the electric utility could reduce the peak demand. This can be accomplished using electricity for conventional refrigeration in non-peak periods, usually at night, to remove heat from a storage medium such as water or materials that undergo a phase change around room temperature. Then, during peak demand periods, the storage medium is tapped for air conditioning and other cooling purposes. During the 1970s and early 1980s, utilities extended cost incentives to customers for installing thermal storage systems. The financial incentive was based on the cost of constructing new power plants. Offering a rebate to customers who shifted peak demand was viewed as a very cost-effective alternative to acquiring new generating capacity, and thermal storage was seen as one of the best ways to shift demand.

There are over 1,500 cool thermal energy sytems in operation in the United States. Eighty seven percent of all systems employ ice storage because it requires smaller tanks and can be installed in a large range of configurations. It is a well-developed technology and a number of systems have been installed. For example, an ice-storage plant located near the Palmer House Hotel in Chicago cools several commercial buildings in the Loop area.

FUTURE GROWTH

Better energy storage technology benefits everyone. For consumers, batteries that are lighter and longer lasting and that recharge more rapidly will continue to accelerate the growth in cordless technology, technology that offers consumers ever greater mobility. For the utilities, more and better storage options limit the need to invest in peak capacity generation, and thereby help lower the electric rates of customers. And for industry, whose rates are discounted if demand can be shifted away from peak periods, there is a great financial incentive to install storage systems. With so many benefits from research and development, the significant storage technology advances in the twentieth century should continue well into the twenty-first century.

SUBSIDIES AND ENERGY COSTS

Subsidy is a transfer of money from government to an individual or a firm to stimulate undertaking a particular activity. Subsidies and subsidy-like programs are major parts of energy policies. However, such energy grants are only one example of government aid and not the most important examples. The basic economic principle that people respond favorably to financial incentives implies that such transfers stimulate the action that is aided.

More broadly, subsidy can comprise any government policy that favors an action. Such assistance includes tax provisions that lessen the burdens on some activities, and regulations designed to promote an activity. Government ownership with regular deficits, whether or not consciously planned, is another subsidy mechanism. Particularly in the United States, where the government is a major landowner, access to government property at below-market prices is another possible form of subsidy. An additional source of subvention is regulation causing the affected firms to favor (cross-subsidize) some customers.

Conversely, in principle but not in practice, completely nongovernmental subsidy could arise in energy. Private subsidies do occur, as with parental support or patronage of the arts. These illustrations suggest that the incentives to private aid are limited. More critically, only governments have the taxing, spending, and regulating powers to facilitate extensive subsidies.

THE NATURE AND EFFECTS OF SUBSIDIES

Implementation can differ widely. Aid may be freely and unconditionally available to anyone undertaking the favored activity, or restrictions may be imposed.

The awards may have an upper limit, be dependent on the income or other characteristics of the recipient, or require the beneficiary to make a contribution from its own resources. Subsidies may be awarded by holding contests to select beneficiaries.

The impact of a subsidy depends upon many factors. These include first the magnitude of the gap between costs and what can be earned in an unregulated market. To attain any goal, the subsidy must fully cover that gap. The more of an activity the government wants to encourage, the more aid is needed. The effectiveness of an outlay depends upon the elasticity (responsiveness to incentives) of production and consumption. In principle, everything from a thriving new industry to total failure can emerge.

THE ECONOMICS OF SUBSIDIES

Economic theory stresses efficiency—encouraging placing resources in their most valuable uses. An extensive theory of market failure shows when markets might fail to lead resources to their most valuable uses and when subsidies could be desirable. The failures most relevant to energy subsidies are (1) publicness, (2) cost-recovery problems, and (3) imperfect knowledge. Publicness is the simultaneous consumption of a product (or the absorption of damages) by all of society. Cost-recovery problems stem from the existence of economies of scale exist such that firms cannot price efficiently without losing money. Imperfect knowledge means that market participants may lack the knowledge needed to make the most efficient choice.

Economists differ widely in their views on the practical importance of these market failures, on what remedies are appropriate, and whether governments can satisfactorily remedy the problem. One clear principle is that the problem be identified as precisely as possible and the assistance be targeted as closely as possible to the problem. For example, if information is inadequate, providing knowledge about options would be preferable to aiding a specific option. The three justifications for subsidies set a *minimum* test of aid that many programs fail to pass.

Further problems arise in moving from principles to practice. To implement an assistance program, quantitative estimates of the magnitude of market failure must exist. Accurate measurement is a formidable problem. Determination of impacts is often difficult. Disputes usually arise about the importance of subsidy to market outcomes. Moreover, with complex tax systems, it is difficult to determine what comprises equal treatment of all activities and what is a favorable (tax-subsidy) measure.

Economists also recognize that another concern is about equity, the fairness of the distribution of income. Economists differ as much as everyone else about the proper criteria of equity. However, economic principles create considerable agreement about how best to attain any given equity goal. A primary principle is that the aid should go to people rather than specific commodities.

Several considerations are involved. First is a preference for consumer sovereignty, allowing recipients to choose how to spend. Second, being a consumer or a producer of a particular commodity is a poor indicator of whether assistance is deserved. Everyone from the poorest residents (but not the homeless) to the richest Americans are residential electricity consumers. Third, commodity-specific policies tend more to aid producers in the industry than consumers. Politicians often dispute these appraisals and institute subsidies on equity grounds.

THE PRACTICE OF ASSISTANCE

Energy subsidies are widely attacked from many different viewpoints about public policy. Thus, among economists, both severe critics of the oil companies, such as Blair, and those such as Adelman and McAvoy who stress defective government policy criticize the subsidies. Environmentalists and other supporters of active government often feel that too many programs aid the unworthy.

Others, however, suggest reorientation to more appropriate realms. The valid point is that uncorrected market failure may prevail. However, often the arguments for subsidies are misstated. Some suggest that the existence of inappropriate subsidies elsewhere justifies aid to those excluded. The preferable reaction to bad existing subsidies is their removal. Past waste cannot be recovered.

PRESERVING ENERGY INDUSTRIES

A major element of energy policy in leading industrial countries such as the United States, Germany, Britain, Japan, and France has been provision of substantial aid to existing energy industries. Part of the aid provided by governments went to meet commitments to provide pensions to retired workers. Subsidy-like measures such as trade restrictions, regulations, and forced purchase plans also were critical parts of the assistance.

Programs were instituted to preserve coal production in Western Europe and Japan. Every involved country (Britain, Germany, France, Spain, Belgium, and Japan) transferred taxpayers' money to the coal industry. The programs started in the period between the end of World War II and the resurgence of the oil supply in the late 1950s.

Germany initially had a particularly complex program. Coal sales to the steel industry were largely subsidized by direct government grants. A tax on electricity consumption partially subsidized electric-power coal use. Electricity producers were forced to contract to buy German coal and cover in higher production costs the substantial portion of their costs that the electricity tax failed to repay. In the late 1990s, a court decision invalidating the tax and the expiration of the purchase contract forced a shift to using general tax revenues to provide aid.

Every one of these programs has contracted. Costs mounted, forcing cutbacks in how much coal output was maintained. Belgium allowed its coal industry to die. Britain cut off aid, ended government ownership, and left the industry to survive on its own. France and Japan are committed to ending subvention. Germany still is willing only periodically to reduce the output target goals used to orient assistance. The nominal defenses relate to alleged national security and sovereignty issues. However, critics contend that the goal is an unwise retardation of transfer of employment from the industry.

Reliance on forcing consumers to subsidize is hardly unique to German coal. U.S. "public utility" regulation long has required unequal pricing among consumers. Historically, emphasis was on rates that caused industrial and commercial users to subsidize residential users. This has encouraged industrial customers to secure rate reforms. These are equity measures that are subject to the criticisms stated above.

STIMULATING ALTERNATIVE ENERGY

Since the energy shocks of the 1970s, other efforts to subsidize energy have arisen. One often-used justification is inadequate foresight. For example, encouraging specific forms of nonutility generation of electricity was part of 1978 U.S. federal energy legislation. That legislation gave individual states discretion about evaluating the economic attractiveness of the types of nonutility generation encompassed. These included various special sources, such as solar and wind. The most important category by far was "cogeneration." This was a new name for a long-established (but, at the time, waning) practice of simultaneously producing electricity and steam in industrial plants and at times selling some of the electricity to utilities. States anxious to promote such alternatives issued predictions of future costs upon which to base current decisions. Typically, the forecasts exceeded the prices that actually prevailed. Thus, governments acting to offset allegedly defective private insight provided forecasts to the private sector that turned out to be inaccurate.

OIL AND GAS PRICING

Complex price-control plans have been devised. Examples include cost-based prices of electricity and the multitiered pricing systems associated with U.S. oil and gas regulation. The U.S. government and many other governments are major producers of electricity. At a minimum, this involves subsidies from the failure to charge prices that fully recover costs. Beyond this, much of the electricity is from waterpower and is sold at cost (or, more precisely, a measure of costs based on economically defective regulatory accounting techniques) rather than market clearing prices. The profits that would result from such market prices thus are transferred to those lucky enough to be charged the lower price. Since the power goes into the transmission network and loses its identity, the actual users cannot be identified. Arbitrary rules are devised to determine which of those drawing from the grid are favored with low prices. Historically, access was based on the ownership of the purchasing utilities. Government and cooperative-owned utilities and thus all their customers were favored. Ultimately, the conflict of this rule with the traditional preferences for households was recognized. The rules for the Pacific Northwest, where the largest portion of federal waterpower is produced, were changed in the late 1970s so that household users, whatever the ownership of their distribution utility, received the low price.

The oil and gas price-control systems were complex devices that subdivided each fuel into numerous categories based on such considerations as the time of discovery and the difficulty of extraction. Each category was subject to different rules about initial prices; allowable price adjustments; and, in the case of gas, the duration of control. This system had the potential, realized in gas, for low-cost producers to subsidize high-cost producers. A further complication was that the operative law required charging households lower gas prices than industrial users. The result was the signing of numerous contracts at unsustainably high prices.

Further government regulation that totally changed how natural gas was distributed resolved this difficulty. Historically, pipeline companies were required to act as purchasers and resellers of gas. The new approach of the 1980s limited pipelines to selling transmission services. Customers of the pipelines purchase the gas directly from producers. By exiting from gas purchasing, the pipelines could similarly back out of unattractive contracts.

DEPLETION ALLOWANCES

Those concerned with proper pricing of energy often also allude to a special provision of the U.S. Internal Revenue Service code that gives tax favors called depletion allowances to mineral production. In particular, producers can reduce their taxable income by a percentage of total gross income (that differs both among minerals and over time for individual minerals), but the deduction is capped at 50 percent of net income without the allowance. In 1963, Stephen L. McDonald presented the first extensive analysis of these provisions and found no reason why they should exist. His updates and others have supported this conclusion. The assistance to large companies in the oil and gas sector was eliminated and aid to smaller producers was lowered in the legislation in 1975.

ENERGY RESEARCH

Market failure arguments exist for government aid to some forms of research. Since the results of research are so broadly disseminated, it may be prohibitively expensive for private investors to charge the users of their discoveries. Thus the inventors are undercompensated, and underexpenditure arises unless the government provides aid. In addition, some theorists contend (and others deny) that governments are more farsighted than private firms.

Nuclear power long has been a major element in government energy assistance. Some critics of nuclear power argue that this aid was wasted because no nuclear technologies came close to recovering the investments made and did not generate a surplus that repaid government outlays. A less severe assertion is that only the initial work on light-water reactors (the dominant technology) was justified. Some argue that even aid to that technology was extended past the time at which the private sector was ready to undertake the needed further steps.

Several alternative technologies that were heavily supported failed to become commercially viable. The most obvious case was the fast breeder reactor. Such reactors are designed to produce more fissionable material from nonfissionable uranium than is consumed. The effort was justified by fears of uranium exhaustion made moot by massive discoveries in Australia and Canada. Prior to these discoveries extensive programs to develop breeder reactors were government-supported. In addition, several different conventional reactor technologies were aided. The main ongoing nuclear effort is research to develop a means to effect controlled fusion of atoms.

The greatest success in new fossil fuel technology has a distant government-aid basis. The combustion turbine is a stationary adaptation of the jet engine. The combustion turbine's development and improvement were aided by government military aircraft programs. However, turbine manufacturers independently developed the electric-power version.

Since the decline of the U.S. coal industry from 1946 to 1960, many proposals emerged (and received government funding) to promote coal use. One type of effort sought to transform coal into a more attractive fuel. The options ranged from producing a better solid fuel to synthesizing natural gas and petroleum products. Efforts also were directed at facilitating coal use. These included design of better coal-using devices (such as a longtime dream of a viable coal-using locomotive technology). Radically new methods of generating electricity such as fuel cells and magnetohydrodynamics were advocated. Such technologies might be desirable whatever the fuel choice but also might particularly encourage coal use. Other suggestions involve noncoal alternatives such as petroleum in very heavy crude oil, tar sands, and oil shale. Once again, fears of depletion of oil and gas are used as reasons for the aid. Despite extensive government aid, these technologies failed to succeed.

South Africa massively invested in an oil and gas substitution program involving synthesis from coal; the effort was at least partially motivated by international attempts to curtail South African access to conventional sources of oil. A U.S. effort in the Carter administration of the late 1970s produced only one modest coal gassification venture that continued operation. The latest drives to find replacements for the internal-combustion engine for automobiles are behind the ambitious schedule established in 1992 U.S. energy legislation.

Government efforts to promote solar power and wind have failed to date to produce substantial results. World data for 1997 indicate that only 0.41 percent of consumption was geothermal, solar, or wind; 0.39 percent was geothermal and the others accounted for 0.02 percent. The 1999 U.S. percents are 0.06 geothermal, 0.04 solar, and 0.02 wind.

It is widely agreed among economists that market failures in energy exist. However, the record in practice has produced widespread criticism of implementaion of energy subsidies.

SUPPLY AND DEMAND AND ENERGY PRICES

The quantity of energy supplied is the flow of energy brought onto the market, and the quantity of energy demanded is the amount of energy purchased for a particular period of time. Quantity can be measured in terms of the number of kilowatt hours produced by an electric generator in a day, the number of barrels of oil or cubic feet of gas brought to the market in a month, or the number of tons of coal produced and sold in a year. Primary energy takes the form of fossil fuels or electricity from primary, sources including hydro, nuclear, solar, geothermal, and biomass, while secondary energy is electricity generated from fossil fuels.

DATA SOURCES

Data on the quantity of energy supplied, called energy production, are available from a variety of government, trade association, and international sources. Some of the better sources include the U.S. Energy Information Administration, the American Petroleum Institute, the International Energy Agency, and the United Nations. Secondary energy quantity is reported as net or gross. Net energy is the amount of energy produced and gross is the amount of primary energy required to produce it.

Quantities of energy demanded and supplied are reported in a bewildering variety of ways. The three typical units of measurement are energy content, volume and weight. Energy content includes British thermal units in the United States or kilocalories and kilojoules in the rest of the world, as well as coal or oil equivalents. Kilowatts are the most common units of measurement for electricity and are sometimes applied to other energy sources as well. Weights are most often expressed as short tons, long tons or metric tonnes. Volumes are expressed as barrels, cubic feet, gallons or liters.

DETERMINANTS OF ENERGY SUPPLY

The quantity of energy supplied is a function of the economic and technical variables that influence the cost of bringing the energy source to market and the price that a supplier receives for the energy source in the market. For example, in a competitive market the quantity of coal (Q_s) supplied at the mine mouth is a function of the price received for the coal (P); the price of the capital necessary to produce the coal, such as drag lines, cutting tools, and loaders (P_k); the price of labor, which includes wages, salaries, and indirect labor costs (P_l); the price of using land or any other natural resource or other factor of production (P_n); and technical variables that could include the technologies available and the geology of the deposits (T). An increasing T in this context represents better technology or more favorable geology.

Prices of other related goods also influence quantity supplied. For example, uranium production may produce vanadium as a byproduct. Thus, uranium and vanadium are complementary goods or are goods produced together. When the price of vanadium increases, uranium production becomes more profitable and will increase. Gas found with oil is called associated gas and is considered complementary to oil in production. If the price of oil goes up, drillers may look harder for oil and find more gas to produce as well.

Alternatively, goods may be substitutes in production. If the price of other minerals increase, coal producers may look for other minerals and produce less coal. If gas is nonassociated, it is found without oil and is a substitute for oil in supply rather than a complement. If the price of natural gas, a substitute good (P_s) or a good that could be produced instead of oil, increases, drillers may spend less time looking for oil and more time looking for and producing nonassociated gas, thus decreasing oil production.

Governments often interfere in energy markets and their policies may influence quantity supplied. For example, environmental regulations (E_r) that require less pollution or more safety when producing fuels decrease the quantity of fuel supplied. Such regulations in the United States include the removal of sulfur from fuels, the addition of oxygenates to gasolines in some areas of the country, and more safety in coal mines. Additional environmental regulations increase cost and should decrease quantity supplied. Aggregate market supply also depends on the number of suppliers (#S) in the industry.

We can write a general supply function as follows:

$$Q_s = f(+ P + P_c - P_s - P_l - P_k - P_n + T - E_r + \#S)$$

The sign before each variable indicates how the variable influences quantity supplied. A minus sign indicates they are inversely related and a positive sign indicates they are directly related. Thus, in the example of coal, raising the price of coal is likely to increase quantity supplied, whereas raising the price of labor is likely to decrease the quantity supplied.

For nonrenewable energy sources such as fossil fuels, expectations about the future price and interest rates influence the current quantity supplied. Expectations of higher future prices should cause less production today and more production tomorrow.

ELASTICITY OF SUPPLY

A measure of how responsive quantity supplied is to a variable (say price) is called the elasticity of supply with respect to that variable. Elasticity of supply is the percentage change in quantity divided by the percentage change in the variable in question or

$$\frac{\%\ \text{change}\ Q_5}{\%\ \text{change}\ P}$$

If the supply price elasticity of oil is 1.27, it follows that if the price of oil increases by 1 percent, the quantity of oil supplied increases by 1.27 percent. A cross elasticity of supply indicates how quantity produced is related to another price. For example, if the cross elasticity of oil supply with respect to the price of gas is 0.15, then if the price of gas increases 1 percent, the quantity of oil produced goes up 0.15 percent. Because energy production is capital-intensive, supply price elasticities are larger or more elastic in the long run than in the short run. The long run is the time it takes for producers to totally adjust to changing circumstances and allows for totally changing the capital stock. In contrast, in the short run capital stock is fixed and total adjustment does not take place. Often the short run is considered a year or less, but the exact length of time depends on the context.

Information about supply elasticities would be highly useful for those involved in energy markets, but unfortunately little is available. Carol Dahl and T. Duggan (1996) surveyed studies that use simple models to estimate energy supply or elasticities. They found estimates for the various fossil fuels and uranium in the United States and concluded that studies estimating these elasticities using reserve costs are the most promising. Such studies yielded a U.S. gas supply own-price elasticity of 0.41, a uranium supply own-price elasticity from 0.74 to 3.08, an Appalachia coal supply own-price elasticity of 0.41 to 7.90, and a U.S. oil supply own-price elasticity of 1.27. Even less is known about cross-price elasticities. Dahl and Duggan (1998) surveyed oil and gas exploration models that include cross-price elasticities for oil and gas but did not find strong statistical results from any of the models.

DETERMINANTS OF ENERGY DEMAND

Energy demand is a derived demand. Consumers and businesses demand energy not for itself but for the services that the energy can provide. A consumer may want energy for lighting, space conditioning in the form of heat in the winters and cooling in the summer, and energy to run vehicles and appliances. Businesses often have these same needs and also need energy to run motors and for process heat.

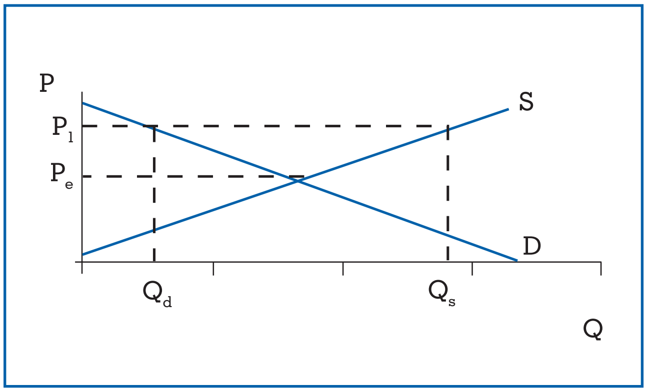

Figure 1.
Energy demand and supply.

For consumers, quantity demanded of energy (Q_{cd}) is a function of the price of energy (P), the price of other related goods, disposable income (Y), and other variables (O) such as personal preferences, lifestyle, weather, and demographic variables and, if it is aggregate demand, the number of consumers (#C). Take for example the quantity of electricity demanded by a household. If the price of electricity increases consumers may use less electricity. If the price of natural gas, a substitute for electricity in consumption (P_s), decreases, that may cause consumers to shift away from electric water heaters, clothes driers and furnaces to ones that use natural gas, thus increasing the quantity of natural gas demanded. If the price of electric appliances (P_c) increases, or decreases quantity of electricity demanded. consumers may buy less appliances and, hence, use less electricity. Increasing disposable income is likely to cause consumers to buy larger homes and more appliances increasing the quantity of electricity consumed. Interestingly, the effect of an increase in income does not have to be positive. For example, in the past as income increased, homes that heated with coal switched to cleaner fuels such as fuel oil or gas. In the developing world, kerosene is used for lighting, but as households become richer they switch to electricity. In these contexts coal and kerosene are inferior goods and their consumption decreases as income increases. We can write a general consumer energy demand function as follows:

$$Q_{cd} = f(-P + P_c - P_s \pm Y \pm O + \#C)$$

Again the signs before the variables indicate how the variables influence quantity. The sign before income (Y) is ±, since the sign would be + for a normal good and – for an inferior good. The sign before other variables is also ±, since the sign depends on what the other variable is. For example, colder weather would raise the demand for natural gas, but an aging population, which drives less than a younger one, would decrease the demand for gasoline.

For businesses the demand for energy is the demand for a factor of production. Its demand depends on the price of the energy demanded (P) as well as the price of its output (P_o), technology (T) and prices of other factors of production—land, labor, and capital—that might be substitutes (P_s) or complements (P_c) in consumption. Environmental policy (E_p) might also affect the demand for fuel. If this is aggregate business demand for energy the number of businesses is also relevant.

We can write a general business energy demand function as follows:

$$Q_d = f(+ P + P_c - P_s \pm T \pm E_p + \#B)$$

The sign on technology (T) and environmental policy (E_p) are uncertain and depend on the particular technology and policy. For example, environmental regulations requiring lower sulfur emissions favor gas over coal, while new technologies that make oil cheaper to use increase oil demand at the expense of gas and coal.

ELASTICITY OF DEMAND

The responsiveness of energy consumption to a variable can be represented by an elasticity, as was the case for energy production. Again the elasticity is measured as the percentage change in quantity over the percentage change in the variable. The demand elasticity is negative, since raising price lowers quantity demanded, and if it is less than –1, the demand is called elastic. Lowering price when demand is elastic means that quantity demanded increases by a larger percent than price falls, thus energy expenditures go up. Alternatively, raising price lowers expenditures. If the demand elasticity is between 0 and –1, then it is called inelastic. Now lowering price means that quantity increases by a smaller percent than price falls. Thus energy expenditures go down. Alternatively, raising price lowers expenditures.

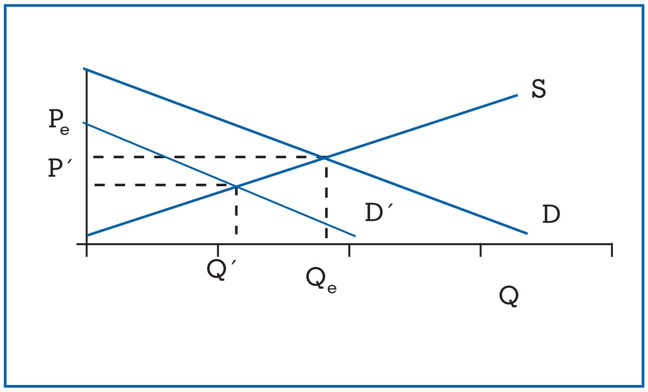

Figure 2.
Shift in demand in response to Asian crisis.

INCOME ELASTICITIES

Income elasticities are positive for normal and noninferior goods, since raising income increases total consumption of these goods. Goods with income elasticities greater than 1 are said to have income elastic demand. Suppose jet fuel has an income elasticity of 3. The in income goes up by 1 percent, the quantity of jet fuel demanded goes up by 3 percent and a larger share of income is spent on jet fuel. Such goods with income elastic demand are called luxuries and they become a larger share of spending as a person gets richer. If the income elasticity is between 0 and 1, it is called inelastic. As income increases, a smaller share of income is spent on goods with inelastic demand. Often necessities such are fuel for heating are income ineleastic.

A cross-price elasticity indicated how the quantity of one good changes when the price of another related good changes. The sign of the cross-price elasticity tells us whether goods are substitutes or complements. Take the case of a cement producer who needs a great deal of heat to produce cement. The producer's cross-price elasticity of demand for natural gas with respect to the price of the substitute good, coal, is the percentage change in natural gas demand divided by the percentage change in coal price. This elasticity for substitute goods will be positive, since an increase in the price of coal will cause an increase in the quantity of natural gas demanded. Alternatively, the cross-price elasticity of demand for complementary goods is negative. If the price of gas furnaces (a complement to gas) goes down, the cement producer may buy more gas

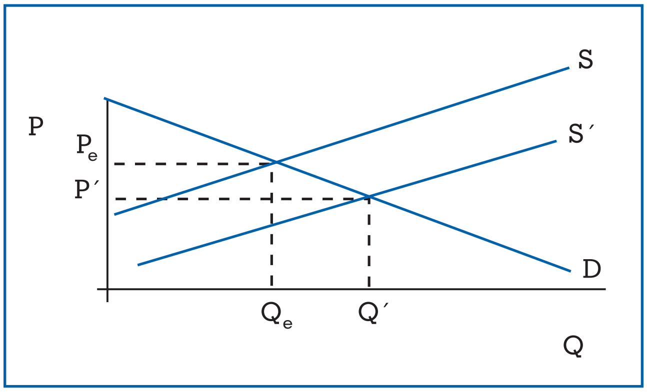

Figure 3.
Shift in supply in response to improved technology.

furnaces, instead of coal furnaces, and use more natural gas.

ESTIMATED ELASTICITIES

More statistical work has been done estimating demand elasticities. Dahl (1993a) surveyed this work for the United States. She found considerable variation in ownprice and income elasticities across studies with the most consistency for studies of residential demand and for gasoline. More products seem to be price and income inelastic and short run elasticities are more certain than long run elasticity. Short run price elasticities for a year are probably between 0 and –0.5 for energy products. Dahl (1995) surveyed transportation demand studies and concluded that the price elasticity of demand for gasoline in the United States is –0.6 and the income elasticity is just below 1. Dahl (1992, 1993b, 1994) looked at energy demand elasticities in developing countries and found that oil and price elasticities of demand are inelastic and near –0.3, while income elasticities of demand are elastic and near 1.3. Dahl (1995b) surveyed natural gas's own, cross and income elasticities in industrial countries but was not able to come to a conclusion about the magnitude of these elasticities. Studies are also often inconsistent about whether coal, oil, and electricity are substitutes or complements to natural gas.

ENERGY PRICES

Elasticities tell us how responsive are quantities demanded and supplied. In a competitive market where many buyers and sellers are competing with one another, the interactions of supply and demand determine the price in energy markets. To see how, we simplify demand and supply by holding all variables constant except price and quantity and graph both functions in Figure 1. Equilibrium in this market is at P_e where quantity demanded equals quantity supplied. If price is at P_1 quantity demanded is Q_d and quantity supplied is at Q_s. There is excess quantity supplied and there would be pressure on prices downward until quantity demanded equaled quantity supplied. Thus interactions of demand and supply determine price.

CHANGE IN DEMAND

If one of the variables held constant in the demand curve were to change, it would shift the whole demand curve, called a change in demand. For example, suppose Figure 2 represents the world market for crude oil. The Asian crisis beginning in 1997 reduced Asian income, which in turn reduced Asia's demand for oil. This decrease in demand lowered price moving along the supply curve, called a decrease in quantity supplied.

CHANGE IN SUPPLY

The 1990s have seen technical changes in finding oil such as 3D seismic and horizontal drilling that have reduced costs. These technical changes shifted the supply of oil as shown in Figure 3. This shift is called a change in supply and is the result a change in the a variable other than the own price. The increase in supply lowers price causing a movement along the demand curve called a change in quantity demanded.

MARKET SETS PRICES

Thus, as economic and political events occur along with changes in demography, preferences and technology, shifting demand and supply interact to form prices in competitive energy markets. The above discussion assumes competitive markets where consumers and producers compete to buy and to sell products, and they have to take market price as given. This is probably the case most often for buyers of energy products. However, in the case of production, sometime market power exists. For

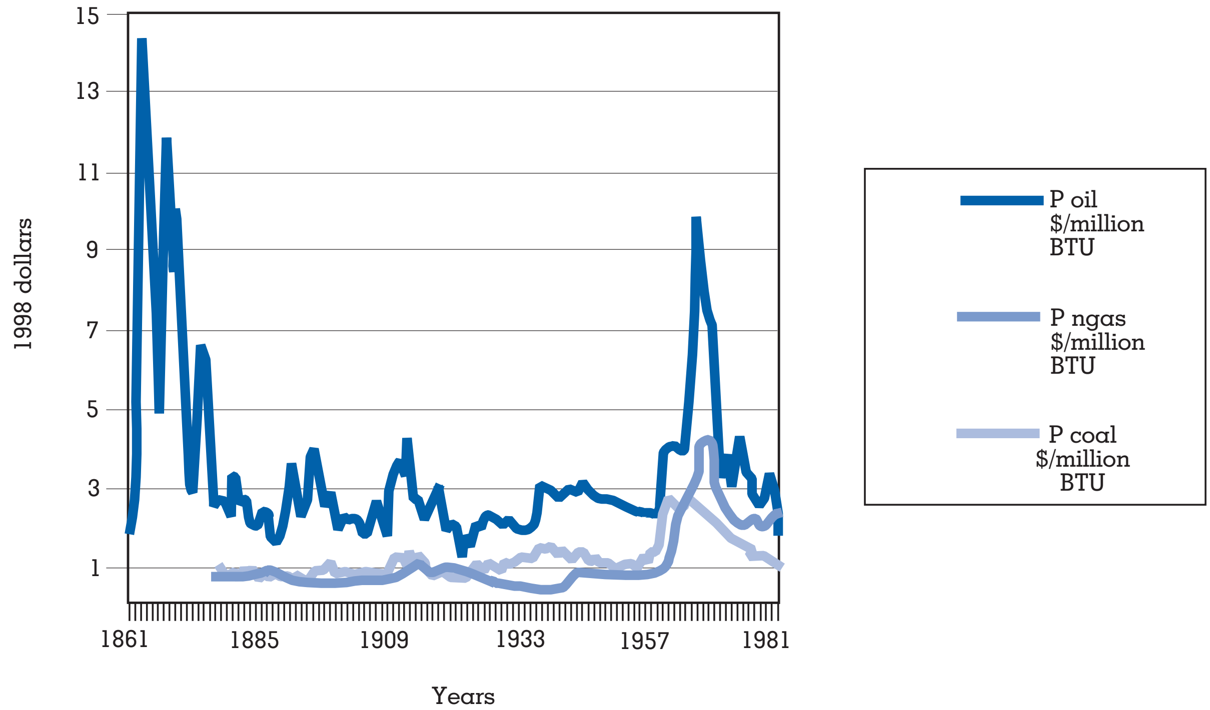

Figure 4.
U.S. prices for coal, oil, and natural gas, 1861–1981.

SOURCE: U.S. Department of Commerce, Bureau or the Census. (1975); U.S. Energy Information Administration, Department of Energy. (1998).

NOTE: Prices have been converted into Btus assuming 5,800,000 Btus per barrel of oil, 3,412,000 Btus per 1000 kWh, 1,000,000 Btus per 1000 mcf of natural gas, and 22,500,000 Btus per short ton of coal. A Btu is about ¼ of a food calorie or a kilocalorie, 1,000 Btus contain the energy content of a candy bar.

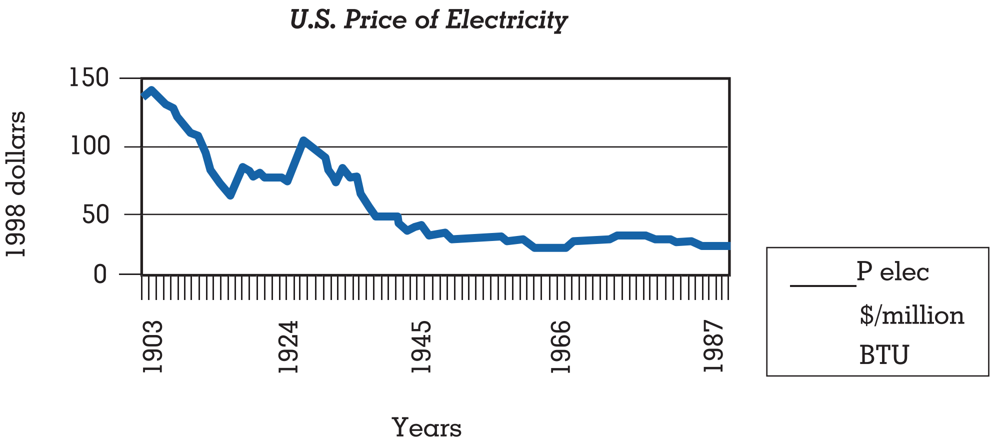

Figure 5.
U.S. Prices for Electricity, 1913–2000.

SOURCE: U.S. Department of Commerce, Bureau or the Census. (1975); U.S. Energy Information Administration, Department of Energy. (1998).

example, in the oil market, first Rockfeller, then the large multinational oil companies, and state regulatory commissions such as the Texas Railroad Commission and then OPEC have exercised pricing power. In such a case, the producer tries to influence price or quantity in order to receive higher prices and earn excess profits.

FOSSIL FUEL PRICES

Figure 4 gives an historical overview of how fossil fuel prices have changed in response to market changes. Price availability varies from series to series and is reported for the period 1861–1998 for the well head price of oil (Poil), 1880–1998 for the fob mine price of bituminous coal, and 1922-1998 for the well head price of natural gas. Figure 4 shows the volatility of oil prices as cartels formed and raised prices and then lost control as higher profits encouraged entry by other. Since the oil market is a global market these prices would be similar to those on the world market, as would prices for coal. The coal market has been reasonably competitive, and from the figure, we can see its price has been more stable than oil. However, coal price has been increased by oil price changes since oil is a substitute for coal in under-the-boiler and heating uses.

Sometimes governments interfere with markets by setting price controls. In the United States wellhead price controls were set on natural gas sold into interstate markets beginning in the early 1950s. These controls which were not completely removed until the early 1990s and sometimes caused natural gas shortages. Prices, which had been reasonably stable, became quite volatile as the price controls were increasingly relaxed throughout the 1980s and into the 1990s.

For electricity, economies of scale have existed making it more economical for one firm to produce and distribute electricity for a given market. One firm would be able to monopolize the market and earn excess profits. This has led governments to regulate electricity in the United States and to produce electricity in most of the rest of the world throughout much of the twentieth century. In such a case, electricity price is set not by the market but by the government. In Figure 5 we can see the evolution of constant dollar electricity prices in the United States from the early 1900s to the present, based on the average real consumer price of electricity (Plec). The falling real price reflects the cost reductions in producing and distributing electricity.

As the size of markets have increased and the optimal size of electricity generation units have decreased more electricity markets are being privatized and restructured to allow more competition into the markets and less government control over pricing.

SUSTAINABLE DEVELOPMENT AND ENERGY

Sustainable development is defined as "development that meets the needs of the present without compromising the ability of future generations to meet their own needs" (Brundtland, 1987). Applied to energy, it is the ability of a society to continue present energy production and consumption patterns many generations into the future, with a focus on the relationship of available energy resource to the rate of resource exhaustion. A sustainable energy market requires the quantity, quality, and utility of energy to improve over time—energy becomes more available, more affordable, more usable and reliable, and cleaner over time (Bradley and Simon, 2000).

Development and population growth adversely impact the sustainability future by accelerating energy resource exhaustion and environmental degradation. For example, the greater the population growth, the greater the desire for development by the growing population, the greater the desire for short-term exploitation of energy resources for the development (less concern for future generations), and the greater the environmental degradation from the greater development and energy use.

All fossil fuels are considered unsustainable because someday they will reach a point of depletion when it becomes uneconomic to produce. Petroleum is the least sustainable because it is the most finite fossil fuel. Although levels of production are expected to begin declining no later than 2030 (U.S. production peaked in 1970), the U.S. and world reserves could be further expanded by technological advances that continue to improve discovery rates and individual well productivity. The extraction of oils found in shales (exceeds three trillion barrels of oil equivalent worldwide) and sands (reserves of at least two trillion barrels worldwide) could also significantly increase reserves. The reserves of natural gas are comparable to that of oil, but natural gas is considered a more sustainable resource since consumption rates are lower and it burns cleaner than petroleum products (more environmentally sustainable).

Coal is the least expensive and most sustainable fossil fuel energy source (world reserves of 1.2 to 1.8 trillion short tons, or five times the world's oil reserves), but many feel it is the least sustainable from an environmental perspective. Coal combustion emits far more of the pollutants sulfur dioxide, carbon monoxide, nitrogen oxides and particulates, and is the fossil fuel that emits the greatest amount of carbon dioxide—the greenhouse gas suspected to be responsible for global warming. However, advances in technology have made the conversion of all fossil fuels to energy more efficient and environmentally sustainable: fossil-fuel availability has been increasing even though consumption continues to increase; efficiency improvements have saved trillions of dollars, and vehicle and power plant emissions in 2000 were only a fraction of what they were in 1970.

Nuclear energy is more sustainable than the fossil fuels. If uranium is used in fast breeder reactors designed to produce large quantities of plutonium fuel as they produce electricity, the world resources could produce approximately 200 times the total global energy used in 1997. However, concerns about the danger of nuclear power, the high cost of building and maintaining plants, and the environmental dilemma of what to do with the nuclear wastes that result is the reason many consider it less sustainable.

Renewable energy is the most sustainable energy because the sources, such as the sun, wind and water are inexhaustible and their environmental impact minimal. But the problem with renewable resources is that most sources produce intermittently (when the sun is shining, wind is blowing). Except for hydroelectricity, which produces about 18 percent of the world's electricity, all the other renewable energy sources combined produce less than 2 percent. Advances in renewable energy technology, coupled with continued efficiency improvements in energy-using products, may be part of the energy sustainability solution, but the demand for energy from the world's ever-growing population is too great for it to be the only solution.

Over 80 percent of the world's energy consumption comes from nonrenewable sources that cannot be sustained indefinitely under current practices. If technological advances continue to make conventional energy resources plentiful and affordable for many years to come, the transition to more sustainable energy sources can be smooth and minimally disruptive.

SYNTHETIC FUELS

Synthetic fuels are usually thought of as liquid fuel substitutes for gasoline and diesel fuel made from petroleum sources. In broad context, the source of these synthetics can be any feedstock containing the combustible elements carbon or hydrogen. These include coal, oil shale, peat, biomass, tar sands, and natural gas. Water could be included here because it can be decomposed to produce hydrogen gas, which has the highest heating value per unit weight of any material (excluding nuclear reactions). The conversion of natural gas is treated in a separate article, so this article will emphasize solid feedstocks.

From a practical standpoint, coal, because of its abundance, has received the most attention as a source for synthetic fuels. As early as 1807, a coal-gas system was used to light the streets of London, and until the 1930s, when less expensive and safer natural gas started to flow through newly constructed pipelines, gas piped to homes in the Eastern United States was derived from coal. Kerosene, originally a byproduct from the coking of coal for metallurgical applications, can be considered the first synthetic liquid fuel made in quantity. But once crude oil became cheap and abundant, there was little serious research on synthetic liquid fuels in the industrial world until the Energy Crisis of 1973. The main exceptions to this generalization are the important work on coal conversion in Germany, cut off from oil imports during the two World Wars, and the Sasol Process in South Africa, which produces a synthetic, waxy “crude oil” from indigenous coal deposits.

The Sasol Synfuel refinery in Secunda, South Africa, produces synthetic fuels for consumers. (Corbis Corporation)

After 1973 the United States invested heavily in synthetic fuel research and development, hoping synthetics could serve as economical substitutes for crude oil. However, coal conversion is not profitable unless the price of crude oil is over $50 per barrel, which is why the processes developed were mothballed when world crude oil prices fell in the 1980s.

CONVERSION

The major chemical difference between natural gas, crude oil, and coal is their hydrogen-to-carbon ratios. Coal is carbon-rich and hydrogen-poor, so to produce a synthetic liquid or gas from coal requires an increase in the hydrogen-to-carbon ratio. Coal’s ratio of about 0.8 has to be raised to 1.4 to 1.8 for a liquid, and to over 3 to produce a synthetic gaseous fuel. Natural gas (chiefly methane) has a ratio of 4. This can be done by either adding hydrogen or rejecting carbon.

Addition of hydrogen can involve reacting pulverized coal with hydrogen-rich liquids. More commonly, pressurized hydrogen gas is reacted with coal (hydrogenation) in the presence of a catalyst. The latter scheme also removes many of the noxious sulfurous and nitrogenous impurities in coal by converting them to gaseous hydrogen sulfide and ammonia. Carbon removal entails pyrolysis in the absence of air (coking) to produce varying amounts of gases, liquids, and char, depending on the reaction time-temperature-pressure conditions employed.

Synthetic Fuel Liquids via Gas Intermediates

Liquids can also be synthesized via an indirect scheme where the coal is first gasified in an intermediate step. The coal is pulverized and reacted with steam to produce "water gas," an equimolar mixture of carbon monoxide and hydrogen:

$$C + H_2O \rightarrow CO + H_2 \tag{1}$$

The carbon monoxide can then be further reacted with steam and/or hydrogen in the water gas shift reaction:

$$CO + H_2O \rightarrow CO_2 + H_2 \tag{2}$$

$$CO + 3H_2 \dashrightarrow CH_4 + H_2O \tag{3}$$

Combining Equation 1 and Equation 2, one can generate hydrogen and carbon dioxide:

$$C + 2H_2O \rightarrow CO_2 + 2H_2 \tag{4}$$

And adding reactions from Equation 1 and Equation 3 yields just methane:

$$C + 2H_2 \rightarrow CH_4 \tag{5}$$

These operations carry energy penalties, and the heat of combustion released when burning the methane, hydrogen, or carbon monoxide produced is less than the energy that would have been released had the coal been burned directly. To produce heavier liquids, the equimolar mixture of hydrogen and carbon monoxide (water gas, also known as synthesis gas) is the preferred feedstock. Badische Anilin pioneered the synthesis of methanol at high temperature and pressure after World War I:

$$CO + 2H_2 \rightarrow CH_3OH \tag{6}$$

Shortly thereafter, Fischer and Tropsch discovered an iron catalyst that would convert synthesis gas to a mixture of oxygenated hydrocarbons (alcohols, acids, aldehydes, and ketones) at atmospheric pressure. In the next decade Ruhrchemie developed new cobalt catalysts that could produce a mixture of hydrocarbon liquids and paraffin wax from Fischer Tropsch liquids at moderate pressure. This, plus direct hydrogenation of coal, was the basis of German synfuel capacity during World War II. Finally, in 1955, the South African Coal, Oil and Gas Co. further improved the technology and commercialized the Sasol Process as the basis for South Africa's fuel and chemicals industry. Favorable economics were possible because government mandates and subsidies dictated the use of local coal resources rather than spending scarce hard currency to import foreign crude oil.

Methanol is an excellent, high-octane motor fuel, but it was not cost-competitive with gasoline made from cheap, abundant, crude oil. It also has a lower specific energy (miles per gallon) because it is already partially oxidized. In the late 1970s, Mobil Oil announced its "Methanol to Gasoline" Process, which efficiently converts methanol to C2 to C10 hydrocarbons via a synthetic zsm-5 zeolite catalyst. This coal-methanol-gasoline technology will probably enjoy use as crude oil prices rise in the future. Since natural gas (largely methane or CH_4) is readily converted into methanol via partial oxidation with pure oxygen, this also offers an alternate to low-temperature liquefaction or pipelining as a way to utilize natural gas deposits that are in remote locations.

There is a parallel technology for the partial oxidation of methane to make ethylene and other olefins. These can then be polymerized, alkylated, and hydrotreated as need be to make hydrocarbon fuels in the gasoline and diesel fuel boiling range. Methane can also be partially oxidized to produce oxygenates, such as methyl tert-butyl ether (MBTE), that are used in reformulated gasoline as blending agents.

Direct Liquefaction of Coal

In comparison to the capital-intensive, multistep gaseous route from coal to gasoline, the direct liquefaction of coal in a single processing step is attractive. While the removal of carbon from coal to generate liquids richer in hydrogen sounds simple, there is not enough hydrogen in coal to yield much useable liquid fuel. Further, the process must have a ready market, such as a nearby smelter, to utilize the major coke fraction. Addition of hydrogen during pyrolysis (hydropyrolysis) increases liquid yields somewhat, but the direct hydrogenation of coal has always seemed a more attractive route. Nevertheless, the Office of Coal Research of the U.S. Deptartment of the Interior sponsored research on this scheme for many years. As a result, the Char-Oil-Energy Development (COED) process was developed by the FMC Corporation in the period 1965–1975. In the COED process, 50 to 60 percent of the coal feed is rejected as char, and finding a market for char is problematic. Working on subbituminous western coals, the Oil Shale Corporation developed a similar scheme (Toscoal Process), which also produced 50 percent solid char.

High-pressure hydrogenation of coal was patented by Bergius in 1918, but the liquids were of low quality. However, by the mid 1930s, plants using on the order of 500 tons per day of low-rank coals and coal pitch had been built in England and Germany. Toward the end of World War II, Germany had 12 large “coal refineries” producing over 100,000 barrels a day of motor and aviation fuels for the war effort. After the war, in spite of the abundance of crude oil in the United States, pilot plant work on coal hydrogenation was continued in by the U.S. Bureau of Mines. This work was further developed by Ashland Oil into the “H-coal” process, and a pilot plant was built in 1980. The hydrocarbon liquids produced were rather high in nitrogen and oxygen, but all heavy materials were recycled to extinction so that no pitch or char was produced.

In the 1920s, I. G. Farben discovered that certain hydrogen-rich solvents, such as tetralin, could dissolve heavy coal components. The heavy extracted liquids could more conveniently be upgraded by hydrogenation, and the extracted residue was converted to metallurgical coke and carbon electrodes. After the war a low-level research effort was undertaken in the United States on solvent-refined coal processes, with primary emphasis on producing boiler fuel. Yields of useful liquids were gradually improved by inserting additional processing steps such as hydrocracking some of the heavier fractions.

Spurred by the OPEC oil crisis, the U.S. Department of Energy encouraged major oil companies to increase efforts to produce liquid fuels from coal, tar sands and shale oil deposits. A key development was the Exxon Donor Solvent Coal Liquefaction Process (EDS). It involves reacting a coal slurry with hydrogenated recycle solvent and hydrogen. The donor solvent transfers some of its hydrogen to the coal, is distilled from the reaction products, hydrogenated, and then recycled to the process. The light ends from distillation are steam-reformed to make process hydrogen. The heavy vacuum bottoms are Flexicoked, and the coke is gasified to provide process fuel gas. Except for some residual carbon in the gasifier ash, very little of value in the coal is wasted.

Work has also continued on the solvent-refined coal + hydrocracking concept (the NTSL, or non-integrated, two-stage liquefaction process), and a pilot plant was operated by Amoco, DOE and the Electric Power Research Institute (EPRI) from 1974 to 1992.

In addition to coal, there have been extensive post-oil-crisis studies aimed at utilizing the extensive western oil shale deposits. Oil shale utilization has many problems common to coal conversion and, in addition, extensive inorganic residues must be disposed of. The products are also high in nitrogen, and this increases refining costs. Tar sands constitute a final hydrocarbon reserve of interest. Here the problems are more tractable. The sands can be extracted with hot water to produce a material similar to a very viscous crude oil. It is refined as such, and thus Great Canadian Oil Sands, Ltd. has been able to justify operation of several very large tar sands refineries at Cold Lake, Alberta. The major process involves fluid coking of the heavy bottoms from distillation.

ECONOMIC AND ENVIRONMENTAL OUTLOOK

The coal conversion efficiency to synthetic, pipeline-quality natural gas or liquid crude oil is in the 60 to 70 percent range. This means that only 60 to 70 percent of the latent heat energy in the coal can be obtained by burning the product of the conversion. However, for the lower Btu per cubic foot products of water gas and coke oven gas, conversion efficiencies can reach over 95 percent.

The reason for the poor conversion efficiency to synthetic fuels is the high energy cost in liberating hydrogen from water (thermal dissociation, electrolysis) and, when distillation does not involve water, the partial combustion needed to produce the gas (CO). The price of crude oil would have to rise to around $40 to $50 a barrel, or need government subsidies of $20 to $30 a barrel, for liquid synthetic fuel to be competitive. Because the conversion to gaseous fuels is less complex and costly than liquid fuels, the subsidy or rise in natural gas prices would not have to be as dramatic.

Besides the economic feasibility problem, synthetic fuels face significant environmental hurdles. During direct liquefaction, heavy, high-boiling polyaromatics organics are produced. Scientists are trying to eliminate these carcinogenic fractions by recycling them through the liquefaction process. Production by the indirect method is less problematic because it tends to produce fewer toxic chain hydrocarbons. There is also a significant release of solid, liquid, and gaseous residual waste that comes from the boilers, heaters and incinerators, or as part of the processing stream.

The process will adversely affect air quality by releasing nitrogen oxides, sulfur oxides, carbon monoxides and other particulates into the atmosphere. Better control of the conversion conditions and better control of emissions can make the process cleaner, yet technology cannot do anything to curb carbon emissions. Since much of the carbon in coal is converted to carbon dioxide in the synthesis process, and is not part of the synthetic fuel itself, the amount of carbon dioxide that will be released to the environment during combustion is 50 to 100 percent more than coal, and around three times more than natural gas.

Since most systems use tremendous amounts of water, the production of synthetic fuels will have a detrimental effect on water quality as well. It will require major technological advances to more effectively handle waste streams—waste-water treatment systems, sulfur recover systems and cooling towers—to make synthetic fuels an acceptable option from an environmental perspective. This emission control technology will be expensive, only adding to the economic disadvantages the synthetic fuel market already faces.

As crude oil reserves dwindle, the marketplace will either transition to the electrifying of the transportation system (electric and fuel-cell vehicles and electric railways), with the electricity being produced by coal, natural gas, nuclear and renewables, or see the development of an industry to produce liquid fuel substitutes from coal, oil shale, and tar sands. It might also turn out to be a combination of both. The transition will vary by nation and will be dictated strongly by the fuels available, the economic and technological efficiencies of competitive systems, the relative environmental impacts of each technology, and the role government takes in the marketplace.

T

TAXATION OF ENERGY

In the United States, the federal government does not impose an energy tax or a general sales tax that is broadly applicable to energy. However, excise taxes are imposed on certain fuels, and there are a number of income tax provisions specific to the energy sector. There are three separate categories of taxes and fees that affect energy use: (1) excise taxes/fees that primarily affect energy demand; (2) income tax provisions that primarily affect energy supply by operating on the after-tax rate of return on investment; and (3) income tax provisions that primarily affect the demand for specific energy sources.

EXCISE TAXES

Excise taxes placed on specific energy sources tend to reduce the demand for these energy sources in both the short and the long run. The federal government imposes excise taxes on almost all petroleum products and coal (see Table 1). The federal government also imposes excise taxes on many transportation uses of methanol, ethanol, natural gas, and propane and imposes a fee on electricity produced from nuclear power plants.

By far the most substantial energy excise taxes imposed by the federal government are those imposed on motor fuels. Gasoline generally is taxed at a rate of 18.4 cents per gallon, and diesel fuel is taxed at a rate of 24.4 cents per gallon. Commercial aviation fuels are taxed at 4.4 cents per gallon, noncommercial aviation gasoline is taxed at 19.4 cents per gallon, and noncommercial aviation jet fuel is taxed at 21.9 cents per gallon. Diesel fuel used by commercial cargo vessels on inland or intracoastal waterways is taxed at 24.4 cents per gallon. Certain users of motor fuels are exempt from the excise tax or pay a reduced rate. For example, state and local governments and motor fuels for off-road use (such as by farmers) are exempt from gasoline and diesel taxes. Reduced rates of tax are paid on gasoline blended with ethanol (gasohol) and by providers of intercity bus service.

Receipts from these taxes are allocated to various trust funds, the largest recipients being the Highway Trust Fund (gasoline and diesel fuel taxes) and the Airport and Airway Trust Fund (aviation fuels taxes). Congress appropriates monies from these funds for surface and air transportation capital projects and operating subsidies. Each of the above tax rates includes 0.1 cent per gallon dedicated to the Leaking Underground Storage Tank Trust Fund. Monies from this fund are appropriated by Congress for remediation of environmental damage at underground fuel storage facilities.

Coal from underground mines is assessed an excise tax of $1.10 per ton, and coal from surface mines is assessed a tax of $0.55 per ton, but in each case, a constraint is added that states that the tax cannot exceed 4.4 percent of the sales price. The receipts from these taxes are allocated to the Black Lung Disability Trust Fund. Monies from this trust fund are used to pay for health benefits to coal miners.

Producers of electricity from nuclear power plants are assessed a fee of 0.1 cent per kilowatt-hour to pay for future storage of spent nuclear fuel at a federal facility. Receipts from this fee are allocated to the Nuclear Waste Trust Fund and are appropriated by Congress to cover the costs of developing and constructing a permanent storage facility.

Each of these excise taxes raises the price of the fuel for uses subject to the tax and might be expected to reduce the demand for petroleum and coal. However, to some extent the excise tax receipts col-

Item	$ Billions
Highway Trust Fund Fuel Excise Taxes	
Gasoline	21.7
Diesel fuel	7.7
Other highway fuels	1.4
Total	30.8
Noncommercial aviation fuels excise tax	0.2
Commercial aviation fuels excise tax	0.6
Inland waterways trust fund excise tax	0.1
Leaking underground storage tank trust fund excise tax	0.2
Motororboat gasoline and special fuels excise taxes	0.2
Black lung trust fund coal excise tax	0.6

Table 1
Estimated 1999 Federal Energy-Related Excise Tax Receipts
SOURCE: Joint Committee on Taxation, U.S. Congress, 1998.

lected are dedicated to trust funds to finance expenditures that directly benefit those paying the tax. To the extent that these taxes are benefit taxes, they may have no independent effect on the demand for the taxed fuel because those paying the taxes are receiving commensurate services. For example, the receipts from aviation fuels taxes generally finance airport expansion and safety projects, providing a wide set of benefits to the flying public. But the tax and the benefit of the tax are not always strongly coincident. For example, in the case of motor fuels taxes, a portion of the Highway Trust Fund is used to support mass transit projects, which are not likely to directly benefit highway users except to the extent that the projects relieve traffic congestion. In the case of electricity, the effect of the fee on overall demand is not clear, because the electricity generation industry is transitioning from a regulated to a more competitive posture and because about 20 percent of electricity is generated from nuclear power plants. Given that the proceeds of this fee are to be spent on disposal of nuclear waste, a cost of production, the fee may make the cost of electricity production more fully reflect social costs. In the case of the Black Lung Disability Trust Fund, the supported benefits are for workers, not users, and hence the tax on coal is expected to operate solely to reduce demand. This tax also is related to the cost of production such that it makes the cost of coal reflect better the social costs.

In a different context, purchasers of automobiles that do not meet specific fuel economy standards must pay a “gas guzzler” excise tax. This tax presumably decreases the demand for such vehicles and should indirectly affect demand for gasoline.

INCOME TAXATION AND ENERGY SUPPLY

Various provisions in the federal income tax treat energy producers more or less favorably than other businesses. By changing the after-tax rate of return on investments in the energy sector, the Tax Code may alter the long-run supply of specific types of energy.

In general, the income of all participants in the energy sector is subject to income tax of one form or another. Two notable exceptions arise in the generation and sale of electricity. Governmental agencies (such as the Tennessee Valley Authority, the Bonneville Power Administration, and municipally owned power companies) account for approximately 14 percent of the electricity sold in the United States. Such public power producers and suppliers are not subject to federal income tax. Electricity providers organized as cooperatives are common in rural areas, accounting for about 8 percent of electricity sales. Income from sale of electricity is not subject to income tax if the income is paid to co-op members as a patronage refund.

To compute taxable income, a taxpayer is permitted to subtract from revenues those expenses that are necessary to create current sales. Expenses related to future sales are required to be capitalized and recovered over time. Distinctions between these two categories—current and suture sales—are sometimes hard to make. In some cases the Tax Code permits energy producers to claim currently, or on an accelerated basis, expenditures that are related to future production and sales. This lowers income for current tax purposes, thereby increasing the after-tax return to investments in the energy sector compared to other investments.

The Tax Code, for example, provides special rules for the treatment of intangible drilling costs, or IDCs. These include expenditures made for wages, fuel, materials, and the like necessary for drilling wells and preparing wells for the production of oil and natural gas. IDCs also may include expenditures for the construction of derricks and tanks, for gathering pipelines, and for roads. Certain taxpayers (generally those without major refining operations) may elect to expense, rather than capitalize, IDCs incurred for domestic properties. Such acceleration of cost recovery may provide preferential treatment for investment in oil and gas production.

The Tax Code also provides special tax advantages through "percentage depletion" allowances. To determine taxable income, the Tax Code permits the owner of a mineral reserve a deduction in recognition of the fact that the mineral reserve is depleted as the mineral is extracted. Some owners of oil and natural gas properties are permitted to compute this deduction as a percentage of gross income from the property (percentage depletion is not available to owners of producing properties who also have substantial refining capacity). Generally, eligible taxpayers may deduct annually 15 percent of gross income, up to 100 percent of the net income from the property (reaching this limit means that income from the property is effectively tax-exempt). Because percentage depletion is computed without regard to the taxpayer's basis in the depletable property, the cumulative depletion deductions may exceed the amount expended by the taxpayer to develop or acquire the property. In such circumstances, an investment in elgible oil and gas properties is tax-favored compared to other investments.

There also are circumstances where income tax provisions reduce the after-tax rate of return on such investments below those available in other sectors. For example, certain types of electricity-generating property (such as those used in distributed power applications) may have useful lives that are substantially shorter than the tax lives permitted for cost recovery. In such instances, the after-tax rate of return will be negatively affected by these specific provisions.

The Tax Code allows credits against income tax liability for various types of specific energy production, including electricity produced from wind or "closed loop" biomass (essentially agricultural operations devoted to electricity generation) and oil and natural gas from "nonconventional" sources (such as natural gas from coal seams, and oil from shale). Credits also are allowed for investments in specific forms of energy production, including facilities to produce geothermal or solar power, and expenditures associated with enhanced oil recovery technologies. Credits against income tax liability directly reduce taxes paid and therefore reduce the cost of production and increase the return on investment. Accordingly, these credits would be expected to increase production of energy from the specified sources.

Item	*$ Billions*
Expensing of exploration and development costs	2.5
Excess of percentage depletion of fuels over cost depletion	5.0
Tax credit for production of non-conventional fuels	7.1
Tax credit for enhanced oil recovery costs	0.3
Tax credit for electricity production from wind and closed-loop biomass	0.4
Tax credit for investments in solar and geothermal energy	0.3
Exclusion of energy conservation subsidies	0.2

Table 2
Estimates of Selected Energy-Related Federal Tax Expenditures, FY 1999–2003
SOURCE: Joint Committee on Taxation, U.S. Congress, 1999.

In addition to specific deductions and credits, the Tax Code permits state and local governments to issue bonds on which the interest is exempt from federal income tax. This provision means that states and local governments can borrow at interest rates below those paid by private corporations. Municipally owned electricity providers often can issue tax-exempt debt; the lower interest rate may have the effect of increasing the provision of electricity by these entities.

To provide a sense of the value of some of these deviations from neutral taxation, Table 2 reports cumulative estimates over five years of selected energy-related "tax expenditures." The Congressional Budget and Impoundment Control Act defines a "tax expenditure" as a revenue loss attributable to a special inclusion, exemption, or deduction from gross income or a special credit, preferential tax rate, or deferral of tax.

INCOME TAXATION AND ENERGY DEMAND

The Tax Code contains various provisions that may affect the demand for energy from specific sources. In the transportation area, purchasers of electric vehicles may claim a credit against their income tax liability for a portion of the purchase price. Taxpayers who purchase or retrofit a vehicle that runs on alternative fuels (such as natural gas, propane, methanol, or ethanol) may claim an accelerated deduction for their expenditure. Taxpayers who commute to work by automobile and whose employer provides parking may have a portion of the value of their parking space included in taxable income (if the value of the parking space exceeds a specified amount). Alternatively, employers may provide their employees with mass transit passes and not include the full value of the benefit in the employee's taxable income. Each of these provisions is expected to reduce the demand for gasoline to some extent.

Taxpayers who receive incentive payments for installing energy-efficient equipment, such as a high-efficiency furnace, do not have to include the payment in their taxable income. This tax-favored treatment may make consumers more likely to purchase energy-saving equipment, thereby reducing demand for energy.

As mentioned above, state and local governments can borrow at relatively low interest rates by issuing tax-exempt debt, and this finance technique is used to a great extent in highway and road construction. By reducing the cost of road construction, tax-exempt debt may increase the amount of construction undertaken, thereby increasing the demand for fuels.

SUMMARY

Tax policy (including excise taxes and income tax provisions) operates in several different ways to affect energy supply and demand, for energy in general and for specific fuels. There is no consensus about the net overall effect on supply and demand, in part because these provisions operate in different sectors, in different markets, and sometimes in different directions.

TESLA, NIKOLA (1856–1943)

Nikola Tesla was born in 1856 in Smilja, Croatia, to parents of Serbian heritage. The region of his birth was at the time part of the Austro-Hungarian Empire. His scientific and engineering aptitude were obvious at an early age, evidenced by stories of inventions consisting of simple mechanical devices he worked on during his childhood. For this reason his parents were persuaded to allow him to pursue an education in engineering rather than becoming a Serbian Orthodox priest as they had hoped. While Tesla studied at Graz Polytechnic and at the University of Prague, he developed an interest in electrical power transmission.

Moving into the commercial world, he accepted a position with a new telephone company in Budapest, where he developed a telephone repeater system, which formed the basis for the modern loudspeaker. Tesla was promoted within the company to a position in Paris. His potential was now clear to the manager of the plant, who recommended that he move to the United States to work with Thomas Edison, then considered the premier engineering genius of the age.

Tesla arrived in New York in 1884 and was hired by Edison. Edison understood Tesla's ability but remained unconvinced by his new employee's insistence on the use of alternating current for electrical power transmission. Nevertheless, Tesla accepted his assignment to work on improving Edison's direct-current method, which was then in use. Working long hours Tesla increased the system output and asked Edison for a $50,000 bonus, which Tesla understood he was to receive. Edison refused, claiming that the bonus had only been a joke. Tesla quit Edison's employ, and thereafter relations were strained between the two men.

Tesla was awarded patents on the alternating-current motor. In the single-phase AC motor, two circuits passing current are set up diagonally opposite with respect to a circular armature. With the currents ninety degrees out of phase, the armature rotates. In the polyphase AC motor, three or more circuits, each having a different phase separation, are employed. George Westinghouse, Jr., is reported to have bought all of Tesla's related patents for $1 million plus royalties, although the exact amount remains in dispute. The two men collaborated very close by. At the World's Colombian Exposition in Chicago in 1893, Tesla's system of alternating-current power transmission was successfully employed. The Westinghouse Company later won the contract to harness the hydroelectric power of Niagara Falls, producing a viable, long-distance, electrical distribution system. When financial difficulties beset the Westinghouse Company between 1891 and 1893, Tesla agreed to give up the royalties to which he was entitled.

Tesla now devoted his energies to work in his own laboratory in New York City. His inventions were numerous. He experimented with the transmission of signals using electromagnetic waves at the same time as Marconi was developing radio. At Madison Square Garden Tesla demonstrated remote control of mechanical objects. His Tesla Coil was capable of generating extremely high voltages. It consisted of three circuits. AC power was applied to the first circuit and, by means of transformers, the voltage was stepped up in the second and third circuits, both of which possessed spark gaps. The third circuit also included a capacitor tunable for resonance, thus allowing extremely large voltages to be developed.

In 1891 Tesla became a U.S. citizen. His naturalization papers remained among his most prized possessions.

Tesla accepted an offer of land and free electricity in Colorado Springs by the local electrical company to continue his research. In 1899, he conducted experiments he considered to be of extreme importance in the conduction of electricity through the earth without the use of wires. He reported that he was able, by means of this principle, to illuminate electric lightbulbs twenty-six miles from the power source. This transmission mechanism, which Tesla explained as taking place by means of the resonant frequency of the earth, has yet to be adequately verified to the satisfaction of the scientific community. In his Colorado Springs laboratory Tesla also performed experiments to simulate lightning that were successful enough to produce a power outage and along with it a withdrawal of the local company's offer of free electricity.

Tesla left Colorado Springs in 1900 and continued his research in a new laboratory on Long Island, which was opened in 1901. However, his efforts were beset by difficulties, not least of which were financial problems, which caused closure of this facility.

His flow of innovative ideas continued unabated. These included improvements for turbines, methods for communication with life on other worlds; and an idea characterized by the press as a "death ray," which may be interpreted as a precursor to the modern laser.

In 1915 it was falsely reported that Edison and Tesla had been jointly awarded the Nobel Prize in physics and that Tesla refused the honor because of his differences with Edison. The circumstances surrounding this news remain cloudy. Nevertheless, Tesla deeply felt the hurt of not receiving this recognition. In 1917 he was persuaded to accept the Edison Medal from the American Institute of Electrical Engineers as an acknowledgment of his pioneering contributions. Among the many honors bestowed on Tesla, perhaps the most important was having an electrical unit named after him, the tesla being the unit for magnetic flux density.

Toward the end of Tesla's life, unflattering articles were written about him, and there were innuendoes that he was involved in the occult. Money problems were never far away, and he moved his residence from one hotel to another, each one cheaper than the one before. His circle of friends contracted. Feeding the pigeons that lived close to his hotel became very important to him, and he developed an almost spiritual bond with them.

Tesla died in 1943. His funeral service was held in the Cathedral of St. John the Divine. As during his lifetime, controversy was not far away. The Serb and Croat mourners sat on opposite sides of the cathedral.

Tesla remains a fascinating man because of his personal life and his engineering genius. However, from a technical point of view Tesla is most remembered for his contributions to the use of alternating-current power transmission.

THERMAL ENERGY

Thermal energy is the sum of all the random kinetic energies of the molecules in a substance, that is, the energy in their motions. The higher the temperature, the greater the thermal energy. On the Kelvin temperature scale, thermal energy is directly proportional to temperature.

All matter is composed of molecules or, in some cases, just atoms. In gases and liquids, molecules are relatively free to move around. In a solid they are not so free to move around, but they can vibrate. Although molecules are microscopic, they do have some mass. Combining mass and speed gives them kinetic energy. Depending on the substance, the particles may interact with each other or their surroundings, in which case they would have potential energy along with kinetic energy. Summing the kinetic energy and potential energy of all the molecules gives the total energy of the substance. This energy is called internal energy because it is internal to the confines of the substance.

In a substance where the molecules may move around, the motion is random. No molecule has a definite speed or kinetic energy, but a molecule has a definite average kinetic energy that depends on the temperature. On the Kelvin temperature scale, the average kinetic energy is directly proportional to the Kelvin temperature. The sum of all the random kinetic energies of the molecules is called thermal energy, therefore, thermal energy is directly proportional to the Kelvin temperature.

Citizen Watch unveils the Eco-Drive Thermo, a wristwatch powered by the heat of the human wearing it. (Corbis Corporation)

When one puts a warm hand in contact with cold water, the hand cools and the thermal energy in the hand decreases. The water warms and the thermal energy of the water increases. The exchange of energy stops when both the hand and water come to the same temperature. While in transit, the energy is called *heat*. When two objects at the same temperature are in contact, no heat flows between either. Accordingly, there is no change in the thermal energy of either, no matter how much thermal energy in either one.

Gasoline-powered engines, diesel engines, steam turbines, and gas turbines are examples of heat engines. All heat engines work on a cyclic principle of extracting thermal energy from some source, converting some of this energy to useful work, and rejecting the remaining energy to something at a lower temperature. In an automobile engine, the ignition of a gasoline vapor-air mixture produces a gas at a temperature several hundred degrees above room temperature. The pressure of the gas forces a piston downward, doing work. The gas cools and is ejected out the exhaust at a temperature significantly lower than at the time of ignition. A heat engine converting thermal energy to work cannot function unless there is a temperature difference between the source and exhaust. The larger the temperature difference, the greater the efficiency of the engine. Usually, the lower temperature is that of the engine's surroundings and the ignition temperature is significantly higher.

If it were it is practical to have a temperature lower than what exists naturally in our environment, a heat engine could be built in which this temperature was the exhaust temperature and the temperature of the environment was the higher temperature. Heat engines extracting thermal energy from the surface water of an ocean, and rejecting thermal energy to the cooler sub-surface water, have been proposed. They would not be very efficient because the temperature difference would be small and they would not be easy to construct. The attraction is related to the huge amount of thermal energy in the oceans, which cover roughly two-thirds of the earth's surface.

THERMODYNAMICS

Thermodynamics, which comes from the Greek word meaning "heat motion" is the science that studies the transfer of energy among different bodies. When a typical power plant produces electricity, water is heated to produce steam by burning fuel. The steam is allowed to expand and perform work, which turns an electric generator that produces electrical energy. The efficiency of this process of energy production—how much electrical energy can be produced for burning a given amount of fuel—is determined by the laws of thermodynamics. These same laws are equally important for the heat engines that propel millions of planes, trains and automobiles around the world. In fact, nearly all energy that powers our energy intensive economy involves, in some manner, the laws of thermodynamics.

THERMODYNAMICS

Scientific descriptions of nature can be categorized as microscopic or macroscopic. A microscopic description involves a discussion of the system using the properties of, and laws governing, atoms and molecules, while in a macroscopic description, one focuses on the large scale, properties of the system. Thermodynamics is a special macroscopic theory that does not involve use of underlying microscopic laws and is, therefore, valid regardless of the form of these laws. A thermodynamic system (or just system) is a specified macroscopic system, that is, a certain specified collection of particles. The matter not included in the system is called the surroundings, and the system plus the surroundings is called the universe. In this context, the universe is not the astronomical universe of galaxies, but the system plus the rest of the matter that can interact with the system, in a measurable manner. As an example of a thermodynamic system consider a gas inside a container (can). The gas could be the system and the walls of the can plus the immediate surroundings would be the universe. Or the gas plus the walls of the can could be the system. The definition of the system is arbitrary and is up to us to define. Failure to have in mind a clear definition of the system often leads to errors in reasoning using thermodynamics principles.

Thermodynamic variables are macroscopic variables associated with the system, such as the system's energy E, volume V, temperature T, pressure P, among others. The thermodynamic variables for a system are measurable properties of the system, and their values define the state of the system. A system is in a thermodynamic equilibrium state if the values of its thermodynamic variables do not change in time. For the gas in the can system, in equilibrium, no change in the values of the temperature, pressure, volume, or any other thermodynamic variable of the gas would be observed. If the system is in an equilibrium state, then one says the system is in a particular thermodynamic state. Thermodynamic processes occur when the system changes from an initial equilibrium state to another final equilibrium state; the thermodynamic variables may undergo changes during this process. If the initial equilibrium state is labeled by i and the final equilibrium state by f then the process i→f corresponds to the energy, temperature and pressure changing from E_i, T_i, P_i to the values E_f, T_f, P_f. An important concept in thermodynamics is the idea of a reversible process. In a reversible process, the system undergoes changes where the system is at all times very close to an equilibrium state; the changes in the thermodynamic variables take place very slowly and can also be reversed by very small changes in the agents causing the process. A reversible process can be realized by changing the external conditions so slowly that the system can adjust gradually to the changes. In our can of gas a very slow compression of the system would be a reversible process. A process that is not reversible is called irreversible; a very rapid compression of the gas that would set up pressure waves and gas flows would be an irreversible process. All real processes that occur in nature are irreversible to a certain extent, but it is possible to carry out processes that are reversible for all practical purposes, and to calculate what would happen in a truly reversible process. Various types of thermodynamic processes are named depending on conditions placed on the system. For example, an isothermal process, such as the compression of a gas held at constant temperature, is a process that takes place at constant temperature while an isobaric process, such as the expansion of a gas held at constant pressure, is a process that takes place at constant pressure.

A process in a system may be associated with work W being done on the system. Work is defined the same as in mechanics—as a force times the distance through which the force acts. For example, in our can of gas it may be stirred, thereby doing work on the gas and changing, say, its temperature. In a compression or expansion of the gas, work is also done on the system. If energy is exchanged between the system and the surroundings due solely to a temperature difference, then this energy is called heat. A thermally insulated system is a system that maintains its thermodynamic state regardless of the temperature of its surroundings. A system enclosed in thermally insulated walls like the walls of a very good thermos bottle cannot sense the temperature of the surroundings. Processes that occur in thermally insulated systems are called adiabatic processes. For an insulated system, the only way to change its energy is by the performance of work; in this case the work is called adiabatic work W_a.

The first law of thermodynamics has two parts. The first part associates the change in the energy of the system in adiabatic processes to the adiabatic work done on the system:

$$DE = E_f - E_i = W_a \quad \text{(adiabatic processes).} \tag{1a}$$

In Equation 1a the symbol DE is used for the change in energy for the process i→f; the final value of the system E_f minus the initial energy of the system E_i. Thus, if the system undergoes an adiabatic compression, the work done on the system would give the change in the energy of the system using Equation 1a. Starting from a given state i, one can perform adiabatic work on the system and define the energy at other states f using Equation 1a written in the form $E_f = E_i + W_a$. In words, Equation 1a can be described by saying that energy is conserved for adiabatic processes; if work is done on the system then this work shows up in the energy of the system. Energy is neither created nor destroyed, but is transferred from the surroundings to the system, or vice versa through the work as agent.

The second part of the first law of thermodynamics arises when the requirement that the process be adiabatic is dropped; recall that this means the system is not insulated, and processes can be caused by heating and cooling. In a general process (the only assumption is that matter is not added or removed from the system), if an amount of work W is done on the system and the energy changes by DE then the heat supplied to the system Q is defined by

$$DE = E_f - E_i = W + Q \quad \text{(general processes).} \qquad (1b)$$

Notice that work is defined from mechanics (force times distance) and can be used to define the energy difference between any two states in Equation 1a. This energy difference and the work are then used to define the heat Q in Equation 1b. In words, Equation 1b says that energy is conserved and heat must be included as a form of energy; or the final energy of the system is the initial energy plus the work done on the system plus the energy added to the system by heating.

Note the following sign conventions for W and Q: the work W in Equation 1a and 1b is positive if it increases the energy of the system, and the heat Q is positive if it increases the energy of the system. If W is positive, then the surroundings do work on the system, for example, compressing the gas, but if W is negative, the system does work on the surroundings, expanding the gas. If Q is positive, the surroundings give energy to the system by means of a temperature difference, but if Q is negative, the energy passes from the system to the surroundings.

In summary, the first law of thermodynamics, Equations 1a and 1b, states that energy is conserved and the energy associated with heat must be included as a form of energy. No process i→f is possible if it violates the first law of thermodynamics; energy is always conserved in our world as dictated by Equation 1b. If Equation 1b is applied to an adiabatic process, then because Q = 0 the first part, Equation 1a is recovered, but one still needs both parts of the first law to define the quantities.

The second law of thermodynamics further restricts the types of processes that are possible in nature. The second law is particularly important in discussions of energy since it contains the theoretical limiting value for the efficiency of devices used to produce work from heat for our use.

The second law of thermodynamics also consists of two parts. The first part is used to *define* a new thermodynamic variable called entropy, denoted by S. Entropy is the measure of a system's energy that is unavailable for work.The first part of the second law says that if a reversible process i→f takes place in a system, then the entropy change of the system can be found by adding up the heat added to the system divided by the absolute temperature of the system when each small amount of heat is added:

$$DS = S_f - S_i = SUM(dQ/T) \quad \text{(reversible process).} \qquad (2a)$$

dQ is a small amount of energy added *reversibly* to the system as heat when the temperature of the system is at an absolute temperature of T. SUM means to add the individual dQ/T terms over the entire reversible process from i→f. The reversible way of adding heat to a system is to put the system in contact, through a heat conducting wall (diathermal wall), with the surroundings that are at a very slightly different temperature. The absolute temperature scale is defined so that the freezing point of water is T = 273 Kelvin or 273 K. The zero of temperature on this scale is an unattainable temperature referred to as absolute zero, although temperatures within one-millionth of a Kelvin and lower of absolute zero have been produced (Note at absolute zero all motion in the system does not cease). Notice that Equations 1a and 2a have a certain similarity since they both are used to define a relevant thermodynamic variable: energy E for Equation 1a and entropy S for Equation 2a. Equation 2a allows the definition of the entropy S

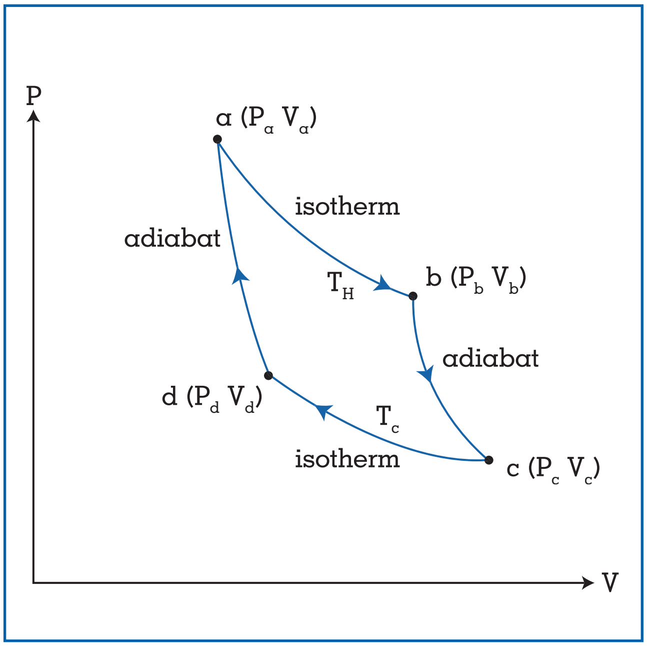

Figure 1.
Carnot cycle for a gas.

at every equilibrium state of the system by starting with the entropy at a particular state and carrying out reversible processes to other states.

The second part of the second law states that where system undergoes an adiabatic process (system surrounded by insulating walls), i→f and the process is reversible, the entropy is not changed, while when the adiabatic process is not reversible the entropy must increase:

$$DS = S_f – S_i = 0$$
(process i→f is adiabatic and reversible),

$$DS = S_f – S_i > 0$$
(process i→f is adiabatic but not reversible). (2b)

Thus, in adiabatic processes the entropy of a system must always increase or remain constant. In words, the second law of thermodynamics states that the entropy of a system that undergoes an adiabatic process can never decrease. Notice that for the system plus the surroundings, that is, the universe, all processes are adiabatic since there are no surroundings, hence in the universe the entropy can never decrease. Thus, the first law deals with the conservation of energy in any type of process, while the second law states that in adiabatic processes the entropy of the system can never decrease.

A heat engine is a device to use the flow of heat energy from a higher temperature to a lower temperature to perform useful work, often mechanical or electrical work. A steam engine heats steam and uses this heated steam and a cooler surroundings to perform mechanical work such as lifting a weight or propelling a steamship. A certain amount of heat Q is converted into a certain amount of work W per cycle of the engine.

In order to investigate heat engines, first focus on a particular cyclic process called a Carnot cycle. Figure 1 shows a Carnot cycle for our gas in the can, and shows the changes in the pressure P and the volume V for the gas during the cycle. The Carnot cycle is the process a→b→c→d→a: from a→b the system at temperature T_H undergoes an isothermal expansion from volume V_a to V_b, from b→c the system undergoes an adiabatic expansion from volume V_b to V_c while the temperature falls to the lower value T_C. Next, the system undergoes an isothermal compression c→d. Finally, the system completes the cycle by undergoing an adiabatic compression d→a, after which its state, a, is precisely the same as before the process was started.

All of the processes in the Carnot cycle are reversible, which is indicated by drawing the lines passing through equilibrium states on the diagram in Figure 1. During the isothermal expansion a→b the system will do work and absorb the energy Q_H from the surroundings that are at the temperature T_H. During the process c→d the system will have work performed on it and liberate energy Q_C to surroundings at lower temperature T_C. The reversible heat exchanges are arranged by having the system in contact with the surroundings, which are held at constant temperature during the isothermal expansion and compression. The surroundings function as a (thermal) reservoir at the temperature T_H and T_C. A reservoir is able to absorb or liberate as much energy as required without a change in its temperature. An oven held at temperature T_H functions as a reservoir. During the adiabatic expansion, the system exchanges no heat, but work is done. Note that in the Carnot cycle only two reservoirs exchange energy during the isothermal process. In other reveisible cycle one needs a series of reservoirs to exchange energy. The laws of thermodynamics may be applied to the Carnot cycle and lead to important results.

Applying the first law of thermodynamics to the Carnot cycle gives

$$DE = E_f – E_i = 0 = Q_H – Q_C – W, \qquad (3)$$

or, solving this for the work done during the cycle in terms of the heat absorbed per cycle and the heat liberated per cycle:

$$W = Q_H – Q_C. \qquad (4)$$

The system does work on the surroundings during the two expansions, and work is done on the system in the two compressions in the Carnot cycle. The net work done in the cycle is work done on the surroundings by the system and is W in Equations 3 and 4. Note that $E_f = E_i$ in the complete cycle a→a since i = f = a, and the total process is cyclic. It is easy to imagine carrying out the Carnot cycle on our can of gas example. In Equations 3 and 4, the proper signs have been used so that the quantities Q_H, Q_C, and W are all positive numbers; the system absorbs energy Q_H from the high temperature reservoir, rejects or liberates energy Q_C at the low temperature reservoir, the system performs work W on the surroundings, and the system is finally returned to the starting equilibrium state. Equation 4 is the application of the first law of thermodynamics to the Carnot engine.

Because the gas in the Carnot cycle starts and ends at the same state, the system's entropy does not change during a cycle. Now apply the second law to the universe for the case of the Carnot cycle. Because the processes are reversible, the entropy of the universe does not change by Equation 2b. This can be written:

$$DS = 0 = Q_C/T_C – Q_H/T_H \quad \text{(Carnot cycle)}, \qquad (5)$$

where the first part of the second law, Equation 2a, is used to determine the entropy change of the two reservoirs in the Carnot cycle. Solving Equation 5 for the ratio of the heat absorbed to the heat liberated, one finds the important Carnot relation connecting the energy Q_H/Q_C ratio to absolute temperature ratio:

$$Q_H/Q_C = T_H/T_C \quad \text{(Carnot cycle)}. \qquad (6)$$

This relation is used to define the absolute temperature scale in terms of energy exchanged with reservoirs in a Carnot cycle. The relations for the Carnot cycle, given by Equations 4 and 6 are general and valid for any system that is taken through a Carnot cycle and not just for our can of gas example.

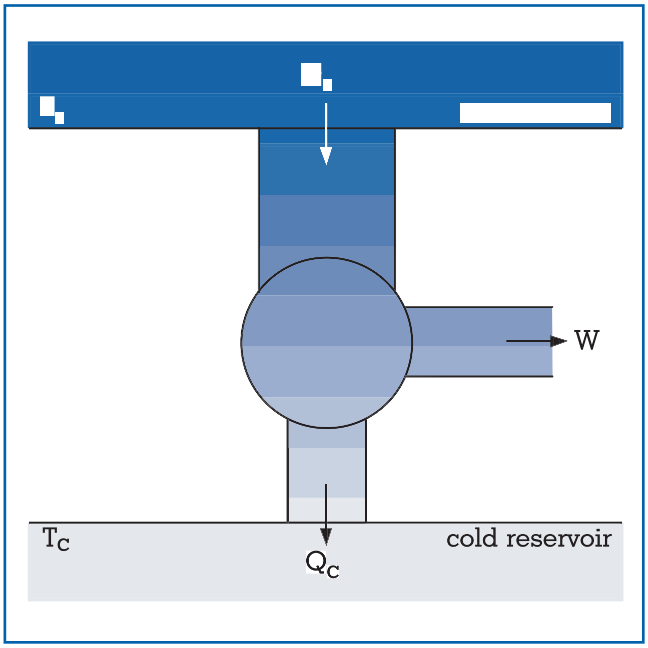

Figure 2.
Schematic of a heat engine.

Figure 1 shows the thermodynamic processes associated with the Carnot cycle. Since these thermodynamic processes produce work, this is also called a Carnot engine. Figure 2 shows another more general picture of a heat engine in thermodynamics. This engine could be a Carnot engine or some other engine. For practical purposes, an efficiency, e, of an engine is defined as the work obtained in one cycle divided by the heat absorbed; this is the what can be sold, W, divided by what must be paid for to produce W, namely Q_H:

$$e = W/Q_H \quad \text{(efficiency of a heat engine)}. \qquad (7)$$

The efficiency of the engine would be greatest if it could be arranged that W = QH, QC = 0, giving an efficiency of 1 or 100 percent efficient. In this case, all the heat absorbed at the high temperature is converted into work. This is perfectly valid from the point of view of the first law of thermodynamics, because energy is conserved. However, from the second law, Equation 5, DS = 0 = $-Q_H/T_H$, which is impossible since $Q_H = W$ is not zero and this implies the entropy of the universe would decrease.

Thus, the second law leads to the conclusion that energy cannot be absorbed from one reservoir and converted completely into work with no other changes in the universe. This is an alternate form of the second law of thermodynamics called the Kelvin-Plank form of the second law. This result is of great practical importance for discussions of energy, since without this result the conversion of heat completely into work would be possible. A steamship could sail on the ocean, absorbing energy from the ocean, and power itself with no need to carry fuel. The fact that heat must be rejected at a lower temperature means that the steamship must carry fuel to produce a higher temperature than the surroundings. The second law of thermodynamics forbids this so-called perpetual motion machine of the second kind, which is an imaginary device that converts heat completely into work with no other change in the universe.

An estimate of the efficiency of a heat engine working between two temperatures T_H and T_C can be obtained by assuming the Carnot cycle is used. By combining the results from applying the first and second laws to the Carnot cycle, the Carnot efficiency e_c may be written:

$$e_c = 1-Q_C/Q_H = 1-T_C/T_H \quad \text{(Carnot engine efficiency).} \tag{8}$$

This remarkable result shows that the efficiency of a Carnot engine is simply related to the ratio of the two absolute temperatures used in the cycle. In normal applications in a power plant, the cold temperature is around room temperature T = 300 K while the hot temperature in a power plant is around T = 600 K, and thus has an efficiency of 0.5, or 50 percent. This is approximately the maximum efficiency of a typical power plant. The heated steam in a power plant is used to drive a turbine and some such arrangement is used in most heat engines. A Carnot engine operating between 600 K and 300 K must be inefficient, only approximately 50 percent of the heat being converted to work, or the second law of thermodynamics would be violated. The actual efficiency of heat engines must be lower than the Carnot efficiency because they use different thermodynamic cycles and the processes are not reversible.

The first and second laws of thermodynamics can also be used to determine whether other processes are possible. Consider the movement of energy from a cold temperature reservoir to a hot temperature reservoir with no other changes in the universe. Such spontaneous cooling processes would violate the second law. From the first law, for such a process $Q_H = Q_C$, the heat lost by the low-temperature reservoir is gained by the high-temperature reservoir; again, the signs are chosen so that both Q_H and Q_C are positive. The change of entropy of the universe in this case is just the change in entropy of the two reservoirs, which, by Equation 2a is DS = $Q_H/T_H-Q_C/T_C = -Q_C(1/T_C-1/T_H)$ which is less than zero since Q_C and $(1/T_C-1/T_H)$ are positive. This means that the entropy of the universe would decrease in such a process. Thus, if heat flows from a cold reservoir to a hot reservoir, with no other changes in the universe, it violates the second law, which says the entropy of the universe can never decrease).

This leads to what is called the Clausius form of the second law of thermodynamics. No processes are possible whose only result is the removal of energy from one reservoir and its absorption by another reservoir at a higher temperature. On the other hand, if energy flows from the hot reservoir to the cold reservoir with no other changes in the universe, then the same arguments can be used to show that the entropy increases, or remains constant for reversible processes. Therefore, such energy flows, which are very familiar, are in agreement with the laws of thermodynamics.

Since the Earth plus the Sun form an approximately isolated system, the entropy of this system is increasing by the second law, while the energy is constant by the first law. The system (Earth plus Sun) is not in an equilibrium state since energy is being transferred from the Sun to the Earth and the Earth is radiating energy into space. The balance of energy absorbed by the Earth (gain minus loss) controls the Earth's temperature. Manmade processes occurring on Earth (burning, automobiles, energy production, etc.) lead to a continual increase in entropy and to an increase in atmospheric pollution. This increase in atmospheric pollution changes the net energy absorbed by the Earth and hence the Earth's temperature. This is the greenhouse effect or global warming. Thus, there is a connection between the entropy increase of the Earth-Sun system and global warming. The main worry is the tremendous increase in atmospheric pollution by the increasing population of the Earth. It is not known how this will end but a "heat-death" of the Earth like that which exists on Venus is a disturbing possibility. Because of the complexity of the process it is very difficult to calculate and predict if this will happen. Unfortunately, past a certain point, such processes could lead to an irreversible increase of the temperature of the Earth, a runaway greenhouse effect, even if we stopped our atmospheric pollution.

The Carnot cycle is reversible so a Carnot refrigerator or air conditioner which removes heat from the cold temperature reservoir is in essence a heat engine operated in reverse. In Figure 3 is shown a schematic diagram of a general refrigerator, where Q_C is absorbed from the low temperature reservoir, work W is done on the system, and heat Q_H is delivered to the high temperature reservoir per cycle. The signs have again been chosen so that Q_C, Q_H, and W are all positive numbers. The first law applied to the refrigerator cycle gives:

$$W = Q_H - Q_C \quad \text{(refrigerator cycle)}, \tag{9}$$

which has the same form as for an engine, Equation 5, since it is just conservation of energy for a cycle. The quantity of interest for a refrigerator is the coefficient of performance k:

$$k = Q_C/W \quad \text{(coefficient of performance)}, \tag{10}$$

which is what is valuable, Q_C, divided by what must be paid for, W. If it could be arranged so that W = 0 this would give the best value for k since cooling without cost would be realized. However, this violates the Clausius form of the second law because energy would be transferred from the cold reservoir to the hot reservoir with no other change in the universe. Therefore, the coefficient of performance of any refrigerator cycle must be finite. The application of the second law to the Carnot refrigerator cycle gives the same fundamental Carnot cycle result relating the temperature ratio to the heat ratio in Equation 6. Equations 6, 9, and 10 can be combined to obtain an expression for the value of k for the Carnot refrigerator:

$$k_c = Q_C/(Q_H - Q_C) = T_C/(T_H - T_C) \quad \text{(Carnot cycle)}. \tag{11}$$

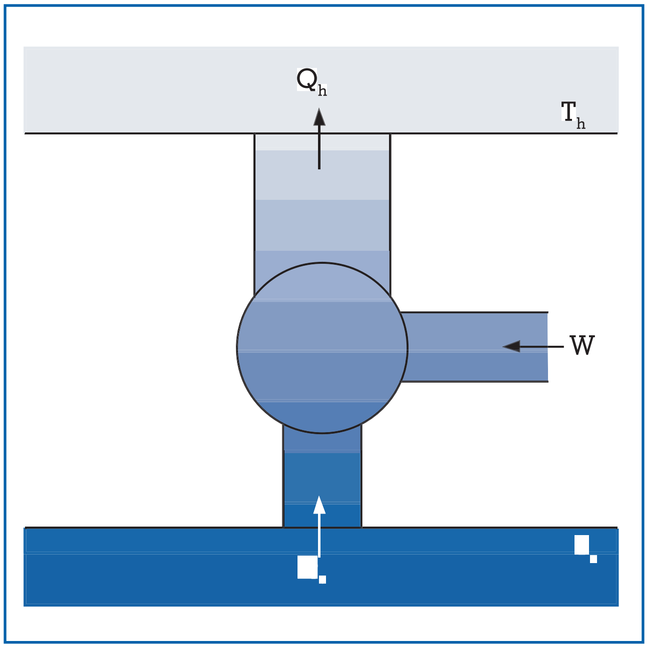

Figure 3.
Schematic of a refrigerator.

In a typical refrigerator, the cold temperature is around 273 K and the compressor raises the temperature of the gas on the high-temperature side by around 100 K so the coefficient of performance is approximately k = 273 K/100 K = 2.7. This means that the amount of heat removed is 2.7 times the amount of work done during one cycle. A heat pump cools the inside of the house in the summer and cools the outside of the house in the winter. It can be discussed as a refrigerator in both cases, but the cold temperature reservoir changes from inside to outside the house as summer changes to winter. This is accomplished by reversing the flow of the working substance in the heat pump. In the winter, as the outside cold temperature falls, the coefficient of performance falls according to Equation 11, and the heat pump produces less heating for the same amount of work. Often the heat pump is supplemented with resistive heating. As long as the coefficient of performance stays above 1, the heat pump is more efficient than simple resistive heating, which produces the same amount of heat as work. One way to make a heat pump have a larger coefficient of performance is to bury the heat exchange unit underground so that the cold temperature is higher than the ambient air temperature. With this change the heat pump can function efficiently even in cold climates.

No heat engine operating between two temperature reservoirs at temperatures T_C and T_H can be more efficient than a Carnot engine operating between these same two temperatures. To show this, first note that the engine can operate in a reversible or irreversible manner. If the engine is reversible, then it has the same efficiency as the Carnot engine since only two temperatures are involved. If the engine is irreversible, then the second law Equations 2a and 2b give

$$DS = Q_C/T_C - Q_H/T_H > 0$$

or

$$Q_C/Q_H > T_C/T_H.$$

If this is used in the definition of the efficiency of an engine,

$$e = 1 - Q_C/Q_H$$

and, compared to the efficiency of the Carnot cycle given in Equation 8, the efficiency of the engine must be less than the Carnot efficiency. This means that the work done in an irreversible engine is less for the same amount of heat absorbed from the high temperature reservoir. In the same way it follows that no refrigerator operating between two temperatures can have a greater coefficient of performance than a Carnot refrigerator. The laws of thermodynamics are of central importance for discussions of energy in our world.

THOMPSON, BENJAMIN (COUNT RUMFORD) (1753–1814)

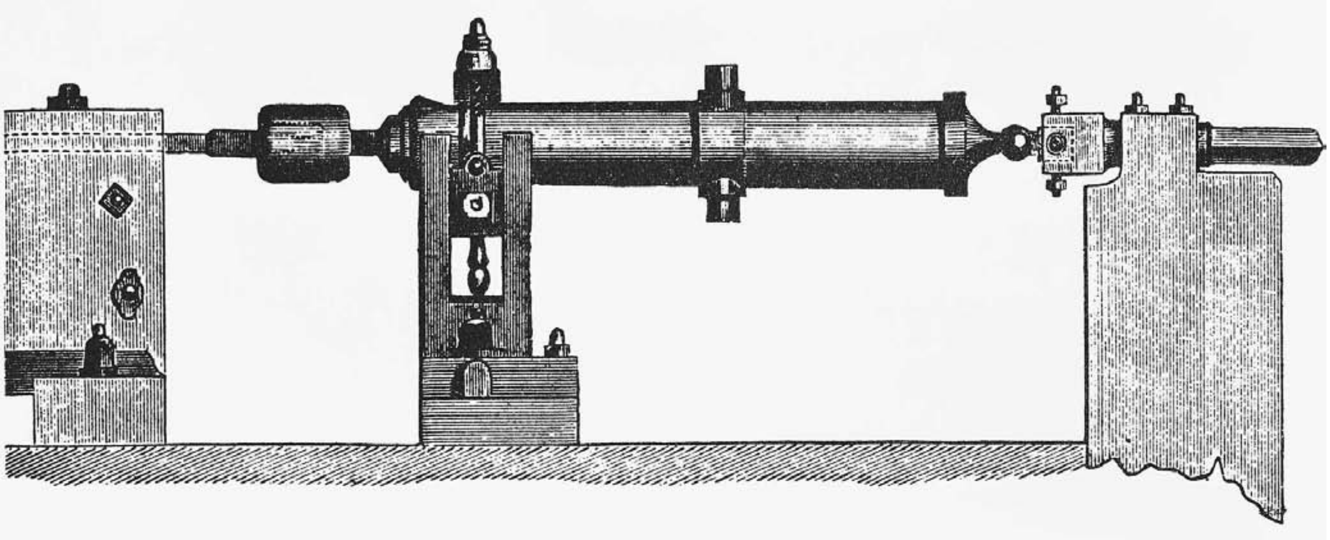
PERSONAL LIFE AND CAREER

Benjamin Thompson, born in Woburn, Massachusetts, in 1753, acquired a deep interest in books and scientific instruments as a youth, and matured into a person of great charm and intellect. In 1772 he received a position as a teacher in Concord, New Hampshire, where he soon met and rather quickly married Sarah Walker Rolfe, a wealthy widow fourteen years his senior, who had been charmed by his brilliant mind and dashing manners. Overnight his status changed to that of a country gentleman, managing his wife's estate and helping John Wentworth, the British governor of New Hampshire, with some agricultural experiments.

To reward Thompson, in 1773 Wentworth commissioned him a major in the New Hampshire militia. There Thompson acted as an informant for the British, so arousing the rancor of his fellow colonists that they planned to tar and feather him. He quietly departed for Boston, leaving his wife and baby daughter behind. He never saw his wife again, and only saw his daughter briefly many years later when he was living in France.

In Boston Thompson worked briefly for General Gage, the highest-ranking British officer in the Massachusetts Bay Colony. When the American Revolution began in 1776, his loyalty to the American cause was clearly suspect, and he left for England. Upon arriving in London his obvious talents led to rapid advancement in his career, and eventually he was appointed Undersecretary of State for the colonies. He also had a brief military career with the British Army in America, and retired in 1784 with the rank of Colonel.

In 1784 this freelance diplomat joined the court of Karl Theodor, Elector of Bavaria, and rapidly rose to become head of the ineffectual Bavarian Army. For his contributions to building up Bavaria's defensive strength, in 1793 he was made a Count of the Holy Roman Empire and took the name "Count Rumford," since that was the original name of the



Benjamin Thompson's 1798 invention for producing heat based on his idea that friction generates heat by increasing the motion of molecules. (Corbis-Bettmann)

New Hampshire town in which he had first taught school.

After returning briefly to London in 1800, Rumford was on the move again, this time to Paris, where in 1805 he married the widow of the great French chemist, Antoine Lavoisier. Rumsford's first wife had passed away by this point. His marriage to Madame Lavoisier was, however, a very stormy affair and two years later, after having ensured a handsome lifetime annuity for himself, he and his wife separated. Rumford then retired to Auteuil, outside Paris, where for the rest of his life he worked energetically and with much success on applied physics and technology.

During his life Count Rumford did much good with the funds he obtained by marrying wealthy widows, and by dazzling the leaders of three European nations with his scientific accomplishments. He established sizable prizes for outstanding scientific research, to be awarded by the American Academy of Arts and Science in Boston, and the Royal Society of London. He designed the lovely English Gardens in Munich, and supervised their construction. Finally he provided the funds to start the Royal Institution in London, which later attained great scientific prestige under the direction of Humphry Davy and Michael Faraday.

RUMFORD'S CONTRIBUTIONS TO SCIENCE

During the eighteenth century, the kinetic theory of heat had gradually lost favor and been replaced by the conception of heat as an indestructible fluid, to which Lavoisier had given the name "caloric." In 1798 Rumford, as Minister of War for the Elector of Bavaria, performed pivotal experiments in negating the existence of caloric. While watching the boring of a cannon barrel at the Munich military arsenal, Rumford was struck by the large amount of heat produced in the process. As long as the mechanical boring continued, heat continued to appear. This was hard to explain on the basis of the prevalent caloric theory. It appeared that continued boring was able to produce an inexaustible amount of caloric, which the limited amount of metal in the cannon barrel could not possibly contain.

Rumford decided to try a more controlled experiment. He placed a brass gun barrel in a wooden box containing about nineteen pounds of cold water, and used a team of horses to rotate a blunt steel borer inside the barrel. After 2.5 hours, the water boiled! As Rumford described it, "It would be difficult to describe the surprise and astonishment expressed on the countenances of the bystanders on seeing so large a quantity of cold water heated, and actually made to boil, without any fire."

Rumford suggested that anything that an isolated body can supply *without limitation* could not possibly be a material fluid. The only thing that could be communicated in this fashion was *motion*, in this case the motion of the steel borer that first produced *heat* in the form of molecular motion of the cannon molecules, which was then passed on to the water as random motion of its molecules. Therefore, according to Rumford heat was a form of random molecular motion. By this and other experiments Rumford had indeed demonstrated that a caloric fluid did not exist, but he had not yet seen the intimate connection that exists between heat, work and energy. That connection was to come later with the research of Sadi Carnot, Julius Robert Mayer, James Joule, and Hermann von Helmholtz.

In addition to this groundbreaking research on work and heat, Rumford made an extraordinary number of important contributions to applied science. He studied the insulating properties of the cloth and fur used in army uniforms, and the nutritive value of various foods and liquids. He decided that thick soup and coffee were the best sources of strength for any army in battle; and introduced the potato as a food into central Europe. He designed a large number of drip-type coffee makers and introduced the first kitchen range, the double boiler, and the pressure boiler found in modern kitchens. Rumford also designed better chimneys and steam-heating systems for houses. His continued interest in the scientific principles behind such devices made Rumford one of the world's first great applied physicists.

Rumford died suddenly at Auteuil in August 1814, leaving his entire estate to Harvard College to endow a professorship in his name. While considered a great scientist and a charming man by the best and brightest of his contemporaries, Rumford was at heart a soldier-of-fortune, and could be arrogant, obnoxious, and cruel to those he considered beneath him. For these reasons, he is less highly respected today as a man than he is as a scientist.

THOMSON, JOSEPH JOHN (1856–1940)

The British physicist, famous for his discovery of the electron, was born in Cheetham, near Manchester, on December 18, 1856. He first entered Owens College (later Manchester University) at the early age of fourteen. In 1876 Thomson won a scholarship in Mathematics to Trinity College, Cambridge, and remained a member of the College for the rest of his life. He became a Fellow in 1880, Lecturer in 1883 and Master in 1918, a position he held with great flair until his death on August 30, 1940.

Thomson met Rose Paget in 1889 when, as one of the first women to be allowed to conduct advanced work at Cambridge, she attended some of his lectures. They married on January 22, 1890, and had two children: a son, George, and a daughter, Joan. The marriage was a long and happy one.

Many were surprised when, at the end of 1884, Thomson was appointed Cavendish Professor of Experimental Physics in succession to Lord Rayleigh. Thomson was not yet twenty-eight, and he had almost no experience in experimentation. Nevertheless he immediately began work on the conduction of electricity through gases and single-mindedly pursued this topic until he resigned the Chair in 1919. Under Thomson's inspiration and guidance the Cavendish Laboratory became the world's foremost research institution. Seven of those who started or continued their careers there went on to win Nobel Prizes, including his own son.

J.J., as Thomson was commonly called, received the 1906 Nobel Prize in Physics in "recognition of the great merits of his theoretical and experimental investigations of the conduction of electricity by gases". He was knighted in 1908, received the Order of Merit in 1912 and was successively President of the Physical Society, the Royal Society and the Institute of Physics.

The demonstration of the independent existence of the negative electron of small mass was a watershed in the long quest to understand the nature of electricity. Many scientists had contributed to this search in the 300 years prior to Thomson's discovery: Gilbert, Franklin, Coulomb, Poisson, Galvani, Volta, Davy, Oersted, Ampère, Ohm, Faraday, Maxwell, and others. In 1874 the Irish physicist George Johnstone Stoney pointed out that, on the basis of Faraday's law of electrolysis, there exists an absolute unit of electricity, associated with each chemical bond or valency. Hermann von Helmholtz, independently, drew similar conclusions, declaring that electricity, both positive and negative, was divided into elementary portions that behaved like atoms of electricity. Stoney later suggested the name "electron" for this elementary charge.

The phenomena exhibited by the electric discharge in rarefied gases had long been known to German and British physicists. Many British physicists held that cathode rays were particles of matter, similar in size to ordinary molecules, projected from the negative pole. In contrast, most German physicists maintained that cathode rays were analogous to electric waves, getting strong support from Heinrich Hertz who in 1892 showed that the rays could pass through thin sheets of metal. That fact was difficult to reconcile with the molecule-sized particle interpretation.

Thomson was convinced that whenever a gas conducted electricity, some of its molecules split up, and it was these particles that carried electricity. Originally, he thought that the molecule was split into atoms. It was not until 1897 he realized the decomposition to be quite different from ordinary atomic dissociation. At the beginning of that year Thomson performed some experiments to test his particle theory.

Joseph John Thomson. (Library of Congress)

First he verified that cathode rays carried a negative charge of electricity and measured their deflection in magnetic and electrostatic fields. He concluded that cathode rays were charges of negative electricity carried by particles of matter. Thomson found that the ratio of the mass, m, of each of these particles to the charge, e, carried by it was independent of the gas in the discharge tube, and its value was of the order of 1/1,000 of the smallest value known at that time, namely the value for the hydrogen ion in electrolysis of solutions. He then devised a method for direct measurements of e as well as m/e, thus allowing the mass of the particles to be determined. The measurements showed that e carried the same charge as the hydrogen ion. Thus m was of the order of 1/1000 of the mass of the hydrogen atom, the smallest mass known at that time. This numerical result was perfectly adequate for the interpretation adopted and, if not at first very accurate, was soon improved by later experiments. Thomson concluded that the negative charge carrier, its mass and charge being invariable, must represent a fundamental concept of electricity, or indeed of matter in any state. With regard to its size he estimated what is now called the "classical electron radius" to be 10^{-15} m.

Thus, the search for the nature of electricity led to the discovery of the electron and the proof that it is a constituent of all atoms. These achievements gave scientists the first definite line of attack on the constitution of atoms and the structure of matter. The electron was the first of the many fundamental particles later proposed. Though Thomson was the undisputed discoverer of the electron, there were others in the hunt who came close to the prize, notably the French physicist Jean Perrin, the German physicists Emil Wiechert and Walter Kaufmann, and the Dutch physicist Pieter Zeeman. The latter had, in 1896, calculated the e/m

ratio for a vibrating "ion"—in other words a bound electron—emitting light. His result was similar to Thomson's corresponding value for a free electron.

Thomson's achievement not only produced explanations for many historically puzzling observations but also opened up new fields of science. Of these the richest is surely the electronic structure of matter, a field of unceasing development that has produced, among other things, the silicon chip, the computer and the technology that provides near-instantaneous global intercommunication and access to an unprecedented amount of information.

THOMSON, WILLIAM (LORD KELVIN) (1824–1907)

In the 1850s the Glasgow professor of natural philosophy (physics), William Thomson, and his colleague in engineering science, Macquorn Rankine, revolutionized the traditional language of mechanics with new terms such as "actual" ("kinetic" from 1862) and "potential" energy. Rankine also constructed a new "science of thermodynamics" by which engineers could evaluate the imperfections of heat engines. By the end of the decade, Thomson and Rankine had been joined by like-minded scientific reformers, most notably the Scottish natural philosophers James Clerk Maxwell, Peter Guthrie Tait, and Balfour Stewart, and the telegraph engineer Fleeming Jenkin. As a group, these physicists and engineers created a new "science of energy" intended to account for everything from the smallest particle to the largest heavenly body.

The fourth child of James and Margaret Thomson, William was born in 1824 in Belfast, then Ireland's leading industrial center, where his father taught mathematics in the politically radical Belfast Academical Institution. His mother came from a Glasgow commercial family, but died when William was just six. Encouraged throughout his early years by his father (mathematics professor at Glasgow University from 1832 until his death from cholera in 1849), Thomson received the best education then available in Britain for a future mathematical physicist. He moved easily from the broad philosophical education of Glasgow University to the intensive mathematical training offered by Cambridge University, where he came second in the mathematics examination (the "Mathematics Tripos") in 1845. Having spent some weeks in Paris acquiring experimental skills in 1846 at the age of twenty-two, Thomson was elected to the Glasgow chair of natural philosophy which turned out to be a post that he held for fifty-three years.

Thomson married Margaret Crum in 1852. She died, childless, in 1870 after a very long illness that rendered her unable to walk. William's second marriage was to Frances Blandy in 1874. Again, there were no children. She outlived him.

Through the engineering influence of his older brother James, William became increasingly committed in the late 1840s to Sadi Carnot's theory of the motive power of heat. Since its somewhat obscure publication in 1824, Carnot's theory had become better known through its analytical reformulation ten years later by the French engineer Emile Clapeyron. The theory explained the action of heat engines by analogy to waterwheels. Just as a "fall" of water drove a waterwheel, so the "fall" of heat between the high temperature of the boiler and the low temperature of the condenser drove a steam engine. This representation gave Thomson the means of formulating in 1848 an 'absolute' temperature scale (later named the "Kelvin scale" in his honor), which correlated temperature difference with work done, thereby making the scale independent of any specific working substance such as mercury or air.

In the same period, James Prescott Joule, son of a Manchester brewery owner, had been carrying out a series of experiments to determine the relationship between work done and heat produced. In the wake of Michael Faraday's electrical researches, electromagnetic engines appeared as a possible future rival to steam power, but in practice their performance failed to match the economy of the best steam engines. Attempting to explain this discrepancy, Joule's early research located the resistances to useful work in various parts of the electrical circuit including the battery. He concluded that, in order to account for all the gains and losses in a circuit, there had to be more than a mere transfer of heat from one part to another; that is, there had to be mutual conversion of heat into work according to a mechanical equivalent of heat. His investigations presupposed that no work (or its equivalent) could be truly lost in nature—only God could create or annihilate the basic building blocks of the universe.

Having met Joule for the first time at the 1847 meeting of the British Association for the Advancement of Science in Oxford, Thomson initially accepted that Joule's experiments had shown that work converted into heat. Committed to Carnot's theory of the production of work from a fall of heat, however, he could not accept the converse proposition that work had been converted into heat could simply be recovered as useful work. Therefore, he could not agree to Joule's claim for mutual convertibility. By 1848 he had appropriated from the lectures of the late Thomas Young (reprinted in the mid-1840s) the term "energy" as a synonym for *vis viva* (the term in use at the time, traditionally measured as mv^2) and its equivalent terms such as work, but as yet the term appeared only in a footnote.

Prompted by the competing investigations of Rankine and the German physicist Rudolf Clausius, Thomson finally reconciled the theories of Carnot and Joule in 1850–51. For the production of motive power, a "thermo-dynamic engine" (Thomson's new name for a heat engine) required both the transfer of heat from high to low temperature and the conversion of an amount of heat exactly equivalent to the work done. His long-delayed acceptance of Joule's proposition rested on a resolution of the problem of the irrecoverability of work lost as heat. He now claimed that work "is lost to man irrecoverably though not lost in the material world." Like Joule, he believed that God alone could create or destroy energy (that is, energy was conserved in total quantity) but, following Carnot and Clapeyron, he also held that human beings could only utilize and direct transformations of energy from higher to lower states, for example in waterwheels or heat engines. Failure to do so resulted in irrecoverable losses of useful work.

William Thomson (Lord Kelvin). (Corbis Corporation)

Thomson's "On a Universal Tendency in Nature to the Dissipation of Mechanical Energy" (1852) took the new "energy" perspective to a wide audience. In this short paper for the *Philosophical Magazine*, the term "energy" achieved public prominence for the first time, and the dual principles of conservation and dissipation of energy were made explicit: "As it is most certain that Creative Power alone can either call into existence or annihilate mechanical energy, the 'waste' referred to cannot be annihilation, but must be some transformation of energy." Two years later Thomson told the Liverpool meeting of the British Association that Joule's discovery of the conversion of work into heat by fluid friction—the experimental foundation of the new energy physics—had "led to the greatest reform that physical science has experienced since the days of Newton."

Through the British Association, Thomson and his associates offered a powerful rival reform program to that of metropolitan scientific naturalists (including T. H. Huxley and John Tyndall) who promoted a professionalized science, free from the perceived shackles of Christianity and grounded on

Darwinian evolution and the doctrine of energy conservation. In critical response to Charles Darwin's demand for a much longer time for evolution by natural selection, and in opposition to Charles Lyell's uniformitarian geology upon which Darwin's claims were grounded, Thomson deployed Fourier's conduction law (now a special case of energy dissipation) to make order-of-magnitude estimates for the earth's age. The limited time-scale of about 100 million years (later reduced) appeared to make evolution by natural selection untenable. But the new cosmogony (theory of the origin of the universe) was itself evolutionary, offering little or no comfort to strict biblical literalists in Victorian Britain.

Thomson also examined the principal source of all useful work on earth. Arguing that the sun's energy was too great to be supplied by chemical means or by a mere molten mass cooling, he at first suggested that the sun's heat was provided by vast quantities of meteors orbiting around the sun, but inside the earth's orbit. Retarded in their orbits by an ethereal medium, the meteors would progressively spiral toward the sun's surface in a cosmic vortex. As the meteors vaporized by friction, they would generate immense quantities of heat. In the early 1860s, however, he adopted Hermann Helmholtz's version of the sun's heat, whereby contraction of the body of the sun released heat over long periods. Either way, the sun's energy was finite and calculable, making possible his estimates of its limited past and future duration.

The most celebrated textual embodiment of the "science of energy" was Thomson and Tait's *Treatise on Natural Philosophy* (1867). Originally intending to treat all branches of natural philosophy, Thomson and Tait in fact produced only the first volume of the *Treatise*. Taking statics to be derivative from dynamics, they reinterpreted Newton's third law (action-reaction) as conservation of energy, with action viewed as rate of working. Fundamental to the new energy physics was the move to make extremum (maximum or minimum) conditions, rather than point forces, the theoretical foundation of dynamics. The tendency of an entire system to move from one place to another in the most economical way would determine the forces and motions of the various parts of the system. Variational principles (especially least action) thus played a central role in the new dynamics.

Throughout the 1860s Thomson and his associates (especially Jenkin, Maxwell, and Balfour Stewart) played a leading role, both in shaping the design of electrical measuring apparatus and in promoting the adoption of an absolute system of physical measurement such that all the units (including electrical resistance) of the system should bear a definite relation to the unit of work, "the great connecting link between all physical measurements." These researches were conducted in the aftermath of the failure of a number of deep-sea telegraph projects, most notably the Transatlantic Cable of 1858. They provided the scientific foundation for a dramatic expansion in British telegraphic communication around the globe in the remaining decades of the nineteenth century, when British Imperial power reached its zenith.

Elevation to the peerage of the United Kingdom in 1892 brought William Thomson the title Baron Kelvin of Largs (usually abbreviated to Lord Kelvin). He was the first British scientist to be thus honored and took the title Kelvin from the tributary of the River Clyde that flowed close to the University of Glasgow. By the closing decades of his long life, when most of his associates had passed away, Kelvin was very much the elder statesman of British science. But the science of energy had been taken up by a younger generation of physical scientists and transformed into quite different modes of scientific understanding, ranging from the "energetics" of the German physical chemist Wilhelm Ostwald (denying atoms in favor of energy) to the "radioactive" physics of Ernest Rutherford (offering new possibilities for estimating the ages of earth and sun). Resisting many of the consequences of these new conceptions, Kelvin published right up to his death at the age of eighty-three, and found at last a resting place in Westminster Abbey, not far from his hero, Sir Isaac Newton.

TIRES

HISTORICAL DEVELOPMENT

The first commercially successful pneumatic tire was developed in 1888 in Belfast by the Scottish veterinarian John Boyd Dunlop primarily to improve the riding comfort of bicycles. Dunlop also showed, albeit qualitatively, that his air-inflated "pneumatic" took less effort to rotate than did the solid rubber tires in use at that time. His qualitative tests were the first known rolling resistance experiments on pneumatic tires. Due to this significant reduction in rolling loss, many professional cyclists in Britain and Ireland adopted air-inflated tires for their bicycles by the early 1890s. Pneumatics for the nascent automobile industry soon followed.

Tires, like everything that rolls, encounter resistance. The resistance encountered by the tire rolling across a surface is a major factor in determining the amount of energy needed to move vehicles. Since Dunlop's original efforts, a considerable number of tire design improvements have been made that have tended to cause a decrease in tire power consumption. For example: separate plies of cotton cord were introduced in the early 1900s to replace Dunlop's square-woven flax (as early tires failed from fabric fatigue before wearing out); in the late 1950s the fuel-efficient radial-ply construction was commercialized in Europe to replace the bias-ply tire; this change also improved vehicle handling and increased mileage. (The radial tire features one or more layers of reinforcing cords or plies disposed perpendicular to the two beads plus a steel belt in the tread region, while the bias construction is built-up with an even number of plies arrayed at alternating, opposing angles between beads without a belt.) There has been a trend toward using larger-diameter tires, which are more rolling-efficient for comfort, appearance and safety reasons as vehicles were downsized in the United States during the 1980s. Elimination of the inner tube by tubeless tires, the use of fewer but stronger cord plies, and the production of more dimensionally uniform tires have each made small but measurable reductions in tire energy loss, although each of these changes was instituted primarily for other reasons.

Scottish inventor John Boyd Dunlop, displays an invention he patented in 1888—the bicycle with pneumatic tires. (Corbis-Bettmann)

By the 1990s, automobile tires in the industrialized portions of the world were often taken for granted by the motoring public because of the high level of performance they routinely provide in operation. This casual attitude toward tires by a large segment of the driving public can be partially explained by the sheer number of units manufactured and sold each year. In 1996 about one billion tires of all sizes and types were marketed worldwide with a value of more than $70 billion; this includes 731 million passenger car tires and 231 million truck tires with agricultural, earthmover, aircraft, and motorcycle tires constituting the remainder. Three regions of the world dominate tire production and sales: North America, Western Europe and Japan. Among them, these mature markets are responsible for more than three-quarters of all passenger car tires and one-half of all truck tires. Bicycle tires are now largely produced in less-developed countries, so an accurate number is hard to assess.

The pneumatic tire has the geometry of a thin-walled toroidal shell. It consists of as many as fifty different materials, including natural rubber and a variety of synthetic elastomers, plus carbon black of various types, tire cord, bead wire, and many chemical compounding ingredients, such as sulfur and zinc oxide. These constituent materials are combined in different proportions to form the key components of the composite tire structure. The compliant tread of a passenger car tire, for example, provides road grip; the sidewall protects the internal cords from curb abrasion; in turn, the cords, prestressed by inflation pressure, reinforce the rubber matrix and carry the majority of applied loads; finally, the two circumferential bundles of bead wire anchor the pressurized torus securely to the rim of the wheel.

However, it is the inelastic properties of the cord and rubber components of the tire that are responsible for the heat buildup and energy dissipation that occur during each tire revolution. This loss of energy results in a drag force that impedes tire rotation. The cyclic energy dissipation of tire materials is a mixed blessing for the tire development engineer. It is required in the contact patch between tire and road to produce frictional forces that accelerate, brake, and/or corner the vehicle, but it must be minimized throughout the tire in the free-rolling condition so as not to adversely impact fuel economy.

Depending on the specific car model and service conditions, tires can consume 10 to 15 percent of the total energy in the fuel tank, and in this respect the power loss of the four tires is comparable in magnitude to the aerodynamic drag opposing the forward motion of the vehicle during urban driving at about 45 miles per hour.

	Rolling Resistance Coefficient
Radial passenger tire	.008 – .015
Bias passenger tire	.016 – .025
Radial truck tire	.005 – .007
Bias truck tire	.008 – .010
Railroad wheel (steel)	.002 – .003

Table 1.
Rolling Resistance Coefficient of Various Tire Types

Rolling resistance coefficient is defined as the nondimensional ratio of drag force retarding tire rotation to wheel load—with lower being better. For most passenger car tires freely rolling on smooth, hard surfaces, this coefficient varies between 0.01 and 0.02, but may increase to 0.03 or higher at increased speeds, at very high loads, at low-inflation pressures, and/or on soft surfaces.

Typical ranges for the rolling resistance coefficients of passenger car and truck tires in normal service (vs. a steel wheel) are given in Table 1.

Truck tires are operated at about four times the inflation pressure of passenger car tires, which principally accounts for truck tires' lower rolling resistance coefficients.

Power consumption is the product of drag force and speed—and four tires on a typical American sedan consume approximately 10 horsepower of engine output at 65 miles per hour.

The radial passenger tire introduced in North America during the 1970s had a 20 to 25 percent improvement in rolling resistance compared to the bias ply tire then in use. This was a major improvement that resulted in a 4 to 5 percent gain in vehicle fuel economy under steady-state driving conditions—that is, an approximately 5:1 ratio between rolling resistance reduction and fuel economy improvement. By the 1990s, evolutionary advances in tire design and materials continued with the general use of higher operating pressures, but an 8 to 10 percent improvement in rolling resistance now translates into only a 1 percent gain in fuel economy.

Trade-offs between rolling resistance (and therefore fuel economy) and safety occur in tire design and usage just as with vehicles. For example, the least hysteretic polymers and tread compound formulas that lower rolling resistance tend to compromise wet grip and tread wear. Also, worn-out tires with little or no remaining tread depth are much more fuel-efficient than new tires, but require greater distances to stop when braking on wet surfaces.

ENERGY FOR MANUFACTURING

The energy required to produce a tire is only about 10 percent of that consumed while in use on an automobile overcoming rolling resistance during 40,000 miles of service. The majority of the manufacturing energy expended, 60 to 70 percent, is for the mold during the vulcanization process.

At the end of its useful life, the tire, with its hydrocarbon-based constituents, is a valuable source of energy, with a higher energy value than coal. By the mid-1990s, approximately 80 percent of the tires worn out annually in the United States were being recycled, recovered, or reused in some fashion, with three-fourths of these serving as fuel for energy production in boilers and cement kilns.

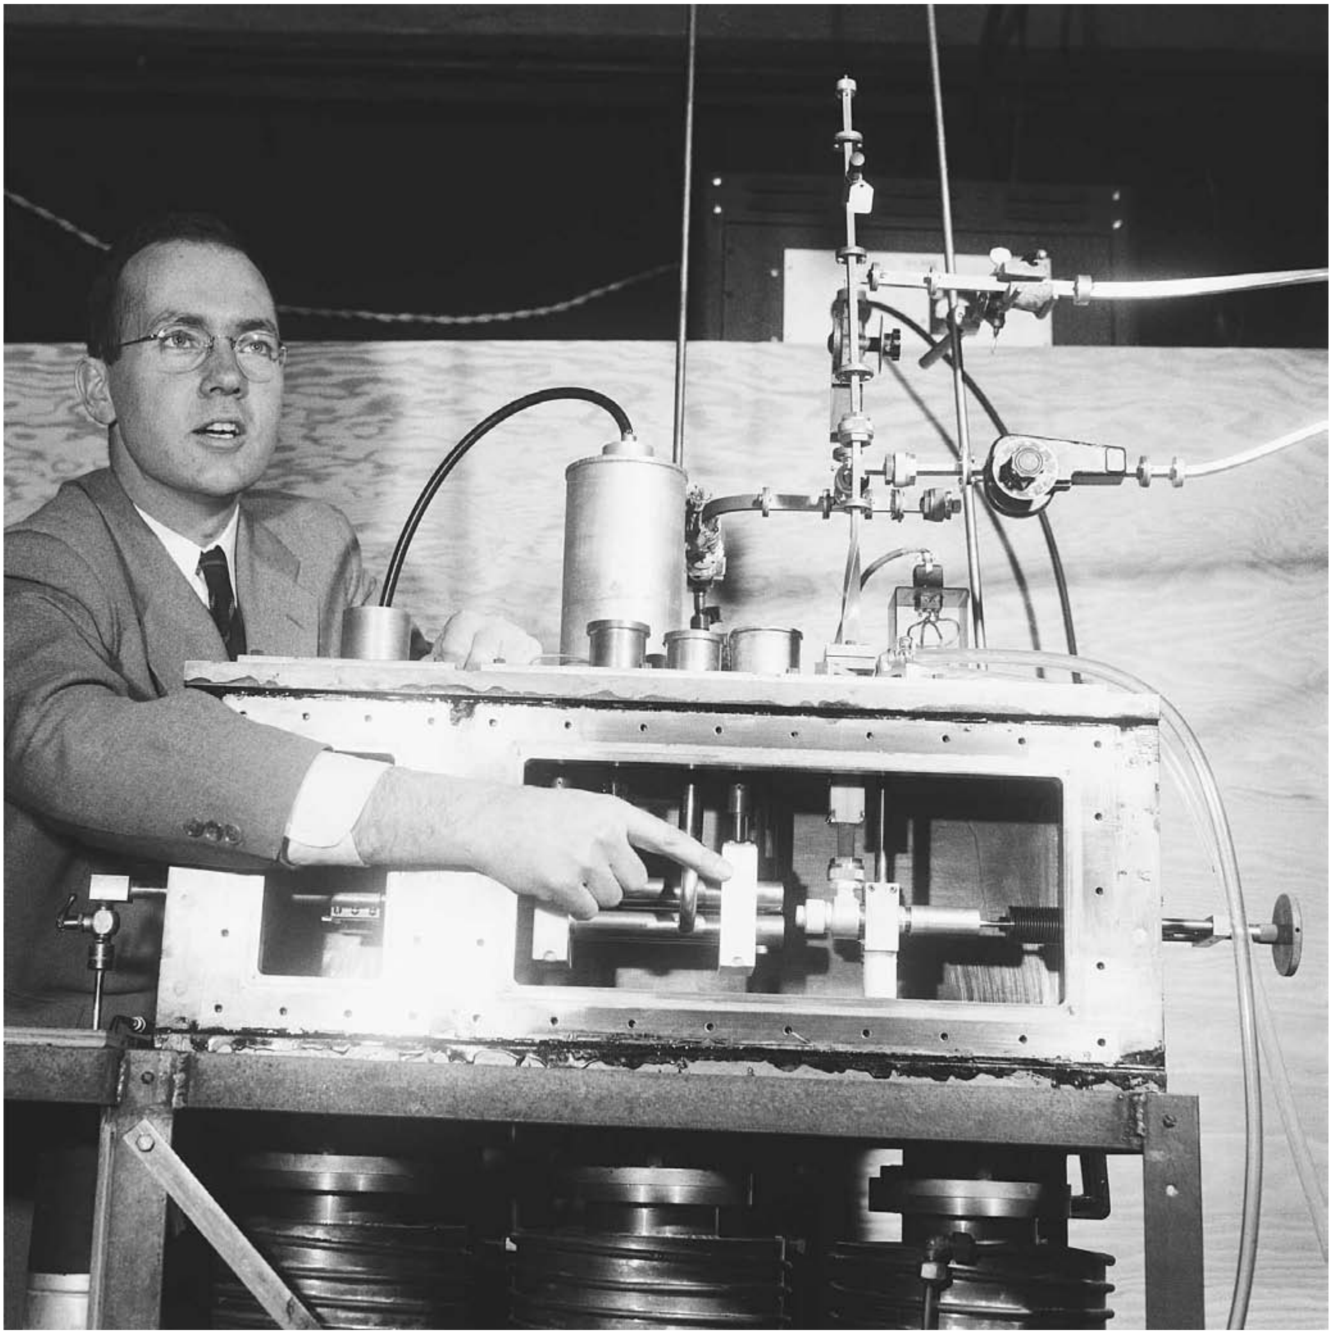
TOWNES, CHARLES HARD (1915–)

Charles Hard Townes had a long, distinguished career as a physicist and educator with years of service to the military and academic research communities. One particular line of work will ensure that his name be remembered by history—his contributions to the early development of the laser. The laser is considered by many historians to be one of the most important technological achievements of the twentieth century. As a source of energy, the laser is extremely inefficient—it devours electricity, converting only a fraction into the laser beam. Yet, due to the special properties of laser versus normal light, this technology is extraordinarily useful. A 100-watt light bulb, for example, can barely light a living room, but a pulsed, 100-watt laser can be used to cut or drill holes in metal.

Born in Greenville, South Carolina, Charles Townes early in his life showed the characteristics of both a highly intelligent individual and a scientist. As a boy, Townes studied continuously, covering daunting subjects such as Greek, Latin, and Old English. He also read every issue of Popular Mechanics. Not limiting himself as a book scholar, however, Townes plunged into the hands-on work of technical subjects. Townes's father owned a shop that he rented to a clock and watch dealer. Townes reveled in disassembling the old, broken clocks. In high school, he took shop and mechanical drawing and developed a special interest in electricity and radio. He even attempted (unsuccessfully) to build his own crystal radio.

At the age of sixteen, Townes entered Furman University and received two bachelor's degrees (modern languages and physics) in 1935. He continued his education, receiving a master's at Duke University in 1937 and a doctorate at Cal Tech in 1939. In the summer of 1939, Bell Labs hired him. Numerous lines of research were being undertaken simultaneously at Bell Labs. Most of the work done by Townes initially dealt with basic research and the transmission of telephone and television signals. Worldwide political events, however, soon changed this emphasis.

In September of 1939, Germany invaded Poland and started what would become World War II. Although the United States was still politically neu-



Charles Hard Townes operates an atomic clock. (Corbis-Bettmann)

tral at the time, in March, 1941 Townes was reassigned to work on radar bombing. Bell Labs had done some research on anti-aircraft aiming systems, and Townes and his colleagues used this knowledge to develop a way to replace the bombsight with radar targeting. Although this advance was not put into practice during the war, it helped forge the future of high-tech warfare and was influential in Townes's later civilian endeavors.

Just as the intellectual atmosphere of Bell Labs shaped Townes's career, the cosmopolitan diversity of New York City molded his personal life. He enjoyed the many theaters, museums, and restaurants there. He signed up for voice and music theory lessons at

Juilliard. And most significantly, he met Frances Brown, an activity director at the International House at Columbia University, whom he married in May 1941. The couple had four daughters. His work at Bell Labs had one downside—it often took him away from his family for trips to Florida where the radar bombing system was tested and re-tested.

In 1948, however, Townes returned to the academic world, accepting a professorship at Columbia University. There, during the early 1950s, he speculated that stimulated emission (an ambitious theory first proposed by Albert Einstein in 1917) could generate microwaves, but he also knew a population inversion was necessary. Population inversion occurs when energy is introduced, causing the majority of a material's atoms to reach an excited level rather than their normal "ground level." Edward Purcell and Robert Pound, researchers at Harvard University, had demonstrated population inversion in 1950 using a crystal composed of lithium fluoride. Using this concept as well as his own radar-related work on amplifying a signal, Townes came up with the idea for a closed cavity in which radiation would bounce back and forth, exciting more and more molecules with each pass. With that, Townes had the basic concept of the laser.

Over the next few years, Townes, with the help of graduate students Herbert Zeiger and James Gordon, calculated the precise size of the necessary cavity and built a device that used ammonia as an active medium. Success came in 1954 with the completion of the first maser, an acronym for microwave amplification by stimulated emission of radiation.

In 1957, Townes developed the equation that showed that this same process could also obtain much smaller wavelengths (in the infrared and visible light range). Townes collaborated with Arthur Schawlow, a research assistant in his laboratory from 1949 to 1951, who then moved on to become a physicist at Bell Labs where Townes was still doing consulting work. When he was a postdoctoral fellow at Columbia, Schawlow met Aurelia, Townes' younger sister, who had come there to study singing. Soon the two married.

In 1957, this team of brothers-in-law started working together on Townes's idea for an optical maser. They found atoms that they felt had the most potential, based on transitional probabilities and lifetimes. However, there was still one major problem: In the visible light portion of the electromagnetic spectrum, atoms don't remain in an excited state as long as microwaves. A new cavity seemed the most appropriate solution. In 1958, Schawlow proposed using a long, slim tube as the resonating cavity to produce a very narrow beam of radiation. With that breakthrough, Townes and Schawlow were well on their way to developing a laser. They authored a paper on the subject and submitted a patent on behalf of Bell Labs.

Others, however, were reaching similar ideas at the same time. R. Gordon Gould, a graduate student at Columbia, had come to the same conclusions. In November 1957 he wrote up his notes on a possible laser and had them notarized. Theodore Maiman, a physicist who had been working with ruby masers at Hughes Aircraft Company in Malibu, California, learned of laser research in September 1959 at a conference on quantum electronics that Townes had organized. Afterwards, he began his research on a laser using a pink ruby as an active medium.

Townes's participation in the race for the first laser lessened in the fall of 1959. He was offered and accepted a position as the director of research at the Institute for Defense Analysis in Washington, D.C. With cold war tensions throughout the world, and science playing an increasingly prominent role in government thinking and funding, Townes felt obligated and honored to serve his country in this role. He still met with and directed graduate students at Columbia on Saturdays, but his active role was dramatically reduced.

Schawlow continued working on his laser at Bell Labs. He had rejected ruby as an active medium because he felt it would not reach population inversion. By pumping the ruby with the light from a photographer's flash lamp, however, Maiman succeeded, created the world's first laser in June 1960.

Townes's academic life continued. He served as provost of MIT from 1961 to 1966. In 1964, Townes received the Nobel Prize in physics "for work in quantum electronics leading to construction of oscillators and amplifiers based on the maser-laser principle." He was named university professor at the University of California-Berkeley in 1967. There he worked for more than 20 years in astrophysics. Ironically, this field is one of many that were transformed by the laser, and Townes often used lasers in his subsequent research.

The career of Charles H. Townes and the development of the laser exemplify the technological revolution of the twentieth century. Following the second world war, the United States experienced a golden age of science. Basic research flourished with unprecedented government funding, and it provided the underlying principles for thousands of future devices.

Pioneers such as Charles Hard Townes helped steer the course for this era in the history of energy, and in doing so forged a path for scientists to come.

TRAFFIC FLOW MANAGEMENT

Americans living in the fifty most congested cities spend an average of thirty-three hours each year stuck in traffic. Congestion causes much more than driver aggravation: air quality suffers, vehicle idling and stop-and-go traffic reduce fuel economy by as much as 30 percent, and we lose billions of dollars in productivity. These are the consequences as the automobile does what it is designed to do—transport a highly mobile population. Continued suburban expansion, reduction in household size, increase in number of workers per household, and general changes in lifestyle have all contributed to increased travel demand and greater congestion.

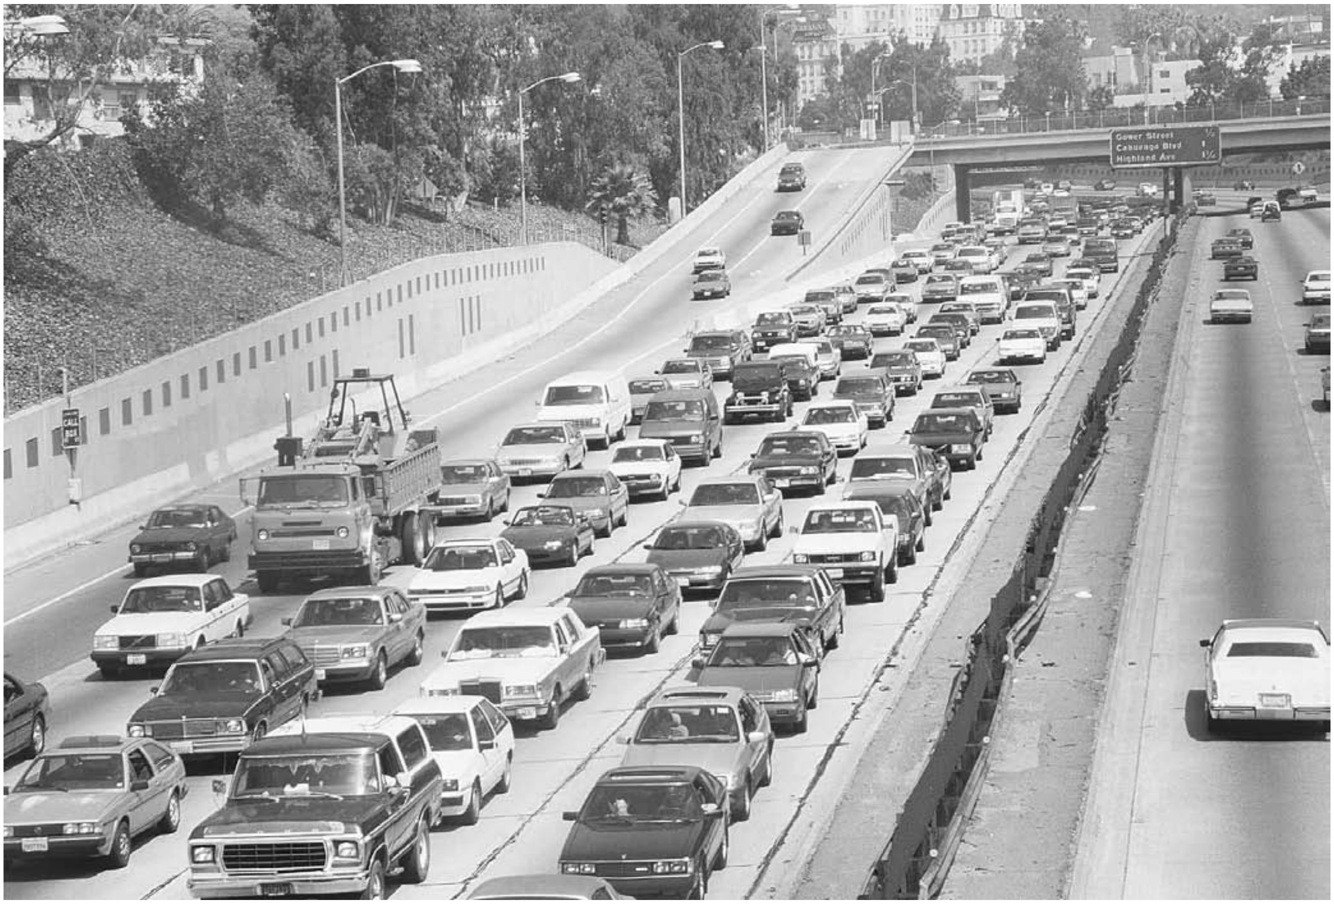
Even without congestion, from the perspective of capital utilization and energy consumption, automobile and roadway use is inefficient. First, the majority of personal transportation energy is consumed in moving personal vehicles that contain only one occupant and drive one or two hours a day. Second, the transportation infrastructure usually operates below capacity. States expend tremendous resources building highways to accommodate peak period demands (7 A.M. to 9 A.M. and 3 P.M. to 6 P.M.). Most of these lanes are not needed for the rest of the day. Rush hour demand still exceeds capacity in many places, resulting in disruption of traffic flow, stop-and-go driving conditions, a drop in freeway throughput, increased fuel consumption, increased vehicle emissions, and wasted time. Nevertheless, the personal vehicle remains the preferred means of transportation in much of the world given the personal freedom and economic opportunity (access to jobs) that it affords.

Using capital and energy more efficiently is a common goal of government, business, and the individual. State agencies have responded to congestion delay by building more capacity and/or increasing the efficiency of existing capacity. At the local level, however, there is growing opposition to the detrimental noise, air quality, and space infringements of building more and bigger highways. Federal environmental and transportation regulations have shifted from capacity expansion to a focus on congestion reduction and air quality improvement. Because mobility enhances regional economic development and productivity, shifting travel demand out of the peak period, or efficiently improving transportation supply (without necessarily adding new major facilities) still provides tremendous public benefits. Recent strategies have focused on behavior modification (transportation demand management strategies) and targeted improvements to the transportation infrastructure (transportation supply improvement strategies).

TRANSPORTATION DEMAND MANAGEMENT STRATEGIES

The objective of demand management strategies is to encourage or require drivers to reduce the frequency and length of automobile trips, to share rides, or to use alternative modes of transportation. When peak period automobile trips are shifted out of the peak, or into alternative transportation (such as carpools, mass transit, bicycling, or walking) congestion declines and the remaining automobile users benefit from improved travel times. Demand management measures include no-drive days, employer-based trip reduction programs, parking management, park and ride programs, alternative work schedules, transit fare subsidies, and public awareness programs. Demand management measures may or may not require intensive capital investment, but are usually characterized by ongoing operating costs.

Researchers have been able to identify strategies (and specific incentives and disincentives) that can



Cars in a traffic jam on the Hollywood Freeway in California. (Corbis Corporation)

change travel behavior at individual facilities. Effective strategies can be tailored for individual businesses and activities as a function of employment classification, land use, and transit service availability. The fact that many strategies are effective at reducing travel demand at individual facilities is not controversial. But it is difficult to implement regional demand management programs that are acceptable to the public without micromanagement by the government. Such regional demand reduction strategies are typically implemented in the form of regulatory mandates, economic incentives, and education campaigns.

Regulatory Mandates and Employer-Based Trip Reduction

Businesses, operating in a market economy, have little incentive to implement demand management strategies on their own. They pay for the costs of shipment delays associated with moving goods and services to the marketplace (these costs are incorporated into the selling price of the goods and services). However, the vast majority of society's congestion cost is external to marketplace price-setting. Companies sometimes implement measures to reduce employee travel to their facility when there's insufficient parking. Normally, they provide convenient automobile access because it makes it easier to attract and keep employees.

Regulatory mandates require, either directly or indirectly, that specific segments of the population change their trip-making behavior. Examples of direct regulatory mandates include: automobile bans in downtown areas, restrictions on motor vehicle idling time (i.e., heavy-duty vehicles), restricted access to airport terminals for certain types of vehicles, odd/even day gasoline rationing at retail filling stations (based on license plate numbers), restricted hours for goods delivery in urban areas, and peak hour restrictions on truck usage in downtown areas. Direct mandates have proven extremely unpopular. Although developing and rapidly growing industrial countries (e.g., Singapore, Mexico, and China) do implement such measures, none are implemented on a sustained and widespread basis in the United States.

Implementation of indirect regulatory mandates has been more common than direct mandates, primarily in the form of trip reduction ordinances implemented by local governments. These ordinances require employers to increase the average vehicle occupancy of employee vehicles during commute periods, but usually allow employers great flexibility in developing their strategies.

During the late 1980s and early 1990s, employers implemented trip reduction measures in many urban areas. Regulatory agencies developed commute vehicle occupancy goals that would result in fewer vehicle trips to the facility during the morning peak. Employers could offer their employees incentives (e.g., cash rebates for carpool participants) or impose disincentives (e.g., parking fees for employees who drove alone)to achieve these ridership goals.

The largest and most prominent experience with trip reduction ordinances in the United States was Regulation XV, adopted December 11, 1987, in the South Coast (Los Angeles) area. The regulation required employers of a hundred or more individuals to prepare and implement trip reduction plans between the home and worksite. Employers developed their own incentive programs to encourage workers to rideshare or use alternative transportation. Facilities reported progress annually, and they adjusted their plans each year until they achieved their ridership goal.

The tripmaking aspects of specific measures implemented by employers under Regulation XV were widely variable. Trip reductions depended on such local factors as employer size and location, employment and site characteristics, location of labor pool, and socioeconomic composition. A 1991 study of seventy-six facilities in the Regulation XV program found no apparent correlation between the number of incentives offered and the improvement in ridership levels. The quality, not the quantity of incentives offered was the driving force for behavioral change. Two factors had a significant effect on ridesharing: (1) use of parking incentives and disincentives coupled with transit pass or commute subsidies; and (2) management commitment coupled with the presence of an on-site transportation coordinator. A program to guarantee rides home for emergencies and last minute work/personal schedule changes was necessary but insufficient condition to encourage ridesharing.

Over the entire Los Angeles region, employer-based demand management strategies were slow to evolve. Employers were required only to develop “approvable” plans to achieve specified ridership goals with no penalty for failure to achieve the goals. A detailed study of 1,110 work sites found that the implementation of Regulation XV reduced vehicle use to participating facilities by about 5 percent during the first year of the program. The most instructive finding of this study is that the primary improvements in ridership came from increased use of carpools. All other changes were trivial: a slight increase in vanpools and compressed workweeks, a slight decrease in bicycling/walking and telecommuting, and no change in transit use. This finding suggested that reduced vehicle use can be achieved with little or no institutional change, because carpools do not require the same level of organizational effort and financial support as many other options.

Even if successfully implemented, the overall travel implications of programs similar to Regulation XV would be modest. Commute trips represent about 25 percent of daily trips, and commute trips to facilities with a hundred or more employees represent approximately 40 perent of commute trips in the Los Angeles area. Even if commute trips to affected facilities are reduced between 5 percent and 20 percent, employer-based trip-reduction strategies may yield total daily trip reductions of between 0.5 percent and 2 percent (although primarily achieved during peak periods). The costs of such initiatives are substantial. Employers often hire rideshare coordinators and provide incentives, and regulators must monitor and enforce the program. In a survey of more than 400 Los Angeles area facilities the typical cost of placing employees in carpools or transit through personalized ridesharing assistance ranged from $7.72 per employee in large firms (~10,000+ employees) to $33.91 per employee in small firms (~100 employees).

A few years after Regulation XV was implemented, when medium-sized businesses (100–250 employees) came under the regulatory requirements, the business community began exerting significantly increased political pressure on the South Coast Air Quality Management District (SCAQMD) to repeal the regulation, and took their case directly to Congress. On December 23, 1995, Congress amended Section 182(d)(1)(b) of the Clean Air Act. The new language allowed air quality planning agencies to opt out of the required employer-based programs.

Overnight, employee commute programs around the nation became voluntary, disappearing entirely from air quality management plans.

The SCAQMD undertook an eighteen-month study in which the agency encouraged voluntary rideshare efforts for medium-sized facilities. However, the exemption of facilities from employer-based trip reduction and ineffective implementation of voluntary programs yielded an increase in pollutant emissions. Despite the failure of voluntary measures, the California State Legislature permanently exempted medium-sized businesses from the Los Angeles regulations. The largest air pollution control agency with the worst air quality in the nation could not retain their commute program for medium-sized employers over public objection.

Public Information and Education

Recent behavioral shifts, such as the overall decrease in the number of smokers and the increase in residential recycling activity, suggest that ongoing media campaigns coupled with formal education programs can effectively influence human behavior. Many of California's local air pollution control districts have implemented education programs as a means of increasing public awareness of how travel behavior affects air quality. The California Air Resources Board prepared a variety of information packets for government decision-makers as well as the public. Numerous states and local air pollution control agencies have followed suit across the United States.

Education campaigns implemented in conjunction with regulatory mandates can make employer-based trip reduction strategies more efficient at both the facility and regional levels. The SCAQMD implemented an education program to support their employer trip reduction program. District staff members advised corporate representatives on cost-effective strategies implemented by other companies in the region. They recommended compressed work weeks, in-house rideshare matching, subsidized transit passes, carpool/vanpool subsidies, preferential carpool parking, flexible hours, telecommuting, bicycle lockers and showers, and company award/prize programs. Agency staff also recommended guaranteed ride home programs as a necessary supplement to successful carpooling strategies. Of the sixty-five employers that received advice and provided final cost information, about 88 percent (fifty-seven) reported a significant decrease in program implementation costs as a direct result of switching to the new options recommended by SCAQMD in 1997. The average annual cost per worksite declined from $35,616 to $16,043 (an average of $19,573 per worksite, or $70 per employee).

Programs aimed at the younger generation through grade school may achieve positive results over time. Children's programs are likely to yield a future generation that is educated about the economic, environmental, and social costs associated with transportation. Given the historic failures of regional travel programs and public resistance of pricing strategies, public awareness campaigns are becoming a major focus of U.S. regulatory agencies. It remains to be seen if these investments will prove cost-effective.

Economic Incentives

Economic incentives in transportation include monetary incentives or disincentives to the transportation consumer (i.e., vehicle operator or passenger) as encouragement to change travel behavior. Economists have long argued that monetary signals serve as the most economically efficient method to achieve changes in transportation demand. They argue that consumers will consume goods and services most efficiently when they are required to pay the full cost of the goods and services. Provided costs are not set too high, economic incentives should achieve behavioral change more efficiently than prescriptive rules. Economic incentives including congestion pricing and gasoline tax increases have received strong support from businesses, environmentalists, and local press editorials in San Francisco.

Transportation economics literature argues persuasively for the implementation of congestion pricing to improve the efficiency of the current transportation system. Area licensing schemes are also an option, where vehicle owners purchase stickers allowing the car to enter the most congested areas of the city during peak hours. Singapore, Hong Kong, and Oslo and Bergen in Norway provide examples of area license schemes.

The Environmental Defense Fund and Regional Institute of Southern California sponsored comprehensive modeling studies of pricing on transportation behavior for the Los Angeles area. The findings are as follows:

- Regional congestion pricing of $0.15 per mile may yield a vehicle miles traveled (VMT) reduction of about 5.0 percent and trip reduction of 3.8 percent;

- Regional \$3.00 per day parking charges may yield a VMT reduction of about 1.5 percent and a trip reduction of 1.8 percent;
- Regional \$0.60 per hour nonemployee parking charges may yield a VMT reduction of about 3.5 percent and trip reduction of 4.3 percent;
- Mileage and smog-based registration fees averaging \$110 per vehicle per year may yield a VMT reduction of about 0.4 percent and trip reduction of 0.7 percent.

Because of academic interest in congestion pricing theory, Congress established the Congestion Pricing Pilot Program in the Intermodal Surface Transportation Efficiency Act (ISTEA) of 1991 to fund congestion pricing studies and demonstration programs. Due to a lack of political support for congestion pricing on public roads, no significant congestion pricing programs have been implemented in the United States.

High occupancy toll (HOT) lanes are proving to be a potentially viable alternative to congestion pricing. HOT lanes allow single occupant vehicles to access new high occupancy vehicle lanes or facilities by paying a toll. HOT lane facilities are now operating in San Diego, California; Riverside, California; and Houston, Texas. Because the public perceives HOT lanes as providing new capacity and appears more accepting of tolls on these facilities, additional investigation into the consumer acceptance and economic benefits of HOT lanes will continue.

Gasoline Taxes. Studies in 1994 indicated that a \$2.00 increase per gallon in gasoline tax (raising United States prices from about \$1.00 to about \$3.00 per gallon) could yield a VMT reduction of about 8.1 percent and trip reduction of 7.6 percent. Determining the long-term effects of higher gasoline prices can be difficult. Fuel costs are a small component of the total cost of owning and operating an automobile. Research indicates that gasoline demand is relatively inelastic over the short-term and somewhat more elastic over the long-term. Significant increases in fuel price can affect short-term automobile use. However, when fuel prices rise significantly, demand for new fuel-efficient vehicles also increases. Individuals who purchase more fuel efficient vehicles can retain many of the trips and VMT without experiencing significant increases in total operating cost. Fuel price, VMT demand, and fuel intensity are interlinked, and the cumulative effect yields the change in net travel demand and net fuel consumption.

Parking Pricing. In the United States, paying for parking is the exception rather than the rule; 90 to 95 percent of auto commuters pay nothing for parking. Nationwide, employers provide 85 million free parking spaces to commuters, with a fair market value of nearly \$36 billion a year. Even in the central business district of Los Angeles, where parking fees are more common than in most areas, of the 172,000 office workers, more than 54,000 drivers park at their employer's expense.

Despite the fact that most employees pay nothing for parking, it is important to remember that there is no such thing as free parking. Even if employers do not pay an outside vendor and instead provide their own lots for employee parking, these lots must be constructed, gated, monitored, and maintained. Companies providing parking to employees at no charge pay an opportunity cost for not putting their property to more productive uses. The land could be developed and used in producing more company income or could be sold for development by others. Employers simply pass on the real and opportunity costs of parking to the consumers of the goods and services provided by the company. These consumers benefit little, if at all, from the parking provided to employees. Failure to charge employees for parking constitutes an inefficient pricing structure.

Travelers are highly sensitive to parking charges because the charges represent a large change in their out-of-pocket costs. Parking costs is one of the three most frequently cited factors (along with convenience and time saved) in the carpool decision. This responsiveness to parking prices is economically rational because motorists treat the vehicle purchase and annual insurance payments as sunk costs with respect to daily travel decisions, leaving parking costs as a large percentage of out-of-pocket expenses. For instance, typical commute trips to the Los Angeles core business district cost less than \$2.00 per day in gasoline costs. Adding the fair market value of parking to gasoline costs can increase out-of-pocket expenses to roughly \$6.00 per day. Studies show that free parking is a greater incentive to driving alone than providing free gasoline.

Various case studies lend support to the finding that parking prices are significant in affecting trip-generation and mode choice. An early study of employer-paid parking effects on mode choice, conducted in the late 1960s in the central business district of Los Angeles, examined county workers receiving employer-paid parking and federal employees paying for their own parking. The CARB (1987) study found that only 40 percent of the employees subject to parking fees drove to work alone, while 72 percent of similar employees that were not subject to parking fees drove alone. The availability of transit and alternative modes, and the amount of available free parking, influence the effectiveness of parking pricing. An analysis of thirteen employers in 1991 found that when they instituted paid parking programs the number of trips at the worksite was reduced by 20 percent. Other studies in the Los Angeles area indicate that between 19 percent and 81 percent fewer employees drive to work alone when they are required to pay for their own parking.

Employer-paid parking is changing in California because of a law requiring employers to "cash out" free parking. The 1992 California law, and subsequent regulations, require employers who provide free or subsidized offsite parking to their employees to provide a cash equivalent to those employees who do not use the subsidized parking (California Health and Safety Code 43845). The program applies to employers of more than fifty persons in areas that do not meet the state ambient air quality standards (between 3 percent and 13% of the medium and large employers in the Los Angeles area).

The California Air Resources Board (CARB) sponsored research in 1997 to evaluate eight case studies of firms that complied with California's parking cash-out. The number of drive-alone trips to these facilities dropped 17 percent after cashing out. The number of carpool participants increased by 64 percent; the number of transit riders increased by 50 percent; the number of workers arriving on foot or bicycle increased by 39 percent; and total commute trip vehicle miles of travel dropped by 12 percent. These findings are a revelation because this significant shift in travel behavior resulted from a regional policy.

Most businesses in Los Angeles have hesitated to implement employee parking pricing, despite the fact that increased parking fees can increase vehicle occupancy much more efficiently that other strategies. Most employees who receive free parking view this subsidy as a right, or fringe benefit of employment.

TRANSPORTATION SUPPLY IMPROVEMENT STRATEGIES

Transportation supply improvement strategies change the physical infrastructure or operating characteristics to improve traffic flow and decrease stop and go movements. They often require intensive capital investment and comprise bottleneck relief, capacity expansion, and construction improvements. Regional transportation plans usually include integrating high-occupancy vehicle (HOV) systems (differentiated from construction of HOV lanes). Many areas are also refocusing efforts on traditional technology-oriented means that reduce traffic congestion: signal timing optimization, rapid incident response, ramp metering, and applications of intelligent transportation system technology.

HOV Systems

Serious congestion delay often exists in the same urbanized areas that fail to meet federal air quality standards. In these areas, capacity expansion projects are usually difficult to implement. The emissions from the increased travel demand that follows corridor expansion can create additional air quality problems. One effective means of expanding capacity while restricting a corridor's travel demand and emissions growth is the addition of HOV lanes. Only carpools and transit vehicles can use these HOV lanes. The efficiency of carpool lanes as a system improvement is a function of the characteristics of the overall HOV system. Vehicles need to remain in free-flowing HOV lanes until they reach the exit for their destination or the time benefits associated with the carpooling activity are limited. Forcing carpools out of dedicated lanes, into congested lanes, and back into dedicated lanes is an impediment to carpool formation. HOV systems that ensure faster travel through congested regions are more successful in attracting users. Many urban areas are integrating HOV bypass facilities, and HOV onramps/offramps into interconnected systems.

Signal-Timing Optimization

Traffic signal-timing improvement is the most widespread congestion management practice in the United States. During the late 1970s and early 1980s, many cities and municipalities began focusing on improving signal timing as a means to reduce fuel consumption. Traffic engineers program traffic signal green, yellow, and red times at a local traffic control box located at the intersection. Signal-timing improvements can range from a simple change of a timing plan (such as increasing green time on one leg of an intersection during a peak period), to complex computer-controlled signal coordination along an

Carpool lanes, like this one on a California freeway near the Westwood neighborhood in Los Angeles, were designed to encourage more people per car. (Corbis-Bettmann)

entire transportation corridor. By linking control boxes at consecutive intersections and coordinating the green lights along a traffic corridor, vehicles moving in platoons can pass through consecutive intersections without stopping. In general, signal-timing programs reduce the number of stops, reduce hours of stop delay, and increase overall system efficiency. Consumers benefit from reduced congestion, increased safety, reduced stress, and improved response times for emergency vehicles.

Transportation engineers model signal-timing improvements using simulation programs and system optimization routines. In optimization programming, timing plans will be changed to purposely delay some vehicles, or platoons of vehicles, whenever such a delay has the potential of reducing congestion delay for many other vehicles on the road.

Numerous studies agree that signal-timing optimization programs are cost-effective. In 1986 California had an average first-year fuel use reduction of 8.6 percent from signal-timing programs. In 1980 the Federal Highway Administration's National Signal Timing Optimization Project examined the effectiveness of signal-timing improvements in eleven U.S. cities. The study found that these cities had reduced vehicle delay by more than 15,500 vehicle hours per year, stops per intersection by more than 455,000 per year, and fuel consumption by more than 10,500 gallons per year. Signal-timing optimization also has the potential to significantly decrease vehicle emissions in urban areas. Many cities do not place signal-timing improvement near the top of their annual resource priority list for transportation funding. Future programs that employ real-time signal controls (traffic responsive control strategies) will become widespread once program resources are made available by states and municipalities for the necessary technology and expertise to implement these systems.

Rapid Incident Response Programs

Roadside assistance programs detect and rapidly respond to crashes and breakdowns to clear the vehicles from the roadway as quickly as possible. Crashes often result in lane blockages that reduce capacity until the crash is completely removed from the system. Even a vehicle stalled on the shoulder of the road can create significant delays. After the incident is cleared, additional time is required for the congestion to clear. Reducing the duration of lane blockages by even a few minutes each can save thousands of hours of total congestion delay each year.

Many urban areas are now using video detection systems to monitor traffic flow. The systems, such as Autoscope, detect changes in video pixels to estimate traffic flow and vehicle speeds on freeways and major arterials. Significant differences in average speeds from one monitor to another indicate the presence of an accident between video monitoring locations. With early detection of an incident, rapid accident response teams (either roving the system or staged in specific locations along the system) can be dispatched immediately. Cellular telephones will also play an increasing role in incident detection programs as the cellular network density increases.

A recent study of the Penn-Lincoln Parkway indicated that the annual program investment of $220,000.00 for their roadside assistance program reduces congestion delay by more than 547,000 hours per year (and a benefit-cost ratio of 30:1).

Ramp Metering

Major urban areas in the United States have begun implementing ramp metering to optimize performance of major freeway systems. A ramp meter brings vehicles on the onramps entering the freeway to a complete stop during peak periods and releases vehicles to the freeway one or two at a time. Metering prevents queues of vehicles from entering the traffic stream and disrupting freeway traffic flow. Ramp meters delay the onset of congested stop-and-go activity, allowing freeways to continue to operate at efficient flow rates for extended periods. Ramp metering delays vehicles arriving at the ramps, but the net congestion savings on the freeway more than offsets the ramp delay. Although emissions are significantly lower on the freeway systems when metering maintains smooth traffic flow, the net emissions benefits of such systems are not clear at this time. The hard accelerations associated with vehicles leaving the stop bar on the ramp result in significantly elevated emissions levels. New ramp metering research projects are trying to determine the systemwide tradeoffs in emissions.

Intelligent Transportation Systems

A variety of intelligent transportation systems (ITS) with the potential to improve traffic flow and relieve congestion are currently being explored. ITS technologies range from simple delivery of traffic information into the vehicle (helping drivers optimize route choice decisions) to complete vehicle automation. Although many of the proposed ITS strategies require development of new roadway and electronic infrastructure systems, some new technologies will evolve over the near term. Drivers can expect to access, via cellular Internet connections, detailed transportation system performance data. Electronic in-vehicle maps and systems data will allow users to optimize travel decisions and avoid getting lost. New radar systems will transmit warnings from roadside systems to vehicles, giving construction zones a new level of protection. Onboard collision avoidance systems may also prevent a significant number of rear-end crashes that cause congestion.

RELATIVE EFFECTIVENESS OF DEMAND AND SUPPLY STRATEGIES

Due to political changes regarding transportation control measures (TCMs), the CARB shifted from advocating TCMs in the late 1980s to evaluating their cost effectiveness by the mid 1990s. In 1995 they studied the cost effectiveness of twenty emissions reduction strategies funded by California vehicle registration fees. The CARB analyses indicate that signal timing, purchases of new alternative fuel vehicles, and construction of bicycle facilities can be cost effective compared to many new stationary source control measures. A videophone probation interview system designed to substitute for office trips resulted in an agency cost savings, indicating that there are still technology projects that can simultaneously attain emissions reductions and save public dollars. Of the twenty measures, eleven tried to change travel demand, and nine tried to improve traffic flow or to shift drivers to new vehicles or alternative fuels. Only six of the eleven demand management measures proved cost-effective. The technology-oriented supply improvement strategies (such as signal timing) and fuel shifts fared better, with eight of the nine measures proving cost-effective.

MODELING THE EMISSIONS IMPACTS OF TRAFFIC FLOW IMPROVEMENTS

Experts believe that current emissions models overestimate emissions at low operating speeds. They predict emissions solely as a function of average speed. However, emissions are a strong function of speed/acceleration operating conditions. Modal emission rate models demonstrate that emissions in grams/second are fairly consistent when the vehicle is operating at low to moderate speed with low acceleration rates. Under these conditions, the gram/mile emissions rates are a function of the constant gram/mile rate and the amount of time the vehicle spends on the road segment in question (which is a function of average speed). Emissions can skyrocket under high-speed conditions and conditions of moderate speed with high acceleration and deceleration rates. The operating condition corresponding to the lowest emissions and reasonably efficient fuel consumption is smooth traffic flow, probably between 20 to 35 mph, with little acceleration and deceleration.

Evaluation of traffic flow improvement projects using the current emission rate modeling regime is bound to underestimate the air quality benefits. Because emissions are activity-specific, it is important to develop methods that can estimate the effect of traffic flow improvements on trip emissions in terms of changes in speed/acceleration profiles. The Georgia Institute of Technology and University of California at Riverside are currently developing emissions models that can assess the benefits of traffic flow improvements. The application of these modal emissions models is expected to show that improved signal timing may have a pronounced impact on improving emissions.

CONCLUSION

Evidence suggests that demand management initiatives have had relatively small impacts on travel behavior and fuel consumption in the United States. Direct agency intervention at the regional level has not worked as intended. During the 1990s, economic incentives designed to internalize the personal and social costs of the automobile seemed to be the most logical and promising ways of achieving changes in travel behavior. As consumers internalize the true costs of owning and operating the personal automobile, individual tripmaking decisions become more rational, increasing system efficiency. Strategies such as congestion pricing, emission fees, and even pay-as-you drive automobile insurance received a great deal of attention in state legislatures and in the popular press. Before the public widely accepts pricing strategies in the United States, regulators need to address a variety of equity dilemmas. In an era of cheap and abundant energy, it is likely that such pricing arguments will focus on potential air quality and congestion benefits rather than on energy consumption benefits.

The most successful transportation-related economic incentive to date has been the parking cash-out program in California. Limited-scale implementation has been very successful. Regional parking pricing is likely to be a viable travel demand strategy, but will be difficult to adopt. Tax codes that allow employers to provide parking as a tax-exempt employee benefit would need to change. Employers and employees need to feel that the costs of parking are real. By implementing pricing strategies that the public will support, and simultaneously continuing public education campaigns explaining the energy and environmental problems associated with owning and operating an automobile, gradual acceptance of more widespread incentives might be achieved.

Despite the implementation and performance limitations of demand management strategies, metropolitan areas have been able to significantly improve traffic flow by implementing of transportation system improvement strategies. Lane expansion projects that provide bottleneck relief have become the focus of new roadway construction. Traffic signal timing optimization, rapid incident response systems, and implementation of HOV systems and high-occupancy toll lanes have significantly enhanced system capacity and reduced congestion. These strategies are capital intensive, but the returns on investment in congestion relief and fuel and emissions savings have been significant. The public seems much more willing to expend resources to enhance capacity than to endure less personal mobility imposed by demand management strategies.

Because of continued increases in vehicle ownership, tripmaking, and mileage, many researchers question the extent to which system improvement projects can mitigate congestion growth. As congestion worsens in major urban areas, there will be a greater focus on demand management strategies. In addition, land use strategies are getting more attention. Transit trips typically account for only 3 percent of the total trips made in the United States. Only in cases where transit is available, where origin and destination land use characteristics match desired tripmaking characteristics, and where transit costs (transit time, wait time, fares, and opportunity) are lower than automobile costs, do Americans opt to commute by transit. Proper design of land use, at densities that support transit operation and provide more opportunity to walk to common destinations, can provide significant long-term changes in travel patterns that minimize congestion, fuel consumption, and motor vehicle emissions. Because land use decisions come under local jurisdiction, federal agencies are now developing guidance documents for state and local agencies.

TRANSFORMERS

A transformer is an electrical component used to connect one alternating current (ac) circuit to another through the process of electromagnetic induction. The input current travels through a conductor (the primary) wound around a conductive core. The current traveling through the primary windings creates an alternating magnetic field in the core. An output conductor (the secondary) is wound around the same core so that the magnetic

Power transformer station in South Carolina. (Corbis-Bettmann)

field cuts through the secondary windings, inducing the output electrical current. For most transformers, the primary and secondary windings never come into direct electrical contact with each other. Instead, the transfer of energy from primary to secondary is accomplished solely through electromagnetic induction.

Transformers were developed through a series of scientific discoveries in the nineteenth century. Most notably, Michael Faraday showed in 1831 that a variable magnetic field could be used to create a current, thus pioneering the concept of electromagnetic induction. It was not until the 1880s that Nikola Tesla was able to use this principle to bolster his patents for a universal ac distribution network.

The majority of power transformers change the voltage from one side of the transformer to the other. The change in voltage is directly related to the number of turns each conductor (primary and secondary) makes around the transformer's core. For example, if the primary makes ten turns around the core, and the secondary makes five turns around the core, the secondary voltage will be half of the primary voltage. This type of transformer would be called a step-down transformer, since it steps down the voltage. On the contrary, if the number of turns in the primary is less than the number of turns in the secondary, the transformer will be a step-up transformer.

The power transformer also must maintain a balance of power from one side to the other. Power is the product of voltage and current. Therefore, neglecting any internal losses, if a transformer steps up the voltage by a given factor, it will also step down the current by the same factor. This has great application in the generation and transmission of electricity. It is difficult to generate extremely high voltages of electricity. Generating plants produce electricity at a relatively low voltage and high current, and step the voltage up to transmission levels through a transformer. This has the added effect of reducing transmission losses, since as the voltage increases, the current decreases, thereby reducing resistive voltage drops.

Iron (or steel) is frequently used as a transformer core because it provides adequate magnetic flux at a relatively low reluctance. In other words, iron cores, however, require additional design considerations to prevent excessive power losses and heat dissipation. The changing magnetic field inside the core creates current not only in the secondary windings of the transformer but also within the core itself. Using a laminated core constructed from small laminated plates stacked together and insulated from each other reduces these losses.

Other types of transformers include instrument, radio-frequency, wide-band, narrow-band, and electronic transformers. Each of these transformers operates similarly and is used in specific applications best suited for the transformer's design characteristics.

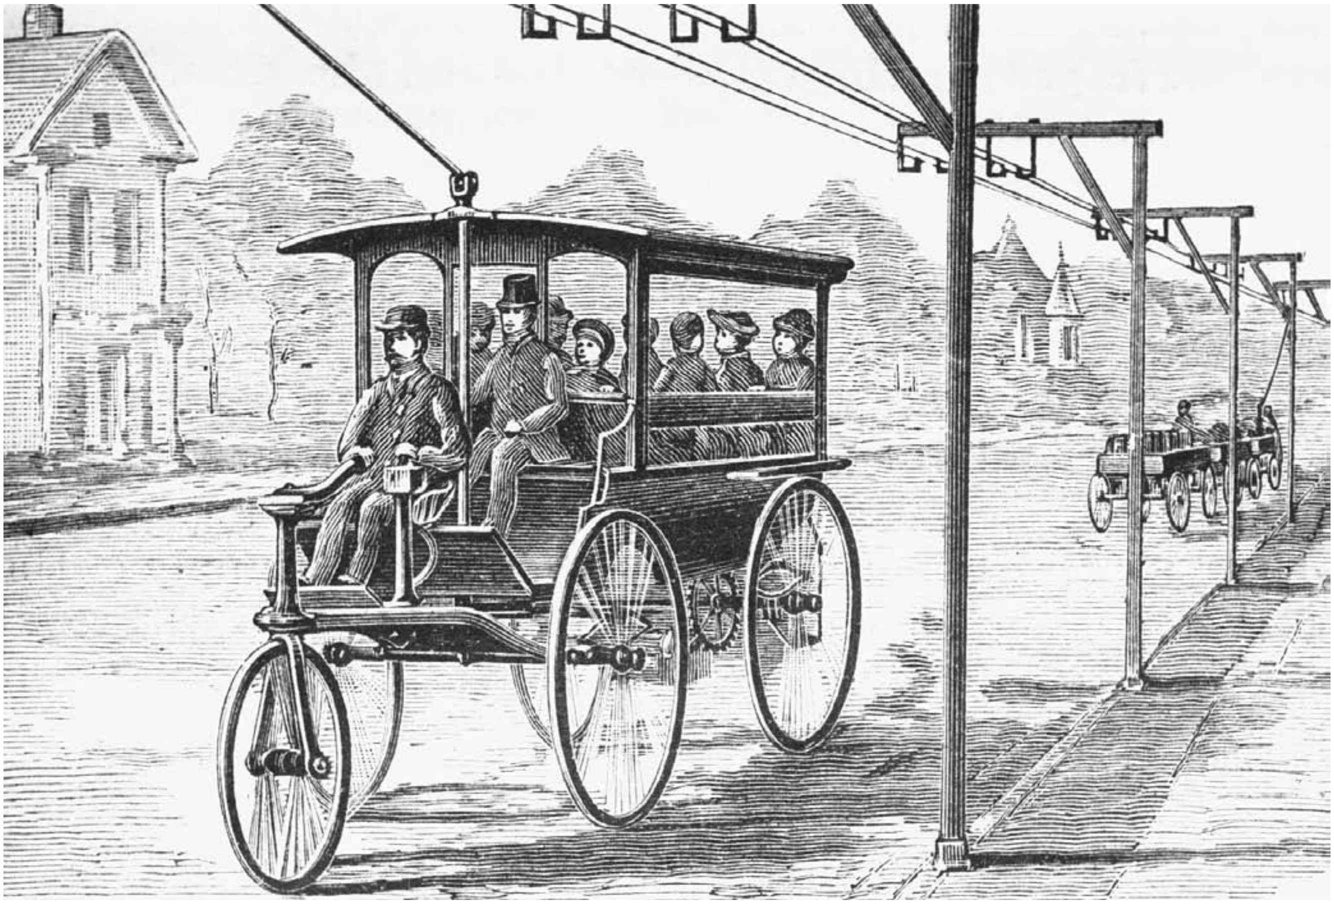
TRANSPORTATION, EVOLUTION OF ENERGY USE AND

Transportation is energy in motion. Transportation, in a fundamental sense, is the application of energy to move goods and people over geographic distances. Freight transportation may be regarded as part of complex logistical and/or distribution systems that carry needed materials to production facilities and finished goods to customers. Transportation of passengers can serve long-distance travelers, daily commuters, and vacationers, among others. Special systems accommodate the requirements people have for mobility throughout the day. A wide variety of specific technologies and management systems are involved, and from the mid-nineteenth century, a large portion of the world's energy supply has been devoted to transportation.

When sailing vessels predominated at sea and when horses or draft animals provided basic land transport, energy demands by transport systems were small. With the advent of increasingly reliable steam power for river, lake, and ocean vessels beginning in the late 1820s, together with the spread in the 1830s of steam railways running long distances in Europe and North America, demand rose sharply in the industrialized countries for wood and coal as fuel. Coal became the fuel of choice for ocean transport as steam gradually displaced sail from the mid- to the late nineteenth century, since far more Btus per volume of fuel could be stored in the limited space of fuel bunkers.

Nearly all locomotives in Britain, and many on the Continent, used coal as well. In North America, wood—because of its plentiful supply—was the principal fuel for locomotives and for western and southern riverboats through the late 1860s. Locomotives of some railroads in Pennsylvania burned anthracite—”hard” coal. Most of the earliest coal production in the United States, starting in the 1820s, was anthracite, which was slow-burning but produced very little smoke. That virtue made anthracite the preferred type of coal for home heating and for industries within large urban centers such as Philadelphia and New York, to which the costs of transporting wood were higher than to smaller cities and towns closer to their wood supplies.



Electric propulsion street cars. (Corbis Corporation)

Railway use of wood as fuel in the United States peaked at almost 3.8 million cords per year in the 1860s and fell slowly thereafter. From the 1850s, the use of coal—preponderantly the more common type, called bituminous or “soft” coal—increased on railways and on waterways, especially in the East and Midwest as coal production in those regions accelerated. (A ton of good bituminous equaled the heating value of 1¾ to 2 cords of seasoned hardwood.) Two major factors influenced the broad conversion to coal: First, as the quantity mined increased, prices fell—from $3.00 per ton in the 1850s to about $1.00 per ton to high-volume purchasers just ten years later. Second, the country’s voracious appetite for wood—for domestic and industrial fuel, for charcoal used in ironmaking, and for construction—had denuded vast stretches of the eastern forests by 1880. In that year U.S. railroads consumed 9.5 million tons of coal, which accounted for about 90 percent of their fuel supply.

Electricity, generated primarily from coal, became widely used for transport within and near cities, as trolleycar systems proliferated after the late 1880s. The enabling developments were, first, successful forms of large-scale electric generation from steam-driven dynamos and, second, a practical method of electricity distribution to the railcars. Most such cars took their power from an overhead wire, with electrical grounding through the track. In many parts of the world, trolley systems became a fixture of urban transportation in large and medium-size cities. Trolley companies usually owned their own power-generation stations and often provided a given city with its first electrical distribution network. Trolley companies were therefore eager to sell electricity and often sponsored efforts to spread the use of electric lighting systems and other electric appliances. Elevated urban railways, powered at first by tiny, coal-fired steam locomotives in the 1880s and converted later to electricity, also helped ease urban congestion in New York and Chicago. A related development by 1900 in a few of the world's major cities was the electric-powered subway.

Especially in North America, a direct effect of the electric trolley—from about 1890 through the 1920s—was the rapid growth of suburbs. In some cases, trolley systems that extended beyond city boundaries accelerated the expansion of existing suburbs. In many other cases, new suburbs sprang up, facilitated by the cheap mobility offered by newly built trolley lines. Long-distance, electric interurban rail systems also grew at a fast rate in the United States after 1890. Throughout New England, the East, and the Midwest, and in many places in the South and West, travelers and longer-distance commuters could use electric railcars connecting small towns with medium-size and large cities, over distances of up to a hundred miles or so.

Since the mid-twentieth century, petroleum has been the predominant fuel stock for energy used in transportation on land, water, and in the air. The shift began slowly. Oil-fired boilers for ships were tried in the 1860s. A railway in Russia fired more than a hundred of its steam locomotives on oil in the 1880s. By the first decade of the twentieth century—and although coal was still the favored fuel for steam transportation throughout the world—several thousand steam locomotives in the western part of the United States as well as a few ocean vessels were fired by residual oil from a rapidly growing number of refineries or, in some cases, by light petroleum.

Regional scarcities of coal initially drove these uses. As petroleum became more abundant and as its price fell, oil became more attractive. In firing boilers, fuel oil possessed only a slight advantage over good-quality coal in Btus per unit volume. But liquid fuels were much easier to handle and store than coal. Competitive pressures kept the prices per Btu of residual oil and coal quite close.

The transition to oil for the boilers of oceangoing steamships was well along by the 1920s. A coincidental development in the early part of the century was the steam-turbine engine for ships, which mostly displaced multicylindered steam piston engines in marine applications; the turbine is more energy-efficient at constant speeds maintained over long periods of time. A decreasing number of older riverboats, towboats, lake boats, and freighters continued to use coal through the 1950s (and a rare few such steam vessels were still in use in the 1980s). As late as 1957, U.S. railroads purchased $48 million worth of bituminous coal for steam locomotive fuel—and $374 million of diesel fuel. By 1960, all use of steam locomotives on major lines in the United States and Canada had ended, and by 1970 the change to diesel locomotives was virtually complete worldwide, except in some parts of China, India, Africa, and Eastern Europe. Thus the use of coal as a transport fuel ended for the most part in the late twentieth century, except for electricity (generated from coal) used on a small percentage of the world's railway mileage.

The burgeoning growth in the use of petroleum-based fuels in transportation came with the widespread use of automobiles and trucks after 1910 and the beginning of air travel after World War I. In the 1890s, little gasoline was consumed. It was regarded as an explosively dangerous by-product of the refining process in the production of kerosene (a petroleum distillate) for lighting. But with the invention of practical automobiles in the 1890s in the United States and Europe, demand slowly grew for a high-energy fuel that could be used readily in small, internal-combustion engines. In such use, the high Btu per unit volume of gasoline was a distinct advantage. The story of the huge oil companies and gasoline distribution systems that arose in the United States and overseas in the early twentieth century is one driven entirely by the rise of the automobile.

During the first two decades of the twentieth century, several hundred firms in Britain attempted automotive production, and nearly 3,000 tried to do so in the United States. But there was one car that created much of the rising demand for gasoline: the Ford Model T. Between 1908 and 1927, 15 million Model Ts rolled out. Ford built half of the automobiles manufactured in the world in 1920. The Model T's low price and high reliability created a vast pool of willing purchasers. A result was to sweep away the economic incentives that might have supported a viable market for alternative fuels or motors for automobiles, such as electric or steam propulsion. Versus the electric, a gasoline engine provided much greater operating range; versus steam (such as the compact boiler and engine used in the temporarily popular Stanley steamer), a gasoline engine was much simpler and less expensive.

After 1910, gasoline-powered trucks became common. Their utility eventually replaced horse-drawn vehicles in farm-to-market and intracity use, though that replacement took decades. Even in the industrial world, horses provided a large but declining share of intracity freight transport through at least the 1930s and early 1940s. Highway buses became popular in the 1920s. Such buses quickly displaced the long-distance, electric interurban rail systems of the 1890s and early 1900s.

Rudolph Diesel first patented his engine in 1892, but it was not until 1910 that a successful application was made in a vessel. The first diesel engines suitable for use in trucks came in the early 1920s. Annual U.S. production of diesels did not exceed one million horsepower until 1935. Over the next two years that production doubled, largely because of railroad locomotive applications. Due to the high compression pressures a diesel engine must withstand in its cylinders, it must be built heavier than a gasoline engine of similar output. But the diesel's advantage is that it is the most energy-efficient internal-combustion engine yet developed. Marine diesel design advanced in the 1930s and during World War II, leading to greater use in larger transport vessels from the late 1940s. The demand for high-quality diesel fuel—similar to kerosene—thus expanded.

With the inception of the U.S. interstate highway system in the late 1950s, the modern long-distance highway tractor and its semitrailer evolved and became the predominant method of freight transportation for time-sensitive, high-value goods. Elsewhere in the world, different forms of the long-distance truck took over most freight transport. Today, in the United States and elsewhere, these trucks are almost universally diesel. In the United States in the 1990s, some 39 percent of intercity ton-miles of commercial freight were borne by rail, 28 percent by trucks, and 15 percent on lakes, rivers, and canals (the rest was carried by pipelines and a fraction of 1% by air). Diesel fuel powered nearly all this road, rail, and water transport.

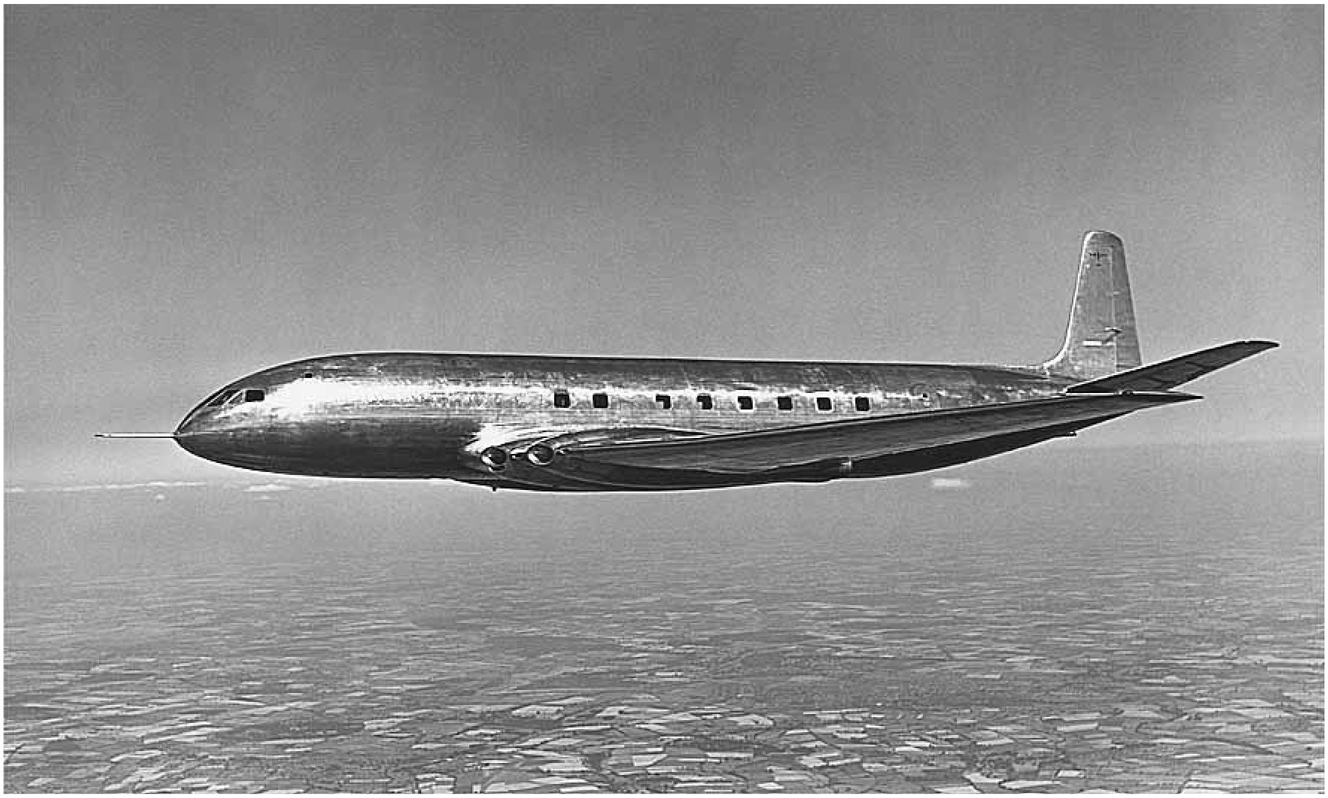
An aspect of transportation that has a heavy bearing on energy consumption is horsepower. Transport can be measured in units of *work*—tons hauled per mile, for example—but energy consumption is more proportionately related to *power*, such as tons per mile *per unit of time*. For a given load carried over a given distance, higher speed requires more power and hence more energy. Thus there is a trade-off especially important in all forms of transportation: Fuel-saving strategies often involve reduced speeds, while increased transport capacities of systems per unit of time often necessitate higher speeds and therefore require higher fuel use per ton-mile or per seat-mile.

Aviation has been powered from its beginnings by gasoline. Only spark-ignited gasoline engines proved able to provide the extremely high power-to-weight ratios needed by aircraft engines, where weight is always at a premium. During World War II, German and British engineers developed the gas-turbine engine for aircraft (known commonly as the jet engine). Such engines ran best on a variation of kerosene. In the "turbojet" form of the gas-turbine, there is no propeller; in the "turboprop" form, the central turbine shaft of the engine turns a propeller through a gearcase.

In transport applications in the 1950s, the jet's favorable power-to-weight ratio and efficiency at high altitudes resulted in a travel revolution. (The first commercial jet, the de Havilland Comet, first flew with paying passengers in 1952; the pioneering Boeing 707 came a few years later.) Speed was only one factor. Flying at more than 30,000 feet—well above the turbulent weather systems ordinarily encountered by piston-engined aircraft, which operate most efficiently up to about 20,000 feet or below—the comfort level of jets allowed millions of people to accept these new planes as long-distance transport.

Turboprop types of aircraft proved more reliable and cheaper to operate than piston-engined airplanes for short hauls and more fuel-efficient than turbojets in such use. Overall airline patronage shot up dramatically after 1960. Since the 1980s, air express has boomed as well. Thus most aviation fuel used today is well-distilled kerosene, with a small portion of antifreeze for the extremely low ambient temperatures at high altitude. High-octane gasoline powers much of the "general aviation" sector of private aircraft, where piston engines are still the norm for planes of up to four or five passengers.

During the oil shortages of the 1970s and early 1980s, researchers in the United States and Europe investigated alternative fuels for transportation. Shale oil deposits were tapped, and other projects experimented with the conversion of various grades of coal to oil (a technology developed by Germany in World War II). Two U.S. railroads (the Burlington Northern and the Chessie System) seriously considered a new-technology steam locomotive that would burn coal in a gasification furnace, thus controlling emissions.



Test flight of the De Havilland Comet 1 jet transport prototype. (Corbis-Bettmann)

Meanwhile, diesel manufacturers experimented with modified engines burning blends of finely pulverized coal mixed in fuel oil. While these engines ran reasonably well, tiny amounts of noncarbon impurities in the pulverized coal inevitably built up within the engines' cylinders, causing rough running or damage. Stabilizing oil prices from 1982 through 1999 removed most incentives for further research.

From 1980 to 1998, total U.S. petroleum consumption ranged between 15 million and 19 million barrels daily, with consumption at the end of the 1990s about the same as in the peak of 1978. Use of petroleum for U.S. transportation was slightly less than 10 million barrels per day in 1980 and was about 12 million barrels in 1997, or some 60 percent of total domestic oil consumption. That oil consumption rate supported a growth in U.S. freight of about 20 percent from 1980 to the late 1990s, amounting in 1997 to a bit less than 15,000 ton-miles of freight transported per person per year.

Travel has also multiplied. The U.S. Departments of Commerce and Transportation surveyed long-distance trips in 1977 and 1995 (with a long-distance trip defined as a round-trip of at least a hundred miles each way). Between those years, long-distance trips per person per year by automobile grew by almost 90 percent; by air, such trips nearly trebled. Increased mobility is a central feature of modern life.

All modes of transport—by road, rail, water, and air—have increased engine fuel efficiency and have instituted other fuel-saving strategies since the oil shortages of the 1970s. New turbine-engine aircraft have doubled the average fuel efficiency of earlier jets. On railroads, a gallon of diesel fuel moved 235 ton-miles of freight in 1980; in the early 1990s, a gallon moved more than 360 ton-miles. Average automobile fuel mileages have improved. Redesigned hull shapes and large, higher-efficiency diesel engines have lowered fuel costs in maritime transport.

New vehicles, propulsion systems, and fuels are on the horizon: "hybrid" automobiles (combining an electric motor, batteries, and a gasoline or diesel engine), better electric cars, greater use of compressed natural gas (CNG) and propane for urban fleet vehicles such as taxis and delivery trucks, fuel cells (using gasoline, natural gas, or propane as the feedstock for hydrogen), methanol or ethanol to supplement gasoline, and other technologies are advancing. For such technologies and fuels successfully to compete with oil in the transportation market, the techniques to liquefy and compress natural gas would need to become cheaper, new types of storage batteries must be made practical, and the necessary infrastructure to support CNG-, fuel-cell-, and electric-powered cars and trucks would need to be developed. The huge worldwide investment in petroleum extraction, refining, and distribution makes economic change in fuel technologies difficult.

In Europe, Japan, and the United States, newer high-speed electric railroad trains are being advanced. Japan has shelved its development since the 1980s of magnetic-levitation trains, but German firms continue work on such systems for possible application in Germany (a "maglev" line has been planned between Berlin and Hamburg) and elsewhere. Engine development for aircraft has recently cut the number of turbojet engines required for a long-distance, high-capacity transport airplane from three or four to two, cutting fuel consumption per seat-mile, and further fuel efficiency increases can be expected in the years ahead.

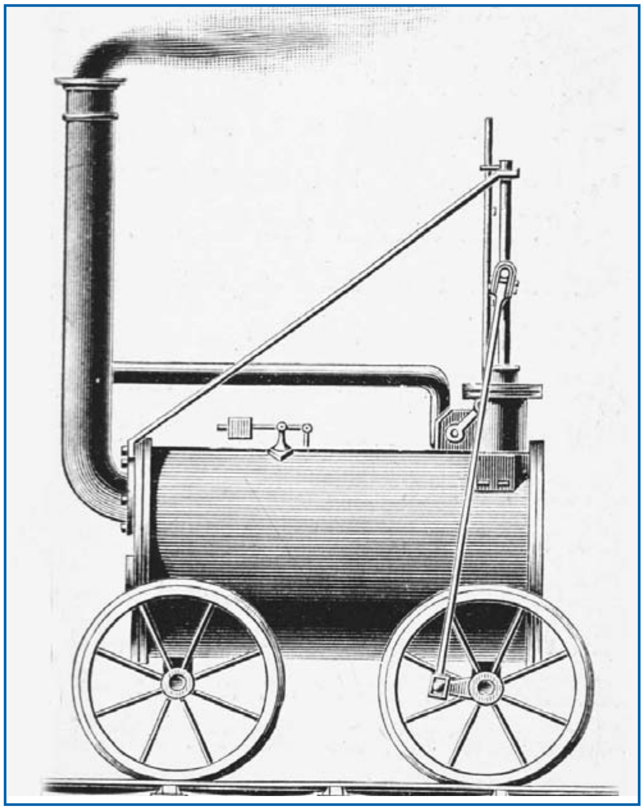
TREVITHICK, RICHARD (1771–1833)

The father of high pressure steam power was born at the village of Illogan in Cornwall, England, on April 13, 1771, the only boy after five older sisters. His father, also Richard, was a mine "captain," as mine managers were called. In 1760 Richard, Sr., had married Anne Teague of Redruth. Her family included several more mine captains.

While the village schoolmaster thought the younger Richard disobedient, slow, obstinate and spoiled, the positive sides of these qualities emerged in independent thought, technical planning, persistence, and the loyalty of his workers and friends. His uninspiring record as a student and lack of formal training in engineering mattered less as he began work in the mines. There his talent and interest in



Richard Trevithick's locomotive around 1804. (Archive Photos, Inc.)

engineering gainied early notice. First employed as a mine engineer in 1790 at age nineteen, he was being called on as a consultant by 1792.

The steam-power systems in Trevithick's youth were massive but lightly loaded low-pressure engines. This technology was controlled by Boulton & Watt, whose business acumen had extended patents far beyond their normal expiration dates. The royalties typically took one-third of the savings in fuel over the Newcomen atmospheric engine. Another necessary evil was the expense of fuel, as coal was not locally mined. Cornish engineers worked incessantly to design and invent their way past these limitations.

Working around the Watt patents, he ensured safety while progressively raising the pressure of his systems to ten times atmospheric pressure, avoiding Watt's condenser altogether. This threat to the income of Boulton & Watt was met with a court injunction to stop the construction and operation of Trevithick's systems. Boulton & Watt had ruined other competitors, and their alarmist views of high pressure steam were largely due to lack of patent control in that emerging technology.

In 1797, Trevithick married Jane Harvey, lost his father, Richard, Sr., and made his first working models of high pressure engines. His wife was of the established engineering and foundry family of Hayle.

Trevithick's high-pressure engine models, including one with powered wheels, were the seeds for a line of improvements to steam engines and vehicles by many developers through the following decades. These departed from the preceding vehicle concepts and constructs of Murdock or Cugnot. These "puffer" engines made better use of the expansive properties of steam since they worked over a wider pressure differential. Using no condenser, Trevithick directed the exhaust up the chimney, inducing draft to increase the firing rate proportional to engine load, avoiding Watt's patents.

The first successful steam road vehicle was demonstrated climbing a hill in Camborne, Cornwall, on Christmas Eve, 1801. A new carriage, fitted with a proper coach body, was demonstrated in London in 1803. Eventually, a backer appeared with confidence and purchased a share in the developments. Samuel Homfray had Trevithick construct the first successful railway locomotive for his Penydarren Ironworks in South Wales. It was first run on February 13, 1804. Eight days later it won Homfray a wager of five hundred guineas. Homfray's existing cast-iron, horse-drawn rails were not yet suitable for continuous use. A similar locomotive was built at Newcastle-on-Tyne in 1805 to Trevithick's design. Again, the wooden rails were too light for the service. Trevithick's final showing of his locomotive concept was on a circular track at Gower Street in London where "Catch-me-who-can" gave rides for a shilling, but did not attract investment. Future developers would found an industry on Trevithick's technical generosity.

Trevithick's engineering reputation was established by the thirty high-pressure engines he built for winding, pumping and iron-rolling in Cornwall, Wales and Shropshire. His patent work and correspondence with members of the Royal Society might have brought him wider notice, but he was on a technical collision course with Watt and the engineering establishment, and conservative investors stayed away. Trevithick was left to financial alliances with indecisive or unscrupulous businessmen. While a near-fatal bout of typhus in 1811 kept him from work for months, his partner Richard Dickinson led him into bankruptcy in 1811.

Trevithick's high-pressure steam engines attracted attention, but his mechanical improvements enabling the boiler to withstand ten atmospheres of pressure were even more significant to power plant economy and practicality. He doubled the boiler efficiency. His wrought-iron boiler fired through an internal flue, the "Cornish" boiler became known worldwide. He applied the high-pressure engine to an iron-rolling mill (1805), a self-propelled barge using paddle-wheels (1805), a steam dredge (1806) and to powering a threshing machine (1812).

Some of Trevithick's other novel accomplishments and inventions include steam quarry drilling, applications for his superior iron tank construction, a "recoil engine" like Hero's Aeolipile, mining engines and mills in Peru, a one-piece cast-brass carbine for Bolivar's army, ship-raising by flotation, being the first European to cross the Isthmus of Nicaragua (from necessity), recoil-actuated gun-loading, iron ships, hydraulic dockside cranes, methods to drain Holland's lowlands, mechanical refrigeration, water-jet-propelled ships, and a portable heat storage heater.

Throughout his lifetime, Trevithick continued to measure his personal success in terms of his technical success in maintaining the fine balance of economy, utility and safety. At the end of his life he wrote, "I have been branded with folly and madness for attempting what the world calls impossibilities, and even from the great engineer, the late Mr. James Watt, who said...I deserved hanging for bringing into use the high-pressure engine. This so far has been my reward from the public; but should this be all, I shall be satisfied by the great secret pleasure and laudable pride that I feel in my own breast from having been the instrument of bringing forward and maturing new principles and new arrangements of boundless value to my country. . . . the great honour . . . far exceeds riches."

After becoming ill during a consulting stint at Dartford, Kent, England, Trevithick died, April 22, 1833, and was buried in a pauper's grave.

Continual disappointment in his business affairs kept him in relative obscurity even as his developments were reshaping the industrial world. Today, even the engineering community rarely notes his successes as the inventor of the first self-propelled road carriage we could call an automobile, and the railway locomotive.

TRIBOLOGY

The word tribology is derived from the Greek word, "tribos," which means "rubbing." Tribology covers the science of friction, lubrication and wear. Virtually any machine ever invented consists of components that must slide or roll relative to other components. Resistance to sliding and rolling caused by friction results in significant loss of energy. In fact, it has been estimated that as much as 33 percent of energy produced worldwide is used to overcome friction.

Friction and wear have many undesirable effects on individuals and society that are not widely known. Transportation vehicles have hundreds of moving parts that are subject to friction. Auto-mobiles generally wear out after about 100,000 miles of operation. Largely because of innovations to reduce friction and improve lubricants, the average lifetime (14 years in 2000) and miles of operation continue to increase. Since it requires as much energy to produce an automobile as it does to operate it for 100,000 miles, extending the life of an automobile would save considerable energy. The same applies to the steam and natural gas turbines that supply electricity and the home appliances that consume that electricity.

Friction and wear is even more important for national security. Downtime of military hardware as parts wear out and lower output power of military engines due to high friction can contribute to decreased effectiveness of the military and increases the costs of keeping highly specialized equipment in operation.

Wear of medical devices and biomaterials can affect quality of life. Wear of tooth fillings, artificial joints and heart valves can be inconvenient, costly (more frequent replacement) or even life-threatening (premature breakdowns). Wear of components can also cause accidents. Worn brakes and tires can cause automobile accidents, worn electrical cords can result in electrocution and fires and worn out seals can lead to radiation leaks at nuclear power plants.

RESEARCH

In the last few decades of the twentieth century the field of tribology has undergone a great surge in interest from industry and the scientific community. This is likely due to greater interest in conserving energy and natural resources. By lowering friction we conserve energy, and by lowering wear we increase product life, which conserves raw materials and the energy needed to turn raw materials into useful technology. However, there are many challenges to be overcome in the study of tribology.

Tribology is a surface phenomenon, and surfaces are extremely complex. As seen in Figure 1, when surfaces are sufficiently magnified we can see they are not flat, but consist of a series of peaks and valleys. In addition to being geometrically complex, surfaces are also chemically complex. Surfaces typically react with oxygen in the air to form a thin oxide film on the original surface. A thin gaseous film then generally forms on top of the oxide film. These films, which are usually so thin that they are transparent to the eye, significantly affect friction and wear.

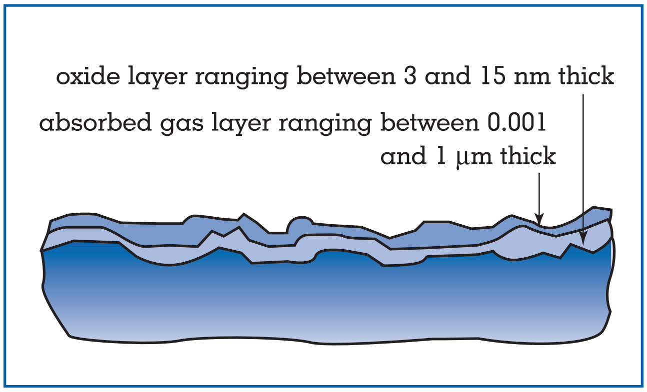

Figure 1.
Roughness of a "smooth" surface and surface films.

Besides surface topography, the hardness of the sliding materials, thickness and properties of oxide films, temperature, and type of lubricant all affect tribology. These factors overlap many fields of study, including physics, chemistry, material science and mechanical engineering. A complete understanding of tribology will require scientists and engineers from these diverse disciplines to work together. Traditionally, interdisciplinary research in tribology has not been done due to researchers being unwilling to cross the boundaries of their own discipline.

Surfaces are not easily observed during sliding. Tribologists study surfaces before and after sliding to determine chemical and geometric changes that occurred, and to infer how these changes came about and how they affected friction and wear. Because of the microscopic nature of tribology research, and the difficulty in duplicating real world conditions, it is not easy to observe and determine the cause of wear.

HISTORY OF LUBRICANTS

The most common method of minimizing friction and wear is through lubrication. The first recorded use of a lubricant was in ancient Egypt in 2400 B.C.E. Records show that they would pour a lubricant in front of a sledge being used to move a stone statue, which weighed tens of tons. The lubricant used was probably either water or animal fat. Various lubricants derived from animals and vegetables were used for thousands of years. Some examples of lubricants derived from animals are sperm oil, whale oil, and lard oil. Sperm oil was taken from a cavity in the head of sperm whales, whale oil from whale blubber, and lard from pig fat. Examples of vegetable lubricants are olive oil, groundnut oil and castor oil.

Lubricants began to receive significantly more attention from the industrial and scientific community in the mid-1800s with the introduction of mineral oils as lubricants. These proved to be effective lubricants; the demand for their use in machinery led to the development of many oil companies.

One common application for oils is the lubrication of automotive engines. When automotive oils were first introduced, their viscosities were classified as light, medium, medium heavy, heavy and extra heavy. This method of classification was too subjective and led to some engines being improperly lubricated. To remedy this, the Society of Automotive Engineers in 1912 introduced a quantitative numbering system for automotive viscosity. These numbers range from zero to fifty with lower numbers indicating lower viscosities. A general trend observed in oils is that as temperature increases, viscosity decreases. If viscosity becomes too small, the oil will be ineffective; if it is too high, the oil will not flow properly. Multigrade oils are now available that behave as lower viscosity oil at lower temperatures and higher viscosity oil at higher temperatures. For instance, a 10W-30 oil would have the viscosity of a 10-grade oil at low temperatures and the viscosity of a 30-grade oil at high temperatures. The use of multigrade oils minimizes change in viscosity with temperature.

In addition to viscosity grade, automotive oils also have a quality designation based on the API Engine Service classification system. This system was developed through the combined efforts of the American Society of Testing Materials (ASTM), the Society of Automotive Engineers (SAE), the American Petroleum Institute (API), automotive manufacturers and the United States military. API ratings describe the oil's ability to provide resistance to factors such as wear and corrosion. The original API rating was termed SA. This type of oil is suitable only for engines operated in very mild conditions. Oils with an API rating of SB are of higher quality than SA; SC has a higher API rating than SB, and so on.

In addition to liquid lubricants, solid lubricants such as graphite and grease have also been used for several centuries. Graphite was mined in the sixteenth century in Cumberland, England. It was originally called "black-lead" and was used in writing instruments. It is still used in "lead" pencils. There are numerous reports of graphite being used to lubricate machinery and silk looms in the nineteenth century. A common modern application for graphite is in the lubrication of door locks.

A specification for grease was given in 1812 by Henry Hardacre as follows: "one hundred weight of plumbago (graphite) to four hundred weight of pork lard or beef suet, mutton suet, tallow, oil, goose grease or any other kind of grease or greasy substance, but pork lard is the best, which must be well mixed together, so as to appear to the sight to be only one substance." Grease is used in many industrial applications including lubrication of gears and bearings.

CONSERVATION OF LUBRICANTS AND ENERGY

Most lubricating oils and greases use mineral oil as their base component. However, oil is a natural resource with a finite supply. Thus, it is imperative that measures such as recycling and extending the life of lubricants be taken to conserve the world's supply of oil and energy. There are approximately 2.5 billion gallons of waste oil generated each year in the United States. Only 83 million gallons are refined and reused, while one billion gallons are burned as fuel and another billion gallons or more are released into the environment. In response to these statistics, the United States Congress encouraged recycling of used oil through the Energy Policy and Conservation Act of 1975 and Resource Conservation and Recovery Act of 1976. The United States Environmental Protection Agency has stated that used oil is an environmental hazard, making the need for recycling even more critical.

Extending the interval between oil changes in automobiles and machinery is another way to conserve lubricants. Oil life is limited by depletion of oil additives, overheating, chemical contamination, and contamination of the oil by foreign particles. Using improved additives and filtering of particles, oil life can be considerably extended.

HISTORY OF FRICTION

DaVinci is well known for his famous paintings, such as the Mona Lisa, but his genius had amazing breadth. The scientific study of friction began with his research in the later part of the fifteenth century. He performed experiments in which he measured the force required to slide wood blocks over a wooden table. One of his most important findings was that the force F, required to produce sliding, increases in proportion with the applied load, L. DaVinci also defined what is today called the coefficient of friction, f, between two sliding objects as:

$$f = F/L$$

where F is friction force and L is normal load, as shown in Figure 2.

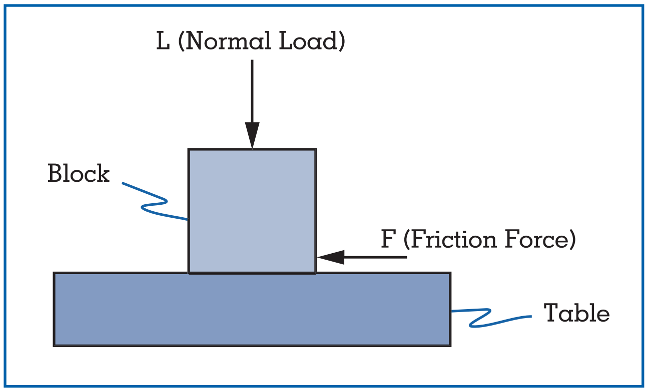

Figure 2.
The friction force between sliding objects resists movement. In this schematic, the block is being moved to the right.

DaVinci's experiments on friction also formed the basis for what today are called the first two laws of friction:

1. The force of friction, F, is directly proportional to the applied load, L.
2. The force of friction is independent of the apparent area of contact.

In general, a larger coefficient of friction between sliding bodies will require a larger force to produce sliding and, hence, more energy will be consumed. The most common method to reduce frictional energy losses is to lubricate the sliding surfaces. The reduction in coefficient of friction due to lubrication can be dramatic; typical values for dry sliding can range from 0.2 to 0.3, while typical values for lubricated sliding can range from 0.03 to 0.12.

The phenomenon of frictional heating is well known; for example, starting fires through the use of friction has been common since prehistoric times. However, frictional heating is generally a detrimental phenomenon. The temperature rise on sliding surfaces that occurs due to frictional heating generally produces a decrease in surface hardness, causing the surfaces to wear more easily, thus decreasing product life.

From an energy consumption point of view, we desire friction to be as small as possible. However, there are specific applications where friction should not be minimized. One common example is the brakes used in automobiles. If friction is too low, automobiles will not stop in a reasonable distance. However, if the friction is too high, a jerky ride will be produced. Other examples where high friction is desirable are shoe soles, nails, screws, and belt drives.

It is interesting to note that although friction has been studied for hundreds of years, there is no universal agreement on the fundamental mechanisms of how friction is produced. The two most popular theories are interlocking and adhesion. The interlocking theory states that as two rough surfaces slide over each other, the peaks on one surface "interlock" with peaks on the adjacent surface, producing resistance to sliding. The adhesion theory suggests that as the sliding surfaces contact each other, adhesive bonds form. These molecular bonds must be broken to continue sliding, which results in increased friction. The cost of not understanding the fundamentals of friction is high. Estimates have shown that as much as 0.5 percent of industrial countries' gross national products are wasted because we do not know enough about minimizing frictional losses during sliding.

FUTURE ADVANCES IN LUBRICATION

The transportation industries are being challenged with increasingly stringent government regulations that demand improved vehicle fuel economy and reduced emissions. Engine oils with greater ability to conserve energy are becoming more important as a way to lower engine friction and thus conserve natural resources. One specific approach under development is to produce engine oils with a friction-reducing additive such as molybdenum dialkyldithiocarbamate which has showed promise in developmental engine tests.

Another approach being used to conserve energy is to increase combustion temperatures in engines. This results in increased engine efficiency that produces energy savings. Combustion temperatures may eventually become so high that liquid lubricants break down and become ineffective. A possible approach for lubrication under these extreme temperatures is vapor phase lubrication, which refers to the deposition of lubricant from an atmosphere of vaporized lubricant. The vaporized lubricant is delivered in a carrier gas, such as nitrogen, to the component to be lubricated where it reacts chemically to form a solid lubricant film. These films are effective at much higher temperatures than liquid-based lubricants. Other approaches that can be used in components that operate in high operating temperatures are the use of gas bearings or magnetic bearings.

TRUE ENERGY COSTS

Market prices of energy often diverge from the true cost to society of consuming that energy. Two of the most common reasons for that divergence are external costs and subsidies, both of which make consumers think that energy is less expensive to society than it really is, and hence lead to more consumption of energy than would be economically optimal.

EXTERNAL AND INTERNAL COSTS

According to J. M. Griffin and H. B. Steele (1986), external costs exist when "the private calculation of costs differs from society's valuation of costs." Pollution represents an external cost because damages associated with it are borne by society as a whole, not just by the users of a particular fuel. Pollution causes external costs to the extent that the damages inflicted by the pollutant are not incorporated into the price of the fuel associated with the damages. External costs can be caused by air pollution, water pollution, toxic wastes, or any other damage to the environment not included in market prices for goods.

Some pollutants' external costs have been "internalized" because the resulting damage has already been incorporated into the price of energy by a tax on the energy source, or because an emissions-trading regime has been established to promote cost-effective control of that pollutant. The pollutants may still cause environmental damage, but these damages have been made internal to the economic calculations of consumers and firms by the taxes or emissions-trading schemes. They are thus no longer external costs.

For example, sulfur emissions from utility power plants in the United States are subject to an emissions cap and an allowance-trading system established under the Clean Air Act. An effective cap on annual sulfur dioxide emissions took effect in 2000, so no more than 8.95 million tons of SO_2 can be emitted annually. Utilities that want to build another coal plant must purchase sulfur emission allowances from others who do not need them. This system provides a market incentive for utilities to reduce their sulfur emissions as long as the cost of such reductions is less than the price of purchasing the allowances.

Subsidies

Subsidies represent an often hidden financial benefit that is given to particular energy sources by government institutions in the form of tax credits, research and development (R&D) funding, limits on liability for certain kinds of accidents, military spending to protect Middle East oil supply lines, below-market leasing fees for use of public lands, and other forms of direct and indirect government support for energy industries. Subsidies affect choices between different energy sources (which garner different levels of subsidy) and between energy-efficiency and energy supply choices (because some energy-efficiency options that would be cost-effective from society's point of view may not be adopted when energy prices are kept artificially low by the subsidies).

Subsidies can be created to reward important political constituencies, or they can promote the adoption of particular technologies. For example, an energy technology that has desirable social characteristics and low external costs might be a recipient of tax subsidies in the early stages of its development, so that it can gain a foothold against more established energy forms. This kind of support can be especially important for mass-produced technologies that have high costs when few units are being manufactured, but could achieve significant economies of scale in large volume production if the technology were widely adopted. The subsidy can provide the initial impetus that allows the technology to achieve lower costs and widespread acceptance. This rationale was the one used to justify the early subsidies of wind generation, which eventually led to the creation of an economically viable and internationally competitive U.S. wind industry.

Subsidies can also apply to the creation of new technology, through funding of research and development (R&D). The rationale for government subsidies for R&D (particularly long-term R&D) is well established in the economics literature. Companies will not fund the societally optimal level of basic R&D in new technologies, because many of the benefits of such research will flow to their competitors and to other parts of the economy (Mansfield 1982, pp. 454–455). Innovations are often easy to imitate, so which the innovators spend money on R&D, the followers can copy those innovations and avoid the risk and expense of such spending. R&D therefore has characteristics of a "public good."

Subsidies for relatively new energy technologies or fuels tend to be small in the aggregate and they tend not to have a measurable effect on the overall price of energy. When subsidies apply to widely used energy sources, however, they may create significant economic distortions, and the divergence from long-term economic efficiency may be substantial. Such distorting subsidies can sometimes exist for years because they are defended by powerful political constituencies.

EXTERNAL COSTS, SUBSIDIES, AND THE FUEL CYCLE

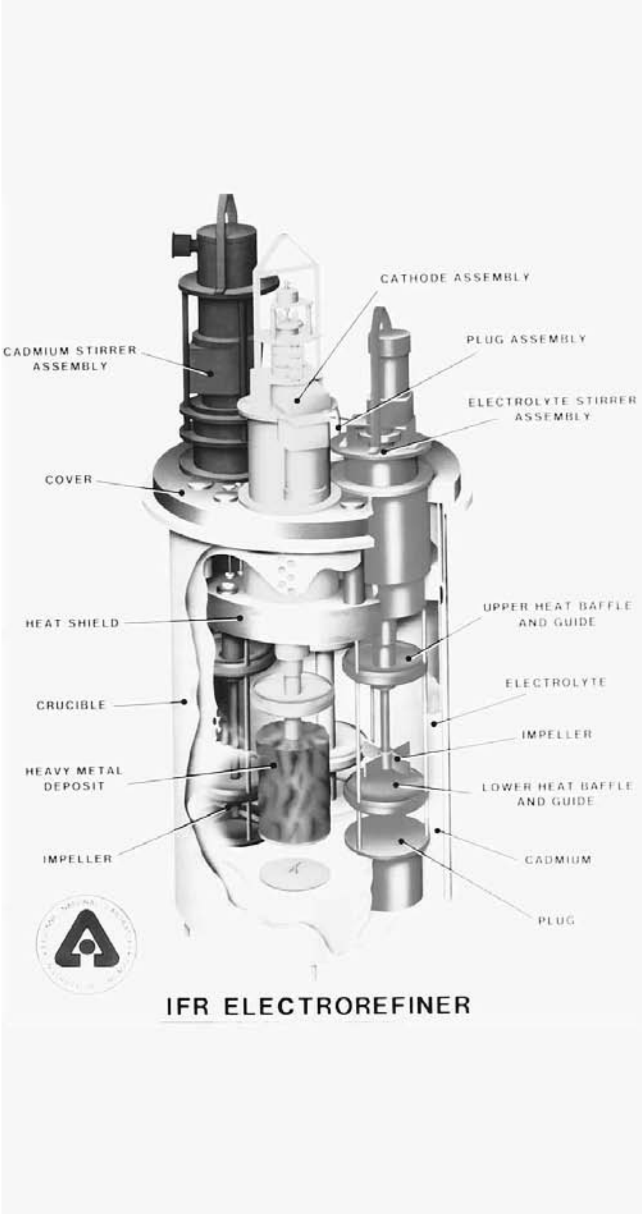
A comprehensive analysis of external costs and subsidies must treat each and every stage and phase in the process, which makes any such calculation inherently difficult. Uncertainties abound in these calculations, especially for external costs. As a result, estimates of total external costs and subsidies for different energy sectors vary widely.

External costs for fossil fuels are generally largest at the point of end use (combustion), though exploration (oil and gas drilling, mining), processing (refineries), and transportation (pipeline ruptures, tanker spills) can each contribute significant external costs in particular cases. For nuclear power, the accident risks associated with the conversion stage and the long-term issues surrounding disposal of spent fuel are the external costs that typically garner the most attention. There are also external costs from other stages of the nuclear fuel cycle, including the various effects of exploration, harvesting, and processing, as well as the risk of nuclear weapons proliferation from the spread of fissionable materials and related knowledge.

For nonfuel renewables such as hydroelectricity and wind power, external costs are most significant at the point of conversion (e.g., salmon migration blocked by dams, birds killed by wind turbine blades, noise and visual pollution from wind turbines). Construction of dams, particularly large ones, can also cause significant externalities by flooding large land areas, displacing people and wildlife, releasing methane from anaerobic decay of plant matter, and affecting local evapotranspiration rates. In contrast, generation of electricity using solar photovoltaics has few external costs, with the exception of small amounts of pollutant emissions from the manufacture and installation of the modules.

Most analyses of external costs have focused on electricity because of regulatory activities in that sector. One analysis of energy-related externalities in all sectors was conducted by Hohmeyer for Germany (Hohmeyer, 1988), but such comprehensive estimates are rare. For those analyses that have been done, estimates of external costs range from near zero (for photovoltaics and energy efficiency), to amounts that are significant relative to the market price of energy for some fossil fuels and nuclear power. The uncertainties in these calculations are typically quite large.

The most common subsidies for fossil fuels have been R&D and production incentives that have affected exploration and harvesting. R&D funding has also been important for fossil-fired, end-use technologies, such as furnaces that use a particular fossil fuel. For nuclear power, significant subsidies exist for processing/refining of fuel, R&D (which affects most stages), limitation of accident liability from operation of the plants, and management of long-lived wastes from the fuel cycle.



Cutaway diagram of an Integral Fast Refiner (IFR). It removes the short-lived by-products of nuclear fusion from the long-lived materials so the latter can be used to create new fuel. (Corbis-Bettmann)

A U.S. federal tax subsidy exists for wind generation and certain kinds of biomass-fired power plants built before December 31, 2001. Qualifying wind and biomass generators are paid 1.7 cents per kilowatt-hour generated over their first ten years of operation (the amount paid per kilowatt-hour increases over time at the rate of inflation). In the early days of wind generation there were subsidies in the United States for wind capacity installed, but these subsidies were phased out in the mid-1980s. R&D subsidies have been important for the development of new and more reliable renewable energy technologies. For energy-efficiency technologies, R&D funding and consumer rebates from electric and gas utilities have been the most important kinds of subsidies, but there has also been subsidization of installation of energy-efficiency measures in low-income housing. As the electric utility industry moves toward deregulation, states are increasingly relying on so-called “systems benefit charges” to fund subsidies for energy efficiency and renewable energy sources.

Unfortunately, the most recent estimates of energy subsidies in the United States date from the early 1990s and earlier, and such subsidies change constantly as the tax laws are modified and governmental priorities change. It is clear that total subsidies to the energy industries are in the billions to a few tens of billions of dollars each year, but the total is not known with precision.

ENERGY EFFICIENCY AND SUPPLY TECHNOLOGIES

External costs and subsidies for both energy efficiency and supply technologies must be included in any consistent comparison of the true energy costs of such technologies. Pollutant emissions from supply technologies are both direct (from the combustion of fossil fuels) and indirect (from the construction of supply equipment and the extraction, processing, and transportation of the fuel). Emissions from efficiency technologies are generally only of the indirect type. Increasing the efficiency of energy use almost always reduces emissions and other externalities.

THE TRUE COST OF ENERGY: AN EXAMPLE

While exact estimates of the magnitude of external costs and subsidies are highly dependent on particular situations, a hypothetical example can help explain how these two factors affect consumers’ decisions for purchasing energy. In round numbers, if subsidies are about $20 billion for energy supply technologies, and total direct annual energy expenditures for the United States are about $550 billion, the combined cost of delivering that energy is $570 billion per year. This total represents an increase of about four percent over direct expenditures for energy.

Including external costs associated with energy supplies would increase the cost still further. Typical estimates for external costs for conventional energy supplies are in the range of 5 to 25 percent of the delivered price of fuel (for the sake of this example, we assume that these percentages are calculated relative to the price of fuel plus subsidies). If we choose ten percent for externalities in our example, we can calculate the “true energy price” that the consumer would see if subsidies and externalities were corrected in the market price. If the average price of fuel (without any taxes) is P, then the price of fuel correcting for subsidies is $P \times 1.04$, and the price of fuel correcting for both subsidies and externalities is $P \times 1.04 \times 1.10$. So in this example, the price of fuel would be about fourteen percent higher if subsidies and externalities were correctly included in the price.

If the particular energy source in question is already taxed (say at a five percent rate), then part of the external cost is already internalized. The true cost of fuel would remain the same ($P \times 1.04 \times 1.10$) but the size of the additional tax needed to correct for the externality would be smaller (about five percent instead of ten percent).

KEY POLICY ISSUES

New subsidies often outlive the public policy purpose that they were intended to address. The better-designed subsidies contain “sunset” provisions that require explicit action to reauthorize them after a certain time. Subsidy and externality policies are often interrelated. It may be politically difficult to tax an energy source with high external costs, but much easier to subsidize a competing energy source with low external costs. Such “second best” solutions are often implemented when political considerations block the preferred option.

Another important consideration is that “getting prices right” is not the end of the story. Many market imperfections and transaction costs affecting energy use will still remain after external costs are incorporated and subsidies that do not serve a legitimate public policy purpose are removed. These imperfections, such as imperfect information, asymmetric information, information costs, misplaced incentives, and bounded rationality, may be addressed by a variety of nonenergy-price policies, including efficiency standards, incentive programs, and information programs.

TURBINES, GAS

The aircraft gas turbine engine, developed more than sixty years ago, uses the principle of jet reaction and the turbine engine. The engine consists of three major elements: a compressor and a turbine expander, which are connected by a common shaft; and a combustor, located between the compressor and the turbine expander. The useful work of the engine is the difference between that produced by the turbine and that required by the compressor. For the simple cycle system shown in Figure 1, about two-thirds of all the power produced by the turbine is used to drive the compressor.

Jet reaction used in the first steam-powered engine, the aeolipile, is attributed to Hero of Alexandria around the time of Christ. In his concept, a closed spherical vessel, mounted on bearings, carried steam

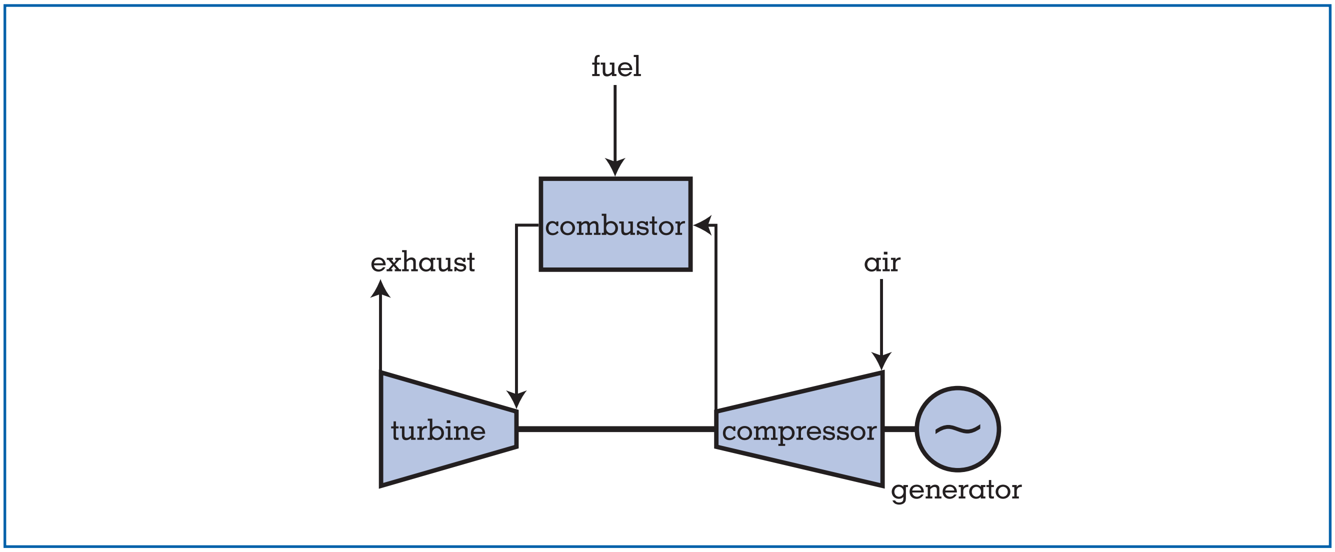

Figure 1.
Simple gas turbine cycle.

from a cauldron with one or more people discharging tangentially at the vessel's periphery, and was driven around by the reaction of steam jets. According to the literature, the first gas turbine power plant patent was awarded to John Barber, an Englishman, in 1791. Intended to operate on distilled coal, wood, or oil, it incorporated an air compressor driven through chains and gears by a turbine operated by the combustion gases. It was actually built but never worked.

There was a steady increase in the number of gas-turbine patents after Barber's disclosure. However, the attempts of the early inventors to reduce them to practice was entirely unsuccessful.

The early inventors and engineers were frustrated in their efforts to achieve a workable gas turbine engine because of the inadequate performance of the components and the available materials. However, gas turbine engine technology has advanced rapidly since the 1940s. Thrust and shaft horsepower (hp) has increased more than a hundredfold while fuel consumption has been cut by more than 50 percent. Any future advances will again depend upon improving the performance of components and finding better materials.

ORIGINS OF THE LAND-BASED GAS TURBINE

Perhaps the first approach to the modern conception of the gas-turbine power plant was that described in a patent issued to Franz Stolze in 1872. The arrangement of the Stolze plant, shown in Figure 2, consisted of a multistage axial-flow air compressor coupled directly to a multistage reaction turbine. The high-pressure air leaving the compressor was heated in an externally fired combustion chamber and thereafter expanded in the multistage turbine. The Stolze plant was tested in 1900 and 1904, but the unit was unsuccessful. The lack of success was due primarily to the inefficiency of the axial-flow compressor, which was based on aerodynamics, a science that was in its early stages of development. The lack of aerodynamic information also led Charles Algernon Parsons, the inventor of the reaction steam turbine, to abandon the development of the axial-flow compressor in 1908 after building approximately thirty compressors of that type with little success.

Several experimental gas-turbine power plants were built in France from 1903 to 1906. Those power plants operated on a cycle similar to that of a modern gas-turbine power plant. The most significant unit had a multistage centrifugal compressor that consisted essentially of a stationary casing containing a rotating impeller. Because of material limitations, the temperature of the gases entering these turbines was limited to 554°C (1,030°F). The thermal efficiency of the unit (work output divided by heat supplied) was less than 3 percent, but the unit is noteworthy, however, because

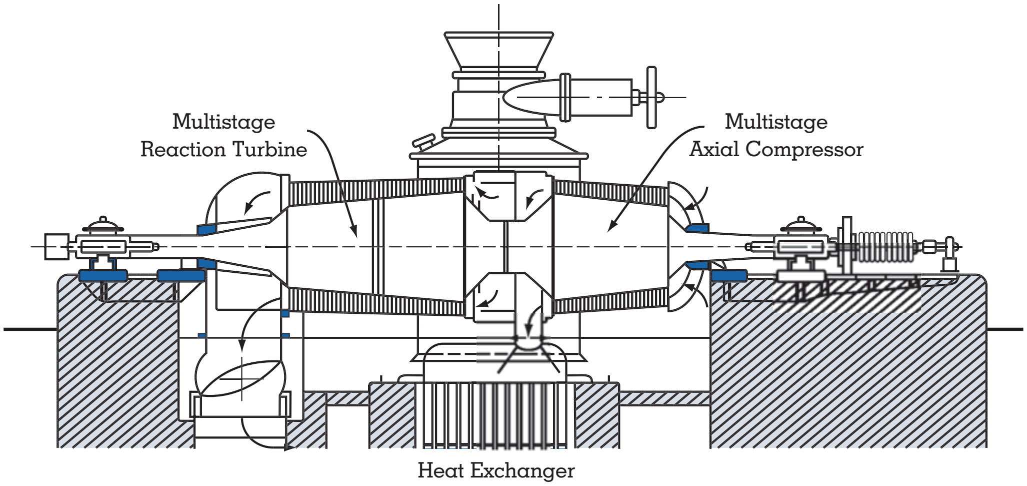

Figure 2.
The Stolze gas-turbine power plant.
SOURCE: Zipkin, 1964.

it was probably the first gas-turbine power plant to produce useful work. Its poor thermal efficiency was due to the low efficiencies of the compressors and the turbine, and also to the low turbine inlet temperature.

Brown Boveri is credited with building the first land-based gas turbine generating unit. Rated at 4 MW, it was installed in Switzerland in 1939. Leaders in the development of the aviation gas turbine during the Second World War included: Hans von Ohain (Germany), Frank Whittle (England), and Reinout Kroon (United States). Thus, combining the technology derived for aviation gas turbines with the experience of using turbines in the chemical industry, the birth of gas turbines for power generation started in the United States in 1945 with the development of a 2,000-hp gas turbine set that consisted of a compressor, twelve combustors, a turbine, and a single reduction gear. This turbine had a thermal efficiency of 18 percent. By 1949, land-based gas turbines in the United States had an output of 3.5 MW with a thermal efficiency of 26 percent at a firing temperature of 760°C (1,400°F).

COMPONENT DEVELOPMENT

Aircraft and land-based turbines have different performance criteria. Aircraft turbine engine performance is measured in terms of output, efficiency, and weight. The most significant parameter in establishing engine output (thrust or shaft hp) is turbine inlet temperature. Power output is extremely dependent on turbine inlet temperature. For example, an engine operating at 1,340°C (2,500°F) would produce more than over two and one-half times the output of an engine operating at 815°C (1,500°F). Engine efficiency, which is next in importance to engine output, is determined largely by overall engine or cycle pressure ratio. Increasing the pressure ratio from one to twenty reduces the fuel consumption by approximately 25 percent. Engine weight is affected most by turbine inlet temperatures (which acts to reduce the physical size of the engine) and by state-of-the-art materials technology that sets the temperature criteria.

During the Second World War, centrifugal compressors were used in early British and American fighter aircraft. As power requirements grew, it became clear that the axial flow compressor was more suitable for large engines because they can produce higher pressure ratios at higher efficiencies than centrifugal compressors, and a much larger flow rate is possible for a given frontal area. Today, the axial flow machine dominates the field for large power generation, and the centrifugal compressor is restricted to machines where the flow is too small to be used efficiently by axial blading.

For land-based gas turbines, the overall plant output, efficiency, emissions, and reliability are the important variables. In a gas turbine, the processes of compression, combustion, and expansion do not occur in a single component, as they do in a diesel engine. They occur in components that can be developed separately. Therefore, other technologies and components can be added as needed to the basic components, or entirely new components can be substituted.

Advanced two- and three-dimensional computer analysis methods are used today in the analyses of all critical components to verify aerodynamic, heat transfer, and mechanical performance. Additionally, the reduction of leakage paths in the compressor, as well as in the gas turbine expander, results in further plant efficiency improvements. At the compressor inlet, an advanced inlet flow design improves efficiency by reducing pressure loss. Rotor air cooler heat utilization and advanced blade and vane cooling are also used.

Several advanced turbine technologies may be applied to the gas turbine expander. These include the application of single crystal and ceramic components to increase material operating temperatures and reduce turbine cooling requirements, and active blade tip clearance control to minimize tip leakages and improve turbine efficiency. The objective of the latter scheme is to maintain large tip clearance at start-up and reduce them to minimum acceptable values when the engine has reached steady-state operating conditions.

ALTERNATIVE THERMAL CYCLES

As an alternative to raising firing temperature, overall power plant performance can be improved by modifications to the cycle. Combining a land-based simple cycle gas turbine with a steam turbine results in a combined cycle that is superior in performance to a simple gas turbine cycle or a simple cycle steam turbine considered separately. This is due to utilizing waste heat from the gas turbine cycle. By 1999, land-based sample cycle gas turbine efficiencies had improved from 18 percent to more than 42 percent, with the better combined cycles reaching 58 percent, and the ones in development likely to exceed 60 percent. Combined cycle efficiency improvements have followed the general advance in gas turbine technology reflected in the rising inlet temperature trend shown in Figure 3, which, in turn, was made possible by advances in components and materials.

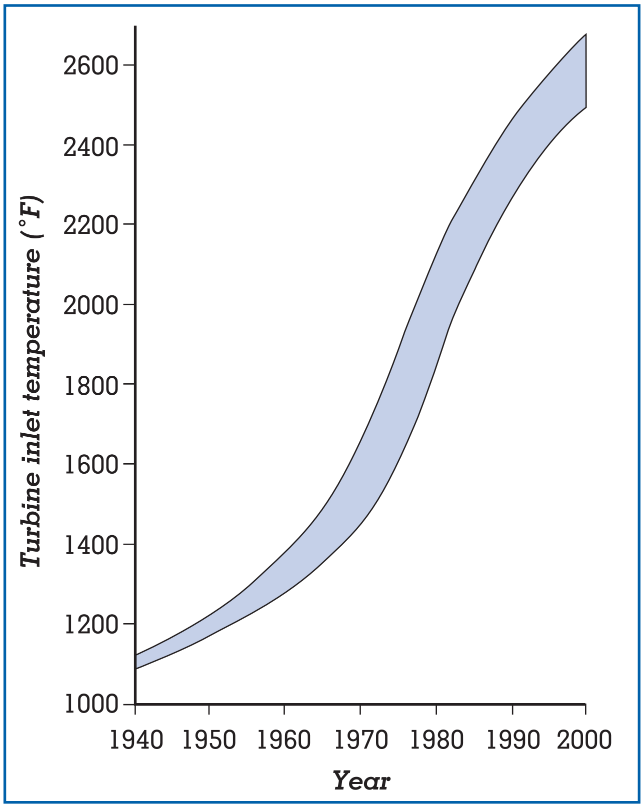

Figure 3.
Gas turbine inlet temperature trend.

Gas turbines can operate in open or closed cycles. In a simple cycle (also known as an open cycle), clean atmospheric air is continuously drawn into the compressor. Energy is added by the combustion of fuel with the air. Products of combustion are expanded through the turbine and exhausted to the atmosphere. In a closed cycle, the working fluid is continuously circulated through the compressor, turbine, and heat exchangers. The disadvantage of the closed cycle (also known as the indirect cycle), and the reason why there are only a few in operation, is the need for an external heating system. That is an expensive addition and lowers efficiency.

Most current technology gas turbine engines use air to cool the turbine vanes and rotors. This allows the turbine inlet temperature to be increased beyond the temperature at which the turbine material can be used without cooling, thus increasing the cycle efficiency and the power output. However, the cooling air itself is a detriment to cycle efficiency. By using closed-loop steam cooling, a new concept, the cooling air mixing loss mechanisms can be largely elimi-

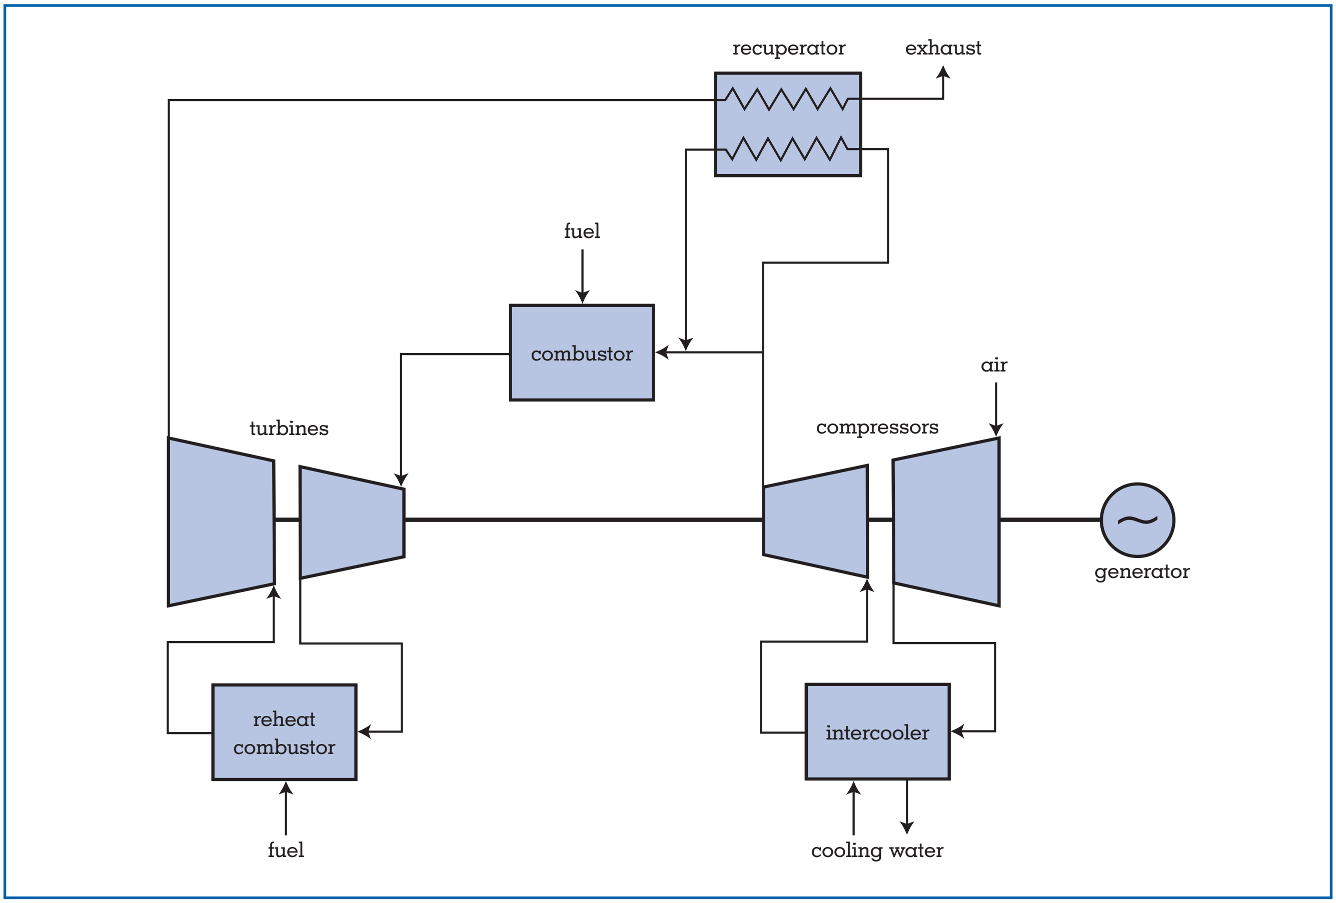

Figure 4.
Some gas turbine cycle options.
SOURCE: Maude and Kirchner, 1995.

nated, while still maintaining turbine material temperatures at an acceptable level. An additional benefit of closed-loop cooling is that more compressor delivery air is available for the lean premix combustion. The result is lower flame temperature and reduced oxides of nitrogen (NOx) emission. In combined cycles, the steam used for cooling the gas turbine hot parts is taken from the steam bottoming cycle, then returned to the bottoming cycle after it has absorbed heat in the closed-loop steam cooling system. For an advanced bottoming steam cycle, closed-loop steam cooling uses reheat steam from the exit of the high-pressure steam turbine to cool the gas turbine vane casing and rotor. The steam is passed through passageways within the vane and rotor assemblies and through the vanes and rotors themselves, then collected and sent back to the steam cycle intermediate-pressure steam turbine as hot reheat steam.

Several of the gas turbine cycle options discussed in this section (intercooling, recuperation, and reheat) are illustrated in Figure 4. These cycle options can be applied singly or in various combinations with other cycles to improve thermal efficiency. Other possible cycle concepts that are discussed include thermochemical recuperation, partial oxidation, use of a humid air turbine, and use of fuel cells.

The most typical arrangement for compressor intercooling involves removing the compressor air flow halfway through the compressor temperature rise, sending it through an air-to-water heat exchanger, and returning it to the compressor for further compression to combustor inlet pressure. The heat removed from the compressor air flow by the intercooler is rejected to the atmosphere because the heat is usually at too low a temperature to be of use to the cycle.

Another intercooling application is to spray water droplets into the compressor. As the air is compressed and increases in temperature, the water evaporates and absorbs heat. This results in a continuous cooling of the compressor. Note that for this concept the heat absorbed by the water is also rejected to the atmosphere. This water is never condensed by the cycle, but instead exhausted with the stack gases as low-pressure steam.

Compressor intercooling reduces the compressor work because it compresses the gas at a lower average temperature. The gas and steam turbines produce approximately the same output as in the nonintercooled case, so the overall cycle output is increased. However, since the compressor exit temperature is lowered, the amount of fuel that must be added to reach a given turbine inlet temperature is greater than that for the nonintercooled case. Intercooling adds output at approximately the simple cycle efficiency—the ratio of the amount of compressor work saved to the amount of extra fuel energy added is about equal to the simple cycle efficiency. Since combined cycle efficiencies are significantly greater than simple cycle efficiencies, the additional output at simple cycle efficiency for the intercooled case usually reduces the combined cycle net plant efficiency.

In recuperative cycles, turbine exhaust heat is recovered and returned to the gas turbine combustor, usually through a heat exchange between the turbine exhaust gases and the compressor exit airflow. The discharge from the compressor exit is piped to an exhaust gas-to-air heat exchanger located aft of the gas turbine. The air is then heated by the turbine exhaust and returned to the combustor. Since the resulting combustor air inlet temperature is increased above that of the nonrecuperated cycle, less fuel is required to heat the air to a given turbine inlet temperature. Because the turbine work and the compressor work are approximately the same as in the nonrecuperated cycle, the decrease in fuel flow results in an increase in thermal efficiency. For combined cycles the efficiency is also increased, because the gas turbine recovers the recuperated heat at the simple cycle efficiency, which is larger than the 30 to 35 percent thermal efficiency of a bottoming steam cycle, which recovers this heat in the nonrecuperated case. Since recuperative cycles return exhaust energy to the gas turbine, less energy is available to the steam cycle, and the resulting steam turbine output is lower than that of the baseline configuration. Even though the gas turbine output is approximately the same as in the baseline cycle (minus losses in the recuperation system), recuperative cycles carry a significant output penalty because of reduced steam turbine work, which is proportional to the amount of recuperation performed.

From a simple cycle standpoint, the combination of intercooling with recuperation eliminates the problem of the reduced combustor inlet temperature associated with intercooled cycles. The simple cycle then gets the benefit of the reduced compressor work and, at all but high pressure ratios, actually has a higher burner inlet temperature than the corresponding nonintercooled, nonrecuperated cycle. This results in a dramatic increase in the simple cycle efficiency.

Reheat gas turbines utilize a sequential combustion process in which the air is compressed, combusted, and expanded in a turbine to some pressure significantly greater than ambient, combusted again in a second combustor, and finally expanded by a second turbine to near ambient pressure. For a fixed turbine rotor inlet temperature limit, the simple cycle efficiency is increased for a reheat gas turbine compared to a nonreheat cycle operating at a pressure ratio corresponding to the second combustor's operating pressure. This is because the reheat cycle performs some of its combustion and expansion at a higher pressure ratio.

Thermochemical recuperation (TCR), also known as chemical recuperation, has been under evaluation for several years as a promising approach to increase power generation efficiencies. In a TCR power plant, a portion of the stack exhaust gas is removed from the stack, compressed, mixed with natural gas fuel, heated with exhaust heat from the gas turbine, and mixed with the air compressor discharge as it enters the combustor. As the mixture of natural gas and flue gas is heated by the gas turbine exhaust, a chemical reaction occurs between the methane in the fuel and the carbon dioxide and water in the flue gas. If this reaction occurs in the presence of a nickel-based catalyst, hydrogen and carbon monoxide are produced. For complete conversion of the methane, the effective fuel heating value is increased. Therefore, the natural gas/flue gas mixture absorbs heat thermally and chemically, resulting in a larger potential recuperation of exhaust energy than could be obtained by conventional recuperation, which recovers energy by heat alone. In fact, with full conversion of the natural gas fuel to hydrogen and carbon monoxide, up to twice the energy recuperated by the standard recuperative cycle may be recovered.

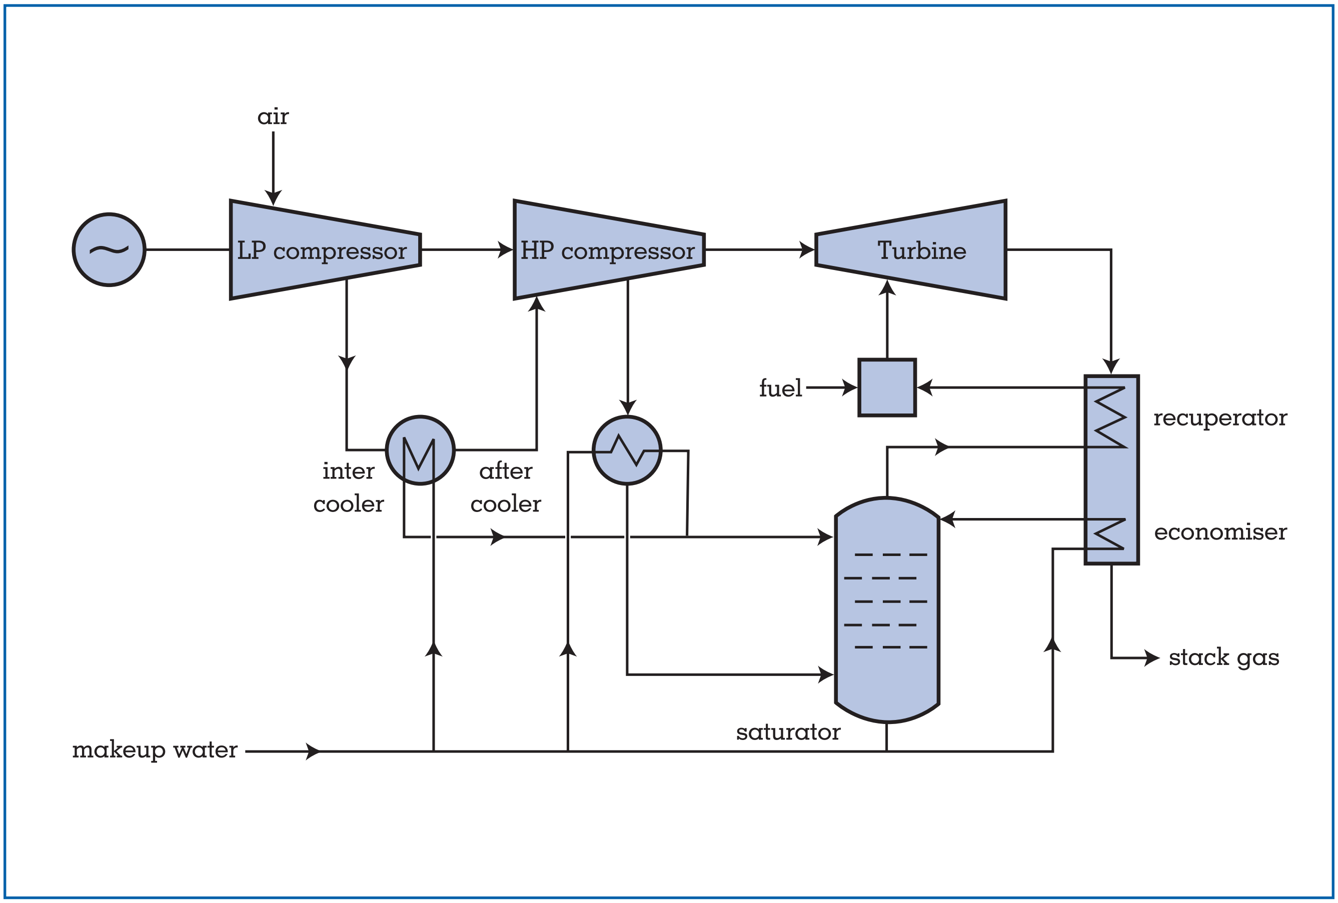

Figure 5.
HAT cycle flow diagram.
SOURCE: Morton and Rao, 1989.

Partial oxidation (PO) has also been proposed as a means to increase the performance of gas turbine power systems. PO is a commercial process used by the process industries to generate syngases from hydrocarbons, but under conditions differing from those in power generation applications. In this concept, a high-pressure, low-heating-value fuel gas is generated by partially combusting fuel with air. This fuel gas is expanded in a high-pressure turbine prior to being burned in a lower-pressure, conventional gas turbine. This process reduces the specific air requirements of the power system and increases the power output. PO has several potential advantages over conventional cycles or reheat cycles: lower specific air consumption and reduced air compressor work; increased power plant thermal efficiency; and potentially lower NOx emissions with improved combustion stability.

One difficulty associated with waste heat recovery systems is the satisfactory use of low grade heat to reduce stack losses. The humid air turbine (HAT), shown in Figure 5, uses a concept that should be considered on how to improve the use of low-grade heat. Warm waste is brought into contact with the compressor delivery air in a saturator tower to increase the moisture content and increase the total mass flow of the gases entering the turbine without significantly increasing the power demand from the compressor. Thus low-grade heat is made available for the direct production of useful power. Also, the high moisture content of the fuel gas helps to control NOx production during the combustion process.

Over a number of years, fuel cells have promised a new way to generate electricity and heat from fossil fuels using ion-exchange mechanisms. Fuel cells are categorized by operating temperature and the type of electrolyte they use. Each technology has its own operating characteristics such as size, power, density, and system configurations.

One concept, a solid oxide fuel cell (SOFC) supplied with natural gas and preheated oxidant air, produces direct-current electric power and an exhaust gas with a temperature of 850° to 925°C (1,560° to 1,700°F). In this hybrid system, the fuel cell contributes about 75 percent of the electric output, while the gas turbines contribute the remaining 25 percent. The SOFC exhaust can be expanded directly by a gas turbine with no need for an additional combustor. SOFC technology can be applied in a variety of ways to configure both power and combined heat and power (CHP) systems to operate with a range of electric generation efficiencies. An atmospheric pressure SOFC cycle, capable of economic efficiencies in the 45 to 50 percent range, can be the basis for a simple, reliable CHP system. Intergating with a gas turbine to form an atmospheric hybrid system, the simplicity of the atmospheric-pressure SOFC technology is retained, and moderately high efficiencies in the 50 to 55 percent range can be achieved in either power or CHP systems.

The pressurized hybrid cycle provides the basis for the high electric efficiency power system. Applying conventional gas turbine technology, power system efficiencies in the 55 to 60 percent range can be achieved. When the pressurized hybrid system is based on a more complex turbine cycle—such as one that is intercooled, reheated, and recuperated—electric efficiencies of 70 percent or higher are projected.

OTHER FUELS

The majority of today's turbines are fueled with natural gas or No. 2 distillate oil. Recently there has been increased interest in the burning of nonstandard liquid fuel oils or applications where fuel treatment is desirable. Gas turbines have been engineered to accommodate a wide spectrum of fuels. Over the years, units have been equipped to burn liquid fuels, including naphtha; various grades of distillate, crude oils, and residual oils; and blended, coal-derived liquids. Many of these nonstandard fuels require special provisions. For example, light fuels like naphtha require modifications to the fuel handling system to address high volatility and poor lubricity properties.

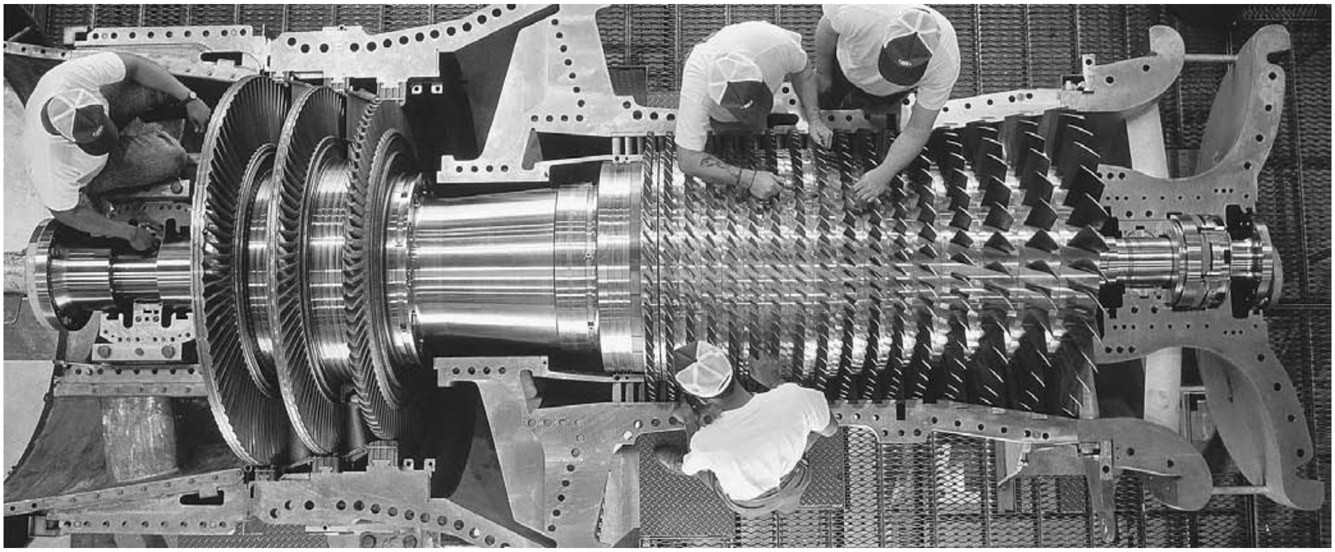
The need for heating, water washing, and the use of additives must be addressed when moving from the distillates toward the residuals. Fuel contaminants such as vanadium, sodium, potassium, and lead must be controlled to achieve acceptable turbine parts life. The same contaminants also can be introduced by the inlet air or by water/steam injection, and the combined effects from all sources must be considered.

The final decision as to which fuel type to use depends on several economic factors, including delivered price, cost of treatment, cost of modifying the fuel handling system, and increased maintenance costs associated with the grade of fuel. With careful attention paid to the fuel treatment process and the handling and operating practices at the installation, gas turbines can burn a wide range of liquid fuels. The ultimate decision on the burning of any fuel, including those fuel oils that require treatment, is generally an economic one.

Due to an estimated global recoverable reserve of more than 400 years of coal that can be used to generate electricity, future power generation systems must be designed to include coal. Today there are a number of gasification technologies available or being demonstrated at commercial capacity that are appropriate for power generation. Most of the development effort has been in the area of gasifiers that can be used in gasification combined cycle (GCC) applications. Other coal-fueled concepts under development include first- and second-generation pressurized fluidized bed (PFBC), and the indirect coal-fired case already discussed as a closed cycle.

Gasification is the reaction of fuel with oxygen, steam, and CO_2 to generate a fuel gas and low-residue carbon char. This char differentiates gasification from other technologies that burn residual char separately or apply char as a by-product. The gasification fuel gas is composed primarily of hydrogen and carbon oxides as well as methane, water vapor, and nitrogen. Generic classes of gasifiers that can be used in a GCC are moving bed, fluidized bed, and entrained flow.

GCC integrates two technologies: the manufacture of a clean-burning synthesis gas (syngas), and the use of that gas to produce electricity in a combined cycle power generation system. Primary inputs are hydrocarbon feeds (fuels), air, chemical additives, and water; primary GCC outputs are electricity (generated within the power block that contains a gas turbine, steam turbine, and a heat recovery steam generator), syngas, and sulfur by-products, waste, and flue gas. The flows



Workers assemble a 38-megawatt gas turbine at a General Electric plant in South Carolina. They build 100 turbines a year. (Corbis-Bettmann)

that integrate the subsystems include auxiliary power for an air separation unit and gasifier; air and nitrogen between an air separator and the gas turbine; heat from gasifier gas coolers to generate steam for the steam cycle; and steam to the gas turbine for NOx control.

Worldwide there are about thirty major current and planned GCC projects. Within the United States, the first GCC placed into commercial service, and operated from 1984 to 1989, was the 100-MW Cool Water coal gasification plant near Daggett, California.

Most commercial-size gasification projects have used oxygen rather than air as the oxidant for the gasifiers. Recent GCC evaluations have looked at using the gas turbine air compressor to supply air for the air separation unit. Typically this air stream is sent to a high-pressure air separator unit, which produces oxygen for gasification and high-pressure nitrogen for gas turbine NOx control. The diluent nitrogen lowers the flame temperature and therefore lowers the NOx.

Through Clean Coal Technology programs, the U.S. Department of Energy (DOE) is supporting several GCC demonstration projects that range in capacity from 100 to 262 MW. One of these plants is fueled by an advanced air-blown gasifier technology, and two of the projects will demonstrate energy-saving hot-gas cleanup systems for removal of sulfur and particulates. In Europe there are several commercial-size GCC demonstration plants in operation or under construction, ranging in size from 250 to 500 MW.

In a first-generation PFBC plant, the PFBC is used as the gas turbine combustor. For this application, the temperature to the gas turbine is limited to a bed temperature of about 870°C (1,600°F). This temperature level limits the effectiveness of this cycle as a coal-fired alternative.

In second-generation PFBC, a topping combustor is used to raise the turbine rotor inlet temperature to state-of-the-art levels. Pulverized coal is fed to a partial-gasifier unit that operates about 870° to 925°C (1,600° to 1,700°F) to produce a low heating value fuel gas and combustible char. The char is burned in the PFBC. The fuel gas, after filtration, is piped back to the gas turbine, along with the PFBC exhaust.

Fuel gas cleaning systems are being developed to fulfill two main functions: controlling the environmental emissions from the plant, and protecting downstream equipment from degraded performance. The fuel gas cleaning system also protects the gas turbine from corrosion, erosion, and deposition damage. Conventional GCC fuel gas cleaning systems, designated as cold gas cleaning, operate at temperatures of less than 315°C (600°F). Alternative technologies for fuel gas cleaning, which operate at considerably higher temperatures, are under development because of potential power plant performance benefits.

A biomass power generation industry is emerging that can provide substantial quantities of feedstock such as sugarcane residue (bagasse), sweet sorghum, rice straw, and switchgrass, as well as various wood byproducts. Today some of these residues are burned to generate power using a steam boiler and a steam turbine. However, operating problems result from ash agglomeration and deposition. Also, plant thermal efficiencies are relatively low, less than 30 percent, and in a number of plants less than 20 percent. The U.S. DOE has supported the development of biomass-fueled gasification systems that can be integrated into a combined cycle power plant and thereby obtain thermal efficiencies of greater than 40 percent.

Coal gasification is fuel flexible so that the process can use the most available feedstock at the best price. Gasifiers have successfully gasified heavy fuel oil and combinations of oil and waste gas. Other possible gasification feedstock includes petroleum coke, trash, used tires, and sewage sludge. Various combinations of feedstocks and coal have been successfully gasified.

Orimulsion is a relatively new fuel that is available for the gasification process. Orimulsion is an emulsified fuel, a mixture of natural bitumen (referred to as Orinoco-oil), water (about 30%), and a small quantity of surface active agents. Abundant Orinoco-oil reserves lie under the ground in the northern part of Venezuela.

ADVANCED GAS TURBINES

As discussed, the efficiency of a gas turbine cycle is limited by the ability of the combustion chamber and early turbine states to continuously operate at high temperatures. In 1992, the DOE started the Advanced Turbine Systems (ATS) Program that combined the resources of the government, major turbine manufactures, and universities to advance gas turbine technology and to develop systems for the twenty-first century. As pilot projects, two simple cycle industrial gas turbines are being developed for distributed generation and industrial and cogeneration markets, and two combined cycle gas turbines for use in large, baseload, central station, electric power generation markets.

DEVELOPMENT OF A HYDROGEN-FUELED GAS TURBINE

Looking to the future, the Japanese government is sponsoring the World Energy Network (WE-NET) Program through its New Energy and Industrial Technology Development Organization (NEDO). WE-NET is a twenty-eight-year global effort to define and implement technologies needed for hydrogen-based energy systems. A critical part of this effort is the development of a hydrogen-fueled gas turbine system to efficiently convert the chemical energy stored in hydrogen to electricity when hydrogen is combusted with pure oxygen. A steam cycle with reheat and recuperation was selected for the general reference system. Variations of this cycle have been examined to identify a reference system having maximum development feasibility while meeting the requirement of a minimum of 70.9 percent thermal efficiency. The strategy applied was to assess both a near-term and a long-term reference plant. The near-term plant requires moderate development based on extrapolation of current steam and gas turbine technology. In contrast, the long-term plant requires more extensive development for an additional high-pressure reheat turbine, has closed-loop steam cooling and extractive feedwater heating, and is more complex than the near-term plant.

OTHER GAS TURBINE APPLICATIONS

In addition to power generation and aircraft propulsion, gas turbine technology has been used for mechanical drive systems, gas and oil transmission pipelines, and naval propulsion. In natural gas pipelines, gas turbines provide mechanical pumping power, using the fluid being pumped as fuel. For marine applications, aero-derivative engines have been developed, yet a major disadvantage is its poor specific fuel consumption at part-load operation. For example, a naval vessel having a maximum speed of thirty knots and a cruise speed of fifteen knots loses considerable efficiency at cruising speed, since the cruise power will be only one-eighth of the maximum power (the power required being proportional to the cube of the speed). One alternative to reduce this concern is the use of a recuperator to heat the air going to the combustor with the heat from the gas turbine's exhaust. Another alternative to overcome high specific fuel consumption at part-load operation is to develop a shipboard combined cycle power plant consisting of gas turbines in conjunction with a steam turbine.

Gas turbines also have been considered for rail and road transportation. The Union Pacific successfully operated large freight trains from 1955 to 1975, several high-speed passenger trains and locomotives were built using aviation-type gas turbines. These, however, gave way to more economical diesels.

The first gas-turbine-propelled car (at 150 kW) was produced in the United Kingdom in 1950. For more than fifty years, significant efforts have been expended on automotive programs; however, diesel and gasoline engines continue to dominate. The major problem is still the poor part-load thermal efficiency of the gas turbine despite the use of a recuperated cycle with variable area nozzle guide vanes. Other problems include lack of sufficient high-temperature material development, and the relatively long acceleration time from idle to full load. For long-haul trucks, gas turbines were developed in the range of 200 to 300 kW. All used a low-pressure cycle ratio with a centrifugal compressor, turbine, and rotary heat exchanger.

A recent convergence of economic opportunities and technical issues has resulted in the emergence of a new class of gas turbine engines called microturbines. Designed for use in a recuperative cycle and pressure ratios of three to one to five to one, they can produce power in the range of 30 to 300 Kw. Initial work on this concept, which is primarily packaged today for cogeneration power generation, started in the late 1970s. In cogeneration applications that can effectively use the waste heat, overall system efficiencies can be greater than 80 percent. Manufacturers are exploring how microturbines can be integrated with fuel cells to create hybrid systems that could raise overall system efficiencies. Many issues, however, are still to be resolved with this approach, including cost and integration.

Another application of gas turbines is in a compressed air energy storage (CAES) system that allows excess base load power to be used as peaking power. It is similar to hydro-pumped storage, and the idea is to store energy during low demand periods by converting electrical power to potential energy. Rather than pumping water up a hill, CAES compresses and stores air in large underground caverns. When the power is needed, the air is allowed to expand through a series of heaters and turbines, and the released energy is then converted back to electricity. To increase output and efficiency, fuel is mixed with the air as it is released, the mixture is burned, and the energy released by combustion is available for conversion to electricity and heat recovery. This is similar to the operation of a standard gas turbine, except with CAES the compressor and turbines are separate machines that each run when most advantageous.

ROLE OF ADVANCED GAS TURBINE TECHNOLOGY

The electricity industry is in the midst of a transition from a vertically integrated and regulated monopoly to an entity in a competitive market where retail customers choose the suppliers of their electricity. The change started in 1978, when the Public Utility Regulatory Act (PURPA) made it possible for nonutility power generators to enter the wholesale market.

From various U.S. DOE sources, projections have been made that the worldwide annual energy consumption in 2020 could be 75 percent higher than it was in 1995. The combined use of fossil fuels is projected to grow faster from 1995 to 2020 than it did from 1970 to 1995. Natural gas is expected to account for 30 percent of world electricity by 2020, compared to 16 percent in 1996.

The power generation cycle of choice today and tomorrow is the combined cycle that is fueled with natural gas. Power generating technologies, regardless of the energy source, must maximize efficiency and address environmental concerns. To support the fuel mix and minimize environmental concerns, advanced coal combustion, fuel cells, biomass, compressed air energy storage, advanced turbine systems, and other technologies such as the development of a hydrogen-fueled cycle are under development.

Beyond the ATS program, the DOE is looking at several new initiatives to work on with industry. One, Vision 21, aims to virtually eliminate environmental concerns associated with coal and fossil systems while achieving 60 percent efficiency for coal-based plants, 75 percent efficiency for gas-based plants, and 85 percent for coproduction facilities. Two additional fossil cycles have been proposed that can achieve 60 percent efficiency. One incorporates a gasifier and solid oxide fuel into a combined cycle; the other adds a pyrolyzer with a pressurized fluidized bed combustor. Also under consideration is the development of a flexible midsize gas turbine. This initiative would reduce the gap between the utility-size turbines and industrial turbines that occurred during the DOE ATS program.

TURBINES, STEAM

EVOLUTION OF AN INDUSTRY

Since the turn of the twentieth century, the steam turbine has evolved from an experimental device to the major source of electrical generation. Practical steam turbine inventions coincided with the development of direct-current electric dynamos first used to power arc-lighting street systems. In the United States, the first central station to provide electrical lighting service was Thomas Edison's Pearl Street Station in New York City in 1882. Powered by 72 kW of steam engines, it served 1,284 16-candlepower dc lamps. This installation demonstrated the feasibility of central station electricity. Initially, Edison's system needed a large number of scattered power plants because it utilized direct current, and dc transmission was uneconomical over large distances. In 1885, George Westinghouse's Union Switch & Signal Co. acquired rights to manufacture and sell a European-design transformer, and the company then developed alternating-current distribution capability to utilize its transformers, which made longer-distance transmission of electricity practical. The Westinghouse Electric Co. was formed to exploit this device. By 1900 there were numerous dc and a few ac generating stations in the United States, all with reciprocating steam engines or hydraulic turbines as prime movers. However, the ac technology quickly became a primary factor in stimulating the development of power generation.

Although they were reliable, the early steam engines were huge, heavy devices that were not very efficient. Nearly all the companies in the electric equipment business seized the opportunity to develop the steam turbine as an alternative. In 1895, Westinghouse acquired rights to manufacture reaction turbines invented and patented in 1884 by the English inventor Charles Algernon Parsons. Allis-Chalmers also acquired rights to manufacture under Parsons' patents, so early machines of these two manufacturers were quite similar. In 1887, the General Electric Co. (founded by Edison) entered into an agreement with Charles Curtis to exploit his steam turbine patent.

The Curtis and the Parsons turbine designs are based on different fundamental principles of fluid flow. The Curtis turbine has an impulse design, where the steam expands through nozzles so that it reaches a high velocity. The high-velocity, low-pressure steam jet then impacts the blades of a spinning wheel. In a reaction turbine such as the Parsons design, the steam expands as it passes through both the fixed nozzles and the rotating blades. High pressure stages are impulse blades. The high-pressure drops quickly through these stages, thus reducing the stress on the high pressure turbine casing. The many subsequent stages may be either impulse or reaction designs.

STEAM TURBINE CYCLES

The basic function of a steam turbine is to efficiently convert the stored energy of high-pressure, high-temperature steam to useful work. This is accomplished by a controlled expansion of the steam through stages consisting of stationary nozzle vanes and rotating blades (also called buckets by one major manufacturer). The size and shape of the nozzle vanes and rotating blades are such as to properly control the pressure distribution and steam velocities throughout the turbine flow path. Blading improvements have increased turbine cycle efficiency by reducing profile losses, end-wall losses, secondary flow losses, and leakage losses. Use of tapered twisted designs for longer blades reduces losses on the innermost and outmost portions of the blades.

A complete turbine generator unit could consist of several turbine elements connected in tandem on a single shaft to drive a generator. To extract as much energy from the steam as possible, as it decreases in temperature and pressure in its passage through the machine, the typical arrangement could include a high-pressure (HP), an intermediate-pressure (IP), and one or more low-pressure (LP) elements, as illustrated in Figure 1.

The HP, IP, and LP turbines may be either single-flow or double-flow designs, depending upon the volume of steam utilized. In a single-flow turbine, the total volume of steam enters at one end and exhausts at the other end. The double flow is designed so the steam enters at the center and divides. Half flows in one direction, and half in the other direction into exhausts at each end of the turbine.

The basic steam cycle for a steam turbine installation is called a Rankine cycle (named after Scottish engineer and physicist William John Macquorn Rankine). This cycle consists of a compression of liquid water, heating and evaporation in the heat source (a steam boiler or nuclear reactor), expansion of the

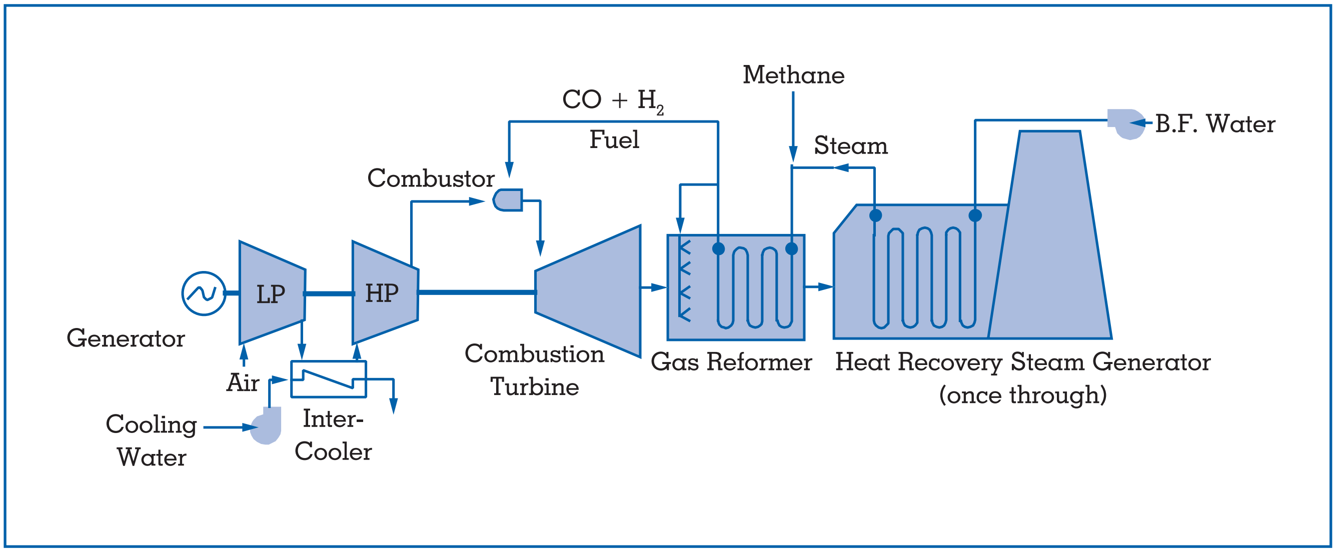

Figure 1.
Diagram of a complete turbine generator unit.

steam in the prime mover (a steam turbine), and condensation of the exhaust steam into a condenser. There is a continuous expansion of the steam, with no internal heat transfer and only one stage of heat addition. By increasing the pressure and/or temperature and decreasing the heat rejected by lowering exhaust temperature, cycle efficiency can be improved.

Weir patented a regenerative feedwater heating cycle in 1876. The regenerative Rankine cycle eliminates all or part of the external heating of the water to its boiling point. In this cycle, a small amount of expanded steam is extracted from a series of pressure zones during the expansion process of the cycle to heat water in a multiplicity of heat exchangers to a higher temperature. Theoretical and practical regenerative cycles reduce both the heat added to the cycle and the heat rejected from the cycle.

Reheat involves steam-to-steam heat exchange using steam at boiler discharge conditions. In the reheat cycle, after partially expanding through the turbine, steam returns to the reheater section of the boiler, where more heat is added. After leaving the reheater, the steam completes its expansion in the turbine. The number of reheats that are practical from a cycle efficiency and cost consideration is two.

EVOLUTION OF THE STEAM TURBINE

The first central station steam turbine in the United States was built for the Hartford Electric Light Co. in 1902. Steam conditions for this 2,000-kW unit and similar units were approximately 1.2 MPa (180 psig) and 180°C (350°F). The evolution of steam turbine power generation in the United States is summarized in Figure 2. Plotted against time are the maximum inlet steam pressure and temperature, along with plant thermal efficiency, and maximum shaft output in megawatts. The steady increase in steam turbine inlet pressure and temperature achieved an increase in plant thermal performance. From 1910 to 1920 steam turbine generators were manufactured in the 30- to 70-MW range. By 1945, the median unit sold in the United States was still only 100 MW. By 1967 the median unit had increased to 700 MW, with a peak of 1,300 MW for several fossil-fueled units placed in service in the 1970s. (A 1,300-MW unit can generate enough electricity to supply the residential needs of more than 4 million people.) During the first fifty years of the twentieth century, inlet steam pressure and temperature increased at an average rate per year of 0.3 MPa (43 psi) and 7°C (13°F), respectively. Until the early 1920s, throttle pressures were 1.4–2.1 MPa (200–300 psi), and throttle temperatures did not exceed 600°F (315°C). Above 450°F (230°C), cast steel replaced cast iron for turbine casings, valves, and so on.

Figure 3 shows the thermal performance evolution of the steam cycle as a function of material development and cycle improvements, starting in 1915. By the early 1920s, regenerative feedheating was well estab-

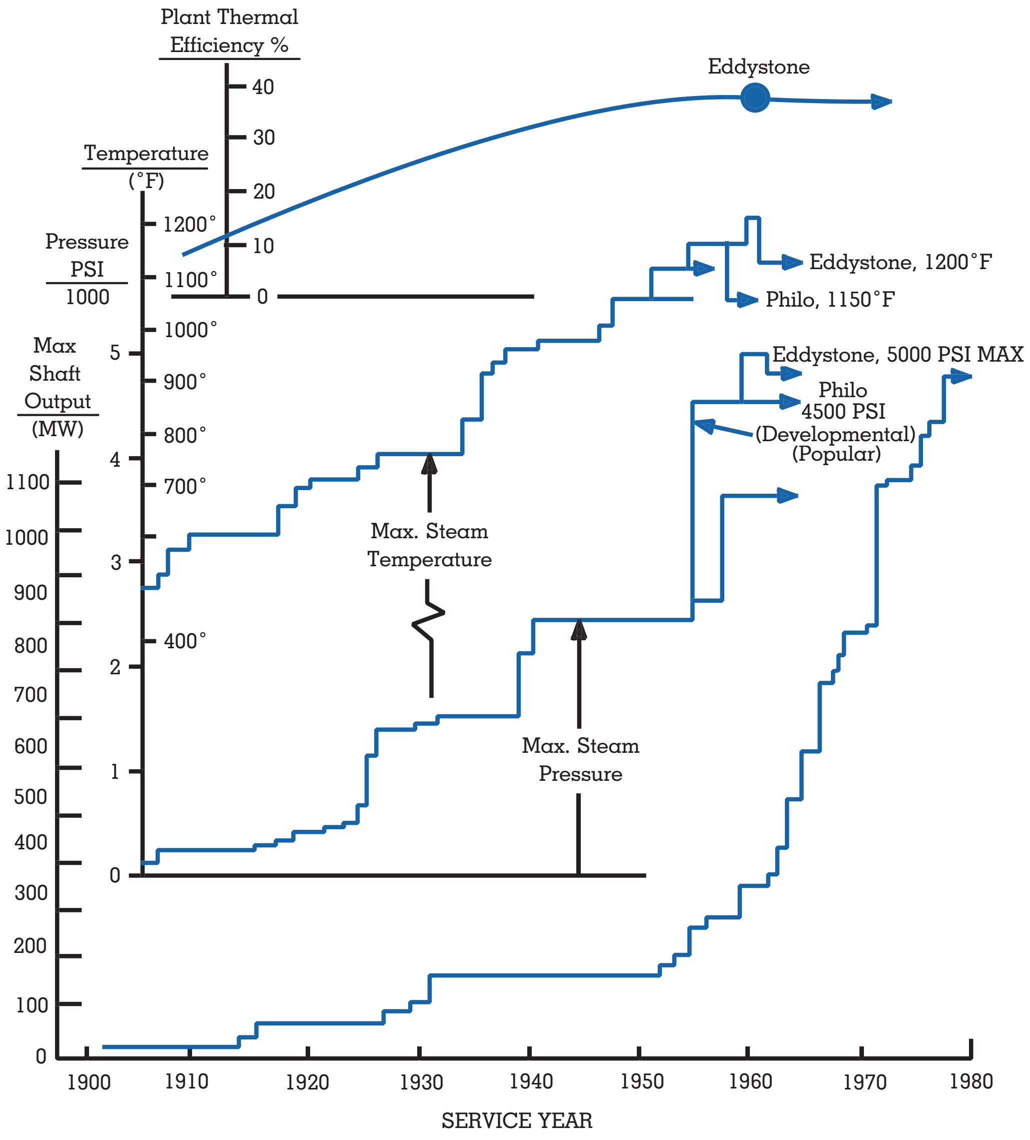

Figure 2.
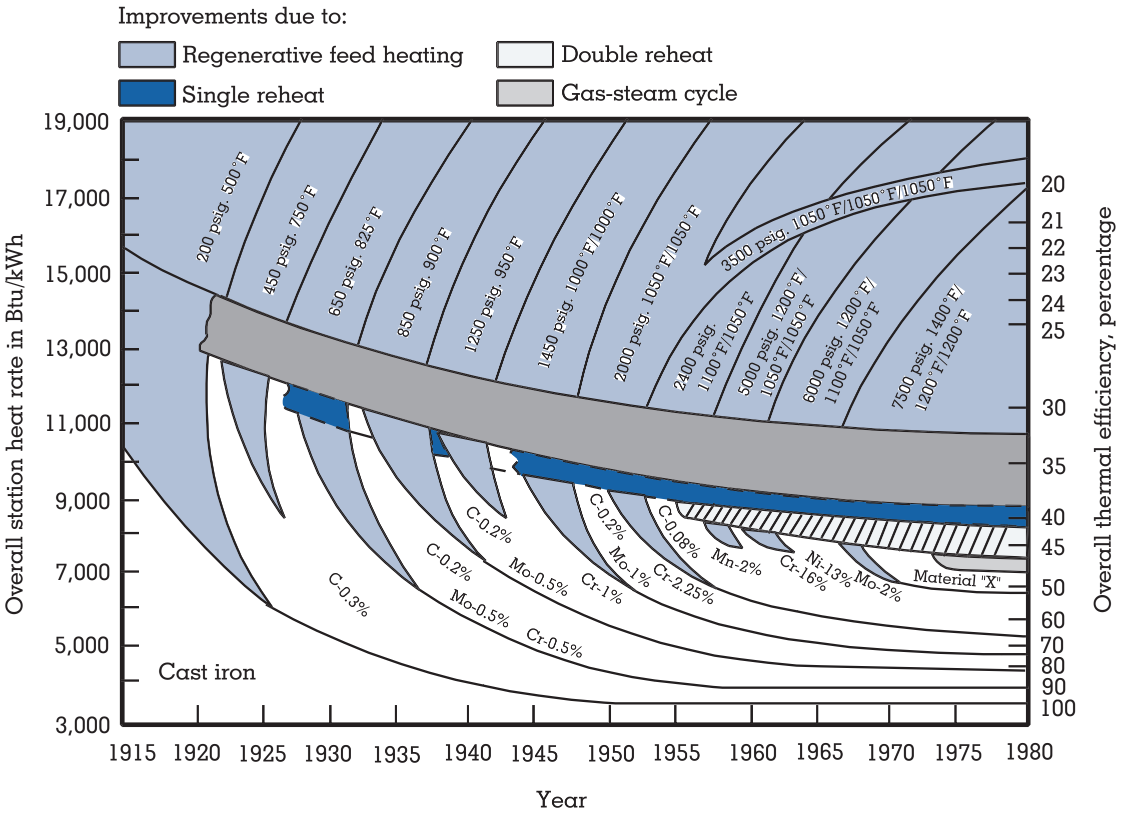
The evolution of steam turbine power generation in the United States.

lished. Reheat cycles came into use in the mid-1920s. At the throttle temperature of 370°C (700°F) that was current when the pioneer 4.1- and 8.2-MPa (600- and 1,200-psi) units went into service, reheat was essential to avoid excessive moisture in the final turbine stages. As temperatures rose above 430°C (800°F) molybdenum proved effective. Using carbon-moly steels, designers pushed temperatures beyond 480°C (900°F) by the late 1930s. As a result of rising throttle temperatures, reheat fell out of use. By the late 1940s, reheat was reintroduced to improve plant efficiency, and second reheats appeared by the early 1950s.

Over the years, exhaust area was a major limitation on size. The earliest answer was the double-flow



Evolution of the steam cycle.

Figure 3.
Evolution of the Steam Cycle in the United States.

single-casing machine. Cross-compounding, introduced in the 1950s, represented a big step forward. Now the speed of the LP unit could be reduced. Thus, the last-stage diameter could be greater, yielding more exhaust annulus area.

Continued advances in metallurgy allowed inlet steam conditions to be increased, as illustrated in Figure 3. In 1959 this progress culminated with the Eddystone 1 unit of the Philadelphia Electric Co. and Combustion Engineering. With initial steam conditions of 34 MPa and 650°C (5,000 psi and 1,200°F) and two reheats of 1,050°F (570°C), Eddystone 1 had the highest steam conditions and efficiency (40%) of any electric plant in the world. The generating capacity (325 MW) was equal to the largest commercially available unit at the time. Eddystone 1 has operated for many years with throttle steam conditions of approximately 4,700 psi and 1,130°F (32 MPa, 610°C), and achieved average annual heat rates comparable to today's best units.

Figure 3, initially published in 1954, summarizes the evolution of the steam cycle from the year 1915 through the steam conditions of Eddystone 1 (average station heat rates were used) and a projection of where the industry might be by the year 1980. The relationship of operating steam pressures and temperatures to available materials in this figure indicates how the increase in pressure and temperature is dependent upon metallurgical development. The magnitudes of heat rate gains resulting from the application of various kinds of steam cycles also are shown.

Since the early 1960s, advanced steam conditions have not been pursued. In the 1960s and early 1970s there was little motivation to continue lowering heat rates of fossil-fired plants due to the expected increase in nuclear power generation for base-load application and the availability of relatively inexpensive fossil fuel. Therefore the metallurgical development required to provide material "X" for advanced steam conditions was never undertaken.

Raising inlet pressure and temperature increases the cycle's available energy and thus the ideal efficiency. However, pressure increases reduce the blade heights of the initial stages and decrease ideal efficiency, offsetting some of the ideal improvement, unless unit rating is increased commensurately. Based on potential heat rate improvement, there is no reason to raise the turbine steam conditions above 48.2 MPa, 760°/760°/593°C (7,000 psi, 1,400°/1,400°/1,100°F).

NUCLEAR POWER APPLICATIONS

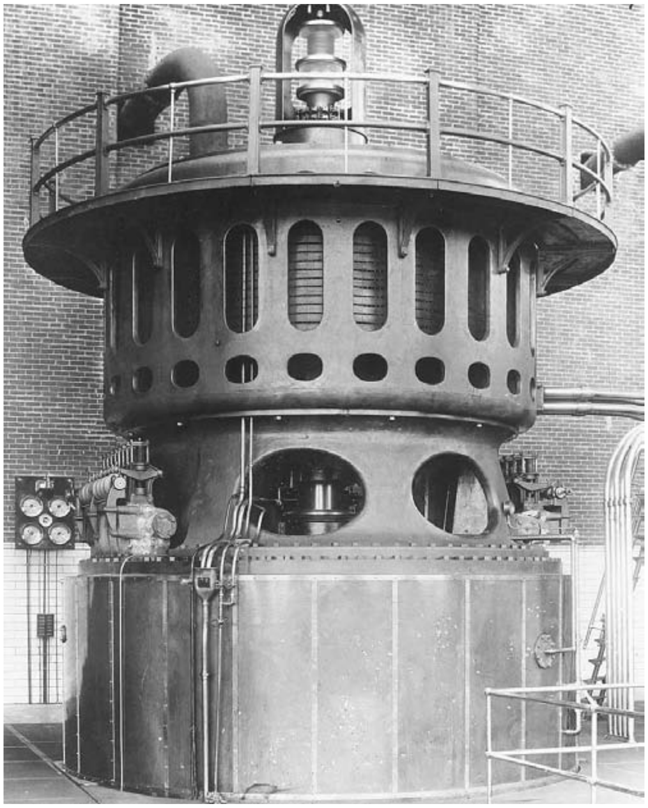
The first steam turbine generator for nuclear power application was placed in service at Duquesne Light Co.'s Shippingport Station in 1957. Initially rated at 60 MW, it had a maximum turbine capability rating of 100 MW. This was the first of a series of 1,800-rpm units, which were developed from a base design and operating experience with fossil-fuel machines dating back to the 1930s. Inlet steam conditions at maximum load were 3.8 MPa (545 psi), with a 600,000 kg (1.3 million-lb.) per-hour flow. This single-case machine had a 1-m (40-in.)-long last-row blade. Second-generation nuclear turbines introduced reheat at the crossover zones for improved thermal performance. Nuclear turbines, ranging in size from 400 to 1,350 MW, have used multiple LP exhausts.

Since moisture is a major concern for turbines designed for nuclear operation, a number of erosion-control techniques were used in the LP turbine. For example, adequate axial spacing between the stationary and the rotating blades minimizes blade erosion. Moisture is removed at all extraction points in the moisture region.

Nuclear turbines designed for use with a boiling-water reactor will be radioactive. Radioactivity could build up in the turbine because of the accumulation of corrosion products. A fuel rod rupture could result in highly radioactive materials entering the turbine. Therefore internal wire-drawing-type leakage paths, ordinarily unimportant in steam turbine design, must be eliminated as much as possible. Where it is impossible to eliminate, the surfaces forming the leakage paths should be faced with erosion-resistant materials deposited by welding.

FUTURE ROLE FOR STEAM TURBINE POWER GENERATION

In 2000, the power generation cycle of choice is the combined cycle, which integrates gas and steam cycles. The fuel of choice for new combined-cycle power generation is generally natural gas. Steam turbines designed to support the large gas turbine land-based power generation industry are in the range of 25 to 160 MW. Steam conditions are in the range of 12.4 MPa (1,800 psi) and 16.6 MPa (2,400 psi) and 538°C (1,000°F) and 565°C (1,050°F).



A Volt Curtis steam turbine, by GE from the designs of Charles G. Curtis, was installed for the Twin City Rapid Transit Company in Minneapolis and photographed in around 1900. (Corbis-Bettmann)

Large natural gas-fired combined cycles can reach a cycle efficiency of 58 percent, higher than a typical steam turbine power plant efficiency of 36 to 38 percent. During the 1990s, experience with optimizing advanced supercritical steam turbine cycles led to thermal cycle efficiencies in the 40 to 48 percent range for units rated at 400 to 900 MW that are existing or planned to be located in Japan, Denmark, Germany, and China.

In Denmark, two seawater-cooled 400 MW units, operating at a steam inlet pressure of 28.5 MPa (4,135 psi), have an efficiency of about 48 percent. Chubu Electric, in Japan, has been operating two 700 MW units since 1989 with inlet steam conditions of 31 MPa (4,500 psi). The efficiency gains of these two units is about 5 percent more than that of previous conventional plants of comparable size at 45 percent.

With an estimated 400 years of coal available for future power generation, coal-powered steam turbines are expected to continue to dominate global electricity fuel markets.

In the United States, coal had a 57 percent share of the electric power fuel market in 2000, up from 46 percent in 1970. This amounts to 430,000 MW generated by steam turbines that are fueled with coal. When considering other sources of generating steam for electric power—such as nuclear reactors, gas- or oil-fired broilers, and waste heat from gas turbines—steam turbines now comprise more than 600,000 MW of capacity, or approximately 75 percent of all generating capacity in the United States.

Since 1900, manufacturers have made many step changes in the basic design of steam turbines. New technology and materials have been developed to support the industry's elevation of steam conditions, optimization of thermal cycles and unit capacity. Steam turbines will continue to be the principal prime mover for electricity generation well into the twenty-first century.

TURBINES, WIND

Harnessing the wind to do work is not new. In 3000 B.C.E. wind propelled the sail boats of ancient peoples living along the coasts of the Mediterranean Sea. The Swiss and French used wind-powered pumps in 600, which was shortly followed by windmills used to make flour from grain. By 1086, there were 5,624 water mills south of the Trent and the Severn rivers in England. Holland alone once had over 9,000. As late as the 1930s in the United States, windmills were the primary source of electricity for rural farms all across the Midwest. Although the advent of fossil fuel technologies shifted energy production from animal, wind, and water, dependence upon these finite fossil energy sources and concern over atmospheric pollutants, including carbon dioxide, are causing a resurgence of interest in early energy sources such as wind.

Wind turbines in use at the turn of the twenty-first century primarily produce electricity. In developed countries where electric grid systems connect cities, town, and rural areas, wind farms consisting of numerous wind turbines produce electricity directly to the electric grid. In developing countries, remote villages are not connected to the electric grid. Smaller wind turbines, singly or in groups, have tremendous potential to bring electricity to these remote locations without requiring the significant investment in trans-

Egg-beater shaped vertical axis wind turbine (VAWT) at the test site at Sandia Laboratories. (U.S. Department of Energy) mission lines that would be required for grid connection. Turbines range in size from less than one meter in diameter to more than 50 meters in diameter, with power ratings from 300 watts to more than one megawatt. This wide variation enables village systems to be sized to meet specific electrical demand in the kilowatt range, while large, grid-connected utility applications produce many megawatts of electricity with a few large wind turbines.

HOW WIND TURBINES WORK

Wind is the motion of the atmosphere, which is a fluid. As the wind approaches an airfoil-shaped object, the velocity changes as the fluid passes the object, creating a pressure gradient from one side of the object to the other. This pressure gradient creates a net force on one side of the object, causing it to move in the fluid. When wind hits the airfoil-shaped blade of a turbine, the lift force that is created causes the blade to rotate about the main shaft. The main shaft is connected to an electric generator. When the rotor spins due to forces from the wind, the generator creates electricity that can be fed directly into the electric grid or into a system of batteries.

Aerodynamic drag has also been used to capture energy from the wind. Drag mechanisms consist of flat or cup-shaped devices that turn the rotor. The wind simply pushes the device around the main shaft. Anemometers used to measure wind speed are often drag devices, as are traditional farm windmills.

Airplane propeller analysis relies upon the "axial momentum" theory, which is based on energy, momentum, and mass conservation laws. This theory has been applied to wind turbines as well. The power (P_w) of a fluid passing across an area perpendicular to the flow is

$$P_w = 1/2\ \rho\ A\ V_w^{\ 3}$$

where ρ is the air density, A is the disk area perpendicular to the wind, and V_w is the wind speed passing through the disk area. For instance, if the wind speed is 10 m/s and the rotor area is 1,200 m^2, the available power is 600 kW. When the wind speed doubles to 20 m/s, the available power increases to 4,800 kW. This value represents the total power available in the wind, but the turbine cannot extract all of that power. If the turbine were able to extract all the available power, the wind speed would drop to zero downwind of the rotor.

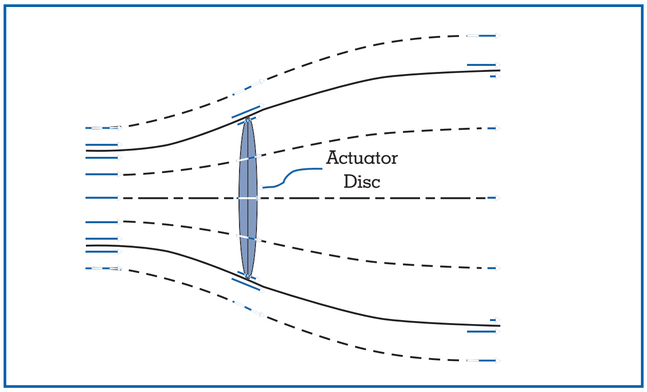

Figure 1.
Disk flow field model of an actuator.

A simple, ideal model of fluid flow through a rotor was used by both F. W. Lanchester and A. Betz (Lanchester, 1915; Betz, 1920) to study the limitation of power extracted from the wind. This "actuator disk" model is shown in Figure 1. It assumes that a perfectly frictionless fluid passes through an actuator disk, which represents the wind turbine. The fluid approaching the actuator disk slows, creating a pressure greater than atmospheric pressure. On the downwind side of the disk, the pressure drops below atmospheric pressure due to extraction of energy from the impinging fluid. As the fluid moves further downstream of the turbine, atmospheric pressure is recovered. Using axial momentum theory, Betz and Lanchester independently showed that the maximum fraction of the wind power that can be extracted is 16/27 or about 59 percent. This is known as the Lanchester/Betz limit, or, more commonly, the Betz limit, and is assumed to be an upper limit to any device that extracts kinetic energy from a fluid stream. Real wind turbines capture from 25 percent to more than 40 percent of the energy in the wind. More refined engineering analyses account for fluid friction, or viscosity, and wake rotation (Eggleston and Stoddard, 1987; Hansen and Butterfield, 1993).

TURBINE DESIGNS

There are two major types of wind turbines: horizontal-axis and vertical-axis. A wind turbine that rotates about an axis parallel to the wind is a horizontal-axis wind turbine (HAWT). Although HAWTs have not been proven clearly superior to Vertical-Axis Wind Turbines (VAWTs), they have dominated recent

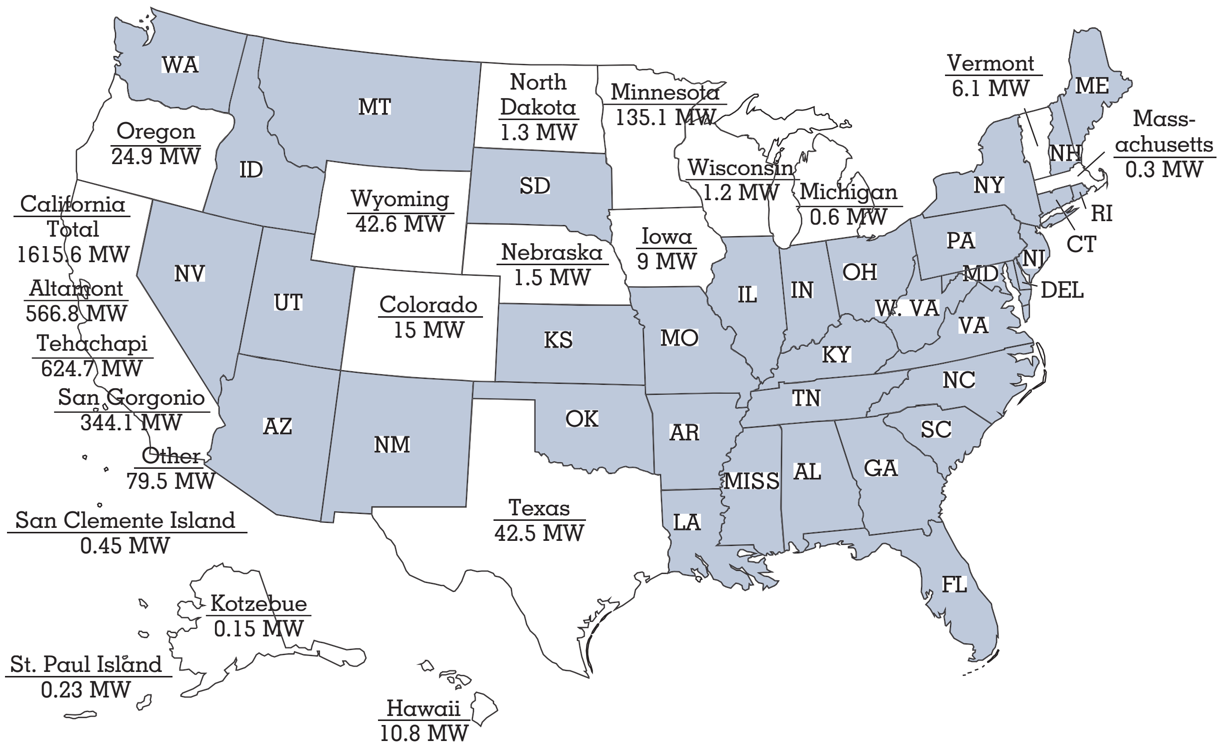

Figure 2.
U.S. capacity as of June 1999.

installations. Of all the utility-scale turbines installed today, 97 percent are HAWTs. A variety of configurations exist. HAWT rotors differ in orientation (upwind or downwind of the tower), flexibility (rigid or teetered), and number of blades (usually two or three).

Horizontal-Axis Wind Turbines (HAWTs)

An upwind turbine rotates upwind of the tower. In order to maintain the rotor's upwind position, a yaw mechanism is required to position the rotor as the wind direction shifts. In this configuration, the wind flowing toward the rotor is unobstructed over the entire rotor. Conversely, the wind flowing toward a downwind rotor is obstructed by the turbine tower over part of the rotor area. This causes fluctuating loads on each blade as it passes behind the tower, which can decrease the fatigue life of the rotor. The downwind turbine, however, aligns itself with the prevailing wind passively, eliminating the need for additional yaw drive components.

Flexibility at the rotor hub has been used to alter the load conditions on the blades. A rigid hub turbine generally has two or three blades attached to the hub. A teetered rotor, however, consists of two blades attached to the hub, which forms a hinge with the main shaft of the turbine. When the wind speed above the main shaft is higher than that below the main shaft, the rotor moves slightly downwind over the top half of the rotational cycle to reduce the loads on the blades. Although the cyclic loads are reduced by teetering the rotor, when the wind causes the rotor to exceed its maximum flexibility range hitting the teeter stops, large, transient loads can be introduced.

Although multiple-blade turbines are effective, two- and three-blade rotors are most cost-effective. Two-blade rotors commonly use teetering hinges, and all three-blade rotors are mounted on rigid hubs. Rotors up to 15 m in diameter are economically fea-

Pacific Gas & Electric engineers at verticle axis wind turbines at Altamont Pass. (Corbis-Bettmann)

sible and simplified with three blades. For large rotors exceeding 30 m in diameter, the blade weight is directly related to turbine costs. Thus, reducing the number of blades from three to two results in lower system costs with respect to the potential power available in the wind. For mid-range turbines, 15 m to 30 m in diameter, the trade off between power production and reduced cost as a result of reduced blade weight is more difficult to determine.

Most turbines are designed to rotate at a constant speed over a specific range of wind speed conditions. The generators in these turbines produce electricity compatible with the established grid system into which electricity is fed. Operating the turbine at variable rotor speeds increases the range of wind speeds over which the turbine operates. The amount of energy produced annually is increased as well. However, sophisticated power electronics is required to convert the electricity to the grid standard frequency.

Vertical-Axis Wind Turbines

A vertical-axis wind turbine (VAWT) rotates about an axis perpendicular to the wind. The design resembling an eggbeater was patented by D. G. M. Darrieus, a French inventor, in the 1920s. Because the axis of rotation is perpendicular to the ground, components such as the generator and gearbox are closer to the ground, making servicing these turbines fairly easy. Also, the turbine is not dependent upon its position relative to the wind direction. Since the blades cannot be pitched, these turbines are not self-starting. The greatest disadvantage of VAWTs is the short machine lifetime. The curved blades are susceptible to a variety of vibration problems, that lead to fatigue damage.

A modern VAWT that relies upon aerodynamic drag is known as a Savonius wind turbine. Sigurd Savonius, a Finnish inventor, developed this design in 1924. Two S-shaped panels are arranged to cup the wind and direct it between the two blades. This recirculation improves the performance of this drag device, but at best only 30 percent of the power available in the wind can be extracted.

UTILITY-SCALE APPLICATIONS

Utility-scale wind turbines range in size from 25 m to more than 50 m in diameter, with power ratings from 250 kW to 750 kW. Modern, electricity-producing wind turbines are often placed in large areas called wind farms or wind power plants. Wind farms consist of numerous, sometimes hundreds, of turbines regularly spaced on ridges or other unobstructed areas. The spacing varies depending upon the size of the turbine. Until recently California had the largest wind farms in the world. In the late 1990s, installations with capacities of 100–200 MW in the midwestern United States. Figure 2 shows the producing wind power plants in the U.S. resulting in a total capacity of 2.471 MW in 2000. This represents a small fraction of the 750 GW generating capacity in the U.S. Globally, wind power exceeded 10 GW of installed capacity in 1999. Much of the worldwide growth in wind energy use is in Europe, particularly Denmark, Germany, and Spain. To reduce pollution, many European countries subsidize wind generated electricity.

Future wind turbines will exploit the accomplishments of many years of U.S. government-supported research and development, primarily at the national laboratories, over the past twenty-five years. During the 1980s, a series of airfoils specifically designed for wind turbine applications were shown to increase annual power production by 30 percent. Detailed studies of the aerodynamics of wind turbines operating in the three-dimensional environment have led to improved models that are used for turbine design. These modeling capabilities allow turbine designers to test new concepts on paper before building prototype machines.

Several avenues for improving power production and cutting costs are being pursued by turbine designers. Building taller towers places the turbine in higher wind regimes, which increases the potential power production. In addition to taller towers, larger rotor diameters will improve power production. Increasing blade flexibility will reduce loads that reduce the fatigue life of blades, but sophisticated dynamic models are required to make such designs. Sophisticated control algorithms will monitor the turbines in order to accommodate extreme load conditions.

SMALL-SCALE APPLICATIONS

Because one-third of the world's population does not have access to electricity, many countries lacking grid systems in remote, rural areas are exploring various methods of providing citizens with access to electricity without costly grid extensions. Wind turbines are an intermittent source of electricity because the wind resource is not constant. For this reason, some form of energy storage or additional energy source is required to produce electricity on demand. Systems designed to supply entire villages or single homes are used throughout the world.

Battery systems are the most common form of energy storage. In some developing countries, battery-charging stations have been built using wind turbines. These sites simply charge batteries that people rent. The discharged batteries are exchanged for charged batteries at regular intervals. Other systems are designed for storage batteries to provide electricity during times when the wind is not blowing.

Wind turbine systems are often combined with other energy sources such as photovoltaic panels or diesel generators. Many remote areas currently rely upon diesel generators for electricity. Transportation costs limit the amount of diesel fuel that can be supplied, and diesel fuel storage poses environmental risks. By combining the generators with wind turbines, diesel fuel use is reduced. Wind and solar resources often complement each other. It is common in many areas for wind resources to be strongest in seasons when the solar resource is diminished, and vice versa. Systems that combine energy sources are called hybrid systems.

Although electricity production is the primary use of wind turbines, other applications still exist. Water pumping, desalination, and ice-making are applications that wind turbines serve. Wind turbine rotors for small-scale applications generally range in size from less than 1 m diameter to 15 m diameter, with power ratings from 300 W to 50 kW.

SITING WIND TURBINES

To obtain the best productivity from a wind turbine, it must be sited adequately. Whether establishing a wind farm with a hundred turbines or a single turbine for a home, documenting the wind conditions at a given site is a necessary step. Several databases of wind conditions have been established over the years (Elliot et al., 1987). Improvements in geographic information systems have enabled mapping wind conditions for very specific regions. Figure 3 shows the wind resource throughout the United States. Class 1 is the least energetic, while Class 7 is the most energetic. Wind turbines are generally placed in regions of Classes 3-7. This map indicates that a large part of the country has wind conditions that are conducive to wind turbine applications. These advanced mapping techniques can be used to compare one ridge to another in order to place the turbines in the most productive regions.

In addition to obtaining adequate wind resources, site selection sites for wind turbines must also consider avian populations. Several studies have been performed to determine the impact that turbines have on bird populations, with inconclusive results (Sinclair and Morrison, 1997). However, siting turbines to avoid nesting and migration patterns appears to reduce the impact that turbines have on bird mortality.

Other considerations in siting wind turbines are visual impact and noise, particularly in densely populated areas (National Wind Coordinating Committee Siting Subcommittee, 1998). Due to Europe's high population density, European wind turbine manufacturers are actively examining the potential of placing wind turbines in offshore wind farms.

ECONOMICS

Deregulation of the electric utility industry presents many uncertainties for future generation installations. Although the outcome of deregulation is unknown, ownership of the generation facilities and transmission services will most likely be distributed among distinct companies. In the face of such uncertainties, it is difficult to predict which issues regarding renewable energy will dominate. However, the benefits of integrating the utility mix with wind energy and the determination of the cost of wind energy, are issues that will be relevant to most deregulation scenarios.

Wind energy economics focuses on the fuel-saving aspects of this renewable resource, but capacity benefits and pollution reduction are important considerations as well. The capital costs are significant, but there is no annual fuel cost as is associated with fossil fuel technologies. Thus, wind energy has been used to displace fossil fuel consumption through load-matching and peak-shaving techniques. In other words, when a utility requires additional energy at peak times or peak weather conditions, wind energy is used to meet those specific needs. In addition to fuel savings, wind energy has been shown to provide capacity benefits (Billinton and Chen 1997). Studies have shown that although wind is an intermittent source, wind power plants actually produce consistent, reliable power that can be predicted. This capacity can be 15 percent to 40 percent below the installed capacity. Last, the emission-free nature of wind turbines could be exploited in a carbon-rading scenario addressing global climate change.

Two methods of determining the cost of wind energy are the Fixed Charge Rate (FCR) and the Levelized Cost of Energy (LCOE). An FCR is the rate at which revenue must be collected annually from customers in order to pay the capital cost of investment. While this incorporates the actual cost of the wind turbines, this method is not useful for comparing wind energy to other generation sources. The LCOE is used for comparison of a variety of generation technologies that may vary significantly in size and operating and investment time periods. This metric incorporates the total life cycle cost, the present value of operation and maintenance costs, and the present value of depreciation on an annual basis.

Subsidies, in the form of financing sources, and tax structures significantly impact the levelized cost of energy. The Renewable Energy Production Incentive (REPI), enacted in 1992, at $0.015/kilowatt-hour (kWh), applies only to public utilities. This tax incentive is renewed annually by Congress, making its longevity uncertain. Private owners of wind power plants are eligible for the federal Production Tax Credit (PTC), which is also $0.015/kWh. A project generally qualifies for this tax credit during its first ten years of operation. This credit is also subject to Congressional approval. Ownership by investor-owned utilities (IOUs), and internal versus external project financing, also affect the LCOE. Cost differences that vary with ownership, financing options, and tax structures can be as great as $0.02/kWh (Wiser and Kahn, 1996).

The annual LCOE for wind turbines has decreased dramatically since 1980. At that time, the LCOE was $0.35/kWh. In 1998, wind power plant projects were bid from $0.03kWh to $0.06/kWh. These numbers still exceed similar figures of merit for fossil fuel generation facilities in general. However, wind energy can become competitive when new generation capacity is required and fossil fuel costs are high, when other incentives encourage the use of clean energy sources. For example, a wind power plant installed in Minnesota was mandated in order to offset the need for storing nuclear plant wastes.

Incentives that currently encourage the use of clean energy sources may or may not survive the deregulation process. Green pricing has become a popular method for utilities to add clean energy sources, with consumers volunteering to pay the extra cost associated with renewable energy technologies. Some proposed restructuring scenarios include a Renewable Portfolio Standard (RPS), which mandates that a percentage of any utility's energy mix be comprised of renewable energy sources. Last, distributed generation systems may receive favorable status in deregulation. Small generation systems currently are not financially competitive in many areas, but through deregulation individuals or cooperatives may be able to install small systems economically.

Wind energy was the fastest growing energy technology from 1995 to 1999. This translates to an annual market value of over $1.5 billion. Supportive policies in some European countries, improved technology, and the dramatic drop in the cost of wind energy, have contributed to the growth of wind energy.

U

UNITS OF ENERGY

The joule, symbol J, is the unit of energy in the science community. It is not widely used outside the science community in the United States, but it is elsewhere. For example, in the United States, the energy content of a food product is likely expressed in food calories. This energy could be expressed in joules, and that is being done in many parts of the world. A Diet Coca Cola in Australia is labeled Low Joule rather than Low Cal as in the United States. To obtain a feeling for the size of a joule, consider the following statistics:

- the sound energy that is in a whisper is about 0.01 joules,
- the kinetic energy of a 1,000-kilogram car traveling 25 meters per second (55 miles per hour) is about 300,000 joules,
- the energy from burning a barrel of oil is 6,000,000 joules,
- the annual energy use in the United States is about 100 billion billion joules, and
- the daily energy input to the Earth from the sun is about 10,000 billion billion joules.

Numerical Unit	*Power of Ten*	*Prefix*	*Symbol*
million trillion	10^{18}	exa	E
trillion	10^{12}	tera	T
billion	10^{9}	giga	G
million	10^{6}	mega	M
thousand	10^{3}	kilo	k
hundredth	10^{-2}	centi	c
thousandth	10^{-3}	milli	m
millionth	10^{-6}	micro	μ

Table 1.
Symbols of Some Numerical Units

Even if the use of units of joules were universal, the numbers involved in energy discussions would be large and cumbersome. Therefore, it is customary to use powers of ten notation and prefixes for powers of ten. For example, the energy from burning a barrel of oil is 6×10^6 joules, which can be expressed as 6 megajoules or, symbolically, 6 MJ. Table 1 summarizes the powers of ten, prefixes, and symbols usually encountered in energy considerations.

The gasoline tank on an automobile holds about 15 gallons, and the automobile can travel about 300 miles before the tank is empty. Even though the gasoline was purchased for its energy content, the driver probably did not know that the energy content of 15 gallons of gasoline is 2×10^9 J = 2 GJ. For reasons like this, there exists a variety of energy units and energy equivalents. The unit and equivalent depends on the type of energy commodity in question. A homeowner pays an electric utility for electric energy, and the

Special Unit	*Study area of main use*	*Symbol*	*Equivalent in joules*	*Other units*
Kilowatt hour	electricity	kWh	3,600,000	3413 Btu
Calorie	heat	cal	4.186	
Kilocalorie (food calorie)	heat	kcal	4,186	1000 cal
British Thermal unit	heat	Btu	1,055	252 cal
Electron volt	atoms, molecules	eV	$1.60\text{x}10^{-19}$	
Kilo-electron Volt	X-rays	keV	$1.60\text{x}10^{-16}$	1000 eV
Mega-electronVolt	nuclei, nuclear radiations	MeV	$1.60\text{x}10^{-13}$	1000 keV
Quadrillion	energy reserves	quad	$1.055\text{x}10^{21}$	10^{15} Btu
Quintillion	energy reserves	Q	$1.055\text{x}10^{21}$	10^{18} Btu

Energy equivalents

1 gallon of gasoline = 126,000 Btu
1 cubic foot of natural gas = 1030 Btu
1 pound of bituminous coal = 13,100 Btu
1 42-gallon barrel of oil = 5,800,000 Btu
1 therm = 100,000 Btu

Variations of these energy equivalents will appear in the literature. The values listed here are typical.

Table 2.
Some Energy Units and Their Equivalents

unit is likely a kilowatt-hour (kWh). A politician interested in imported oil will likely talk in terms of barrels of oil. Table 2 summarizes some special energy units and their equivalents.

UTILITY PLANNING

Electricity is a commodity that has captured the attention of Americans, from its creation to the present and onward to projections of the future. From an object of luxury to a mainstream "staff of life" and forward into the sophisticated world of tomorrow, electricity has become a critical necessity. The criteria have become: electricity on demand, reliably delivered, in sufficient quantities, and at the right price. At the heart of meeting this challenge is the utility planner.

Generating and delivering electricity requires a complicated infrastructure, significant funding, competitive markets, and adequate regulation. Broken into its simplest terms, utility planning is beginning with the most optimum operation of existing electrical facilities and foreseeing the future well enough to provide additional facility to "guarantee" an adequate supply of a reliable product (electricity) at an acceptable cost. Generation provides the product, transmission is the vehicle to deliver the product over long distances, and distribution is the functional method of providing the product to the individual customer.

Originally all facilities, financing, and decisions related to building an electrical system resided within a utility. In this simplistic approach, projections of load growth, established construction and planning criteria, and coordination of facilities remained within the single entity. In today's competitive unregulated marketplace, the planners, designers, generators, and transmission providers are within a complicated mix of organizational units; thereby providing a complicated network of system participants. The challenge for utility planning today is to coordinate all of the inputs for constructing and maintaining an electrical system that combines the economics efficiencies necessary for survival and the maintenance of a reliable network where generated power can be delivered to an ultimate customer on demand, in sufficient quantities, both today and in years to come.

HISTORY

The history of the interconnected high-voltage electric power system has roots in the early decades of the twentieth century. Moving power from generating plants remote from load centers began as utilities and customers realized that costs associated with many small generating entities placed strategically at concentrated load points would soon escalate to unacceptable values. Likewise, the many advantages of the new power source would be restricted to cities and other high-density areas. The efficiencies of larger generating units utilizing fuels of choice and availability soon became the economic choice for resources thus developed the need to "push" power across long distances.

There were many examples of early interconnected electric transmission systems extending across state territories and beyond state boundaries. Statements from a speech by Samuel Insull at Purdue University in 1924 indicated that Minneapolis, St. Paul, St. Louis, Louisville, and Cincinnati soon would be interconnected and that extension of these systems to Pittsburgh and across the Allegheny Mountains to the Atlantic Seaboard could be easily conceivable in a few years. This was but one example across the United States. To quote Insull, "It makes electric service available in new places for new purposes, so that aggregate demand for service is spread over more hours of day and night, and thus opens the way to utmost economy in production and distribution."

The interconnected power system grew and the load demand increased, over time, at varying rates and reached an average growth of some 10 percent, or a doubling every ten years. Utilities financed, constructed, and controlled the vast majority of the generation and transmission facilities in what was classified a "monopolistic society." In this environment, while the processes were complicated, the data necessary to plan these extensive projects were readily available.

One example of the complexity of the process was in load forecasting technology. By the 1960s and 1970s, utilities had developed processes to replicate the extensive electric power system for study purposes to include generation resources, transmission networks and individual points of load service to customers. The most complicated of these were the load forecast and load distribution techniques. No matter how fast technology developed, certain parameters of forecasting created significant challenges. Companies forecasted load as a composite for their territory, primarily using historical trends. Often, these forecasts were economically based, thus having boundaries driven by non-technical issues. Load growth varied within areas of individual companies. New and increased industrial loads, which made up significant portions of the forecasts, diluted the forecast and often appeared on the system later (or earlier) than planned.

In the 1980s, as the complexity of forecasting became more challenging, utilities chose to augment their forecasting methodologies through the use of consultants who possessed sophisticated databases that included topography, diversity, trends, population growth and other intricate variables and impactors. These forecasts enabled a finer tuning of the process and in many cases a more efficient and economical forecast.

No matter how accurate the forecast, other planning techniques, while state of the art, introduced trending, estimating, and engineering judgment in the facility planning cycle. One such issue involved the time and expense to plan a project, budget the project, and place the project in service when required. Because of constraints, most planning studies considered only the estimated annual peak load for a company. This peak could occur in the summer or winter, depending on the region of the country. Obviously other variations on the annual load curve occurred, such as off-peaks (spring and fall seasons) and shoulder peaks (related to time of day). Normally these variations were trended or estimated or ignored in the interest of time, and an ultimate plan was developed. In the very early years of planning, utility planners assumed that planning for the peak load covered all other times of the year. History recorded it to be a valid theory.

In later years, studies involving variations of the peak load were initiated to answer specific questions. Generation maintenance schedules, which were initially developed to accommodate only peak load periods, were revised to protect extended off-peak periods of large energy usage. The components of generation and load include real power for load service and reactive power for voltage support. The effects of various load levels to voltage profiles were tested to plan economic generation reactive parameters and adequate capacitor levels, and to define optimum capacitor locations. In addition, off-peak voltage profiles were sensitive to generator outages and maintenance. Power transfer capabilities between entities had been routinely studied at peak load. As peak periods began to lengthen and as generation locations were more widely distributed, it became necessary to consider the impacts to transfers at load levels less than peak. The transfer capability issues have become of more specific importance with the move to greater open access and competition.

Transmission parameters for existing systems were translated into appropriate input data for calculation systems available at the time. During early periods of the twentieth century, calculations for expansion of the transmission network or grid were actually made by laborious longhand manual monotonous iterations. Fortunately, the areas of study were small or abbreviated sections not affecting other areas. In the 1940s, network analog calculators were introduced for use in modeling the power system. These calculators were large "black boxes" composed of resistors, capacitors, meters, controls, dials, plotting boards, etc., and often covered an entire room, usually at an area university.

The analog calculator employed a quantitative methodology. The engineer calculated the impedance (parameters) of a transmission line and physically dialed in the valve between points A and B. The calculator also included metering windows where various information could be readily observed. With this method an experienced planner could actually sense a "feel" of the system as the dials and data were manipulated. Likewise, the analog computer became a significant training tool for utility engineers.

By the late 1960s, digital computers began to replace the "black boxes." Despite forebodings of utility planning engineers regarding training of engineers and planning, adaptations to the new technology became commonplace.

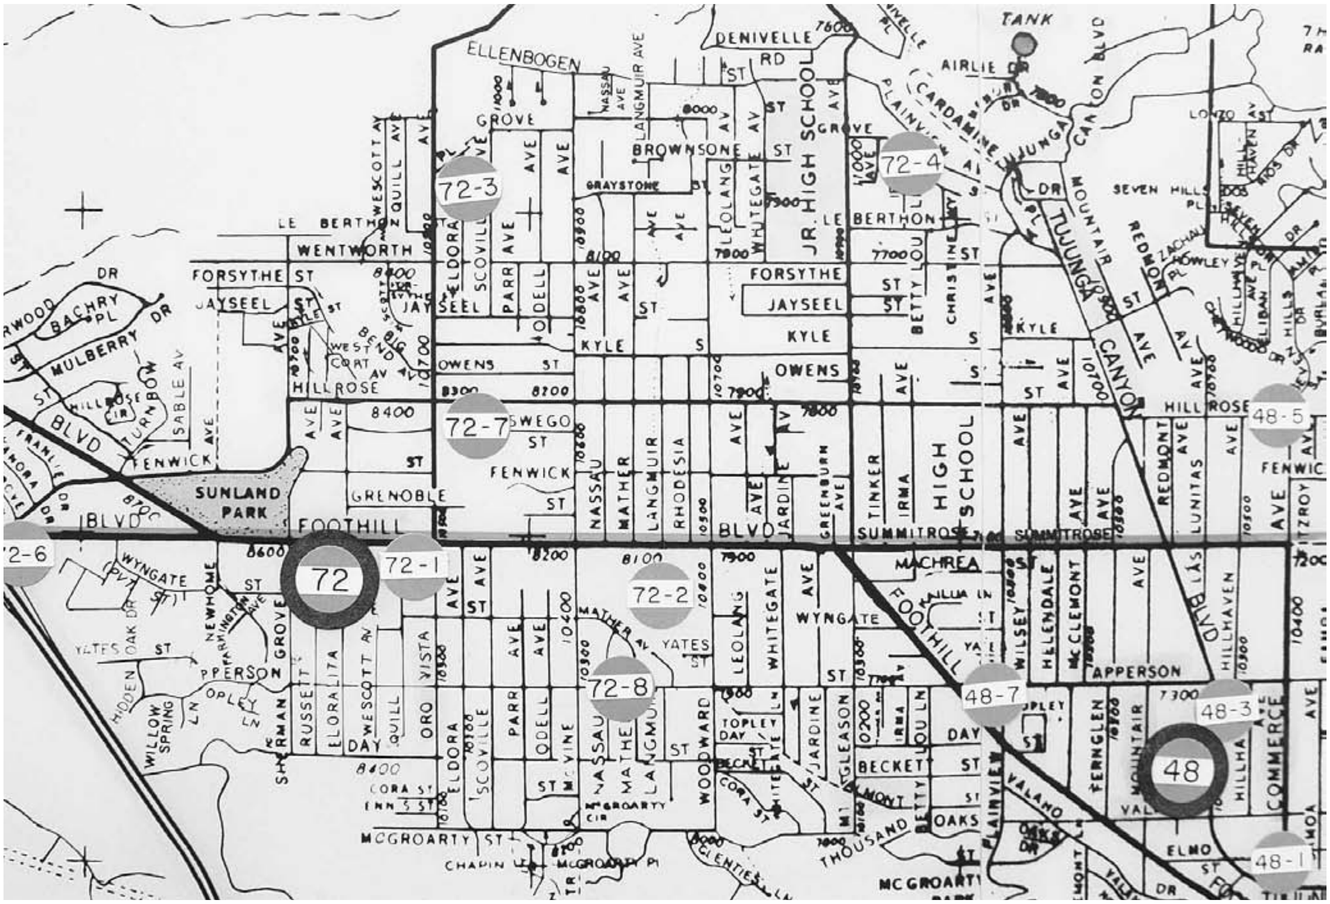
The digital computer began as a mammoth blue or black giant mechanism hidden in some corporate information resource office. The planner's view of data processing was keypunching a "deck" of cards and dropping them into an open "hopper" to mysteriously disappear into the computer. Similarly, once the magic of the calculations was accomplished, white punched computer paper arrived from an output device with guaranteed solutions to difficult questions.

The process improved. Computers became smaller, and today it is rare for a planning engineer to be void of computer power available at his desk many times greater than the early corporate computer could muster. Computer tools of the future can only be envisioned as technology advances.

Generation data to complement the planning study were plentiful. As long as the utilities owned the physical facilities and were in control of future facility expansion, data were generally a nonissue. The parameters of generating plants were dialed into the calculations or computers, similar to transmission. Obviously, alternate locations for new plants could be evaluated, and oftentimes studies were finalized some ten years ahead of construction, with only limited analysis required as the in-service date approached.

Planning studies to identify the magnitude of generation required on a particular system for a specific time period were based on parameters such as loss of load probability (LOLP) or loss of load energy (LOLE). These studies modeled the system load curve throughout the year for projected years into the future and included existing generation resources. The purpose of the studies was to identify the probability statistics where the system could not serve its load requirement or to identify an amount of unserved energy. These data would be compared to specific criteria, and future generation requirements would be developed. The ability to obtain emergency or specific contracted generation resources from neighboring systems would normally be factored into the data. In addition, in many cases generation reserve sharing agreements were factored into the final determination of capacity required. Reserve sharing agreements were contractual arrangements, usually within power pools (groups of systems) or areas where each system involved factored in the pro rata share of neighboring generation available to that system. Both concepts of utilizing off-system resources as an integral part of a system's total resources involved risk, which had to be coordinated with economic advantages and reliability levels.

Given that there were numerous alternatives for the resources, including demand-side management, interruptible loads, and off-system purchases, many case studies were necessary. Each plan for service to future loads had to be tested for conformance with system and regional reliability criteria. The plans were further examined for cost, including losses, and examined for flexibility. Any acceptable plans had to



A map at Los Angeles's energy troubleshooting facility in 1987. Circuit 72–4, the source of an earlier blackout, is marked in the upper right. (Corbis-Bettmann)

be considered for ease of modification, should future load patterns differ from present projections.

Generation was normally modeled in system studies using economic dispatch schedules developed from individual unit fuel cost and heat-rate data. To serve a particular load level, the units would be "stacked" (added to the system) in order of priority based on cost and performance. Additional capacity options were available from off-system purchases or reserve sharing arrangements with neighboring systems. A system's ability to import power was a strong indicator of its territorial reserve requirements.

Prior to the 1990s, generation lead time was generally the critical factor in project planning. As smaller units, low run-time peaking plants, environmental issues, and more diversified fuel availability appeared, the lead time for transmission construction began to be of more concern than the generation construction period. In addition, line citing, environmental impact, and condemnation issues contributed to longer lead times for transmission projects.

The planning processes described herein were traditional in nature, with little variation from year to year. Growth was steady, equipment technology advancements were available for the conditions expected, and while utility facilities were capital-intensive, a regulated guaranteed return on investment resulted in adequate financing capital. The utility planner had a vision of the future with acceptable accuracy.

TRANSITION

Many events signaled the beginning of a lengthy transition period for the utility industry in general, and more specifically, for the facility planning activity. The timeline in many instances was blurred, with some of the blurring attributable to a reluctance to change.

Perhaps the Public Utilities Regulatory Policies Act (PURPA) of 1978 was the initial formal driving force for change. The introduction of nonutility generators (NUGS) with qualified facilities and almost guaranteed sales opportunities was the first major nonutility resource activity. Whether the cause was the actual construction of these facilities or the resource atmosphere it stirred, transition was on the way. Independent power producers (IPPs) soon followed. These projects were introduced into the competitive resource market on an equal footing with utility-sponsored plants and could not be ignored by utility management.

In parallel with the new approaches to generating capacity additions, the utilities, with encouragement from regulators, introduced incentives during the 1980s for reducing load demand. Since the system peak hour load provided the inertia for capacity requirement definition, “shaving” of the peak became the focus of these incentives.

Enticements to involve the retail customer base, as well as the industrial sector, in the solutions desired became popular. Interruption of large commercial load, a provision by contract, had long been used to offset capacity shortages. Interest in this method mounted. In addition, retail customers were provided enticements to “cut load,” either by manual participation or by automatic devices. These enticements will like continue into the future.

Further involvement by the typical industrial or commercial utility customer, both large and small, was stimulated by time-of-day price incentives. Encouragement was provided in the form of reduced rates if use of electricity was shifted from peak periods of the day to off-peak or shoulder-peak periods. Even the residential customer was invited to participate in load shifting with price incentives or rewards. A popular example of the day was encouraging the household laundry activity to be moved to late-night hours. This suggestion was met with varying enthusiasm.

Initially there were attempts to quantify and project magnitudes of power shifted and relief provided to the capacity resource requirements. Ultimately the shifting of load became embedded in the subsequent forecast and became harder to identify.

The impact of these tactics to augment capacity resources was successful to some degree. Currently, the values identified are marginal; however, much of the impact is unidentified and embedded in the load growth.

Industrial customers, early a driving force in the industry, began to react not only to local utility incentives but also to more competitive pricing opportunities in other systems and exerted significant pressure on regulators. Forces in Washington, D.C., following the industry trends, finally acted in 1992 with open access of the transmission system to the wholesale market, and more extensive competition resulted. Possibly this one act, more than any other, provided the stimulus for a major shift in the industry through deregulation, restructure, and more specifically, in the planning process of the bulk electric system.

With the opening of the transmission network to all resource suppliers, many marketing entities entered the game in the mid-1990s. Many of these marketers are subsidiaries of already established gas suppliers. Some have been created solely for the electric industry. Still others have been formed from the utilities themselves. All of these entities are competition-motivated. Facility planning and reliability issues, while important to their business, are left to other organizations.

The planning and construction of generation and transmission facilities by utilities came to a virtual halt. With no guaranteed market, no control over the use of their transmission networks, no assurance of stranded investment recovery, and no assurance of federal remedial treatment, the economic structure of utility planning and construction of generation facilities basically stopped in place.

The transition for utility planners has been difficult. Generation and transmission margins have deteriorated. Shortages have been noted. The number of transactions within and across systems has escalated to levels that not only test the reliability of a transmission network not designed for this level of activity but that also have challenged the ability to operate such a system with existing technology. Prices have reacted. Emergency disturbances have occurred. Basic questions regarding authority, planning, responsibility, and finances have been raised.

Several alternatives have been offered by the Federal Energy Regulatory Commission (FERC). Regional transmission groups (RTGs) were suggested. While the basic premise of these wide-area coordinating and planning organizations was sound, many of the questions involving economics and responsibility were left unanswered.

Systems of independent system operators (ISOs) were introduced as another alternative. Some have been implemented and many have been evaluated. Adoption of these systems has been slow, the same basic reasons as those affecting RTGs. The regional transmission organization (RTO) is the most current alternative being proposed and initial plans will be provided to FERC during 2000. All of these organizational arrangements are devised to segregate ownership, planning, construction, and operation in an appropriate manner to produce a nondiscriminatory, totally competitive marketplace for electricity. All of this activity will likely result in the complete deregulation of the industry, wholesale and retail. Restructuring of the electric business on all fronts is required to make deregulation complete.

The North American Electric Reliability Council (NERC), established in 1968, and its associated ten regional councils have been reliability monitors of the electric bulk power system. Their emphasis on compliance with reliability standards through peer pressure was effective in the past. NERC and the councils, with oversight from FERC, are engaged in a complete restructuring of the reliability organizations. This move will ultimately involve a move from peer pressure to mandatory compliance.

In the meantime, the utility planner struggles with how to approach the planning process in this changing environment. Perhaps these issues are more critical in the transition, since so many of the traditional parameters of planning have disappeared, and few new parameters have taken their place.

Future-generation location, timing, and ultimate customer designations are generally unknown. Transmission construction has become more of a patchwork activity. Power transactions across the various systems are at an all-time high, a condition the network was not designed to handle. System operators struggle with daily and weekly operational planning because of the volume of transactions. Many of these transactions are not identified beyond buyer and seller. The marketing of power continues to follow the traditional contractual-path power flow route from seller (source) to buyer (load), as opposed to the actual system flow path. The contract path is a predetermined contractual route from the source system to the load system, through any interconnected intermediate system or systems. The contract assumes that all or a majority of the power will flow along this path. Only systems outlined in the contract are involved or compensated. In reality the power flows over the path of least resistance, as determined by the parameters (resistance) of the transmission lines involved. While there are economic considerations involved between the two alternatives, this is an issue of significant magnitude to the system planners and operators, who must know the path of actual power flow to properly address facility planning and operating security. In addition, many operating problems arise from the lack of automated software, a requirement for the volume of daily business being handled.

One alternative to planning in this environment of unknowns is called “scenario” planning. Utility planners in 2000 continue to estimate resource requirements for five to ten years into the future. These resources could be constructed indigenous to their systems or external to their systems, or purchased from off-system. By considering multiple alternatives for generation sources, the planner can simulate power transfers from within and outside each system. The results of these scenario analyses can be used to estimate where critical transmission might be constructed to be most effective for wide-area power transfer. Similarly, analyzing multiple transfers across a system can provide further justification for a new transmission path.

Other new planning processes are being considered to aid the transition. These include variations of probability analysis, optimum planning tools, and short-lead-time projects. None of these addresses all of the constraints discussed above. This should not, however, be construed as an impossible task.

As new generation is announced from all market segments, and as physical locations are determined, the planning picture will slowly evolve as well. It is also assumed that as retail access is introduced during the first decade of the twenty-first century, it will be controlled to some extent by contract terms long enough to provide practical development of demand forecasts. It is further assumed that future legislation and regulation also will assist in defining many aspects of the planning process. While the transition may be lengthy, the utility planner may be immersed in a full competitive environment without realizing that the transition has been completed.

FUTURE

The future of utility planning is uncertain. Good engineering judgment and technological advancements, however, will prevail as future system requirements are defined.

Major wholesale load shifts, unidentified transactions, dynamic scheduling (services provided by systems remote from the load served), unknown generation locations and timing, and retail wheeling will contribute to difficulty in planning for the future. The issues of planning, however, are likely to be easier to solve than the political issues that have a major impact on the health of the electrical infrastructure. The threats are many. An environment created by new deregulation legislation that fails to consider or impacts critical electrical phenomena and proper division of responsibility between the state and federal domains will be difficult to plan for. Environmental restrictions that curtail or impact generation resources or transmission availability will be costly to overcome and may lead to undesirable shortages. Retail customer access to systems remote from the host system will present future projection issues and change obligation-to-serve regulations. While stranded investment recovery will continue to be an economic issue, it may impact future planning in the restriction of alternative choices. Finally, mandatory compliance with reliability standards, while necessary to maintain a reliable system in a competitive marketplace, can become a constraint to good planning practices if the program becomes more bureaucratic than functional.

Based on history and the inherent unknowns related to planning, it is likely that full retail access and customer choice will present the utility planner with the most difficulty in future planning of the system. Since load demand is the principal driver of the facility developmental process, it has been necessary in the past to have a high degree of probability in the forecast. Without significant improvement in planning techniques for more accurate forecasts, planning for a changing (fluctuating) load demand in a given service area will be a significant challenge.

The various restructures of the industry are all planned to address these major issues. Wide-area planning, while undefined, may solve certain issues resulting from the unknown parameters. Divestiture of the industry into generation, transmission, and distribution companies will strengthen emphasis on the facilities involved. Many of these new structures will move the industry toward full competition; however, coordination of their activities could become more difficult.

Entry into a true competitive market suggests that the market will resolve all issues created by this move. Supply and demand will likely prevail. Full retail wheeling will introduce issues into utility planning never before addressed. Planning strategy for the future is difficult to envision based on history and current transition difficulties. It is assumed, however, that the need will create the solutions.

New technology, in both long-range planning and operational planning, will aid the entrance into a full competitive market. New tools and ideas will offset increased business and downsizing of manpower created by a more competitive environment. Each significant transition in the past was met with creative solutions. Utility planning expertise and experience will be major factors in the twenty-first-century electric industry. The goal, as always, is to continue the planning, construction, and operation of an economic and reliable electric power system.

VOLTA, ALESSANDRO (1745–1827)

Alessandro Volta, now known as the inventor of the electric battery and eponym of the volt, the unit of electrical potential, was a prominent figure in late eighteenth-century science. A younger son from a family of the lesser nobility, he was born in 1745 in the commercial town of Como, in Northern Italy, at that time part of Austrian Lombardy. He received an irregular education and did not attend university. As a sometime pupil of the Jesuits, however, he developed a lifelong interest in natural philosophy, combining it with a commitment to Enlightenment culture and the notion of "useful knowledge," then fashionable among the educated classes and the public administrators of Lombardy. Having chosen the science of electricity and chemistry as his fields of expertise, at twenty-four he published a treatise "on the attractive force of the electric fire." At thirty he embarked on a career as a civil servant and a teacher in the recently reformed educational institutions of Lombardy. Appointed professor of experimental physics at the University of Pavia in 1778, he held the position until he retired in 1820. He traveled extensively, sharing his enthusiasm for natural philosophy with colleagues in Switzerland, the German states, Austria, Britain, the Low Countries, and France where in 1782 he met Benjamin Franklin.

Regarded in some circles as "the Newton of electricity," by the 1780s Volta had won a European fame as an "electrician," a chemist specializing in the chemistry of airs (especially "the inflammable air found in marshes," i.e., methane, his discovery), and the brilliant inventor of intriguing machines. Volta's machines prior to the battery included the electrophorus, or the "perpetual bearer of [static] electricity," a eudiometer, the electric pistol, the "condensatore" (a device that made weak electricity detectable), and a straw electrometer. Volta's contributions to the science of electricity included the notions of tension, capacity, and actuation (an ancestor of electrostatic induction). Thanks to painstaking measurements taken throughout his life, Volta managed to combine these notions into simple, quantitative laws that offered effective guidance through the intricacies of eighteenth-century investigations into electricity. In 1794, the Royal Society of London awarded Volta the Copley Medal for his work on Galvanism. In 1801, in the wake of his discovery of the battery, Napoleon publicly rewarded him. Volta died in 1827 in Como.

The Voltaic battery conceived and built toward the end of 1799 in Como, was the first device to produce a steady flow of electricity, or electric current. The instrument enabled other natural philosophers, notably Humphry Davy, to develop electrochemistry as a new branch of science, and still others, notably Hans Christian Oersted and Georg Simon Ohm, to explore electromagnetism. Because of these later developments—showing that chemical, electrical

Alessandro Volta. (Corbis Corporation)

cal and magnetic phenomena could be converted into each other—after the early 1840s the battery was a frequent topic for reflections on what was subsequently known as energy conversion, and energy conservation.

Volta saw the battery in a different light. He had conceived it as a demonstration device to show his contact theory of electricity at work. He had developed this theory to refute Galvani's notion of a special electricity intrinsic to animals. Volta claimed that the mere contact between different conductors (especially metals) was able "to set the electric fluid in motion." He also claimed that the electric fluid—one of the several, imponderable fluids then found in physics—was the same in organic and inorganic bodies. He built the battery after reading a paper by William Nicholson, who suggested imitating the electric organs of the torpedo fish by means of an apparatus combining many electrophoruses together. Having discarded his own electrophorus as unable to perform as Nicholson expected, Volta tried instead with pairs of discs of two different metals (like silver and zinc) that he knew could give weak signs of electricity. When he managed to pile up several such pairs, always in the same order and inserting a wet cardboard disc between each metallic pair, he found that an electric current was produced at the two ends of the pile, and that the power of the current increased with the number of pairs making the pile.

In the first circulated description of the battery—two letters addressed to the Royal Society of London on March 20 and April 1, 1800—Volta mentioned no chemical phenomena associated with the new apparatus. It was William Nicholson and Anthony Carlisle who, having had access to Volta's letters prior to publication, first observed the "decomposition of water" (electrolysis) while experimenting with the battery in London in May 1800. Nicholson, in particular, emphasized the chemical phenomena accompanying the operations of the battery. After that, a struggle between Volta's contact interpretation and the chemical interpretation of the battery developed; a struggle that Wilhelm Ostwald still regarded as unsettled in 1895. The struggle had obvious if complex implications for reflections on energy conversion and conservation; the more so because people like Nicholson already perceived the battery as the herald of a new family of machines, and wondered how the "intensity of action" of these machines could be measured.

Viewing things from the perspective of his physical theory of contact electricity, Volta was intrigued by the apparently endless power of the battery to keep the electric fluid in motion without the mechanical actions needed to operate the classical, friction, electrostatic machine, and the electrophorus. He called his battery alternately the "artificial electric organ," in homage to the torpedo fish that had supplied the idea, and the "electromotive apparatus," alluding to the "perpetual motion" (his words) of the electric fluid achieved by the machine. To explain that motion Volta relied, rather than on the concepts of energy available around 1800, on his own notion of electric tension. He occasionally defined tension as "the effort each point of an electrified body makes to get rid of its electricity"; but above all he confidently and consistently measured it with the electrometer.

WASTE HEAT RECOVERY

See: Cogeneration Technologies

WASTE-TO-ENERGY TECHNOLOGY

Solid waste disposal has been an issue since the dawn of humanity. In the earliest times, land filling, or, more simply, land application, was the most likely scenario for disposal, as anything unusable or nonessential for immediate survival was discarded and left by the trail as the hunter-gatherers moved to follow life-sustaining herd migrations. As humans became more "civilized" and established permanent residences and villages and obtained an existence through means of agriculture, trade, etc., the accumulation of wastes increased due to the localized populations and increased permanence of those societies. Waste disposal practices included both landfill and combustion, as anything of fuel value was most likely burned for heat or cooking purposes. In all likelihood, landfill accounted for a minimal fraction of the waste in those early times, until the advent of the industrial revolution opened the way for greater leisure time and the economy to create and consume greater quantities of nonessentials, which, in turn, created a greater flow of disposable waste from the thriving communities.

Solid waste disposal has always consisted of two methods, burning or discarding. Requirements of communal living conditions and a greater understanding of the health and sanitary implications of haphazard waste disposal created the need to concentrate solid wastes into a landfill and bury the material. Convenience and availability of seemingly unlimited space favored land filling as the universal means of waste disposal until midway through the twentieth century. As populations increased, however, capacities in existing landfills were rapidly used up and sites for new "garbage" dumps were being pushed farther and farther from the population centers, leading to increased hauling and operating costs for the newer facilities. Since the early 1990s, a new environmental regulations continue to increase both the complexity and the costs for new landfill facilities in the United States and the other more developed nations worldwide.

Where any pressures arose concerning the siting or operating costs of land filling, consideration has been immediate for the option of combustion of the same waste stream. The earliest systems were designed to incinerate the incoming waste. With no energy recovery capabilities and only basic wet scrubber gas cleanup technology, this practice reduced the quantity of waste ultimately routed to the landfill by seventy-five to eighty-five percent. These early incinerators were typically small, only fifty to one-hundred tons per day capacity, mass burn, starved air, multistaged incinerators. During operation, the waste would be introduced into the furnace onto the first of a series of ram-activated cascading grates. In this primary zone, the fresh fuel contacted some combustion air and a stream of recycled gases from the exhaust header. As the waste began to volatilize and burn, the ram feeders on the grate pushed the pile out on the grate where it fell to the next step. In the process, the material was stirred and agitated to present a fresh combustion surface to the air stream. Likewise, the material from this second step was ram-fed inward until it "cascaded" onto the next grate. This process continued until the remaining material, primarily unburnable material plus some uncombusted carbon, fell into the water-cooled ash trough and was removed from the furnace in an ash conveyor. The combustion and volatile gases driven off from the fuel pile were mixed with combustion air in the primary chamber directly above the grate. Further combustion and quench occured in the secondary and tertiary chambers where additional ambient air and recycled flue gases were mixed into the combustion exhaust stream. All of the gases from the tertiary chamber were conveyed into the wet scrubber where particulate was removed.

In the early 1970s, the surge in energy costs, spurred by the oil embargo, created a demand for energy recovery in these waste disposal facilities. At that time, while still in its infancy stage, waste-to-energy was poised to take one of two paths to implementation—mass burn (MB) or process fuel, typically called refuse derived fuel (RDF). Like the predecessors, mass-burn technology opted to burn the waste virtually as it is received, eliminating preprocessing of the material prior to burning. The mass-burn units are typically very large furnaces, most often field erected, wherein the waste is literally plucked from a receiving floor with a grappling hook and ram-fed into the furnace onto a cascading grate design. Following the success of other European designs beginning in the 1950s, these systems were typically of the waterwall furnace design, as opposed to a more "conventional" refractory furnace. One advantage of this was the direct removal of much of the furnace heat by the waterwalls, minimizing the need for significant volumes of excess combustion air or recycled flue gas to maintain acceptable operating temperatures in the furnace. These plants have also evolved into much larger capacity facilities. They were already field erected, so up-sizing the capacity did not represent any further economic disadvantage, and have been built to capacities as great as 2,500 tons per day.

Because the mass burn systems are designed to handle the fuel as it is received, implying the obvious variations in quality, sizing, and handling therein, the combustion systems must be extremely robust and conservative in design with regard to the quality of fuel being introduced. In addition, the ash removal system must be capable of handling the size and capacity of material coming out the furnace as is fed into the furnace on the front end. While this universal acceptability has proven to be one of the most important features of the mass burn success, it has also created two major liabilities in the performance of the furnace. First, extreme variations within the fuel pile on the grate can creat significant temperature variations across the grate which, in turn, can cause high temperature damage to the equipment or generate greater emission from products of incomplete combustion. Second, unpredictable fuel composition can create surges in ash quantities, resulting in slagging and fouling of the boiler surfaces and increased emission levels of unburned hydrocarbons, acid gases, and dioxins/furans in the outlet gases. In spite of these drawbacks, the mass burn technology has captured a majority of the waste-to-energy market in the United States in the last three decades of the twentieth century. Part of that success came as a direct result of the early failures of RDF in the industry.

Simplified in process terms, RDF involves processing the incoming municipal solid waste (MSW) stream to remove a substantial portion of the non-combustible components, namely aluminum, ferrous, glass and dirt. Various sources list these components in the range as follows:

Aluminum	2%
Ferrous	6-11%
Glass	11-12%
Dirt/ grit	2-20%

A review of this composition would indicate the noncombustibles in the raw MSW range from twenty to forty percent. By removing as much of these fractions as possible from the fuel stream, the quality of fuel presented to the combustor is improved as well as the contaminants from the combustor being reduced.

Unfortunately for the RDF industry, the first attempts at implementing an RDF processing system met with disappointment and failure. With no European technology to draw from, RDF processing evolved from experience and inspiration gained from the U.S. applications. In the earliest processes, the design called for all of the incoming waste to be shred-

The Bridgeport RESCO power plant mixes garbage to facilitate the drying process, which improves the efficiency of energy generation by incineration. (Corbis Corporation)

ded as it entered the process. Conceptually, this was a good idea, providing a means to get all of the material sized to a maximum particle size, thereby enabling further separation based upon particle sizing and density; however, the actual results were less favorable. First, shredding all material as it was introduced into the process included numerous explosive items such as propane bottles, gas cans, etc. The damage caused to the equipment in these early processes was significant but the loss of life and limb from some of the early accidents was even more devastating. Aside from the catastrophic failures due to explosions, this initial shredding also contaminated the waste mixture and made further separation difficult. Shards of glass and shredded metal became imbedded in the paper or biomass fraction of the material in the shredder and were carried through the process in that fraction, thereby reducing the removal efficiencies of those noncombustible fractions. Although many of the earliest RDF processes are still in operation, numerous modifications have been made to improve their performance.

With such a rocky beginning, the RDF option soon fell out of favor and yielded the market to the mass burn technology. The complexity, added costs of material handling, and the poor operating history of the RDF processes proved to be sufficient negative factors for any significant consideration of RDF fired waste-to-energy facilities for the next ten to fifteen years. That situation did not turn around until the push toward more waste recycling activities in the late 1980s and early 1990s. With that new impetus, plus many years of experience in operating RDF processing systems, the new generation of automated waste processing plants gained favor from a political/social base as well as from a more proven technical design basis. In numerous instances, RDF systems were promoted strictly to comply with mandated recycling directives. These material recovery facilities, or MRFs, accomplished essentially the same function as the earlier RDF processes in separating combustible from noncombustible materials, but were now done in the name of "recycling" with the recovery of ferrous and aluminum metals, glass, newsprint and corrugated paper, and plastics being the primary objective. Although oftentimes reduced yields of RDF were achieved because of the higher removal of recyclable materials, the quality of the fuel stream was strongly enhanced by this approach. With a national mandate in the United States on recycling, the cost and need for preprocessing of the waste became a burden to be borne by all new waste management plans. The advantages of mass burn technology had just been eliminated via the legislated mandate for higher recycling.

With more proven methods for RDF processing being demonstrated, the increase in RDF combustion technology has followed. Some of the facilities burning RDF utilize similar grate and furnace technology as the mass burn, but others, most notably fluidized bed or circulating fluidized bed combustion, offer a new and enhanced means of combusting the waste. Fluidized bed technology refers to the concept of burning a fuel in a combustion zone comprised of small particles of sand suspended in a stream of upward flowing air. The air velocity provides a buoyancy force to lift and suspend the individual sand particles such that they are able to float throughout the mixture and move freely within the furnace. The sand bed displays the characteristics of a pot of boiling water, hence the term, fluid bed. In a circulating fluid bed, the air velocities are actually increased to the terminal velocity of the sand particle, thereby carrying the sand up and out of the furnace. The sand is mechanically separated from the air/gas stream at the outlet of the furnace, and the sand is recirculated back into the furnace at the bottom of the bed. Hence, the term circulating, or recirculated, fluid bed.

The advantages of fluid bed combustion over the more traditional technology arise from the increased turbulence provided by the bed particle action. This fluidization increases the interaction of the fuel particles with the combustion air and creates a very accelerated combustion environment for the incoming fuel. Additionally, the sand, initially heated to an ignition temperature for the incoming fuel, provides a means of heating and drying the new fuel introduced into the furnace and igniting that fuel as it heats up. The thermal stability provided by the hot sand in the bed plus the turbulence of the fluidization causes the fuel particles to be consumed in a very short period, typically a few minutes or less. Complete combustion is achieved by the uniform temperature zone within the furnace plus the enhanced intermixing of fuel and combustion air. Historically, fluidized bed combustion systems have been able to achieve better operating flexibility, lower emission levels, and improved combustion and boiler efficiencies.

All methods of combustion of the waste pose certain "problems." The fuel, or waste, stream is nonhomogeneous, so the likelihood of variances in operation and performance are typical. With mass burn systems, the inventory of fuel within the furnace is maintained fairly high, for up to thirty minutes, and the "management" of the fuel feeding system is responsible for selecting a feed blend that maintains some measure of constancy throughout the process. With RDF systems, the processing of the fuel and sizing/ shredding has enhanced the fuel homogeneity significantly, but variations in quality, content, etc., can still be expected. The fuel is known to contain measurable levels of sulfur, chlorine and other contaminants that can generate acid gases in the combustion products. These acids can, and do, attack the boiler surfaces and other equipment in the gas train, causing corrosion and necessitating continuous maintenance. Most boilers establish steam conditions of 650 psi and 750°F (398.9°C) as the maximum design condition in order to minimize the corrosion losses in the boiler. Recent improvements in metallurgy and furnace designs have enabled these design limits to be pushed to 850 psi and 825°F (440.6°C) or higher.

As a fuel, municipal solid waste (MSW) does not compare too favorably with more traditional solid fuels, such as coal. MSW averages somewhere around 4500 Btu/lb, versus coal at 10,500–13,000 Btu/lb. However, given the current U.S. population of 250 million and the annual generation of waste per person of fifteen hundred pounds, the potential energy content in the annual waste generated in the U.S. alone is comparable to nearly seventy million tons of coal and has the potential to generate over 13,000 MW of electrical power. As of a published report in 1993, 128 facilities were actually in operation, with an additional forty-two planned or under construction. Of the existing plants, ninety-two produced electricity to some degree. The remaining thirty-six produced only steam or hot water. The number of plants in the various sizes range from twenty plants less than one-hundred tons per day to twenty plants greater than two-thousand tons per day. Roughly forty plants are in the capacity of one-hundred to five-hundred tons per day and about twenty-five plants are sized for each of the five-hundred to one-thousand tons per day and the one-thousand to two-thousand tons per day capacity. Most of the smaller plants were installed in the early period of waste to energy development. Most of the facilities installed in the last ten years represent sizes from five-hundred to one-thousand tons per day. As of 1993 the capacity of waste consumed in these facilities was approximately 103,000 tons per day, representing approximately 18 percent of the projected annual waste generation in the United States.

Although waste-to-energy probably will never supply more than one percent of U.S. electricity (U.S. electricity generation in 1997 was 3,533 billion kilowatts), it is still a very useful renewable energy source. A state-of-the-art RDF cogeneration plant (hot water and electricity) burns much cleaner than the majority of existing coal-fired plants. At the same time, it is an attractive option in communities that desire inexpensive electricity and predictable waste disposal costs ten to fifteen years into the future, and that lack the real estate for additional landfill space. The major obstacle facing new waste-to-energy facilities is the considerable resistance contingency of the community who voice the "not-in-my-backyard" objection to the smell, noise and emissions. New facilities are likely to be located in rural areas, or as supplemental energy suppliers for industrial complexes, or on or near existing landfill operations.

The potential economic benefit exists for many regions to elect to become "host" facilities for disposal of wastes shipped in from greater metropolitan areas, such as New York City, which is closing its Freshkill landfill and already ships thousands of tons to Ohio, Georgia, and elsewhere for disposal, mostly in landfills. As the cost for energy (oil and natural gas) increases, the energy value of the waste will escalate. Its value as an alternate fuel will compensate for some of the underdesirable attributes and create a greater demand for future waste-to-energy facilities.

WATER HEATING

Heating water consumes over 3.5 quadrillion Btus per year of primary energy which makes it the third largest energy end use for the residential and commercial sector in the United States, after space conditioning and lighting. Although indoor domestic hot water is nearly universal in the United States, this is a relatively recent historical development.

One of the earliest recorded uses of heated water was the Roman public baths. Starting in the first century C.E., many Roman cities had public baths with pools of cold, warm and hot water. The water was heated with wood or charcoal, although some of the baths incorporated passive solar features for space heating.

Prior to World War II, only about half of households in the United States had complete indoor plumbing facilities, including hot and cold water. Before indoor plumbing became widespread, water was heated on stoves in pots and pans, a difficult process that meant a lot less hot water was used.

The first water heaters used heat from a wood or coal stove to heat water in an uninsulated storage tank. Eventually, separate heating sources were

Water Heater	Installed Cost	Energy Factor	Annual Energy Cost	Life/ Reliabilty	Market Share 1995	Best Application

Summary of Typical Water Heater Costs and Efficiencies

added. Either coal or wood heaters provided by a side-arm coil outside the tank. The hot water moved into the tank by convection.

The first instantaneous water heaters which started appearing in the 1890s when gas or liquid fuels started becoming available, were un-pressurized. The first models had no automatic controls and very limited safety features. Some early models were more efficient than standard modern gas-fired water heaters.

Early in the twentieth century over 150 different manufacturers were making storage tank, instantaneous, and solar water heaters. Then as indoor plumbing became more common and as people started using showers more and baths less, storage type water heaters became more popular. Accurate hot water temperatures were not possible in early instantaneous water heaters. This was not much of a problem with baths where the water temperature is adjusted before getting in the water, but it is a much bigger concern when using showers.

Solar water heating became commercially available in Southern California in the 1890s. Early models consisted of four large cylindrical tanks of heavy galvanized iron mounted horizontally in a wooden box under a glass cover.

In 1909 one company began selling solar water heaters with separate collectors and insulated storage tanks. The collectors were made of copper tubing soldered to a copper plate in a glass covered box. The hot water was transferred to the storage tank by thermosyphon action, so the insulated tank had to be installed above the collector, typically in the attic or on the roof. It was often connected to an auxiliary heater on the stove or furnace to supplement solar heat. Well insulated storage tanks meant hot water was available the next morning.

Solar water heating declined in Southern California in the 1920s due to the development of natural gas, but it continued in Florida where natural gas was very expensive. In 1941 more than half Miami's population had solar water heaters, and more than 80 percent of new homes built then were equipped with solar water heaters. By the end of the 1950s in Florida, solar water heating was displaced by electricity as the price dropped and the storage tanks of solar water heaters failed because of galvanic corrosion from connecting steel tanks to copper collectors.

Corrosion of the tank is the major factor limiting water heater lifetimes. The A. O. Smith company invented the glass-lined tank in 1939, where an enamel coating is baked onto the inside surface of the tank at high temperatures. The technology has subsequently been adopted by other manufacturers, although other linings are used such as cement or plastic.

Total sales of water heaters have climbed steadily over the past several decades with sharp increases corresponding to times of high home construction rates.

In response to the oil crisis in 1970s, and temporary curtailment of new gas connections, the percent of sales of electric water heaters grew to almost match gas-fired water heater sales. Since 1987, however, the percent of water heaters sales that are gas-fired has exceeded electric water heater sales by 5 to 10 percent.

Tax credits were provided for solar water heating systems in response to the energy crisis. After tax credits expired, the solar water heater business declined drastically. The only segment of solar water heater market that has continued to have growth is the pool heater.

Outside of the United States and Canada, storage water heaters are common in Australia, Southern Africa, Latin America, and Britain. Instantaneous water heaters are much more common particularly in Asia and Europe. In countries that were once part of the British Empire, unpressurized storage tanks that relied on gravity were common, however most have changed over to pressurized storage tanks.

STANDARD STORAGE TANK WATER HEATER CONSTRUCTION

A typical storage water heater consists of a steel tank that is lined with ceramic coating fused to the inside of the tank at high temperature during manufacturing. The tank is typically about sixteen inches in diameter and about four to five feet tall. The top of the tank is domed upward and the bottom of the tank is also domed upward in a concave manner. The outside of the tank is insulated with a polyurethane foam insulation that is squirted into the gap between the tank and a thinner sheet metal jacket. The polyurethane is made of two different components that react and harden when mixed. Included in the mixture is a blowing agent that causes the polyurethane to expand in a foam-like manner. Prior to about 1980, water heaters were insulated with fiberglass insulation. The foam insulation process was developed to allow automation and increased manufacturing speed and reduced costs. A side benefit was improved insulating ability leading to a slight increase in efficiency.

In response to concerns about ozone depletion, the original blowing agent, CFC-22 was phased out. In 1994 and 1995 the manufacturers switched to HCFC-141b, a substance with lower ozone depletion potential. HCFC-141b is much more difficult to use, and manufacturers had some difficulty learning to use the new blowing agent effectively. New formulations of polyurethane and much tighter tolerances on the manufacturing processes, such as temperatures and pressures, were required.

Electric water heaters typically use two 4,500 watt heating elements. One element is located in the lower part of the tank and provides the bulk of the energy. The other element is located near the top of the tank and is used to quickly heat a small amount of hot water after a large draw empties the tank of hot water. The elements are each controlled by separate thermostats and are interlocked so only one can come on at a time. The thermostats on electric water heaters are snap type devices that are installed directly on the outside of the tank, but inside the jacket. They are located a few inches above the element which they control.

Gas-fired water heaters use the same general method of construction, except that the elements are replaced with a burner beneath the tank. The combustion products from the burner are vented through a flue made out of the same thickness steel as the tank, that goes up through the center of the tank. To increase heat transfer from the hot flue gases to the inner wall of the flue, a baffle is inserted down the flue. This baffle is a twisted strip of sheet metal with folds and tabs on it. The folds and tabs are designed to increase the turbulence of the hot combustion products as they pass through the tank. The burner is normally a circular burner made out of sheet metal or occasionally cast iron. Nearly all gas-fired water heaters use a standing pilot for ignition purposes. The pilot is a safety pilot: If it goes out, the small amount of electricity generated by a thermocouple in the pilot flame will no longer hold open an solenoid valve, and gas to the main burner will be turned off. The thermostat on a gas-fired water heater is an iron rod within a copper tube that is inserted into the water near the bottom of the tank. As the copper tube is heated it expands and allows a click disc to close a gas valve and shut off the flow of gas to the burner. The pilot continues to burn even when the burner is not needed.

In the North American market, water heaters are almost always made with the cold water inlet and hot water outlet lines coming out of the top of the tank. The hot water outlet opens right into the top of the tank and so draws off the hottest water. The hot water has risen to the top of the tank because of its lower density. The cold water on the inlet side is directed to the bottom of the tank by a plastic dip-tube. In some models the dip-tube is curved or bent at the end to increase the turbulence at the bottom of the tank. This is to keep any sediment from settling on the bottom of the tank. As sediment— usually calcium carbonate or lime—precipitated out of the water by the increased temperature builds up, it will increase the thermal stress on the bottom of a gas-fired water heater and increase the likelihood of tank failure. On electric water heaters the sediment builds up on the surface of the elements, especially if the elements are high-density elements. Low-density elements spread the same amount of power over a larger surface of the element so the temperatures are not as high and lime doesn't build up as quickly. If the lower elements get completely buried in the sediment, the element will likely overheat and burn out.

Another required safety feature on water heaters is a temperature and pressure relief valve. This is mounted near or on top of the tank. The temperature and pressure valves are designed to vent water if the temperature or pressure in the tank becomes too high. If there is no relief valve and the controls fail to limit water temperature, there is a danger of a powerful explosion from superheated, pressurized water flashing to steam as the water heater bursts.

All glass-lined steel tanks have at least one anode. This is a long metal rod made of magnesium, aluminum or zinc, metals that are more reactive than steel. The glass lining is never perfect, and any pinholes or defects around welds would allow water to touch steel. The anode protects the steel in the tank from corrosion by "sacrificing" itself and corroding first. This prolongs the life of the tank and protects against galvanic corrosion when two dissimilar metals are in contact in water.

Storage type water heater tanks also have a drain valve at the bottom so the tank can be drained for maintenance, or in case it ever needs to be removed. These drain valves are often plastic, although higher quality models use a brass drain valve.

EFFICIENCY STANDARDS

Under the National Appliance Energy Conservation Act of 1987, residential water heaters in the United States are required to meet a minimum energy efficiency. This is measured as energy factor. The minimum allowed energy factor depends on the fuel type and decreases with increasing rated volume. The minimum energy factor for fifty gallon electric water heaters is 0.86, for forty gallon gas-fired water heaters it is 0.54.

Average efficiency of new gas-fired water heaters has increased from an estimated 47 percent in the mid-1970s to about 56 percent in 1999. Over the same period the efficiency of electric water heaters has risen from about 75 percent to 86 percent. Revised efficiency standards were expected to be adopted during 2000.

Energy factor is a measure of average service efficiency at a specified condition and hot water draw pattern. It includes the effects of both standby losses and recovery efficiency of the water heater. Currently, water heaters are shipped from the manufacturers with thermostats set at 120°F (48.9°C) to reduce the risk of scalding. This is a drop from values of 140°F (60°C) that were reported from the early 1970s.

Efficient models of water heaters have thicker insulation, up to three inches thick, on some of the most efficient electric water heaters. Another means to increase efficiency is installing heat traps, or anti–convection devices, on the inlet and outlet pipes. Standard heat traps consist of short pipe nipple containing a small plastic ball. On the inlet side the ball is lighter than water and floats up to seal the inlet pipe. On the outlet side the ball is heavier than water and sinks against the seal. This prevents the heated water, which is slightly buoyant, from setting up convection loops within the pipes.

Gas-fired water heaters are also made more efficient by a variety of designs that increase the recovery efficiency. These can be better flue baffles; multiple, smaller-diameter flues; submerged combustion chambers; and improved combustion chamber geometry. All of these methods increase the heat transfer from the flame and flue gases to the water in the tank. Because natural draft systems rely on the buoyancy of combustion products, there is a limit to the recovery efficiency. If too much heat is removed from the flue gases, the water heater won't vent properly. Another problem, if the flue gases are too cool, is that the water vapor in the combustion products will condense in the venting system. This will lead to corrosion in the chimney and possible safety problems.

One design that is used for installation convenience, but can also allow higher efficiency, is an induced draft fan that pulls in extra air to cool the flue products to temperatures that can be safely vented through plastic pipe. Because of the fan, long horizontal venting runs are possible with this system.

Flue dampers that block the flue when the burner is not firing increase the efficiency of gas-fired water heaters. These can operate electrically or thermally. Because gas-fired water heaters lose so much heat up the flue during standby periods, this can provide significant savings. These are readily available on larger water heaters used in commercial settings but haven't been applied in the residential market because of their cost.

The most effecient gas-fired water heaters are condensing models. These are designed to be so efficient that the water vapor in the combustion gases condenses out and must be drained off. The recovery efficiencies of these models can be as high as 94 percent. As of 1999, four of the major manufacturers offered condensing water heaters in the small commercial sizes (over 100 kBtu/hr rated input). To reach this efficiency level, most used a pre-mix power burner with a central flue that starts up the center of the tank, but instead of going out the top as in standard water heaters, the flue (or flues) turn and spiral down inside the tank and exit out the side at the bottom. Because of the corrosive nature of the condensate, the flues are specially protected, either by glass coating on the gas side as well as the water side or by being made out of stainless steel alloys. These models can cost as much as $1,000 to $1,500 more than standard water heaters. The best applications are where heavy hot water loads can justify the extra cost.

On standard electric resistance water heaters, not much can be done to improve efficiency other than adding more insulation and heat traps. Heat pump water heaters extract heat from air and add it to the water in the tank. Energy factors as high as 2.60 have been achieved, meaning about two-thirds less electricity is used compared to a typical electric resistance water heater. This technology is mature in space heating and household refrigerator applications (where heat is pumped out of the refrigerator into the surrounding room); however, despite several attempts by different manufacturers, heat pump water heaters have never gotten established in the market. The main problem seems to be much higher equipment costs than simple electric resistance water heaters and a poor reliability record on the part of some models.

A small fraction of homes use the same appliance to provide both space heating and water heating. This has been done for over a century with tankless coils in cast-iron boilers. Water heating can be provided by modern boilers supplying heat to an indirect water heater that uses the water from the hydronic system to heat water for domestic uses in a storage tank. Since the early 1980s a technology has been developed that uses hot water from the water heater to heat a forced air system via fan coils. Ground-source heat pumps that provide space conditioning while extracting or storing heat from the ground are often also equipped with the capability to provide water heating.

Perhaps the ultimate combined appliances, which are currently under development, will be microturbines or fuel cell power generators used as small-scale co-generation systems. These would supply not only electricity, but space and water heating as well.

WATT

See: Units of Energy

WATT, JAMES (1736–1819)

Born fourth of five children to a merchant family in coastal Greenock, Scotland, on January 19, 1736, Watt was an ingenious modelmaker as a youth, being exposed to all the ship chandler's tackle and instruments, and was fascinated with natural philosophy, as science was called. His grandfather Watt was a very successful professor of mathematics in this remote locale. His mother's death when he was seventeen set his determination to pursue instrument making.

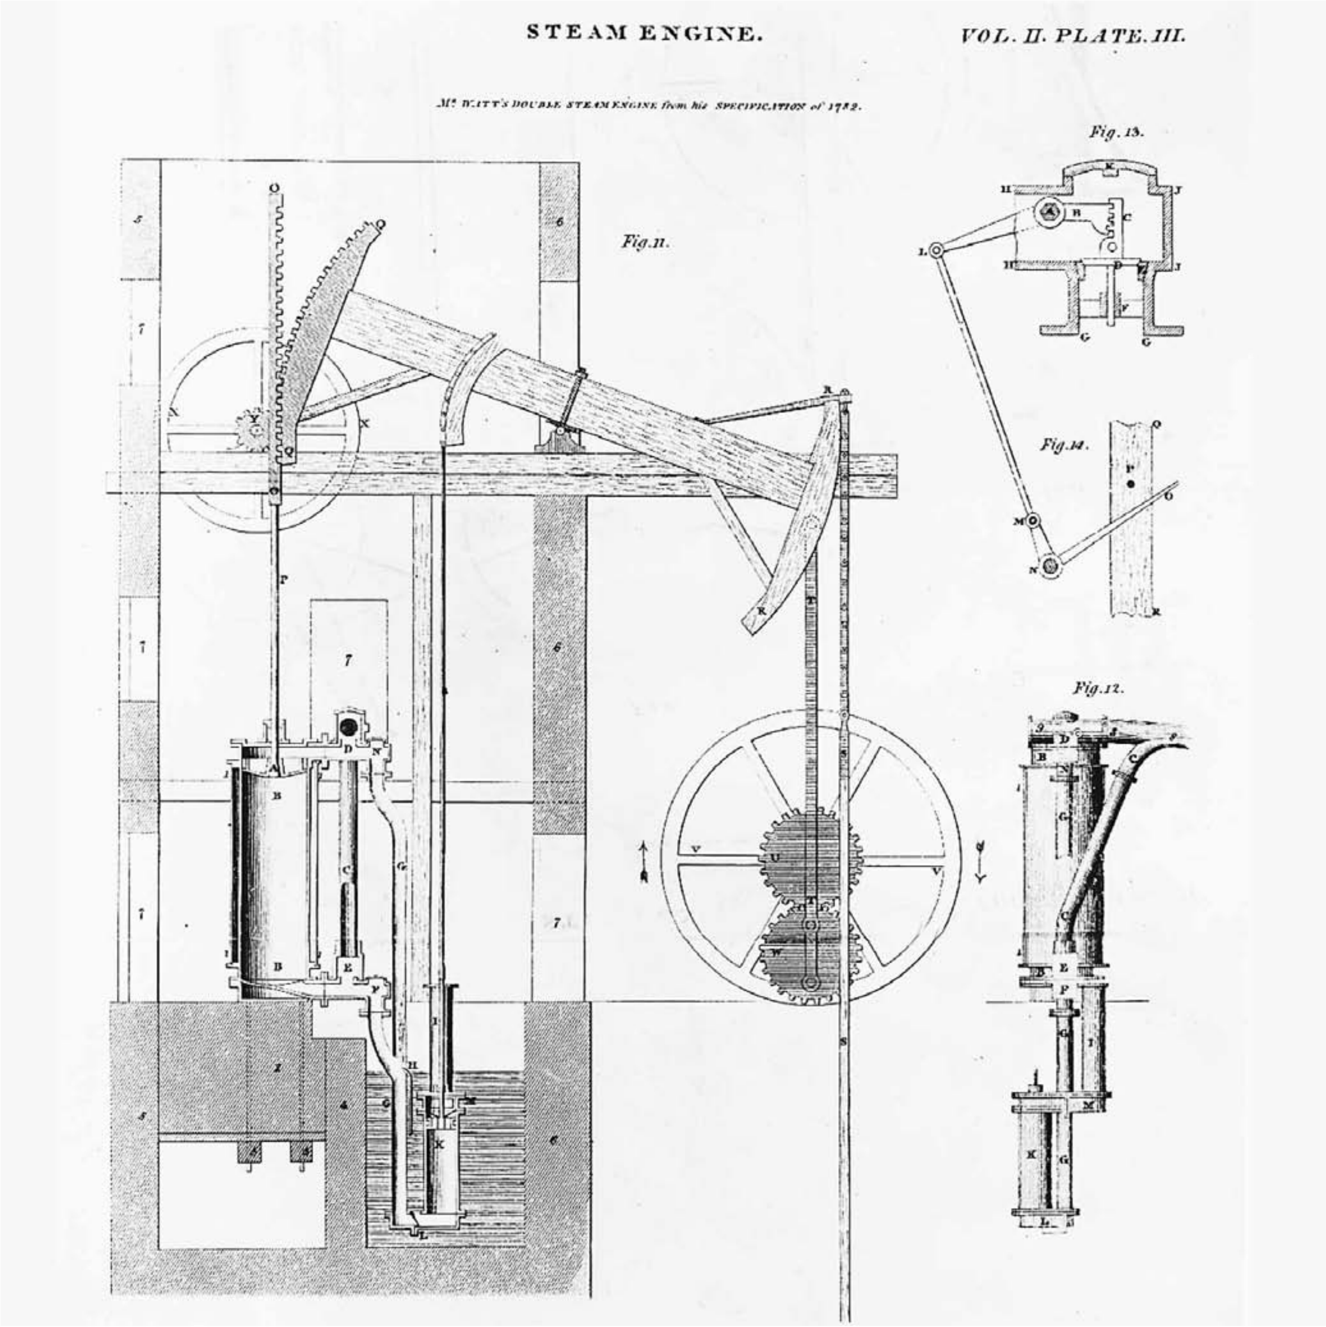
After nine years of some difficulty but considerable learning opportunity in London and at the University of Glasgow, while he was repairing a poorly built Newcomen engine for the university, he had the flash of inventive intuition that a separate condenser would greatly improve its efficiency. For this patented improvement, and its eventual technical and economic success, he is popularly credited with the invention of the steam engine. In 1765, while at the University of Glasgow, he married his cousin Margaret Miller.

At the age of thirty-three, Watt wrote, "Of all things in life, there is nothing more foolish than inventing." Just widowed with six children, he had put away his love of science, engineering and fine technical instrumentation to feed his family by contracting to survey for the Caledonian canal. Bankruptcy of his financial partner in steam development, John Roebuck, had derailed his efforts to improve the steam engine.

For some years previous, the successful Birmingham manufacturer Matthew Boulton had enjoyed an increasing correspondence in natural philosophy with such notables as Benjamin Franklin, Erasmus Darwin and Watt's partner, Roebuck, regarding practical uses of fuel and steam. Boulton's discussions with Watt in 1768 led him to discontinue his own developments, since Watt was clearly ahead technically and had obtained basic patents. With the bankruptcy of Roebuck, Boulton bought out Roebuck's interest, and Boulton's investment continued to fund Watt's demonstrations and developments. By then however, Watt's patent had nearly expired. With the leverage of Boulton's contacts in London, a Bill of Parliament extended the patent 24 years until 1800. The success of Watt's engine applications in the next few years brought Boulton and Watt together as partners, Boulton having two-thirds interest and managing the business, and Watt having one-third interest and managing the engineering and erection of engines.

While traveling on business, Watt met a Miss MacGregor who was connected with the University of Glasgow, and they married in 1776. Their two children did not live into adulthood.

The business acumen of Boulton provided profound industrial leverage to the technical creativity of Watt. The success of the steam engine for the rest of



Plan of a low-pressure steam engine designed by James Watt. (Library of Congress)

the century was substantially controlled by this partnership. The partners initially obtained annual royalties based on the horsepower of their engines, then set the royalty at one-third the cost of fuel saved by the use of their engines over the Newcomen engine.

The engines were initially used in pumping and winding in the mines, then were extended to iron-rolling, spinning and weaving mills, and virtually any factory use of rotative power.

Retiring from their business just as the patents began to expire in 1800, the firm of Boulton & Watt was turned over to the junior Boulton and Watt as its industrial preeminence slipped away and royalties dwindled. Watt's friends and family aged and passed, and he settled into twilight development of three-dimensional replicating equipment for sculpture. His workshop from his home at Heathfield Hall, near Birmingham, is preserved at the Science Museum in South Kensington. The most famous engineer of his time, Watt died at home on August 19, 1819 at 82, and was buried alongside his partner Boulton in his country churchyard. A monument was erected in his memory in Westminster Abbey. Contemporary eulogies and biographies show Watt as a fine person with a brilliant mind, little business sense, and a tendency toward melancholy. It is clear that he valued Boulton as a friend as much as a business partner.

James Watt recognized the steam engine to be a heat engine, not a pressure engine, demanding the conservation and complete use of heat energy. His long acquaintance with scientists at the University of Glasgow, and his study of new information on heat and energy, gave him the intellectual tools to make these great steps, which he backed up with technical analysis. While many of the principles in Watt's 1769 patent had been previously described academically or constructed in other mechanical examples, Watt combined these principles and patented them just at the time when they could be technically applied to advantage. Coincidently, the quality of heavy machine work necessary for their success was at last becoming practical on a commercial basis. Previously, fine machine work was confined to technical, medical and other instruments.

To paraphrase the claims of Watt's 1769 patent: Keep the engine cylinder hot; condense the steam separately and keep the condenser cold; air in the steam system is defective to performance and must be removed by pumping as necessary; use the expansive energy in high-pressure steam without using a condenser; re-use the steam by compressing and reheating to avoid loss of the latent heat of evaporation. Additional patent claims were the concept of a rotary expansive engine and using materials other than cold water to seal and lubricate the engine to avoid loss of heat energy.

To more fully exploit the key patent claim for the separate condenser, the firm avoided the use of high-pressure steam since it did not absolutely require a condenser. The patent claim for expansive use of steam without a condenser was used only as ammunition to restrict development in that field, although high-pressure steam replaced low-pressure steam during Watt's lifetime, and noncondensing systems became the norm for railway locomotives and steam road vehicles.

Many of Watt's further innovations for the steam engine added to its utility, remaining in use long after patent protection expired, while some were merely stopgaps to avoid using the patents of other inventors. These include the double-acting engine in which the piston is powered in both directions with the rod passing through a seal, a parallel motion using links to guide the piston rod through a relatively straight path (Watt linkage), and the sun-and-planet gear method of driving a rotary shaft from a connecting rod, avoiding another's patent for the crank.

Watt also applied the flyball governor to the steam engine and invented the steam engine indicator, which gives a graphical representation of cylinder pressure versus displacement. In other fields, Watt invented the copying press for hand-written letters, which was in universal use for over a century, and a cloth drying machine using copper cylinders internally heated by steam.

WAVES

Waves which are involved in many aspects of life, are disturbances that propagate through a medium with a definite speed. A wave of light conveys information to the eyes, a wave of sound brings music to the ears, a water wave rolling onto a beach can topple the swimmer, and electromagnetic waves cook food (microwave oven), and carry television reception. It takes energy to create the wave disturbance, and how the wave travels through the medium (elastic or damped) is quite variable.

There are two important categories of waves, mechanical and electromagnetic. Mechanical waves require a material medium. Water waves in a pond require water, sound waves in a room require air, a stadium "wave" must have people, and a wave produced by plucking a guitar string needs a string. Mechanical waves are produced when the medium is disturbed. A stone dropped in a pond disturbs the water, a spoken word results from a pressure disturbance, the guitar player disturbs the string by plucking it, and the sports fan disturbs the audience by standing up. The disturbance moves through the medium with a speed that is determined by the properties of the medium. In a stringed musical instrument, for example, the mass of the string and how tightly it is stretched determine the speed. That is why there are different size strings and a mechanism for tightening them.

A stone dropped in a pond pushes the water downward, which is countered by elastic forces in the water that tend to restore the water to its initial condition. The movement of the water is up and down, but the crest of the wave produced moves along the surface of the water. This type of wave is said to be transverse because the displacement of the water is perpendicular to the direction the wave moves. When the oscillations of the wave die out, there has been no net movement of water; the pond is just as it was before the stone was dropped. Yet the wave has energy associated with it. A person has only to get in the path of a water wave crashing onto a beach to know that energy is involved. The stadium wave is a transverse wave, as is a wave in a guitar string.

When air in a room is disturbed by a person speaking the molecules of the air have movements that are along the path of the wave. If you were to draw a line from the speaker's mouth to your ear, the movement of the molecules would be along this line. This type of wave, called an acoustical wave, is said to be longitudinal. The pleasant sounds of music are produced by acoustical waves. On the other hand, destruction by a bomb blast also is caused by acoustical waves. Instead of oscillating up and down, molecules in the acoustical (or compression) wave bunch together as the wave passes. It is not a transverse wave.

Imagine something floating in a pan of water with both the float and the water motionless (Figure 1A). If you were to continually bob the float up and down, you would see a continuous train of crests and troughs moving away from the float (Figure 1B). The separation of adjacent crests is called the wavelength, and given the lower case Greek lambda (λ) for a symbol. The time it takes one of the crests to travel a distance equal to the wavelength is called the period, and given the symbol T. The speed that the crest moves is just the distance traveled divided by the time so that $v = 1/T$. The period measured in seconds is just the time for one cycle of the oscillation. The reciprocal of the period is the number of cycles per second and is called the frequency, symbol f. The speed of the wave can also be written $v = f\lambda$.This simple relationship is a very important feature of all types of waves.

When waves encounter something in their path, they may bounce off (reflect) somewhat like a ball bouncing off a wall. A sound echo is produced by sound waves reflecting from something, a building, for example. We see our image in a mirror because of reflection of light. Reflection as well as other phenomena involving light led to the notion that light is a wave. It is decidedly different from a sound wave because there is no material medium required to sustain its motion. Light traveling to Earth from a distant star encounters virtually no matter until it reaches Earth's atmosphere. Modeling light as a wave has many virtues and uses.

Light is an example of electromagnetic waves. Electromagnetic waves propagate electric and magnetic fields. All electromagnetic waves travel with the same speed in a vacuum. This speed is given the symbol c and has a value 3.00×10^8 m/s (300,000,000 m/s). The general equation $v = f\lambda$ becomes $c = f\lambda$ for electromagnetic waves. Because c is the same for all electromagnetic waves in vacuum, $f\lambda$ is constant. Therefore, when the frequency of an electromagnetic wave increases, the wavelength must decrease. The range of wavelengths of electromagnetic waves is staggering: about 10^{-14} m (roughly the diameter of the nucleus of an atom) to about 1,000,000 m (approximately the distance from New York to Chicago). Because $f\lambda$ is constant, the frequency varies from a high of about 10^{22} Hz to a low of about 10^3 Hz.

Electromagnetic radiation is classified according to ranges of wavelength. Although the classifications are not precise, they are useful. For example, visible light to which our eyes are sensitive has wavelengths between about 4×10^{-7} m and 7×10^{-7} m. Microwaves have much longer wavelengths, about 0.001 m to 0.3 m.

Energy streams to Earth from the sun by electromagnetic waves. Photosynthesis depends on solar energy, and humans and animals rely on photosynthesis for food. In this sense, solar energy is not a luxury, it is essential.

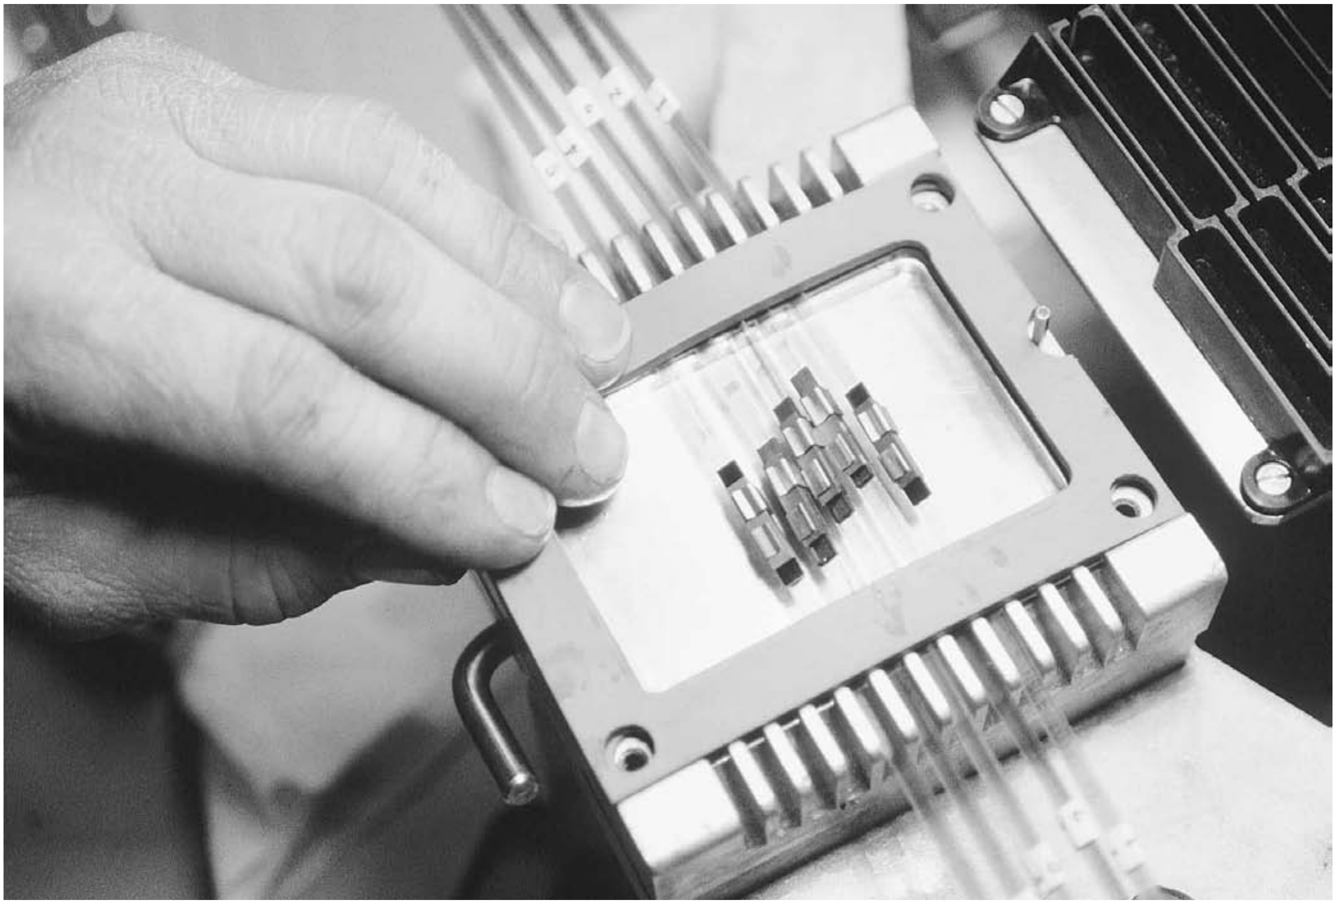
All objects, including the sun and incandescent light bulbs, emit electromagnetic radiation. The radiant energy and the type of radiation depend on the temperature. When an electric toaster is switched on, the heating element begins to glow and one can feel the radiant energy increase as the temperature increases. Visible radiation is produced by both the sun and a light bulb because the temperature of both is roughly 6,000 K. When the bulb cools to room temperature, about 300 K, the visible radiation disappears for all practical purposes. Nevertheless, the bulb at 300 K is still radiating, but the radiation is predominantly infrared that our eyes do not sense.

Radiation from the sun includes significant ultraviolet and infrared radiation in addition to visible radiation. Contributions of each type to the radiation that reaches Earth's surface are reduced significantly through absorption in Earth's atmosphere. The rate at which solar radiation falls on a square meter of Earth's solid surface is called the solar insolation. Solar insolation depends on the time of day, the day of the year, and where the square meter is located on Earth's surface. During an eight-hour period, the solar insolation in midwestern United States is roughly 600 W/m^2. If the 600 watts striking a 1 m^2 surface could be collected and converted to electricity, there would be enough electricity to operate six typical 100-watt light bulbs.

Solar energy can be used in many ways: heating buildings and houses, providing heat for producing steam for a turbogenerator in an electric power plant, producing electricity with photovoltaic cells, and so on. But since solar energy is not highly concentrated, it takes a considerable area of collection to even heat



Fiber optic cables, such as this one being spliced, allow for more information to be passed in smaller "packages." (Corbis Corporation)

a small home, which makes it uneconomical and impractical in many situations.

One of the most interesting and fascinating methods of electronic communication uses electromagnetic waves of light. The light is literally piped around in tiny bundles of transparent strings called optical fibers. Because the frequency of the light is thousands of times greater than the frequency of radio and television waves, a much higher concentration of information is permitted. The telephone industry makes great use of transmission of information via optical fibers. Using this technology allows information to be transmitted between North America and Europe via optical fiber cables strung beneath the surface of the Atlantic Ocean.

The back-and-forth motion of a child's swing is an example of an oscillating system, oscillator, for short. Set into motion, these systems oscillate at a frequency determined by properties of the oscillator. For example, the length of a child's swing and the acceleration due to gravity (g) determines the frequency of the back-and-forth motion of a child's swing. Periodically feeding energy into such a system at the same rate as the natural frequency gradually increases the energy of the oscillator. This is the phenomenon of resonance. Children achieve resonance with a swing by "pumping" at the resonant frequency of the swing. Molecules are microscopic oscillators that can be "pumped" by electromagnetic waves. If the frequencies match, the molecules absorb energy. Water molecules have a resonant frequency that falls in the microwave region of the electromagnetic spectrum. Water-based materials exposed to microwaves of the proper frequency absorb energy and heat up. This principle is exploited in a microwave cooker. When food on a plastic plate is placed in a microwave oven. the food warms because of its water content, and the plate does not warm because it is essentially devoid of water.

Ozone is a molecule formed from binding together three oxygen atoms. Gaseous ozone readily absorbs selected frequencies of ultraviolet radiation because ozone molecules have a resonant frequency in the ultraviolet region of the electromagnetic spectrum. A natural concentration of ozone exists twenty to thirty kilometers above Earth's surface. Ozone molecules absorb nearly all ultraviolet radiation from the sun having a wavelength less than about 0.3 micrometers. Accordingly, the natural ozone layer protects humans from harmful effects such as skin cancer. Human-made products migrating into the ozone layer can react with ozone molecules and convert them to other forms that do not absorb ultraviolet radiation. Chlorinated fluorocarbons, CFCs for short, once commonly used in refrigerators and aerosol spray cans, were found to be depleting the ozone, and in 1978 were banned from use in aerosol sprays. Banning the use of CFCs has not totally solved the ozone depletion problem.

Carbon dioxide is a molecule formed from binding together two oxygen atoms and one carbon atom. Gaseous carbon dioxide readily absorbs selected frequencies of infrared radiation because carbon dioxide molecules have a resonant frequency in the infrared region of the electromagnetic spectrum. Coal, natural gas, and oil all have carbon as a component, and carbon dioxide is produced when they are burned. It is a fact that the concentration of carbon dioxide in the atmosphere has been increasing since the Industrial Revolution. The carbon dioxide has little effect on solar radiation penetrating Earth's atmosphere. Earth absorbs the solar energy and, like any object, emits electromagnetic radiation. The temperature of Earth is more than 5,000 K lower than the sun, and Earth's radiation is mostly infrared. Carbon dioxide can absorb energy from the infrared radiation, resulting in a temperature increase of Earth. This is the so-called "greenhouse effect."

Coping with the greenhouse effect is a very difficult sociopolitical problem. A greenhouse effect existed on Earth long before the Industrial Revolution. Had it not, Earth's surface would be much colder than it is now. The introduction of gases absorbing infrared radiation only enhances the greenhouse effect. Carbon dioxide is not the only gas of importance; water vapor and methane, for example, are also of concern. The industrial world is dependent on coal, oil, and natural gas, so it is not easy to quit burning them to stop producing carbon dioxide.

The radiation one sees from a neon advertising sign or a laser is not produced by accelerated electric charges or by thermal effects. It comes from atoms or molecules that have absorbed energy and given this energy up as photons. A photon is a unit of electromagnetic energy having energy equal to Planck's constant (6.63×10^{-34} joule·seconds) times the frequency of the radiation ($E = hf$). The frequency of the radiation is determined by the magnitude of energy associated with atoms and molecules. Radiation from atoms and molecules is usually in the infrared, visible, and ultraviolet regions of the electromagnetic spectrum. Electromagnetic radiation also results from energy transitions in the nucleus of an atom. However, the nuclear energy scale is roughly a million times larger, making the frequency of the radiation correspondingly larger. This radiation is called gamma radiation.

All electromagnetic radiation has energy to some extent. Absorption of electromagnetic energy can be put to good use, as in photosynthesis or a microwave oven. On the other hand, electromagnetic energy can do damage. Skin cancer can result from absorption of ultraviolet radiation from the sun. This is why young and old are encouraged to stay out of the summer sun between the hours of 10 A.M. and 2 P.M. Gamma radiation is more energetic and more penetrating than ultraviolet, and the damage it can do is not confined to the surface of the skin. This is why some are concerned about the gamma radiation produced by radioactive nuclei in the spent fuel of a nuclear reactor. Ironically, gamma radiation is used to treat certain types of cancer.

WHEATSTONE, CHARLES (1802–1875)

Charles Wheatstone was born on February 6, 1802, at the Manor House, Barnwood, near Gloucester, England, and died in Paris, France, on October 19, 1875. His father, William, was in business as a shoe maker in Gloucester but he also taught music and several members of the family made musical instruments. On the death of an uncle, Charles and his older brother inherited the uncle's musical instrument manufacturing business in London. Although a competent businessman, he much preferred to give his attention to understanding the basic physics of music and musical instruments. He enjoyed the delicate work of designing and manufacturing musical instruments, and he devised new ones, in particular the highly successful concertina, patented in 1827.

Wheatstone's research into the physics of music addressed two practical questions. What is the difference between the sound vibrations of two notes having the same pitch but different timbre such as the same note played on a flute and a violin? How is sound transmitted through the bridge-piece from the string to the sound board of a violin or piano, and how far can sound be transmitted? These studies brought him into contact with Faraday, who gave several lectures at the Royal Institution in London about his discoveries. They also led to his appointment as Professor of Experimental Philosophy in the new King's College London in 1834.

Before 1831, the usual way of producing an electric current was by chemical means in the electric battery. Each cell of a battery had two different metals, or one metal and one carbon, separated by an acidic liquid. All electrical research in the first third of the nineteenth century made use of such batteries, and many combinations of materials were expired.

In 1831 Michael Faraday showed that an electromotive force is produced when a wire is moved through the lines of force of a magnet. If the wire is part of a complete circuit, a current flows. In the following years, several inventors made magneto-electric generators ("magnetos") in which coils of wire were rotated close to the poles of a fixed magnet, or a magnet was rotated close to a coil of wire. Most such machines were turned by hand and generated electricity without the consumption of expensive chemicals. They offered the prospect of larger machines driven by steam power that could generate electricity in large quantities.

A fundamental limit to the current that could be generated was imposed by the strength of the available permanent magnets. Some inventors sought to overcome this by using pairs of generators, the first being a magneto as just described, and the second being a similar machine except that electromagnets were used in place of the permanent magnets of the magneto. Current produced by the first machine was passed through the coils of the second, which then generated a larger current than could be produced by a magneto alone. Wheatstone was not primarily interested in producing large currents, but he used magnetos in some of his telegraphs.

In February 1837 Wheatstone was introduced to William Fothergill Cooke, an enthusiastic but unscientific inventor and entrepreneur who saw the commercial possibilities of a telegraph, but whose own instruments would not operate through long lengths of wire. The two went into partnership and established the first few working telegraphs in England. Their very first connected Paddington and West Drayton stations on the new Great Western Railway, using Wheatstone's five-needle system. The system also required five wires, which made it costly. Cooke preferred a telegraph with a single wire and a single needle, using a code such as Morse. Sadly, the partners quarrelled and parted. Cooke, with his Electric Telegraph Company, concentrated on the main commercial telegraph business. Wheatstone concentrated on instrument design and on user-friendly telegraphs for private use where letters were indicated directly on a dial, rather than being sent in code.

Wheatstone thought it might be possible to develop a communication system in which the vibrations of speech were transmitted many miles through solid rods or stretched wires, but he could not find a suitable material. Having become interested in the idea of communication at a distance, he took up the idea of the electric telegraph, and soon had an arrangement working in the College with which he could send signals through several miles of wire and deflect the needle of a galvanometer at the far end. He designed an arrangement in which any two of five galvanometer needles in a line could be deflected to point out a letter on a board.

The direct-reading instruments required a series of pulses to be transmitted along the line, each pulse causing the needle to advance one position. Some of Wheatstone's telegraphs used batteries and a switching system to produce the drive pulses, but magnetos naturally produced a series of pulses, and Wheatstone wanted a magneto-electric machine as his telegraph transmitter. In the course of this work he studied the action of the magneto and made some of the earliest measurements of the waveform of the current it produced. A machine that was not dependent on permanent magnets was undoubtedly an attraction for his purposes. He described his self-excited generator in a paper to the Royal Society on February 14, 1867. At that time there was widespread interest in the possibility of more powerful generators. Wheatstone's demonstration machine was driven by two large handles, possibly turned by two of his students. William Siemens described a similar machine at the same meeting. Siemens' title was "On the Conversion of Dynamical into Electrical Force without the aid of Permanent Magnets." Wheatstone approached the matter differently. His title was "On the Augmentation of the Power of a Magnet by the reaction thereon of Currents induced by the Magnet itself."

Wheatstone's self-excited generator was an important step in the development of the electric generator. Although it proved to be the last of Wheatstone's inventions in that field, the remainder of his life was devoted to further improvements in the telegraph.

WINDOWS

HISTORICAL BACKGROUND

In primitive homes, the only essential opening was a door for entry and exit. The first window was probably a hole to vent smoke from cooking and heating fires. That first opening offered the same advantages and disadvantages of windows that please and plague building occupants today: it allowed indoor pollutants to escape and daylight to enter; at the same time, it allowed heat to escape in cold weather and to enter in warm weather, creating discomfort for occupants.

Shutters were eventually added. When open, they permitted light and air to enter, along with undesirable visitors, such as intruders, rain, insects, and dust. Closed shutters provided darkness as well as protection. The next addition was translucent materials such as oiled paper or animal skin, framed into window openings.

Transparent glass was first used in Roman times, allowing daylight to enter unaccompanied by unwelcome elements, and giving building occupants a view of the outdoors. The largest surviving piece of Roman glass, three feet by four feet, came from a bath in Pompeii.

Venice became the world's glassmaking center in medieval times. Small, flat panes were produced by cutting and rolling flat hot, blown glass. This technique was used for the buildings constructed by early European settlers in America.

The next advancement in glassmaking was called sheet glass. In this method, a long sheet of glass was developed by dipping a long rod into molten glass and drawing it upward. The glass from this vertical process was then fire-polished.

During the 1600s, a plate glass casting method developed in France produced larger, higher-quality pieces of glass than previously possible. It was the first horizontal process, where glass was flattened through rollers, then ground to polish. The first uses of glass on a grand scale resulted, including the Hall of Mirrors at Versailles and the architectural feature still known as the French door.

Nineteenth-century innovations made larger, stronger, higher-quality pieces of glass more widely available. During the 1950s the float glass technique

Marble walls and crystal lamps flank windows that let light into the Hall of Mirrors in the Chateau de Versailles. (Corbis Corporation)

was developed, in which glass is produced floating on a tank of molten tin. This method produces extremely flat, uniform surfaces with few visual distortions. The desired thickness of glass can be achieved by varying the flow of molten glass from the tin bath. This process is still commonly used for residential windows in the United States.

Prior to 1965, single-pane (single-glazing) windows were standard in U.S. buildings. In cold weather, second panes of glass—storm windows—could be installed for added insulation.

WINDOWS FROM 1970 TO THE PRESENT

The energy crisis of 1973 drew attention to windows' impact on the heating and air conditioning of buildings. Windows were responsible for approximately 5 percent of total energy loss in the United States at the time, or the equivalent of all the energy provided by the Alaska pipeline. Research priorities, which had previously focused on sizing heating, ventilation, and air conditioning (HVAC) systems to meet the heating and cooling energy loads created by windows, turned to improving window energy efficiency. Double-glazed windows—two panes of glass sealed in a frame with air space in between—had been developed prior to the 1960s, but the seals on which their insulating value depended were not always reliable, and they were not widely used. As the quality of sealants improved, the market penetration of those double-pane products increased.

Window Energy Basics

To understand the energy efficiency of windows, it is necessary to define some solar, thermal, and optical properties. All heat transfer through a window is performed through conduction, convection, or radiation. Conduction is transfer of heat through solids by molecular interaction; an example of thermal heat transfer by conduction is heat being lost from a warm room, through the frame of a window. Convection is transfer of heat by fluid—in this case, air—that moves as a result of temperature differences; convection currents involving room air that comes in contact with cold glass are commonly called drafts. Drafts also can be caused by infiltration, described below. Radiation is the physical phenomenon of emitting heat; the Sun and all other objects radiate heat. Radiation can occur in winter when a fire radiates its heat to the objects and surfaces of a room to warm it. Radiation is also at work in the summer when the Sun's energy penetrates a window and heats up the room inside.

To measure the efficiency of a whole window, special testing takes into account all heat transfer from conduction, convection, and radiation. Certain values are used to represent the thermal and solar efficiency of high-performance windows by measuring reduced thermal heat loss (measured by the U-factor), solar heat loss and gain (measured by solar heat gain coefficient, or SHGC), and air infiltration (measured by air leakage).

U-factor. This is the total heat-transfer coefficient of a window system (window plus frame). It represents the amount of heat that moves through the window glass and frame. U-factors are expressed in watts per square meter per degree of temperature difference (Centigrade) or BTUs per hour per square foot per degree of temperature difference (Fahrenheit). In climates with heating requirements, low U-factors are recommended. U-factor is generally expressed as a fraction between zero and one, but in cases of very inefficient products the number can be greater than one.

Solar heat gain coefficient (SHGC). This is a measure of how much of the Sun's energy that is transmitted through the window becomes heat. It includes both the heat that is transmitted through the window and the heat that is absorbed by the window and then reradiated into a room. SHGC is also expressed as a fraction between zero and one. The SHGC can be determined for any angle at which sunlight hits the glass, but the most commonly used reference is for "normal incidence" —sunlight striking the glass at a ninety-degree angle. In climates with cooling requirements, low SHGC numbers are recommended. Because low SHGC numbers also improve the thermal performance of a window (i.e., U-factor), they are also recommended in heating climates, depending on the architectural design of the building.

Visible transmittance (VT). This is a window system's transmittance across the visible portion of the solar spectrum; it is a measure of the visible light that comes through window glass without being reflected or absorbed. VT is expressed as a fraction between zero and one. It is desirable to preserve visible transmittance—building occupants' access to daylight and views of the outdoors—while reducing U-factors, SHGC, and transmission of UV radiation. In all climates, a high VT is recommended.

Infiltration rate. This is the rate at which air moves through a window system as a result of pressure differences between the inside and the outside. Infiltration rates are expressed as airflow rates—cubic meters per hour or cubic feet per minute per square foot of window. An infiltration rate below 0.3 cfm/sq ft is recommended in all applications.

Technological Advances in Window Energy Efficiency

Reducing unwanted heat loss. Technological advances in window performance have come in the components of windows (glass, frames, spacers, sealants, warm edge design) and in the way those components fit together to make the whole window more efficient. A major goal in window energy efficiency starting in the late 1970s has been to design products with lower U-factors to achieve the benefits described above. Efforts to produce highly insulating window products in the 1970s and early 1980s focused on existing technologies: double-glazed windows led to triple- and quadruple-glazed windows, which lowered U-factors by increasing the number of still air spaces in the window system. Each layer reduced U-factors by approximately 1 hr-ft^2-F/Btu but also increased the window's weight and cost of fabrication as well as significantly lowering visible transmittance, which diminished the quality of the light and view.

In the mid-1970s it became clear that most of the heat transfer through a typical double-glazed window was through thermal radiation exchange from one layer of the window to another. Although glass blocks direct transmittance of long-wave infrared radiation in sunlight, it absorbs the radiation and reemits it at a high rate. To solve this problem, the first transparent, optically clear, low-emissivity (low-e) coating was developed in 1983 to reduce radiative heat transfer without compromising visible transmittance.

Radiant heat transfer had historically been the biggest heat transfer mechanism for windows. Low-e materials were developed and have historically been used to control for heat transfer. An example of the popularity of using metals to reflect heat to control for radiant heat transfer is the thermos bottle. Applying that new technology to windows, and getting materials that normally would affect transparency of the product to remain visually neutral, was a huge advance to the industry.

Low-e coatings are microscopically thin, virtually invisible metal or metallic oxide layers deposited on a window or glazing surface. Low-e coatings are virtually transparent to visible light. At the time of its invention, technology had not been developed to apply this product, a thin polyester film with a silver-based coating, directly to large pieces of glass, so it was applied to a substrate that was then suspended

An estate of houses installed with solar panels and other energy-saving devices at Shenley Lodge in Milton Keynes, England. (Corbis Corporation)

between two glazing layers. This technique had the advantage of creating another insulating air space in the double-glazed window unit, cutting window heat loss rates by up to 50 percent, but it also increased manufacturing costs.

Two processes, referred to as sputtered and pyrolitic, were developed to produce large volumes of quality, low-e coated glass. Pyrolitic coatings are incorporated into float glass production and tend to be more durable. Sputtered systems use a stand-alone vacuum deposition process to produce coatings that are have lower emissivities but that are softer and need more protection than pyrolitic coatings.

Reducing heat transfer with gas fill. Conduction and convection cause heat transfer across the air spaces in multilayer windows. Although air is a relatively good insulator, other gases that have lower thermal conductivity can be sealed into the cavities between panes. These gases include argon, carbon dioxide, and krypton. Developments in sealants and quality control during the 1980s reduced gas leakage in some window units to less than 1 percent per year.

By the late 1980s, many manufacturers offered double-glazed units with low-e coatings and inexpensive gas fills such as argon. Even greater efficiency could be achieved with extra-low-conductivity gases such as krypton filling small gaps between panes. Three-layer units with two gas-filled gaps and low-e coatings to reduce radiative heat transfer were designed at Lawrence Berkeley National Laboratory (LBNL), a leader in U.S. energy-efficient windows research. Products using these concepts appeared on the market in 1991.

Reducing heat transfer through warm-edge design. As new efficient glass technologies emerged, the relative fraction of heat lost through window frames decreased. During the 1990s, existing metal-framed windows were increasingly replaced by lower-conductivity vinyl. Pultruded fiberglass also became an energy-efficient framing option. The high-conductivity aluminum spacers typically used to hold panes in place in multilayer windows were replaced with more energy-efficient materials: metal-reinforced butyl, stainless steel, thermally broken aluminum or steel, and silicone foam.

Reducing infiltration. Traditional "brute force" approaches to weather stripping were redesigned to reduce infiltration with less material that contacted a larger surface area. New materials such as thermoplastic elastomers offered additional potential to control for infiltration. But perhaps the most important way to control infiltration is proper installation.

Controlling unwanted solar heat gain. The first generation of low-e coatings, described above, was designed for colder climates, where controlling heat loss is important. The next generation, introduced during the 1980s, selectively blocked the UV and shortwave infrared or "heat" radiation parts of the solar spectrum while admitting as much daylight as possible. These new spectrally selective coatings were useful in warmer areas, where reducing solar heat gains in summer and interior heat loss in winter is important. Where building energy codes are restrictive about the percentage of glazing allowed or the total energy performance of the unit, use of low-solar gain coatings can permit architects to increase total window area compared to what would be allowed in a building design with less efficient glazing.

TODAY'S WINDOWS

Today, nearly 90 percent of all residential windows sold in the United States have two or more layers of glazing. Approximately one-third of all windows sold for residential buildings and 20 percent of windows sold for commercial buildings in 1996 had low-emissivity coatings and insulating frames appropriate for the local climate. Besides the energy savings, energy-efficient windows increase thermal comfort, increase daylight and view, decrease condensation, decrease utility bills, and offer protection from UV fading.

Consumers buy homes with windows for the aesthetics, daylighting, and improved view of windows, yet they don't want to sacrifice comfort, that condition of mind that expresses satisfaction with the environment. Energy efficient windows transfer less energy, so less indoor heat is lost in cold weather and less unwanted heat from the outside enters in warm weather. Heating and cooling energy costs are therefore reduced, and occupants are more comfortable because the window's surface temperature is closer to the ambient indoor temperature. Windows without energy-efficiency features have very warm surfaces in warm weather and cold surfaces in cold weather, so occupants near a window feel uncomfortable.

During the heating season, high performance windows create warmer interior glass surfaces, reducing frost and condensation. The development of low-conductance spacers to reduce heat transfer near the edge of insulated glazing, and improved seals have significantly reduced condensation under all conditions.

Fading is probably one of the least understood consequences of visible and ultraviolet (UV) light transmitted through windows. Fabrics fade at different rates; UV radiation can fade organic materials such as carpet, artwork, paints, and wood differently than it fades synthetic materials. Energy efficient windows that reduce transmission of the UV spectrum not blocked by ordinary glass can reduce the potential for fading damage. Although most fading damage occurs from UV, visible light also has the potential to cause some damage.

People prefer windows in buildings to add light, open up space, and create aesthetically pleasing environments in which to live and work. Windows are also used for natural ventilation in some climates. Energy efficient windows allow increased daylight to enter a building without compromising the comfort of a room by allowing in unwanted heat or cold, particularly infiltration that can create drafts. Several studies also suggest daylighting can increase productivity, health and welfare.

Homeowners can realize substantial reductions in energy bills by selecting energy efficient windows. It is possible to save up to 30 percent on the heating and cooling portion of one's utility bill by selecting high performance windows. Moreover, building owners can rely on smaller heating and cooling equipment to meet smaller loads, and power suppliers that can meet customer demand with less generating capacity.

Research has shown that if all new windows sold in warmer U.S. regions had low-solar gain coatings, cooling energy use could be reduced by 25 percent in 2010; if residential windows in all parts of the United States had these coatings, heating energy use would

Buildings in downtown Detroit with sunlight reflecting off the myriad windowpanes. (Field Mark Publications)

decline by 19 percent. The total projected energy savings would be $1.2 billion per year. However, the market share for windows purchased with low-e coatings in the late 1990s is less than 20 percent in the southern United States, compared to 50 percent or more in the coldest states.

Choosing Efficient Windows

Window recommendations for a particular installation depend on local climate variations and the intent of the occupant and designer. If reducing energy costs is the primary goal, local utility rates must be taken into account along with which space-conditioning loads (heating or cooling) dominate. If comfort is the primary goal, occupant preferences must be addressed along with local site characteristics such as nearby shade trees that may help keep the building cool.

To achieve maximum energy performance, an energy-efficient window's characteristics must compensate for local climate conditions. In residential buildings in cold climates, the majority of building conditioning energy goes to heating, so efficient windows must keep heat indoors. In some cases, the solar gains that enter through a window may exceed the energy lost through the window, capturing passive solar gains and retaining captured heat. By contrast, solar heat gain is a liability in a residential building in a warm climate where cooling accounts for the majority of space conditioning energy use. Passive solar design in cooling climates necessarily employs different strategies: maximizing shading, using light roof colors and, in some cases, allowing natural ventilation.

Commercial buildings, such as offices with large windows, present a different challenge from residences. In almost all climates, commercial buildings suffer from excess solar heat gains, which produce large cooling loads. These buildings are best served by windows that filter out unnecessary solar radiation (and complementary technologies that redirect daylight to spaces away from windows to offset electrical lighting needs, see below).

A number of efforts assist U.S. consumers and homeowners in choosing windows. The National Fenestration Rating Council (NFRC), a non-profit organization created in 1989 by members of the window industry, code officials, energy officials, utilities and architects to devise a technically sound, impartial way to compare windows, has established a rating, labeling, and certification system. All NFRC ratings are for the whole window, that is, window plus frame. In the past, ratings were based on glass performance only, which sometimes over-rated the performance of a real installed window production. Laboratory tests and computer simulations determine a window's basic thermal and optical properties, which appear in NFRC certification documents for most windows sold in the U.S. Air infiltration and ratings of annual heating and cooling energy performance may be added sometime in the early 2000s. Work is under way to rate condensation resistance and long-term energy performance.

The U.S. Department of Energy (DOE) and the Environmental Protection Agency (EPA), have established the Energy Star program for energy-efficient windows to certify which products meet minimum energy performance criteria. Because window efficiency depends on the local climate, Energy Star window certifications are based on three U.S. climate zones: northern (heating energy dominated), southern (cooling energy dominated), and central (roughly equal heating and cooling).

The Efficient Windows Collaborative (EWC), managed by the Alliance to Save Energy, is a coalition of window and window component manufacturers, research organizations, non-profits, and federal and state government agencies interested in expanding the market for high-efficiency window products. Established in 1997, the EWC educates builders, remodeling contractors, home energy raters, utilities, and consumers about efficient window products.

WINDOWS OF THE FUTURE

Future energy-efficient window technologies will likely emphasize further control of heat loss and solar gain and integration with other building components. New technologies also will likely find ways to harness the power of thermal and solar heat transfer rather than just controlling it. Harnessing the power of the Sun, wind, and elements to make windows power-generation sources rather than energy losers will occur in the future. Designers, planners, and window industry visionaries foresee windows as dynamic, integrated, controllable "appliances in the walls." Windows of the future may very well be automated home systems that serve many purposes. The technologies listed below are only a few in a list of hundreds that may improve efficiency, performance, and visibility.

Future Window Technologies for Controlling Heat Loss

The gas fills that reduce the U-factors of low-e, insulated windows require very low pressure—that is, a vacuum or evacuated window. Research is focusing on improving seals, which are critical in vacuum windows, and methods of trapping the gas fill, which would otherwise diffuse through the seals. Spacers that keep the glass layers from collapsing under the required low pressure are significant sources of heat transfer; reducing their thermal bridging effect is under study.

Another promising means to reduce conductive, convective, and radiative heat transfer through windows is to fill the space between panes with a transparent insulating material. Silica aerogel is under development for this purpose. Because the silica particles are much smaller than the wavelengths of visible light, aerogel is transparent to the human eye. Its thermal conductivity is lower than that of air, and it is opaque to most longwave infrared radiation, so radiative heat losses through an aerogel-insulated window are minimal. It is much easier to vacuum-seal a window with aerogel insulation than with gas insulation. Aerogel is also strong enough to balance external atmospheric pressure on the window, so no spacers are needed. Testing and evaluation to confirm the performance of silica aerogel is under way.

Future Window Technologies for Controlling Solar Heat Gain

Solar heat gain through windows can add to or detract from energy efficiency, depending on a building's type and use, the local climate, the season, and even the time of day. For some applications, SHGCs should be maximized; for others, SHGCs should be minimized.

For residential buildings in climates where heating energy use dominates, it is important to maximize solar gains through windows. Solar heat transmission rates can be decreased by minimizing impurities in the glass (e.g., using low-iron glass). Low-e coatings may also be designed to be "smart" about maximizing or minimizing gains as a result of inside environmental conditions.

Controlling solar heat gains is equally important because

1. Residences are increasingly being built with air conditioners; in northern climates, cooling costs may be similar to heating costs even though the annual demand is heating-dominated, because electricity used for cooling is generally much more expensive than gas for heating.
2. Almost all commercial buildings are cooling-dominated, and solar gains through windows are major contributors to cooling loads.
3. Cooling loads are most significant on hot summer afternoons when electric utilities typically have annual peak loads. Lower solar heat gains lead to reduced peaks, which reduce peak demand charges and power plant capacity requirements.

Solar heat gain needs to be controlled in three ways: by intensity, by variations in time, and by spatial distribution

Controlling solar heat gain intensity. As described above, low-solar gain low-e glazing blocks out parts of the solar spectrum. Approximately half of incident solar energy is in the solar infrared; this solar radiation will not light interior spaces, but it is responsible for most of the heat gain, so it should be the first to be rejected by a selective glazing.

Controlling solar heat gain variations in time. Optical coatings that control solar heat gain on a time-dependent basis may be advantageous in applications such as commercial buildings where the benefits of solar gain and daylight vary daily or hourly, and in residential buildings where the desirability of solar gains varies seasonally. Glazings with variable properties, typically called chromogenic (switchable) glazings or "smart" windows, can be more effective and efficient than traditional shading devices.

There are several different types of switchable glazings. All are activated by a physical phenomenon (light, heat, or electricity), and, once activated, they switch, either incrementally or completely, to a different state. The state in which they permit the highest solar transmittance (typically the inactivated state) is called the bleached state; the state with the lowest solar transmittance is called the colored state.

Three switching mechanisms have been identified: photochromic (light-sensitive), thermochromic (heat-sensitive), and electrochromic (electrically activated). Photochromic materials alter their optical properties when exposed to light, typically UV, and revert to their original state in the absence of light. Probably the most familiar and widespread consumer use of photochromics is in sunglasses. Photochromic glass cannot yet be produced using the float glass process, so it is prohibitively expensive for windows. Current research is on developing plastic photochromic layers that are durable enough for use in windows. Photochromic glazing may be appropriate to control daylight transmission but is insensitive to solar heat gain.

Thermochromic materials change optical properties when subjected to temperature change. Their primary commercial uses to date are in inks, paints, security devices, and temperature indicators. Research in window thermochromics is focusing on durability, specification of switching or activation temperatures and ranges, and achievement of sufficient optical clarity in the colored state. Thermochromics can respond well to thermal effects but may not allow desirable daylight transmittance and may not distinguish between high ambient temperatures and incident solar radiation.

Electrochromic glazings are complex, multilayer coatings whose optical properties vary continuously from a highly transmissive (bleached) state to a low-transmitting (colored) state. A small electrical potential difference, typically one to five volts, triggers the change in state. The longer the potential difference is applied, the more the electrochromic layer will switch until it reaches its maximum or minimum. Electrochromics can be tied into building energy management control systems that optimize trade-offs between lighting energy and cooling consumption. Electrochromics appear to have greater potential for energy savings and user comfort than photochromics or thermochromics.

Controlling solar heat gain distribution. Commercial buildings often have a surplus of daylight near exterior windows and a lack of daylight deep in their interiors. Skylights can help on the top floor; strategies are being explored to redistribute daylight from side windows to the center of the building on lower floors.

Various technologies are being studied to maximize daylight, direct daylight and reject heat gain, and avoid visual glare. Two types of technology are being studied: holographic and angular selective glazing. Light shelves and complex light pipes also can redirect daylight. Light shelves often are simple horizontal elements on a building's exterior. Light pipes are rectangular "pipes" extending into a building from the exterior. Variations on these kinds of architectural features are being studied.

Transparent or translucent insulating materials (TIMs) can provide light or solar gains without view. TIMs typically have thermal properties similar to conventional opaque insulation and are thicker than conventional insulating glass units, providing significant resistance to heat transfer.

TIMS often have the same thermal conductance as a wall, so they are appropriate to admit daylight in areas where insulated walls would otherwise be installed. In Europe, where there are many uninsulated masonry buildings, TIMs with solar control mechanisms could be excellent retrofits. TIMs' optical properties are different from those of conventional insulating glass units; solar radiation often is scattered as is passes through a TIM. As a result, measuring the optical properties of TIMs can be challenging. Laminated and safety glazings were originally designed to help structurally support the building. They also may help to control daylight and reduce solar heat gain.

Integration of Windows with Other Building Components

Windows often are thought of as independent components of a building. However, to maximize windows' energy efficiency, they must be integrated with the rest of a building system.

Projects around the country are beginning to demonstrate that the energy consumption of new houses can be reduced by as much as 50 percent with no behavioral changes and little or no impact on the cost of construction. This is possible because cost savings in one component can then be reinvested to improve energy performance and product quality. New techniques for improving the building envelope, such as upgrading to high-performance windows, often enable builders to install smaller, less expensive heating and cooling systems than would be needed with traditional windows. Equipment cost savings in heating, ventilation, and air conditioning (HVAC) offset the added envelope improvement costs.

At a demonstration project in Las Vegas, low-solar gain low-e windows were a key technology used to reduce measured cooling energy by 20 percent and heating energy by 50 percent in new homes. After improvements to the construction, including energy-efficient windows with an SHGC of 0.4 and a U-factor of 0.35, the HVAC was sized at three tons, with a resulting cost savings of $750 to the builder. Energy-efficient windows accounted for half a ton to one ton of those savings.

Specific integrated residential applications. An Integrated Window System (IWS) is a window-wall panel with a number of energy-efficient features:

- movable interior or exterior insulating night shades recessed into the wall cavity;
- seasonally deployed solar shading, that can be interior, exterior, or in-between;
- optional overhangs;
- insulated box beam headers;
- larger glazed area;
- elimination of structural window form elements.

IWSs would most likely be factory-built and integrated into conventional construction, replacing likely framing components. IWS prototypes are being designed.

Commercial applications. Exterior building design, glazing, lighting systems, and heating, ventilation, and air-conditioning equipment are typically specified and installed separately in commercial buildings. However, to realize the energy-saving potential of advanced products such as electrochromics or light shelves, it will require concurrent advances in sensor, software, and hardware of energy management control systems.

Other Integrated Energy Issues

In addition to the examples cited above, many manufacturers and researchers in the industry are trying to identify methods of reducing embodied energy costs. Glassmaking is an energy-intensive industry; vinyl, aluminum, and fiberglass extrusion also is energy-intensive. Making wood windows out of an ever-shrinking supply of forestry is becoming difficult. Researchers hope to identify whether there is some advantage to recycling whole window products at the end of their useful life and whether that process is more energy- and resource-efficient than beginning again with virgin materials.

WORK AND ENERGY

Work, in general, is an activity in which one exerts strength or faculties to do or perform something. In physics, work is defined as a force on an object multiplied by the displacement of the object. Measuring force in newtons (N) and displacement in meters (m) yields newtons times meters (Nm) as the units of work. To honor James Prescott Joule, who did pioneering work in the science of thermodynamics, a newton-meter is called a joule (J). A person pushing on a box with a force of 200 N (about 50 pounds) and moving the box 1 m would do 200 J of work. Energy is capacity, or ability, for doing work. Work and energy are both measured in joules.

After being outside on a cold day, a person's hand warms when shaking hands with someone who has spent time in a warm room. Heat flows from the warm hand to the cool hand to produce the warming. Rather than shaking hands, the person could briskly rub his hands together. In this case, warming is a result of doing work, not due to a flow of heat. Heat is energy in transit and, accordingly, is measured in joules. It takes 4,200 joules of heat to raise the temperature of 1 kilogram of water 1 degree Celsius. The same temperature rise would occur if 4,200 joules of mechanical work were done on the water using a food mixer, for example.

The concepts of heat and work are very important for understanding the roles of automobiles, airplanes, trucks, trains, and electric power plants that are essential for a modern industrial society. Examining the technology, one always sees the involvement of an engine of some sort. Most automobiles employ a gasoline engine, trucks and trains use diesel engines, and an electric power plant uses a steam turbine to drive an electric generator. There are significant differences in the size and complexity of the engines involved, but they all convert heat to useful work.

The word kinetic implies motion. An object in motion has a capacity for doing work and has kinetic energy. Forces acting on an object do work when the object moves and the kinetic energy changes. When pulling on a sled to start it moving, force and displacement are in the same direction. Work done by this force is taken to be positive. While the sled is moving, frictional forces on the runners pull backwards. The force and displacement are in opposite directions and the work is taken to be negative. The net amount of work is the algebraic sum of the work due to all forces acting on an object. For example, if pulling on the sled produced 100 J of work and friction produced –50 J the net amount of work is 100 J – 50 J = +50 J.

A very important principle called the work-energy principle reads as follows: net amount of work is equal to the change in kinetic energy. Emphasis is placed on net and change. If the net work is positive, this means the net force and displacement have the same direction, and the kinetic energy increases. Increasing the kinetic energy of a car requires positive work. Conversely, decreasing the kinetic energy requires negative work. When a braking system brings a car to rest, forces must act in a direction opposite to the direction the car is moving. If a car travels down a highway at constant speed, its kinetic energy does not change. This means the net work on the car is zero. Air always pushes against the car and does negative work. To keep the speed from changing, forces that propel the car forward must do positive work of equal magnitude. The faster the car travels, the greater the negative work done by the air. As a result, forces driving the car forward must do more work. This means more consumption of gasoline. This is the basic reason why the fuel economy of a car is sensitive to speed.

ENERGY TIMELINE

ENERGY SOURCE, PROCESSING, AND STORAGE EVENTS

B.C.E.

2600	Construction of Lake Moeris in Egypt, a reservoir created by a dam 27 miles long.
2589	Construction of Great Pyramid of Khufu begins and lasts until 2566 B.C.E.; innovative use of available power for transportation and construction.
1500	Water clocks being used by Egyptians.
850	Natural gas utilized in China.
400	An oil well is completed on an island in the Ionian Sea and the oil used in lamps.
180	Revolving mill invented; it is powered by slaves and asses.
65	Earliest known reference to the use of a windmill is made by Antipater of Thessalonica.

C.E.

600	Arabs develop a windmill in which the paddlewheel revolves in the vertical plane.
1000	Burmese successfully drill oil wells.
1003	Wells are drilled in China for natural gas, which flows through bamboo pipes to be used perhaps in porcelain manufacture.
1200	Coal being mined in Europe.
1269	Frenchman Pèlerin de Maricourt writes a treatise on magnetism that includes the earliest description of the compass in the Western world.
1430	Turret windmill invented.
1600	England suffers from timber and fuel wood scarcity.
1619	Coke first used instead of charcoal in a blast furnace.
1635	John Winthrop, Jr., opens America's first chemical plant in Boston. They produce saltpeter (used in gunpowder) and alum (used in tanning).
1640	Oil well completed in Italy; kerosine from the oil later used for lighting
1670	First distillation of gas from coal.
1678	Dutch mathematician Christiaan Huygens first states his wave theory of light, published in *Traité de la lumière* in 1690.
1682	Law of gravitation announced by English mathematician and physicist Isaac Newton; five years later his *Philosophiae Naturalis Principia Mathematica* is published, setting forth the laws of motion as well as gravitation.
1694	Oil produced in England by retorting oil shale and cannel coal.
1793	British physicist Benjamin Thompson (Count Rumford) shows that work is convertible into heat and vice versa.
1799	Production of coal gas.
1800	Italian physicist Alessandro Volta demonstrates the galvanic cell, also known as the voltaic cell.
1802	Gas lighting.
1819	English chemist and physician John Kidd obtains naphthalene from coal tar, pointing the way toward the use of coal as a source of many important chemicals.
1830	American physicist Joseph Henry discovers the principle of electromagnetic induction. English chemist and physicist Michael Faraday independently discovered the same principle a year later but is the first to publish his findings.

1850s	The first petroleum refinery consisting of a one-barrel still is built in Pittsburgh by Samuel Kier.
1850	Scottish chemist James Young starts to produce “coal oil” (kerosine) from coal.
1853	Kerosene is extracted from petroleum.
1854	The Pennsylvania Rock Oil Company becomes the first oil company in the United States.
1855	Chemist Benjamin Silliman, of New Haven, Connecticut, obtains valuable products by distilling petroleum. They include tar, gasoline, and various solvents.
1856	The first synthetic dye is developed by William H. Perkin (English); he accidentally creates a mauve dye from the impure aniline in coal tar.
1857	Oil is discovered in Romania and Ontario.
1859	The first commercially successful U.S. oil well is drilled by E. L. Drake near Titusville, Pennsylvania. This 70-foot well launches the petroleum industry.
1867	Swedish philanthropist Alfred Nobel patents dynamite.
1886	There are forty to fifty water-powered electric plants reported to be online or under construction.
1888	The first dry cell battery, consisting of a moistened cathode and a swollen starch or plaster of paris separator, is invented.
1895	The Edison dry cell nickel/cadmium battery and the Jungers nickel/iron cell are developed; work on these endeavors lasts until 1905.
1900	American chemist Charles Palmer makes a breakthrough in devising a thermal process to produce gasoline from crude petroleum.
1900	First off-shore wells, fixed to piers, are drilled in the Caspian Sea.
1901	Oil drilling begins in Persia.
1905	German-American physicist Albert Einstein formulates the Law of Mass-Energy Equivalence ($E=mc^2$) and the Photon Theory of Light.
1907	Atlantic Refining Company introduces the tower still refinery, in which petroleum is separated in a continuous process rather than in batches.
1913	The world’s first geothermal power station begins operation in Italy.
1918	Shell introduces the first drill with diamond tooth edges.
1921	Federal Energy Regulatory Commission statistics show hydropower generation at 3,700 MW (cf. 1992 figure of 91,600 MW).
1918	Ethyl gasoline is developed by General Motors Laboratories in the United States.
1926	Du Pont and Commercial Solvents begin synthetic methanol production in the United States.
1931	Oil drilling becomes more accurate because of the gyroscopic clinograph that stabilizes the drill.
1932	After American physicist Ernest Orlando Lawrence invented the cyclotron three years earlier, the E. O. Lawrence Cyclotron becomes operational. It helps scientists discover what an atom is composed of, how it behaves, and how its energy can be tapped.
1933	Construction of Grand Coulee Dam begins. Originally built to meet irrigation needs, it has more electric generating capacity than any dam in North America by 1975.
1935	From 1920 to 1935, 6.5 million windmills have been erected in the United States to pump water, run sawmills, or generate electricity.
1936	The Hoover Dam is completed.
1936	The Houdry Process is used in the catalytic cracking of petroleum.
1937	Westinghouse constructs its “Atom Smasher” in Forest Hills, Pennsylvania. The five million volt van de Graaff generator represents the first large-scale program in nuclear physics established in industry, makes possible precise measurements of nuclear reactions, and provides valuable research experience for the company’s pioneering work in nuclear power.
1939	Enrico Fermi (Italian-American), Otto Hahn (German), F. Strassman, Lise Meitner (Austrian), and Otto Frisch (Austrian) discover and describe nuclear fission.
1940	Standard Oil Co. (Indiana) develops catalytic reforming to produce higher octane gasoline.

1941 American nuclear chemist Glenn Seaborg's team of experimenters isolates plutonium, which proves to be a better fuel for nuclear reactors than uranium because of its greater energy yield.

1942 The Manhattan Project at the University of Chicago Laboratory, headed by Enrico Fermi (Italian-American), creates the first self-sustaining nuclear chain reaction.

1942 Natural gas liquified for first time in Cleveland, Ohio.

1944 Seismic profiling for oil deposits begins in the Gulf of Mexico.

1947 Offshore oil wells drilled off coast of Louisiana.

1951 An electricity-producing nuclear breeder reactor commissioned by the U.S. Atomic Energy Commission.

1952 The first hydrogen (fusion) bomb to be tested by the United States is exploded at Bikini Atoll.

1954 First submersible drilling unit, "Mr. Charlie," is used.

1954 First solar cell developed by Bell Telephone Laboratories researchers.

1959 Liquified natural gas is shipped via cryogenic tanker from Lake Charles, Louisiana, to London.

1960s First large-scale U.S. nuclear power plants go on line.

1960 Geysers near San Francisco begin supplying geothermal electric power.

1976 Clinch River Breeder Reactor Project, the first large-scale demonstration breeder reactor is constructed near Oak Ridge, Tennessee. The project died for lack of support, however.

1982 The Tokamak Fusion Test Reactor at the Princeton Plasma Physics Laboratory produces fusion.

1992 Federal Energy Regulatory Commission statistics show hydropower generation at 91,600 MW (cf. 1921 figure of 3,700 MW).

TRANSPORTATION AND AGRICULTURE

B.C.E.

8000 Settled agriculture occurs in the Near East and other centers of human habitation.

7500 Dugout canoes are used in northwestern Europe. Reed boats are developed in Mesopotamia and Egypt.

7000 Agriculture starts in Mexico.

3500 The earliest illustration of a sail dates from this period and was found near Luxor, Egypt. The sail is fixed to a single mast and there is a shelter aft.

3200 The first wheeled vehicles are believed to have appeared in Sumer (now Iraq).

2700 Spoked wheel appears; traction plow already developed.

2400 First canal for ships built at Elephante in Egypt.

2000 Horse-drawn vehicles are used.

312 Roman road building prowess is exemplified in the construction of the Appian Way.

C.E.

400 Paddlewheel propulsion invented in China.

500 Invention of the modern horse collar in China helps produce agriculture surpluses.

700 Lateen sailing vessels are established in the Mediterranean Sea, increasing directional sailing ability.

730 Stern post rudder invented for sailing vessels.

1701 English agriculturist Jethro Tull invents a seed drill that sows seed in neat rows, saving seed and making it easier to minimize weeds.

1705 English inventor Thomas Newcomen builds his atmospheric steam engine.

1769 French engineer Nicholas-Joseph Cugnot builds his steam road-carriage.

1786 Scottish inventor Andrew Meikle builds his first thresher.

1783 First manned flight via balloon.

1787 American John Fitch launches the first U.S. steamboat.

1804 English inventor Richard Trevithick's steam railway locomotive.

1805 Twin-screw propeller developed by American John Stephens.

1814 Railway locomotive by Englishman George Stephenson.

1816 The forerunner of the bicycle is patented by German inventor Karl D. Sauerbronn.

1819 Atlantic first crossed by a steam-powered vessel, the *Savannah*.

1825 Stockton and Darlington Railway completed, first public steam powered railway.

1827 Steam automobile invented by Hancock.

1829 First horsedrawn carriage “omnibus,” which carries eighteen passengers, introduced by G. Shillibear in London.

1830 Liverpool and Manchester railroad.

1831 American inventor Cyrus McCormick develops the harvester.

1834 Electric streetcar invented by Thomas Davenport (American).

1844 American inventor Charles Goodyear patents “vulcanizing” of rubber.

1847 German-English electrical engineer William Siemens creates the regenerative steam engine.

1852 American inventor Elisha G. Otis develops the first “safety” elevator; it incorporates a brake that prevents elevators from falling even if the main cable is completely cut.

1852 The first nonrigid, powered, manned airship is flown by its builder, French engineer Henri Giffard; this marks the beginning of the practical airship.

1860 French inventor Jean-Joseph-Étienne Lenoir builds the first practical internal-combustion engine, fueled by illuminating gas.

1865 Samuel Calthrop (American) creates a streamlined locomotive.

1867 Gas engine built by German engineers Nikolaus August Otto and Eugen Langen.

1868 American engineer George Westinghouse introduces the air brake. The new power braking system uses compressed air as the operating medium.

1869 The Transcontinental Railroad is completed as the Golden Spike is driven in at Promontory Point, Utah.

1875 Internal combustion engine invented by Siegfried Marcus (Austrian).

1877 German aeronautical engineer Otto Lilienthal invents his first glider.

1877 American meatpacker Gustavus Franklin Swift invents the refrigerated railcar.

1883 Elevated electric railroad opens in Chicago.

1884 English engineer Charles Algernon Parsons invents his compound steam turbine.

1885 The gasoline automobile is developed by German engineer Karl Friedrich Benz. Before this, gasoline was an unwanted fraction of petroleum that caused many house fires because of its tendency to explode when placed in kerosene lamps.

1886 The first modern oil tanker, *Gluckauf,* is built for Germany by England.

1887 Scottish inventor John Boyd Dunlop creates an air-inflated rubber tire.

1888 Richmond Union Passenger Railway electric street railway system designed by American electrical engineer Frank Julian Sprague.

1889 Carl Gustaf de Laval (Swedish) improves the steam engine by devising a small, high-speed turbine in which jets of steam hit a single set of blades set on a rim of a wheel.

1889 Petroleum-fueled agricultural tractor developed in the United States.

1900 Worldwide railways total 470,000 miles of track.

1901 First merchant vessel, *King Edward,* driven by steam turbines in Scotland.

1902 Steam superheaters dramatically improve the performance of railway engines.

1903 American inventors Orville and Wilbur Wright fly the first powered aircraft at Kitty Hawk, North Carolina.

1903 The Ford Motor Company is founded.

1905 Long Island Railroad is the first to abandon steam completely in favor of electrification.

1911 American industrialist and electrical engineer Elmer A. Sperry creates a gyrocompass.

1924 Constant speed propeller brings better efficiency to aircraft.

1926 American physicist R. H. Goddard builds and launches the first liquid-fuel rocket.

1927 First electrically powered, automatically controlled pipeline is built in California.

1930 English inventor Frank Whittle patents the basic design of the turbojet engine.

1939 Russian-American aeronautical engineer Igor Sikorsky makes the first successful tethered helicopter flight.

1941 The Whittle jet engine is flown from Britain to the United States and provides the model for the first practical American jet engines that will be built by General Electric.

1947 Diesel-electric locomotive is built.

1952 First regular jet air passenger service begins; it goes from London, England, to Johannesburg, South Africa.

1954 U.S. Navy launchs the first nuclear-powered submarine, *U.S.S. Nautilus,* the first use of nuclear propulsion. It could cruise 62,500 miles before refueling.

1956 German engineer Felix Wankel develops the prototype for his Wankel engine, a rotary-piston engine.

1956 English engineer Christopher Cockerell designs the hovercraft.

1959 *NS Savannah* launches; it is the first nuclear-powered merchant ship.

1961 *USS Enterprise,* a nuclear powered aircraft carrier and the world's largest ship, is launched. It operates at speeds of 20 knots for distances of up to 400,000 miles.

1966 Electronic fuel injection is developed; it eventually replaces the carburetor.

1968 Supersonic transport plane.

1972 Ford invents the sodium sulfur battery.

1977 Hydrogen gas used to power vehicles in two California experiments.

LIGHT, HEAT, ELECTRICITY, AND COMMUNICATION

B.C.E.

c. 500000 Peking man uses fire for heat, light, and cooking.

c. 17000 Stone oil lamps enable Paleolithic artists to paint and engrave the walls of caves.

c. 2400 Greek civilization designs buildings to take advantage of solar heating.

c. 8000 Oil lamps are used in Mesopotamia.

c. 2500 Glass-making occurs in Egypt and Mesopotamia.

c. 600 Greek philosopher Thales observes that amber, a fossilized type of tree sap, attracts bits of paper and certain materials, like straw, when rubbed. This is the first mention of static electricity.

285 The Lighthouse at Alexandria is constructed; a mirror projects the light of fire for thirty miles.

1 Roman engineers develop a vertical watermill known as a Vitruvian mill.

C.E.

551 Jerome Cardan, an Italian mathematician, determines that while amber attracts light objects, a magnetic black stone attracts only iron. This is the first in a series of discoveries that links electricity to magnetism.

1340 Blast furnaces are developed in Europe.

1600 English physician William Gilbert discovers that materials like glass, sulfur, and diamonds behave just like amber. He calls these materials electrics, which means amber in Latin.

1646 Walter Charlton coins the word "electricity" to explain the attraction between these substances.

1672 German physicist Otto von Guericke molds a large sphere out of sulfur. Holding a piece of wool against this spinning sphere produces a large spark. This is the first generator to use friction to create electricity.

1729 Englishman Steven Gray first discovers that metals are conductors and non-metals are non-conductors.

1745 Dutch mathematician and physicist Pieter van Musschenbroek invents the Leyden Jar, which stores an electric charge.

1747 American statesman and inventor Benjamin Franklin deduces the existence of positive and negative electric charges.

1752 Benjamin Franklin flies a kite during a thunderstorm with a key dangling on the end of a wire. A silk string collects a charge from the thunderclouds which is conducted into a Leyden Jar. Thus, he makes the connection between lightning and electricity. This experiment leads to his invention of the lightning rod.

1762 Oil street lamps used in New York City.

1767 The city of Philadelphia lights streets with whale-oil lamps.

1790 First steam-heated factory.

1792 Coal-gas lighting invented by William Murdock in Cornwall.

1794	Italian physicist Allessandro Volta creates the first continuous electrical current by making a battery out of silver and zinc strips placed in salty water. Prior to this discovery all man-made electrical sources came from static.
1795	British physicist Benjamin Thompson (Count Rumford) invents the Rumford stove, a close-toped range that economizes fuel.
1800	The first commercial battery is manufactured. Scientists realize that if chemical changes can create electricity, then electricity can create chemical change.
1803	First factory illuminated by coal-gas lighting, in James Watt's foundry (Scotland).
1803	Italian cities of Genoa and Parma are lighted by kerosine from an oil well in Modena.
1813	London Bridge is lighted by gas.
1819	Danish physicist Hans Christian Oersted creates a magnet with electrical current, establishing the connection between electricity and magnetism.
1826	German physicist George Simon Ohm publishes *Die galvanische kette, mathematisch bearbeitet,* in which he describes his discovery that the voltage across an electrical conductor is proportional to the electrical current, and that the current is inversely proportional to the resistance of the conductor. His formulation becomes known as Ohm's Law.
1828	English chemist and physicist Michael Faraday discovers electromagnetic induction.
1829	American physicist Joseph Henry develops a coil magnet that grows stronger as more wire is wound around an iron core. He succeeds in lifting more than a ton of metal.
1830	Thermostat is invented.
1831	English chemist and physicist Michael Faraday creates the first electrical generator by using a magnet and a spinning copper plate to produce a current. Using a steam engine to keep the copper plate spinning within the magnetic field, electrical current is produced.
1831	American physicist Joseph Henry, by reversing Faraday's discovery, passes an electrical current through a magnetic field to turn a copper wheel, creating the first electric motor. For the first time in history, electrical energy can be used to power machines to do work that was formerly done by humans and animals.
1834	The first practical liquid refrigerating machine is patented by American inventor Jacob Perkins.
1835	The electric automobile is created by American inventor Thomas Davenport.
1838	American inventors Samuel F. B. Morse and Alfred Vail first demonstrate practical telegraphy.
1844	Samuel F. B. Morse builds the first electric telegraph. By transmitting short or long signals along a wire, messages can be sent anywhere. The Morse code makes it possible to send messages long distances at the speed of light.
1845	Safety matches are developed.
1849	American engineer James B. Francis invents the hydraulic turbine.
1851	American inventor John Gorrie patents an expansion cycle refrigerating machine.
1852	Heat pump is invented.
1868	The Siemens brothers (German) design the regenerative gas furnace.
1864	Scottish physicist James Clerk Maxwell publishes his theory of light and electricity.
1866	The first transatlantic cable is laid, creating a permanent electrical communications link between the old world and the new.
1868	French chemist Georges Leclanche invents the zinc-carbon battery, a precursor of the dry cell and the modern portable battery.
1875	A building in France is iluminated by electricity.
1876	American inventor and educator Alexander Graham Bell develops the telephone by converting electrical impulses into sound.
1878	American inventor Charles F. Brush invents the arc lamp.
1879	The streets of Cleveland are lit by carbon-arc lamps.
1879	Thomas Edison invents the incandescent lamp.

1879	English physicist William Crookes develops the cathode ray tube.
1882	October. The pioneering firm of United States Electric Illuminating Company starts up South Carolina’s first central station for incandescent electric lighting one month after Thomas Edison opened his central station on New York City’s Pearl Street. In the following years, U.S. Electric becomes one of Edison’s main competitors.
1885	American electrical engineer William Stanley invents the transformer.
1886	Austrian chemist Carl Auer (Freiherr von Welsbach) invents the Welsbach mantle, tripling the output of kerosene lamps and gas burners.
1884	American engineer Lester A. Pelton develops the hydraulic turbine.
1884	First large-scale use of natural gas in Pittsburgh.
1887	Italian-American physicist Nikola Tesla invents a motor that produces alternating current. This discovery changes the way electricity is transmitted over long distances.
1889	The first commercial, long-distance transmission of electricity takes place when a direct-current line provides power from Willamette Falls for street lights in Portland, Oregon.
1893	German physicists Julius Elster and Hans F. Geitel invent the first photoelectric cell as a result of studying the photoelectric effect.
1895	The first hydroelectric generator at Niagara Falls, New York, produces alternating current from a Nikola Tesla design.
1900	A hydroelectric plant is built at Niagara Falls.
1901	The first reception of transatlantic radio signals.
1904	Gas is used for the first time for heating and hot water in London, England.
1904	English electrical engineer John Ambrose Fleming patents the first electron tube, which he calls a diode vacuum tube.
1904	American electrical engineer Ernst Alexanderson creates a high-frequency alternator; it allows reliable transoceanic radiotelegraph communication.
1909	Shoshone Transmission Line, power generated by the Shoshone Hydroelectric Generating Station to Denver.
1910	French chemist and physicist Georges Claude invents the first neon light.
1911	English engineer Charles Algernon Parsons improves the turbo-alternator for generating electricity in power stations.
1913	Austrian inventor Victor Kaplan patents his turbine; the invention enables hydroelectric power stations to be more consistently efficient.
1920	Martin Hochstadter introduces a three-core power cable that does not become deformed or burn by the high voltage electricity.
1930	First domestic gas water heater to work efficiently is developed.
1934	Power from the Boulder (Colorado) dam is transmitted 270 miles to Los Angeles, California.
1937	First commercial convective heater equipped with an electric fan.
1937	The five million-volt van de Graaff generator, Westinghouse “Atom Smasher, 1937,” represents the first large-scale program in nuclear physics established by industry.
1939	The Massachusetts Institute of Technology builds a solar house.
1939	American physicist John Vincent Atanasoff collaborates with Clifford E. Berry to design the first digital electronic computer.
1940	The first gas-powered turbine to generate electricity is developed in Switzerland.
1943	Electric cables are filled with pressurized gas for insulation in England.
1945	Perry L. Spencer (United States) patents the first microwave oven.
1948	Bell Telephone Laboratories first demonstrates the transistor, a non-vacuum device that will eventually replace the conventional electron tubes.
1952	Four thousand die in London, England, from smog during air-inversion event.
1953	Four hundred die in New York City from smog event.
1954	Americans D. M. Chapin, C. S. Fuller, and G. L Pearson develop the silicon photovoltaic cell.

1955 Narinder Kapany invents optical fiber in Germany.

1958 American Gordon Gould develops the laser.

1959 Jack Kilby and Robert Noyce invent the integrated circuit.

1962 American Nick Holonyak, Jr., invents the light-emitting diode.

1963 Solar furnace capable of generating temperatures greater than 9,300°F becomes operational in Japan for scientific research.

1964 Generating electricity without turbines via magnetohydrodynamics (MHD) could theoretically double the output from nuclear power plants.

1964 George Heilmeier develops the liquid-crystal display.

1966 First superconducting motor.

1971 Ted Hoff invents the microprocessor.

1986 April. A severe nuclear accident occurs at Chernobyl in the former Soviet Union.

1986 High Temperature Superconductors developed by J. Georg Bednorz and Karl A. Muller.

MECHANICAL ENGINEERING

B.C.E.

1550 Levers used for well sweep in Egypt as well as India.

1500 Simple pulley employed in Egypt.

900 Rotary bucket pump invented.

700 First mention of the pulley; chain of pots used to raise water.

600 Compound pulley crane first used in Greece.

300 Tooth wheels and gears developed.

180 Quern or revolving mill is invented; turned by slaves or asses.

150 Force pump appears.

100 Undershot water-wheel first designed.

27 Vitruvian waterwheel created; first known instance of the transmission of power through gearing.

C.E.

1–100 Aeolipile, earliest recognized steam-powered mechanism, built by Hero of Alexandria.

200–300 Barbagal water-mills developed in Provence, France.

600–700 Windmills appear on Iranian plateau.

1240 Water-powered saw and jack invented by Honnecourt in France.

1335 Mechanical clock erected in the tower of Milan.

1472 In the next fifty years, Leonardo Da Vinci constructs the following devices: centrifugal pump, dredge for canal building, breech-loading cannon, rifled firearms, universal joint, rope-and-belt drive, link chains, bevel gears, spiral gears, parachute, and propeller.

1530 Foot-driven spinning wheel invented.

1698 Steam pump created by Thomas Savery (English).

1698 Denys Papin’s steam engine, France.

1705 Reciprocating steam engine developed by Thomas Newcomen (English).

1720s Thomas Newcomen’s steam engine comes into general use.

1769 James Watt receives main patent on condensing steam engine.

1769 Richard Arkwright invents his spinning water frame to spin yarn and silk; later to be used in North America as an industrial mill.

1772 Ball-bearings developed.

1772 James Watt’s double-acting steam engine first used in Britain.

1782 Double-acting steam engine patented by James Watt.

1785 Screw propeller invented invented by Joseph Bramah.

1801 Richard Trevithick demonstrates first successful steam-powered road vehicle in Cornwall, England.

1816 Robert Stirling patents a forerunner of the Stirling engine, tauted as “A New Type of Hot Air Engine with Economiser.”

1827 Benoit Fourneyron develops a water turbine in France.

1877 Invention of a hydraulic elevator with jugger mechanism.

1884 First practical steam turbine patented by Charles Algernon Parsons.

WARFARE AND SPACE

B.C.E.

30000 Bow and arrow first used.

1000	Assyrians use battering rams mounted on wheeled fighting towers.
1000	Crossbow invented in China.
400	Catapult and mechanical crossbow (ballista) invented at Syracuse and used against Carthage.
400	Catapult first used in China.
215	Archimedes' catapult used against the Romans.

C.E.

950	Gunpowder invented in China.
1000	The trebuchet, a missile thrower of great force operated by a hundred or more men, appears in China.
1118	Cannon used by Moors.
1232	Chinese use rockets against the Tartars and invent hot-air balloons.
1259	First cannons used in China.
1405	Portable firearms appear.
1490s	First portable siege guns used in a military campaign in France.
1515	Wheel-lock gun invented in Germany.
1525	Rifled musket designed.
1835	American Samuel Colt invents the revolver.
1840s	Guncotton (nitrocellulose) and nitroglycerine developed.
1850s	First ocean-going steam-powered naval vessels.
1860s	Railroads provide important support for armies in the U.S. Civil War and the Wars of German Unification.
1864	Self-propelled torpedo invented by Robert Whitehead (England).
1867	Alfred Nobel invents dynamite.
1880s	Electric power introduced on warships, which allows significant improvement in their capabilities.
1904–1905	Japan defeats the Russian army; first use of telephone and telegraph to coordinate troops and supplies.
1914	Tank invented by E. D. Swinton (England).
1926	Liquid-fuel rocket developed by R. H. Goddard (United States).
1939	August 2. Albert Einstein writes to U.S. President Franklin Roosevelt to warn him of the possibility of Nazi Germany developing atomic weapons.
1944	Ballistic missile developed by Wernher von Braun (Germany).
1945	July 16. First atomic bomb test at Alamogordo, New Mexico, under the code name "Manhattan Project."
1945	August. United States drops atomic bombs on Hiroshima and Nagasaki, Japan, during World War II.
1949	The Soviet Union tests its first atomic bomb, which launches the "arms race" with the United States.
1952	United States tests the first hydrogen bomb.
1955	World's first nuclear submarine, *Nautilus,* is tested (United States).
1957	First artificial satellite, Sputnik, in orbit (Soviet Union).
1958	Neutron bomb developed in the United States
1965	First nuclear reactor in space is launched.
1983	U.S. President Ronald Reagan announces the Strategic Defense Initiative, intended to shield the United States from nuclear attack.
1991	January 15. United States and allied countries launch Operation Desert Storm against Iraq, a military operation characterized by some as an "energy war."
1992	May. The nuclear arms race ends—for the first time since 1945, the United States builds no nuclear weapons.

BUSINESS, GOVERNMENT, AND CULTURE

C.E.

529	St. Benedict founds Monte Cassino; the Benedictine Order, which is to become a very powerful force in Western Christianity, adopts manual labor as a virtuous action.
716	St. Boniface, an English Benedictine, visits Germany and establishes abbeys and country estates as centers of industry and material progress.
1066	With the Norman conquest of England, industry moves from the abbeys and country estates to the towns because of energy—water mills and water transportation.
1095	The First Crusade begins (ending in 1099); the Crusades, of which there were ten—if one counts the tragic Children's Crusade—reflected a growing energy surplus (as did

	the universities) in western Europe, not yet channeled into national military establishments.
1150	Cistercians introduce use of city garbage and sewer water as fertilizer near Milan (Italy); both Benedictines and Cistercians drain swamps and lakes in Germany, France, the Low Countries, and Italy.
1273	Coal smoke in London, England, provokes complaints from the gentry.
1306	King Edward I of England makes it a capital offense to burn coal in London.
1345	Division of hours and minutes into sixties (Germany); without linear time, the Industrial Revolution would not have been possible.
1798	T. R. Malthus publishes *An Essay on the Principle of Population,* as pessimistic in its conclusions as the Marquis de Condorcet's work was optimistic
1863	The British government passes the "Alkali Works Act" in an attempt to control environmentally harmful emissions.
1870	John D. Rockefeller founds the Standard Oil Company.
1882	Standard Oil Trust is formed and buys controlling interest in a number of oil companies.
1901	Oil found at Spindletop, Texas, which leads to the formation of Gulf, Texaco, and Sun oil companies.
1907	First drive-in gas station opens in St. Louis, Missouri.
1908	Oil is discovered in Persia; Anglo-Persian (later British Petroleum) is formed.
1911	U.S. Supreme Court breaks Standard Oil monopoly into thirty-four companies.
1920	The U.S. Congress passes the Federal Water Power Act of 1920, which authorizes the first Federal Power Commission (later Federal Energy Regulatory Commission). It has authority to issue licenses for hydroelectric projects that are best adapted to the comprehensive development of a waterway.
1930	Huge oil discovery in East Texas.
1935	Federal Water Power Act becomes part of the Federal Power Act to regulate interstate commerce in electricity.
1937	The Bonneville Project Act creates the Bonneville Power Administration (BPA), which markets electricity generated at Federal hydro projects to the northwestern United States; it also owns the nation's largest network of long-distance, high-voltage transmission lines needed to bring hydropower to market.
1938	Oil discovered in Kuwait and Saudi Arabia.
1941	The United States, Britain, and the Netherlands put an oil embargo on Japan after it takes over Indonesia.
1952	Smog identified for the first time in Los Angeles, California, from the combination of a large number of automobiles, bright sunlight, and frequently stagnant air.
1953	December 8. U.S. President Dwight Eisenhower delivers his "Atoms for Peace" speech before the United Nations.
1954	The Atomic Energy Act of 1954 permits and encourages the participation of private industry in the development and use of nuclear energy.
1955	Atomic Energy Commission announces the Power Demonstration Reactor Program, a cooperative effort with private industry in constructing experimental power reactors.
1956	Celilo Village, a traditional Indian tribal fishing ground, is flooded by the Dalles Dam. The sovereign rights of tribes lead to several court cases and agreements that affect use of rivers and hydropower in the United States.
1957	The United Nations establishes the International Atomic Energy Agency in Vienna, Austria, to promote the peaceful use of nuclear energy.
1960	The Organization of Petroleum Exporting Countries (OPEC) founded in Baghdad, Iraq.
1961	The United States and Canada sign the Columbia River Treaty. Under the treaty, Canada builds two storage dams and one dam for generation, resulting in greater power and flood control benefits at U.S. facilities downstream.
1964	The Pacific Northwest Coordination Agreement is signed; it seeks to meet the region's electricity needs most efficiently by

operating the diverse generating resources as a coordinated system, as if they were owned by a single utility.

1965 First major blackout occurs in northeast United States and Canada.

1966 The Public Power Council is formed to give a voice to publicly owned utilities in the Northwest. PPC represents and advocates the common legal and technical interests of the Northwest's consumer owned utilities.

1967 The Pacific Northwest-Pacific Southwest Intertie creates the only direct way to move electricity between the Northwest and California. Billions of dollars are saved by the Northwest trading some spring and summer surplus power for fall and winter power from California.

1967 The Air Quality Act becomes law in the United States.

1968 Oil is discovered on Alaska's North Slope.

1969 Santa Barbara, California, oil spill.

1970 Production of crude oil in the United States reaches an all-time peak.

1970 Clean Air Act goes into effect in the United States.

1973 October 6. The Yom Kippur War breaks out in the Middle East.

1973 October 17. The Organization of Arab Petroleum Exporting Countries declares an oil embargo; prices rise to nearly $12 a barrel from $3.

1975 December. U.S. President Gerald Ford signs the Energy Policy and Conservation Act, extending price controls into 1979, mandating automobile fuel economy standards, and authorizing creation of a strategic petroleum reserve.

1977 June 3. The U.S. Department of Energy is created by the consolidation of the Federal Energy Administration, the Energy Research and Development Administration, and the Atomic Energy Commission.

1978 U.S. Congress passes Public Utility Regulatory Policies Act (PURPA). This law requires utilities to purchase electricity from qualified independent power producers. Portions of the act helped stimulate growth of small scale hydro plants as a means of meeting the nation's energy needs.

1978 November. U.S. President Jimmy Carter signs the National Energy Conservation and Policy Act, which promotes conservation activities, requires development of standard measures of energy efficiency and its reporting to the public.

1978 Last new nuclear power plant ordered in the United States.

1979 March. An accident occurs at the Three Mile Island nuclear power plant in New York.

1979 June. U.S. President Jimmy Carter announces program to increase the nation's use of solar energy.

1979 July. U.S President Jimmy Carter proposes $88 billion effort to enhance production of synthetic fuels from coal and shale oil reserves.

1980 U.S. Congress passes the Pacific Northwest Electric Power Planning and Conservation Act. The Northwest Power Planning Council is formed. The Council is charged with developing a plan to meet Northwest energy needs. The act also called for the Council to develop a fish and wildlife mitigation and enhancement plan.

1980 June. U.S. President Jimmy Carter signs the Energy Security Act.

1981 July. U.S. President Ronald Reagan signs Executive Order 12287, effectively decontrolling crude oil and refined petroleum products.

1979–1981 Panic caused by Iran's revolution and the Iran-Iraq war sends oil prices as high as $34 a barrel from $13.

1983 January. U.S. President Ronald Reagan signs the Nuclear Waste Policy Act of 1982, the first comprehensive nuclear waste legislation.

1986 Congress amends the Federal Power Act, increasing environmental review of hydropower projects.

1986 Oil price collapses to $12 a barrel.

1987 December. U.S. Congress approves Yucca Mountain, Nevada, as the only repository site for high-level nuclear waste.

1988 The Northwest Power Planning Council designates 44,000 miles of Northwest streams as "protected areas" because of their importance as critical fish and wildlife habitat.

1989 New York Governor Mario Cuomo and the Long Island Power Authority announce that the already built Shoreham Nuclear Power Plant will never open.

1989 *Exxon Valdez* runs aground off the Alaska coast.

1990 August. Iraq invades Kuwait, triggering an international crisis.

1991 January 15. United States and allied countries launch Operation Desert Storm against Iraq to end its invasion of Kuwait.

1991–1995 By some estimates, fish and wildlife protection measures reduced firm electric generation by about 850 megawatts annually.

1992 June. Representatives from many nations convene at the Earth Summit in Rio de Janeiro, Brazil.

1993 April. U.S. President Bill Clinton announces that the United States will stabilize greenhouse gas emissions at 1990 levels by the year 2000.

1994 The U.S. Supreme Court rules that states have the authority under the Clean Water Act to establish minimum streamflows at hydro projects. The ruling gives states more authority in hydro licensing and relicensing decisions.

1997 December 11. The Kyoto Protocol is adopted by the United Nations Framework Convention on Climate Change.

1998 United States oil and utility industry companies spend over $100 million to influence federal government energy policy.

1998 Oil prices fall sharply; collapses in Asian economies severely curtail demand.

2000 Oil prices surge to highest levels since the mid-1970s.
