Rand accordingly defended the power of reason: She argued that the testimony of the senses is unquestionably valid, that human concepts and language con connect one to the facts of reality, and that logic is the only method for reaching truth. She rejected all forms of mysticism and supernaturalism on the grounds that such doctrines defy reason and contradict the fundamental laws of reality.

In regard to ethics Rand advocated rational self-interest. The task of ethics, she argued, is to teach one the principles—the virtues—that one must practice to realize the values that sustain one's life. No outside power, whether society or an alleged god, has the right to demand that one sacrifice one's values and live for its sake. The good is to live one's own life and attain happiness. This is accomplished through a resolute commitment to the virtue of rationality. For Rand the moral and the practical are one.

In regard to political philosophy Rand argued that a proper social system must accord with the individual's nature as a rational being. Individuals in society must be free to live, think, produce and keep the results of their work, and pursue their own goals. They must have the rights to life, liberty, property, and the pursuit of happiness. The social system that results from the protection of individual rights, Rand taught, is laissez-faire capitalism. That system was approached in the freest countries in the nineteenth century, and Rand argued that the thought and productivity that capitalism unleashed made possible the ensuing unprecedented prosperity in those countries.

Rand was one of the twentieth century's champions of science and technology and the rational mind that creates them. She therefore was an opponent of ideological movements that praise more primitive lifestyles, such as the New Left and environmentalism. An increasingly industrialized society, Rand held, is the proper environment for a rational being. Although her thought, which challenged contemporary views, was largely ignored in academic circles during her lifetime, it is receiving growing attention from scholars in the early twenty-first century.

RATIONAL CHOICE THEORY

Rational choice theory is a tool for devising a scientific explanation of the way individuals make choices; it is based on the notion that individuals attempt to find the most effective method of attaining their personal goals. Rational choice theory is a fundamental instrument for understanding ethical behavior and is compatible with the idea that such behavior is rooted in the biology of human nature.

An Illuminating Example

Suppose a person has \$10 to spend in a store that has goods X and Y at prices p_x and p_y. To determine how the person will spend the \$10, an economist assumes that the person has a preferences function $u(x, y)$ that he or she maximizes subject to the income constraint $p_x x + p_y y = \$10$, where x is the amount of X purchased and y is the amount of Y purchased. The preference function $u(x, y)$ reflects exactly how the person values different "bundles" of X and Y. For instance, if $u(2, 5) = u(3, 1)$, it is known that if the person has two units of X and five units of Y and if one takes four units of Y from the person, one must give the person an additional unit of X to compensate for the loss.

The assumption that people maximize their preferences subject to the appropriate constraints has proved fruitful in economics. Maximization subject to constraints also is used widely in biology to predict, for instance, how a predator will allocate its time among various prey or how a bumblebee will decide which flower patches to harvest and which ones to ignore (Alcock 1993).

However useful this function is, it may not be true that humans and animals really have utility functions in a meaningful physiological sense. Rather, their choices are the product of extremely complex and poorly understood neurological and hormonal processes. Why, then, is maximization subject to constraints used so successfully? The answer is that a choice process need only satisfy three simple conditions to be represented by a utility function. It is said that an agent is rational when those conditions are satisfied.

Basic Conditions

By a *preference ordering* $\succeq$ on a set A it is meant that a relation such that $x \succeq y$ may be either true or false for various pairs x, y in A. In words one states $x \succeq y$ as "x is weakly preferred to y" (Kreps 1990).

The first condition on $\succeq$ is *completeness*, which means that for any two members of the set, one is weakly preferred to the other (for any x, y in A, either $x \succeq y$ or $y \succeq x$). Note that this implies that any member of A is weakly preferred to itself (for any x in A, $x \succeq x$). Generally, this is a very plausible condition, but it is possible to think of cases in which it will fail to hold. Note that it is necessary to have $x \succeq x$ by the completeness condition. This is why $\succeq$ is referred to as weak preference. One can define strong preference as $x \succ y$, meaning that "it is false that $y \succeq x$." One can use elementary logic to prove that if $\succeq$ satisfies the completeness condition, then $\succeq$ satisfies the following *exclusion condition*: If $x \succeq y$, then it is false that $y \succeq x$.

The second condition is *transitivity*, which states that if x is weakly preferred to y and y is weakly preferred to z, then x is weakly preferred to z. In symbols this is written $x \succeq y$ and $y \succeq z$ implies $x \succeq z$. It is hard to see how this condition could fail for anything one would be likely to call a preference ordering. In terms of strong preference the transitivity condition becomes "if x is strongly preferred to y and y is strongly preferred to z, then x is strongly preferred to z." Again, one can use elementary logic to show that weak preference transitivity implies strong preference transitivity.

The third condition is the *maximization condition*, which states that from any set an agent will choose an element that is weakly preferred to any other member of the set. This condition, which also is called the *independence of irrelevant alternatives*, seems completely unobjectionable, but one can think of cases in which it will fail to hold. For instance, suppose A is a big basket of crumpets of different sizes. When given any pair of crumpets to choose from, the agent chooses the smaller of the two or chooses randomly if they are the same size. This satisfies completeness and transitivity. But suppose that if given a choice among any number of crumpets, the agent always chooses the next to largest, perhaps because he or she does not want to seem greedy. Then the agent will always choose the smaller when choosing among two but will not do this when choosing among more than two.

When these three conditions are satisfied, along with a technical *continuity* condition, there always exists a utility function such that the agent behaves as if maximizing this utility function over the set A from which he or she is constrained to choose. *Rational choice theory* is the study of the behavior of agents who satisfy these conditions, who are called *rational actors*.

Background and Misconceptions

The origins of the rational actor model lie in nineteenth-century utilitarianism and particularly in the works of Jeremy Bentham (1748–1832) and Cesare Beccaria (1738–1794), who interpreted utility as happiness. In *Foundations of Economic Analysis* (1947) the economist Paul Samuelson (born 1915; winner of a Nobel Prize in economics in 1970) removed the hedonistic assumptions of utility maximization by arguing that utility maximization presupposes nothing more than the conditions listed above.

The rational actor model has been misrepresented by those who embrace it and thus has been misunderstood by those who do not. The most prominent misunderstanding is that rational actors are self-interested. For instance, if two rational agents bargain over the division of money they jointly earned, it is thought that rational action requires that each agent try to maximize his or her share. Similarly, it is thought that if a rational actor votes in an election, he or she must be motivated by self-interest and will vote for the candidate most likely to secure his or her personal gain.

Of course, if one considers the term *rational* in the broadest philosophical sense, there is nothing irrational about caring for others, believing in fairness, or making sacrifices for social ideals, and such personal goals do not contradict rational choice theory. For instance, suppose a man with \$100 is considering how much to consume personally and how much to give to charity. Suppose he enjoys a tax break such that for each \$1 he contributes to charity, he is obliged to pay only $p < 1$. Then that person can be treated as maximizing his utility for personal consumption x and contributions to charity y, say, $u(x, y)$, subject to the budget constraint $x + py = 100$. Clearly, it is perfectly rational for him to choose $y > 0$. Indeed, James Andreoni and John H. Miller (2002) have shown that people in fact behave as rational actors in making choices of this type. For instance, when the price p increases, individuals tend to lower the quantity q of contributions to charity.

A second misconception is that the rational choice model assumes that the choices people make are in their own interest, when in fact people often are slaves to passions that are distinctly self-harming. For instance, it often is held that people are deluded or irrational when they choose to smoke cigarettes, engage in unsafe sex, commit crimes in the face of extremely heavy penalties, or sacrifice their health to junk food consumption. It is not clear, however, that these behaviors in any way violate the principles of rational action.

Weakness of Will

Those behaviors have in common a certain *weakness of will*. Smokers may know that their habit will harm them in the long run but cannot bear to sacrifice the present urge to indulge in favor of a far-off reward of a healthful future. Similarly, a couple in the throes of sexual passion may appreciate the fact that they may regret their inadequate precautions in the future, but they cannot control their present urges. This is not irrational but rather time-inconsistent.

A very clear laboratory experiment illustrates this time inconsistency (Ainslie and Haslam 1992). If subjects are offered a choice between $10 today and $11 a week from today, many will take the $10 today. However, if the same subjects are offered $10 to be delivered a year from today or $11 to be delivered a year and a week from today, many of the same subjects who could not wait a week right now for an extra 10 percent prefer to wait a week for an extra 10 percent provided that the agreed on wait is in the future. This finding corresponds to the everyday notion that people are subject to temptation and failure of will, leading them to accept high long-term penalties for small short-term pleasures.

It is instructive to see exactly where the conditions for rational choice are violated in this example. Let x mean "$10 at some time t" and y mean "$11 at time t + 7," where time t is measured in days. Then the present-oriented subjects display x Y when $t = 0$ and Y x when $t = 365$. Thus, the exclusion condition for is violated, and because the completeness condition implies the exclusion condition, the completeness condition must be violated as well.

Despite first appearances time-inconsistent agents can be modeled as rational actors (Ahlbrecht and Weber 1995). To do that one simply insists that the distance between the time of choice and the time of delivery of the object chosen be included explicitly in the analysis. Thus, x_0 means $10 delivered immediately and x_{365} means $10 delivered a year from today, and similarly for y_7 and y_{372}. Then the observation that x_0 Y_7 and Y_{372} x_{365} is not a contradiction.

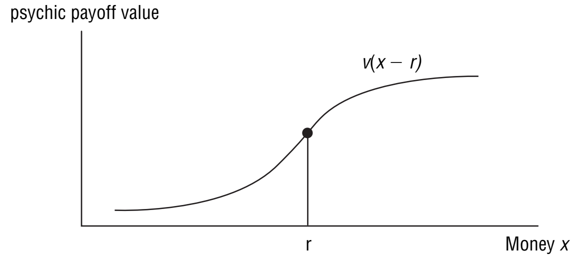
Indeed, here is a simple utility function involving what is called *hyperbolic discounting* (Ainslie 1975). Let zt mean the amount of money delivered t days from today. Then let the utility of zt be $u(z_t) = z/(t + 1)$. The value of x_0 is thus $u(z_t) = u(10_0) = 10/1 = 10$ and the value of y_7 is $u(z_t) = u(11_7) = 11/8 = 1.375$, and so x_0 Y_7. But $u(x_{365}) = 10/366 = 0.027$ whereas $u(Y_{372}) = 11/373 = 0.029$, and so Y_{372} x_{365}.

Prospect Theory

Prospect theory represents a fundamental contribution to rational choice theory that first was proposed by Daniel Kahneman (born 1934; winner of a Nobel Prize in economics in 2003) and Amos Tversky (1937–1996). According to prospect theory, agents value alternatives with respect to a *status quo* position that represents their current situation. This status quo position serves as a reference point with respect to which gains and losses are evaluated.

FIGURE 1

Prospect Theory



SOURCE: Courtesy of Herbert Gintis

Suppose, for instance, an agent has utility function $v(x - r)$, where r is the status quo and x represents a change from the status quo. Prospect theory asserts that there is a "kink" in $v(x - r)$ such that the slope of $v(\cdot)$ is two to three times as great just to the left of $x = r$ as it is to the right, the curvature of $v(\cdot)$ is positive for positive values and negative for negative values, and the curvature goes to zero for large positive and negative values. In other words agents (a) are two to three times more sensitive to small losses than they are to small gains; (b) exhibit declining marginal utility over gains and declining absolute marginal utility over losses; and (c) are very insensitive to either large gains or large losses. This utility function is exhibited in Figure 1.

There are many regularities in experimental data on human behavior that do not fit prospect theory well (Kahneman and Tversky 2000). For instance, returns on equities (stocks) in the United States have exceeded the returns on bonds by about 8 percentage points averaged over the last 100 years. If this were due to risk aversion (concavity of utility function) alone, the average individual would be indifferent between a sure $51,209 and a lottery that paid $50,000 with probability 1/2 and a lottery that paid $100,000 with probability 1/2. This is, of course, implausible, as virtually everyone would choose the risky lottery in this situation. However, a loss aversion coefficient (the ratio of the slope of the utility function over losses at the kink to the slope over gains) of 2.25 is sufficient to explain this phenomenon. This loss aversion coefficient is very plausible from experiments. In a similar vein people tend to sell stocks when they are doing well but hold on to stocks when they are doing poorly. A similar phenomenon holds for housing sales: Homeowners are extremely averse to selling at a loss and will sustain operating, tax, and mortgage costs for long periods in the hope of obtaining a favorable selling price.

One of the earliest recognitions of loss aversion took the form of the so-called *ratchet effect* discovered by James Duesenberry (born 1918). Duesenberry noticed that over the business cycle, when times are good, people spend all their additional income, but when times start to go bad, people incur debt rather than curb their consumption. As a result there is a tendency for the savings ratio to decline over time. For instance, in one study unionized teachers consumed more when the next year's income was going to increase (through wage bargaining) but did not consume less when the next year's income was going to decrease. This behavior can be explained with a simple loss aversion model. A teacher's utility can be written $u(c(t) - r(t))$, where $c(t)$ is consumption in period t and $r(t)$ is the reference point (status quo point) in period t. Suppose the reference point changes as follows: $r(t + 1) = \alpha r(t) + (1 - \alpha)c(t)$, where α [0, 1] is an adjustment parameter ($\alpha = 1$ means no adjustment, and $\alpha = 0$ means complete adjustment to last year's consumption). Note that when consumption in one period rises, the reference point in the next period rises, and vice versa.

One curious implication of prospect theory is the *endowment effect*: By virtue of bhaving something, people tend to value it more than they are willing to pay for it if they do not have it. A common example is the rare wine effect: If a typical consumer wins a $200 bottle of wine in a contest, she will save it for a special occasion and drink it then. However, the consumer would never pay more than $20 for a bottle of wine and could have sold the prize wine if she desired to.

The status quo bias inherent in prospect theory leads to important *framing effects* that can distort effective decision making. In particular, when it is not clear what the appropriate reference point is, decision makers can exhibit inconsistency in their choices. Kahneman and Tversky (2000) give a dramatic example from health care policy. Suppose it is expected that there will be a flu epidemic in which 600 people are expected to die if nothing is done. If program A is adopted, 200 people will be saved, whereas if program B is adopted, there is a $\frac{1}{3}$ probability that 600 will be saved and a $\frac{2}{3}$ probability that no one will be saved. In one experiment, 72 percent of a sample of respondents preferred A to B. Suppose that if program C is adopted, 400 people will die, whereas if program D is adopted, there is a $\frac{1}{3}$ probability that nobody will die and a $\frac{2}{3}$ probability that 600 people will die. It was found that 78 percent of the respondents preferred D to C even though A and C are equivalent and B and D are equivalent. Note that in the choice between A and B the alternatives involve gains whereas in the choice between C and D the alternatives involve losses, and people are loss-averse. The inconsistency stems from the fact that there is no natural reference point for the decision maker because the gains and losses are experienced by others, not by the decision maker himself or herself.

Why Rational Choice Theory Works

One important question remains: Why might one expect the conditions for rational choice to hold? The traditional answer is that humans are rational beings and the conditions for rational choice are the only conditions that satisfy the demands of reason. There are several problems with this justification. The most important is that the rational choice model often applies extremely well to nonhuman species, including insects and plants (Alcock 1993), whose mental apparatus falls far short of the capacity to exercise rational thought. Perhaps equally important, it is clear that humans often make choices that fail the test of right reason (e.g., weaknesses of will, including substance abuse, procrastination, and impulsive behavior), yet their choices do not violate the rational choice conditions.

A more contemporary explanation of the ubiquity of rational choice comes from evolutionary biology. Biologists define the fitness of an organism as its expected number of offspring, and the basic tenet of evolutionary biology is that fitness maximization is a precondition for evolutionary survival. If organisms maximized fitness directly, the conditions of rational choice would be directly satisfied because one could represent the organism's utility function as its fitness.

However, it is known that organisms, including humans, do not maximize fitness directly. For instance, moths fly into flames, few animals are capable of avoiding automobiles in the road, and humans voluntarily limit family size. In fact, biological fitness is a theoretical abstraction that is unknown to virtually every real-life organism. Rather than literally maximizing fitness, organisms have relatively simple preference orderings that are themselves subject to selection in accordance with their ability to promote fitness (Darwin 1872). One can expect preferences to satisfy the completeness condition because an organism must be able to make a choice in any situation it habitually faces or it will be outcompeted by another organism whose preference ordering can be used to make such a choice.

For similar evolutionary reasons one would expect the transitivity condition to hold in regard to choices that have some evolutionary meaning to the rational agent. Of course, unless the current environment of choice is the same as the historical environment in which the individual's preference system evolved, one would not expect an individual's choices to be fitness-maximizing or even welfare-improving. For instance, people in advanced technological societies have a tendency to obesity that can be explained by a weakness of will and a preference for high-calorie foods that may not be fitness-enhancing today but doubtless was at some times in the evolutionary history of the human species, which until about 10,000 years ago reflected the conditions of existence of small hunter-gatherer bands under constant threat of starvation.

Implications

Rational choice theory lies at the foundation of all behavioral science because natural selection strongly tends to select for preferences that satisfy the conditions of the rational actor model. Rational choice does not presuppose "reason," but it does presuppose adaptivity to an evolutionary environment. The fact that some behavioral disciplines, such as sociology, anthropology, and psychology, tend to ignore or reject the rational choice model through misunderstanding it arguably explains their relative immaturity and lack of unified principles in comparison with biology and economics, which tend to accept the principles of rational choice.

The most important implications of rational choice theory for ethics are as follows: (a) Weakness of will is not irrational and probably is an ineluctable dimension of the behavioral repertoire of humans; (b) because rational agents need not be selfish, it is not irrational to act altruistically and to care for others or to hate or act vindictively; and (c) what humans want and what they find ethically satisfying depend on their preference structures, which derive from an interaction between their species history and their personal histories. This argues for a behavioral ethics in which ethical principles are derived not from an appeal to introspection or reason but from the material conditions of the life of the human species.

RAWLS, JOHN

Bordley John Rawls (1921–2002) was born in Baltimore, Maryland, on February 21, educated in philosophy at Princeton University, and served in the military in the Pacific theater during World War II. He taught at Cornell University and at the Massachusetts Institute of Technology before becoming a professor at Harvard University where he taught philosophy for almost forty years. His theory of justice transformed twentieth-century political philosophy and has important implications for understanding the ethics of science and technology in terms of political governance and economics of the marketplace. He died in Cambridge, Massachusetts, on November 24.

Major Works

Rawls's major works include *A Theory of Justice* (1971), *The Law of Peoples* (1993), *Political Liberalism* (1993), and *Justice as Fairness: A Restatement* (2001). His writings have been widely distributed and translated into more than twenty languages.

Rawls developed his thought against the background of two existing philosophies: (a) utilitarianism, which employs the principle "the greatest good for the greatest number," and (b) emotivism, which claims moral and political judgments are basically personal or social preferences. Rawls finds both views inadequate, and in *A Theory of Justice* argues at length for a concept of "justice as fairness," which entails the economically "just distribution" of societal benefits and burdens through democratic procedures and institutions. Political procedures for advancing justice must run parallel to those of technological and economic progress.

In effect, Rawls revivifies theories of justice, rights, and international law that have their roots in Immanuel Kant (1724–1804) and social contract theory, as a broad response to totalitarianism and post–World War II inequities. Also, as a World War II veteran, Rawls authored "Fifty Years after Hiroshima," in which he argued against the use of the atomic bomb, and the employment of nuclear technology for nuclear weaponry. The crux of Rawls's argument may be found in a set of hypothetical conditions as follows. Imagine yourself in some "original position" in which you know that you are going to be placed in a complex world among persons with different abilities living in complex social institutional arrangements. At the same time you are prohibited by a "veil of ignorance" from knowing which abilities you might be given or which social institutions you will initially occupy.

In such a situation, Rawls argues, all persons, being both rational and self-interested, would choose to structure their social world around two principles of justice. The first, the "equal liberty principle," would establish equal basic rights and liberties for all. The second, the "difference principle," would defend inequalities on two conditions: (a) equality of opportunity (positions open to all having comparable prospects, talents, and abilities) and (b) economic and social inequalities distributed to benefit those disadvantaged by their social position. Rawls's argument is that when people do not know what abilities or benefits, or deficits and liabilities they might be given, such frame of mind affects the social order they would accept as just or fair. Moreover, such a well-ordered society based upon these principles will justly pair political democracy with economic capitalism.

Since the democratic-inspired revolutions of the eighteenth century, liberal philosophers have argued that rational individualism, republican democracy, and capitalism together could do more than any other systems to increase human rights, opportunities, and goods for more people. Historically, however, philosophers have also noted the recurring divide between rich and poor. In *Political Liberalism,* Rawls thus charges future progress, whether in government or business, in science or technology, with a moral imperative: Use political liberalism to promote justice, to ensure equal rights, and to acquire human rights as well as economic ones.

Rawls's principles of justice remain critical in evaluating these future problems and progress. Reminding his readers, in *The Law of Peoples,* that burdens accompany goods, and responsibilities come with liberties, Rawls analyzed who and what institutions will bear these responsibilities and duties to provide just and more equitable rights in a world in which people are actually situated, and materially advantaged or disadvantaged. Rawls directly formulated definitive tenets for law, rights, and duties that must be publicly instituted to address ongoing concerns and conflicts of minorities, pluralities, or the majority of global peoples. Therein, cosmopolitan individuals, technical experts, scientists, political leaders, and multinational corporations alike could find the principles, laws, and procedures in place to address fairly their worldly operations, disputes, and affairs.

Assessment

Rawls's work has inspired countless commentaries and critical replies in the United States and abroad. For instance, from its first publication in 1971 to its revised edition in 1999, *A Theory of Justice* has been challenged by communitarians and feminists. Both argue that *Theory* is too abstract and individualistic, despite its broad global outreach to diverse peoples, governments, and cultures. Arguably, Rawls draws heavily from Kant's rationalist, individualistic ethics and political philosophy of contractarian government, whereby citizens and their states jointly contract and consent (implicitly and explicitly) to institute and legitimate the just rule of their government.

Rawls has been criticized not only from the left (communitarians and feminists) but also from the right (libertarians and free-market theorists). Most notably, Robert Nozick (1938–2002), Rawls's well-renown Harvard colleague, was also his life-long critic, promulgating a counter theory known as the "entitlement theory" of social justice. In short, Nozick's theory extends another long-standing Western trend, libertarianism, which, like political liberalism, also originated in the eighteenth century, starting with Adam Smith's *The Wealth of Nations* (1776). Nozick wrote *Anarchy, State, and Utopia* (1974) in direct response as a critique of Rawls's *Theory of Justice*. Nozick thereby enlivened visions of justice based upon free-market capitalism and a minimalist state, in which the state serves solely to protect its members from violence and theft, and hence should possess no rights to interfere with one's property acquisition, use, and distribution, nor with any technological innovations and enterprises, unless fraud and unlawful force have been committed or contracts breached.

Rawls's political liberalism provides critical assurance that rational principles of justice and ethical government can control global capitalism, biotechnology, and engineering enterprises, so as to assure more of the world's people that liberties, goods, and opportunities can be more fairly distributed. Because Rawls rejects the premise that the powers and forces of right, possessed by people who are merely empowered and advantaged by circumstance or their societal position, can legitimately constitute justice, his *Theory* can test the progress made, and that still must be made, toward expanding global liberties and economic justice. In demonstrating "justice as fairness," Rawls firmly reestablishes liberal political philosophy: In facing global pluralism—diverse beliefs, values, and bases for differing notions of good—politically just principles and powers for human rights-distribution are morally required to evaluate and improve the actual positions of individuals, states, and global peoples in working toward greater fairness.

REGULATION AND REGULATORY AGENCIES

Regulation is a concept that is associated intimately with science, technology, and ethics. In the most general sense regulations control or direct human activities in accordance with a rule that has been promulgated. Neither sciences nor technologies could exist without internal processes of professional self-regulation. Biology includes research on the processes that regulate early embryonic development. The larger societies in which science and technology are embedded are dependent on forms of regulation that run the gamut from social to legal and governmental. Ethics is a form of regulation that often is seen as being more conscious or self-critical than social regulation and more broad than legal regulation.

The modern social construction of regulatory agencies as part of government was one attempt to respond to the complexity of advancing technological societies by "delegating legislation" that established appropriate institutional bodies to create and enforce "administrative laws" in specific areas of need such as water treatment, radio wave frequency allocation, and air traffic control. Reactions to the bureaucratic inefficiencies sometimes introduced by such agencies has led to countermovements for deregulation.

Historical Background and Modern Emergence

Regulations existed from the earliest periods of human history. Heads of tribes established rules that enabled closely related groups to live at peace within defined territories; rules of marriage, divorce, compensation for damage, bequests, and the status of slaves were set out in the Code of Hammurabi, which was carved in stone in Babylon in the 1700s B.C.E. Before that time the definitions of key weights and measures were established; for example, the mina (one-sixtieth of a talent) was a unit of payment that was mentioned specifically in the Code of Hammurabi. A talent, which might have been the weight a man could carry with comfort (about sixty pounds), had superseded the ox or cow as the unit of exchange.

In the era that preceded democratic governments the all-powerful prince was able to promulgate regal (regulatory) powers to modulate the behavior of his subjects according to his wishes. After the emergence of liberal democracies in the 1700s C.E. individuals and organizations within a society often were allowed to behave as they wished as long as they did not violate any of the rules and regulations crafted to ensure social order and the well-being of the society.

Those rules and regulations constitute a subset of the ethics of a society that are formulated and promulgated by those elected to a representative assembly. That assembly or body of lawmakers acts in place of the prince and therefore may be seen as an agent that regulates the affairs of the society. This is an example of the first level of the regulatory agency: the parliament or legislature.

In a democracy this type of regulatory agency involves the full complement of the members of the society who are eligible to vote and provides laws that have to be obeyed on pain of penalty when they are flouted. Those laws are upheld by an enforcement authority consisting of the police and if necessary the army that brings people suspected of lawbreaking before a judiciary where argument is presented with or without lawyers before a judge and a body of peers (the jury). If the guilt of the accused is established, punishment is meted out in the form of a fine, imprisonment, or another type of penalty.

The second level consists of religious authorities. In this case regulations or ethics are based on interpretations of sacred texts by clerics who have been given the authority to make such determinations by the head of the order or by the collective will of the congregants. The matters that are dealt with at this level are subject to compliance with laws of the state that override ecclesiastical regulation if there is a conflict. Thus, the way the church conducts its business and the messages the church promotes in helping members establish a workable relationship with the deity are an area of regulation for which this agency is fully responsible.

A third tier of regulation operates through groups of individuals who are selected by governmental departments and given authority by the issuance of specific laws to regulate the behavior of particular industries or service organizations. The first body of this type was set up in 1852 by the U.S. Congress as the Steamboat Inspection Service. That body was required to establish and maintain standards of design and production for the boilers that were used to power the paddles of steamboats plying the Mississippi River. Before that time explosions of those boilers resulted in the deaths of hundreds of passengers. Eventually that situation led to the establishment of a professional society, the American Society of Mechanical Engineers (ASME), that drew up codes of conduct to govern the education and practical training of the engineers involved in boiler design and construction along with specific codes that governed the construction of boilers that then were incorporated into local and state law.

In 1887 in the United States the Interstate Commerce Commission (ICC) was established to, among its other regulatory activities, prevent destabilizing competition in railway fares and set fare rates that would allow investment in new track and facilities as well as provisions for maintenance and safety measures without preventing the delivery of dividends to encourage further investment.

Other countries and international organizations established their own regulatory agencies. The United Nations (1945) and its subagencies, notably the World

Health Organization, the Food and Agricultural Organization, and the World Bank, were set up. In addition to a variety of international laws, those agencies provide regulations that control trade and the sustainable use of resources as well as the financial control of terrorism. The Treaty of Rome in 1957 established the European Union, which may issue directives whose power is binding on its members. There is also an International Organization for Standardization (1947) that has issued 14,000 international standards that enable world trade to proceed with confidence and a World Intellectual Property Organization that deals with regulations involving patents.

U.S. Regulatory Agencies

During the twentieth century some fifty regulatory agencies were established by the U.S. Congress. Some of the tasks undertaken by those bodies can be of major importance, for example, regulation of the quality of food and drugs through U.S. Food and Drug Administration regulations for pharmaceuticals and vaccines that often require manufacturers to test their products for safety, efficacy, and the consistency of their production process over a period of five to fifteen years at a cost of $500 million to $1 billion per product. Other tasks are trivial, including setting the when times a drawbridge may be raised or lowered.

Those agencies regulate financial operations (the Securities and Exchange Commission, established in 1933) and control the way people use their local environments (the Environmental Protection Agency, established in 1970). All aspects of the work environment are covered by the Occupational Safety and Health Administration (1970), and the Nuclear Regulatory Commission was set up in 1977 to supervise the development of civil nuclear installations. The development of the executive department of the Congress devoted to agricultural matters has spawned numerous regulatory agencies that oversee most aspects of agricultural practice. When it can be demonstrated that there is an overarching social need for regulation, members of Congress seem to be willing to provide the legal powers or instruments that give the agencies they create the tools to do their jobs.

Some of the functions that are served by American regulatory agencies include the following.

REGULATION OF COMPETITION. Although the liberal nature of the American democracy provides for the freedom of individuals and corporations to compete in attracting the attention of customers, corporations sometimes have colluded in setting prices or availabilities that have affected prices in ways that benefit corporations disproportionately. Such conglomerates have been disaggregated by law, and competition has to be active between the disaggregated entities that have been formed. For this reason the Standard Oil Company was broken up in 1911 and the Bell System's telephone monopoly was broken down to the AT&T company and the seven "Baby Bells" in 1982.

CONTROL OF COMPANY ACTIVITIES IN RELATION TO THE ENVIRONMENT. Most manufacturing companies acquire raw materials and convert them to final products, in the process producing solid, liquid, and gaseous wastes. At one time the disposal of that waste was a matter for company determination. Because there have been serious examples of wastes contaminating environments and damaging the health of local people (the Love Canal in New York State was so polluted that it took twenty years to clean up), regulations have been used to protect local residents and workers in the polluting factories.

PROVISION OF INFORMATION ABOUT PRODUCTS. The need to provide composition and calorific data on foods has turned supermarket shopping into an exercise in nutritional virtuosity. Additionally, data in advertisements have to comply with the realities of products and financial deals have to be expressed in ways that provide complete and comprehensible information to those about to take out loans or mortgages.

PROTECTION OF THE WEAK (CHILDREN) AND INFIRM. Regulations also may express the more basic virtues that are considered the hallmarks of a proud and independent society. These virtues include equality of opportunity; nondiscrimination on the basis of racial, ethnic, or religious affiliations; and the need to protect privacy on the street on in a column of data.

Criticisms

Any regulatory regimen is established at a cost. There is a burgeoning bureaucracy to deal with and costs in terms of time and trouble whenever a licence is required to make or do something. This may provide a hurdle for those who are innovating, who may be put off by the specifications they will have to meet to manufacture a product. There is also the consideration that regulations depart from the ideals of a liberal democracy that is premised on the least involvement of the state in the day-to-day activities of its citizens. In the United Kingdom the criticism that is leveled at the government as it seeks to advise and regulate the way people live, eat, and use mind-affecting drugs is that the government has become the "nanny" of the state.

A corollary of this situation is that regulations have to be devised to regulate the regulators. In the United States the Office of Management and Budget (OMB) was set up by a presidential executive order to determine the cost-effectiveness of the activities of the regulatory agencies that have been established by Congress.

People may live in a liberal society that purports to promote freedom of the individual and the corporation, yet they are biological organisms that need to have multiple levels of control to enable them to function. There are at least four levels of biochemical control of cellular function—environmental, enzymatic, energetic, and genetic—in addition to hormonal, neuronal, instinctive, subconscious, and conscious control systems. There are also social control systems, among which regulatory agencies are only one. There is little doubt that the application of a multitiered system of controls provides people with enhanced survival chances: Whether survival is always the only value is another issue.

REGULATORY TOXICOLOGY

Regulatory toxicology is the branch of toxicology (the study of adverse effects of chemicals) that uses scientific knowledge to develop regulations and other strategies for reducing and controlling exposure to dangerous chemicals.

The legal framework in this area is promulgated by governmental agencies. Examples of such agencies in the United States are the Food and Drug Administration (FDA), the Environmental Protection Agency (EPA), and the Occupational Safety and Health Administration (OSHA). Corresponding agencies exist in the European Union (EU) at the national or union level. The primary examples of authorizing legislation in the United States are the Food, Drug, and Cosmetic Act (1938), the Occupational Safety and Health Act (1970), the Clean Air Act (1970), the Federal Insecticide, Fungicide, and Rodenticide Act (1972), the Toxic Substances Control Act (1976), and the Clean Water Act (1977). Corresponding laws exist in the EU.

The Society of Toxicology (United States), EUROTOX (Europe), and the International Union of Toxicology (IUTOX) (global) are major professional organizations. The Society of Toxicology has published a code of ethics for toxicologists that requires its members to:

- Strive to conduct their work and themselves with objectivity and integrity.
- Hold as inviolate that credible science is fundamental to all toxicologic research.
- Seek to communicate information concerning health, safety, and toxicity in a timely and responsible manner, with due regard for the significance and credibility of the available data.
- Present their scientific statements or endorsements with full disclosure of whether or not factual supportive data are available.
- Abstain from professional judgments influenced by conflict of interest and, insofar as possible, avoid situations that imply a conflict of interest.

- Observe the spirit, as well as, the letter of law, regulations, and ethical standards with regard to the welfare of humans and animals involved in their experimental procedures.
- Practice high standards of occupational health and safety for the benefit of their co-workers and other personnel. (Society of Toxicology)

Toxicological Data and Assessment

Toxicity or adverse effects data are obtained either from experimental systems using animals or cell cultures, or from epidemiological studies of humans. The legally required testing differs among groups of chemical substances, ranging from no testing for many industrial chemicals to extensive requirements for pharmaceuticals.

A general problem is that the adverse effects of many chemicals, whether alone or in combination, are unknown. This is due to low data requirements, to statistical limitations in the available data, and to the cocktail effect or the interaction of chemicals. As a rough rule of thumb, epidemiological and experimental studies cannot reliably detect excess incidences of adverse effects of about 10 percent or smaller, and in many cases excess incidences of higher than 10 percent may go undetected. For relatively common types of disease, incidences are between 1 percent (leukemia) and 10 percent (breast cancer in Swedish women). Therefore even in the more sensitive studies, the limits of an observable excess lifetime risk are in the order of 1/100 or 1/1000, a level the public often considers unacceptable.

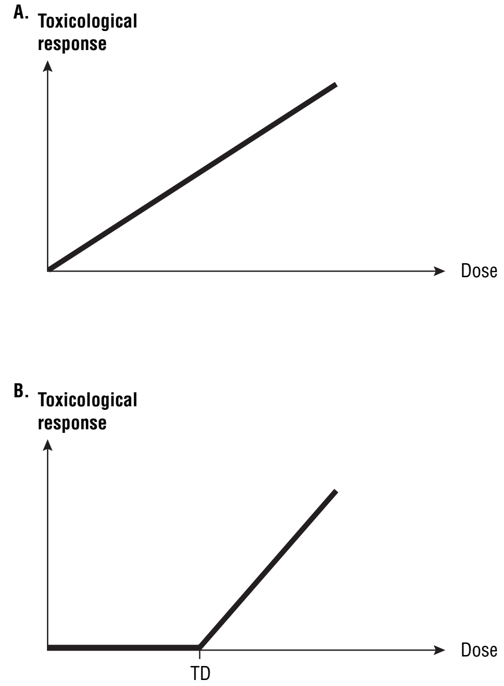
Once data are collected they are used to formulate toxicological assessments. Toxicological *health assessments* aim at identifying the potential adverse effects that a substance may cause in humans. This includes a description of the nature of these effects, their likelihood of occurrence, and their extent or severity.

The process of toxicological assessment is usually divided into four steps (National Research Council 1983, European Commission 2003). The first step of *hazard identification* aims at determining the inherent properties of a substance in order to identify the types of adverse effects to be included in further analysis.

The second step is *dose-response assessment*. The purpose of the dose-response assessment is to describe the relationship between the size of the dose and the response in the exposed. This is essential, because a high dose of a substance with low toxicity can be lethal, while a very low dose of a substance with high toxicity may be harmless. See Figure 1.

FIGURE 1

Dose-Response Relationships



TD = Threshold dose

SOURCE: Courtesy of Christina Rudén.

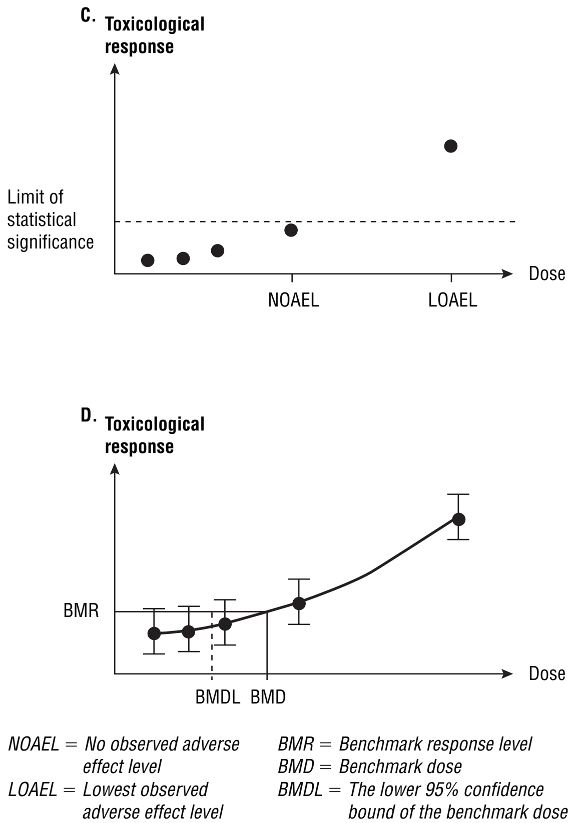
Diagram A shows a linear dose-response relationship increasing from zero exposure. In diagram B a threshold dose is indicated (denoted "TD").

The choice of a toxicological management strategy may depend on whether the dose-response relationship is considered to be linear from zero exposure or if a *threshold dose* is anticipated. A threshold dose is a dose under which no adverse effects are expected.

The lowest dose that has been shown to give rise to a statistically significant adverse effect compared to unexposed controls is the *Lowest Observed Adverse Effect Level* (LOAEL). The highest dose that has been administered without any observed statistically significant adverse effect is the *No Observed Adverse Effect Level* (NOAEL). A *benchmark dose* (BMD) is obtained by fitting a dose-response model to data, and from that model estimating a dose that corresponds to a predetermined change in the toxicological response investigated. The low-level change in response compared to background associated with the BMD is commonly termed the *benchmark response level* (BMR). Continuous dose-response data or incidence data may be used as a basis for these calculations. In the latter case, the BMD is

FIGURE 2

Effect Levels



SOURCE: Courtesy of Christina Rudén.

Diagram C shows the NOAEL/LOAEL approach, and diagram D shows the benchmark dose approach (BMD). The NOAEL/LOAEL is based on effect data for specific dose levels, while the BMD is obtained by curve-fitting of effect data.

generally defined as a 1 percent to 10 percent change in the incidence of the effect compared to background. In any case, the lower 95 percent confidence bound of the benchmark dose (the BMDL) is suggested as an alternative to NOAEL or LOAEL as a starting point for the determination of reference values for estimating acceptable exposure levels. See Figure 2.

The NOAEL, LOAEL, or BMDL should be defined for *critical effect*. Critical effect is the adverse effect that occurs at the lowest dose.

The third step is *exposure assessment*. This aims at determining the likelihood of exposure and estimates the magnitude and duration of the doses, as well as the potential exposure routes. Exposure assessment must be based on monitoring data and/or the use of theoretical exposure models.

The final step is *risk characterization*, which involves comparing the exposure data to the dose-response information in order to characterize the risk in qualitative and (if possible) quantitative terms.

Conclusive dose-response data are rarely available in humans, and therefore risk characterization often involves *extrapolation* from animal data to assess human risk. Absent contrary evidence, it is generally presumed that the effects seen in the test species under experimental conditions are relevant to humans. This presumption is supported by the fact that common test species are physiologically similar to humans.

In *environmental risk assessment* the same basic procedure applies. The outcome of hazard identification and dose-response assessment is the *Predicted No Effect Concentration* (PNEC), and exposure assessment estimates the *Predicted Environmental Concentration* (PEC). In the risk characterization process, the PEC/PNEC ratios are calculated. Extrapolation is made from experimental data (a limited number of single species) to the ecosystem (millions of species and multiple exposures interacting).

Extrapolation of data is hampered by scientific uncertainty. Resolving all uncertainties inherent in extrapolation would require testing on humans and/or an unreasonable number of animals. The presumptions used to overcome gaps of knowledge in assessment involve value judgments.

Toxicological Management

There are a number of possible risk management options in regulatory toxicology, ranging from public education to the banning of toxic substances. Two central systems are classification with labeling and exposure limits.

The *classification and labeling system* is an important part of international chemicals control because the classification process constitutes a background for further regulatory actions. According to the criteria for classification, substances (and preparations) are classified according to their inherent properties. Those fulfilling the criteria have to be provided with a warning label. Agenda 21, adopted at the United Nations Conference on Environment and Development in 1992, provided the international mandate to develop a globally harmonized system (GHS) for the classification and labeling of chemicals. The work was coordinated and managed under the auspices of the Interorganization Programme for the Sound Management of Chemicals (IOMC), administered by the World Health Organization (WHO). The aim is to have the GHS system fully implemented and operational by 2008.

Another major regulatory strategy is the setting of *exposure limits*. In the workplace such limits are called Occupational Exposure Limits (OEL), or Threshold Limit Values (TLV). Limits for exposure via food and drinking water are called Acceptable (or Tolerable) Daily Intake (ADI or TDI).

A health-based exposure limit is usually derived starting with either an experimentally estimated NOAEL/LOAEL, or a BMDL for the effect of concern. To overcome variability and other uncertainties, the experimental dose level is adjusted with an appropriate *uncertainty factor* to reach an exposure level assessed as not associated with adverse effects in humans.. The size of the uncertainty factor may vary from one to several thousands depending on the severity of the effect, the nature of the exposure, the exposed population, data-gaps, and uncertainties in the database.

Toxicological management is based on scientific evidence, but in the decision-making process nonscientific considerations are also taken into account. Examples of such considerations are the technical feasibility of the decision including availability of alternative technical processes, socioeconomic consequences, and value-based judgements of what health effects are acceptable.

RELATIVISM

SEE *Pluralism: Social Pluralism.*

RELIABILITY

• • •

The term *reliability* can be used to indicate a virtue in a person, a feature of scientific knowledge, or the quality of a product, process, or system. Personal unreliability makes an individual difficult to trust. Unreliability in science calls the scientific enterprise into question. Lack of reliability in technology or engineering undermines utility and public confidence and perhaps commercial success. In all cases the pursuit of reliability is a conscious goal.

Scientific Reliability as Replication

Reliability in science takes its primary form as replicability. Research experiments and research must be performed and then communicated in such a way that they can be replicated by others or the results cannot become part of the edifice of science. Both replicability in principle and actual replication by diverse members of the scientific community are central to the processes of science that make the knowledge produced by science uniquely reliable and able to be trusted both within the community and by nonscientists.

Replication is easier to achieve in some scientific domains than in others, but when it fails, the science is judged unreliable. Historically replication was established first in physics and chemistry, and so in the physical sciences especially lack of replicability can become newsworthy. For example, the inability of other scientists to replicate the experiments on which Stanley Pons and Martin Fleischmann based their announcement of the discovery of cold fusion in 1989 doomed the credibility of their claims.

As Harry Collins and Trevor Pinch (1998) have shown in case studies, the replication of particular experiments often depends on the phenomenon of "golden hands." Not all experimenters are equally skilled at setting up and performing experiments, and subtle differences can be more relevant than it is possible to articulate clearly in the methods section of a research article.

In science another version of replicability is associated with peer review. Peer review procedures for scientific publication and for decision making about grants in effect depend on two or more persons coming to the same conclusion about the value of a report or proposal. Assessments must be replicated among independent professionals to support reliable decisions. Several evaluations of the peer review process in various disciplines have been performed (Peters and Ceci 1982). Many of those reports suggest that the system is unreliable because reviewers often fail to agree on the quality of a scientific article. Unreliability in this process undermines the internal quality controls of science, thus hampering progress. It also raises epistemological questions about the constitution of truth.

For instance, even if two reviewers judge a paper to be of high quality, both may be mistaken because they failed to spot a statistical error. In this sense reliability (agreement between reviewers) does not constitute validity (internal consistency or the absence of obvious errors of logic) (Wood, Roberts, and Howell 2004). However, on another level the negotiation of scientific claims within the scientific community is an integral part of determining what is true. Thus, in this sense reliability is a way of making or legitimating truth claims. These issues are made more complex by the role of editors in synthesizing disparate claims by reviewers and the question of whether reliability can be assessed by the metric of agreement between reviewers.

Another example of the issue of replicability in science is associated with the development of the *Diagnostic and Statistical Manual of Mental Disorders (DSM)* in psychiatry. Before this compendium of standardized descriptions of mental disorders was published, diagnoses of psychological illnesses lacked reliability. For example, if three physicians independently saw a patient with a psychological illness, it was unlikely that they would make the same diagnosis. Indeed, this remained the case through the publication of the original *DSM* in 1952 and *DSM-II* in 1968. It was only with the increasing detail and sophistication of *DSM-III*, published in 1980, that the psychiatric community began to achieve a significant measure of reliability in its diagnostic practices and psychiatry became more respected as a science.

This case suggests the connection between reliability and professionalization (the formation of a specialized academic discipline) because replicability was made possible only after a community of practitioners developed a shared conceptual language and a methodology that were sufficiently nuanced to communicate and establish likes as likes. Reliability as a way of establishing truth through replication thus is a product of both material reality and the way peers conceptualize the world and are able to replicate that conceptualization among themselves.

Functional Reliability in Engineering

Engineering or technological reliability is the probability that a product, process, or system will perform as intended or expected. Issues include the expected level of reliability, the cost-benefit trade-offs in improving reliability, and the consequences of failure. When these issues involve persons other than those inventing or tinkering with the relevant products, processes, or systems, with consequences for public safety, health, or welfare, ethical issues become prominent. Just as in science, reliability, in this case in the form of functional reliability, is a precondition for the integration of a particular technological device into the accepted or trusted edifice of the built environment.

Any technological product, process, or system is designed to perform one or more specified functions. In principle, the performance of the system can be defined mathematically and the demands placed on the system can be specified. Because uncertainties are associated with all aspects of systems in the real world, these descriptors should be defined in terms of uncertainties and reliability should be computed as the probability of intended performance. Because most systems have effects beyond their stated output (radiation, accidents, behavior modification, etc.), a comprehensive model must include all possible outcomes. Because complicated models all are based on extrapolations of the basic principles, the fundamental concepts are described in this entry.

The demands placed on a system include environmental and operational loads, which for simplicity will be designated here as a single demand, D. The capacity of the system to absorb those loads and perform its function is designated C, for capacity. The satisfactory operation of the system simply entails that the capacity be at least as large as the demand. This is expressed mathematically as $S = C - D \geq 0$ in which S represents satisfactory performance. In probability terms this becomes $P(S) = P(C - D) \geq 0$.

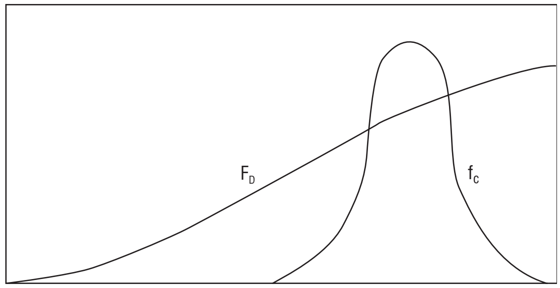
Each of these basic quantities can be described probabilistically by its probability function: $F_D(d)$ for demand and $F_C(c)$ for capacity. It is usually a safe assumption that the capacity (a function of the physical system) and the demand (a function of the operating environment) are statistically independent. In this case the reliability of the system is given by

$$P(S) = \int f_C(x) F_D(x)\, dx$$

in which $f_C(x)$ is the probability density function of the capacity (the derivative of the capacity probability function, $F_C(x)$) if the capacity is a continuous variable and otherwise is the probability mass function of the capacity (analogous to a histogram). In words the preceding equation indicates that one should assign a probability that the capacity is a particular value ($f_C(x)$) and then multiply by the probability that the demand is no greater than that value of capacity ($F_D(x)$). This process then is repeated for all possible values of the demand and the capacity, and the results are added (that is what the integration function does for continuous variables). The integrand of the equation above is shown in the Figure 1.

FIGURE 1

Capacity and Demand



SOURCE: Courtesy of Ross B. Corotis.

The probability function of demand, F_D, is multiplied by the probability density function of capacity, f_C, and the resulting quantity is then integrated over all values to yield the reliability of the system.

TIME DEPENDENCY. Most systems are not designed to be used just once but instead to perform over an intended period. In this case, the demand and the capacity become time-dependent variables and the probability of satisfactory performance is interpreted as being over an intended design lifetime. The formulation of the previous section then is interpreted as being at a single point in time, and the results are integrated over the lifetime.

Most technology displays a characteristic failure curve that is relatively steep at the beginning of the design lifetime, during which time initial defects are discovered. The failure rate then decreases to a steady-state value that exists over most of the design lifetime of the technology. As the technology nears the end of its useful lifetime, the failure rate again rises as parts begin to wear out.

When failure is due to relatively rare events such as environmental hazards, unusual parts wear, and abnormal use, simplified time-dependent models can be developed on the basis of the independent occurrence of these unusual events. These models usually are based on the Poisson process model, which is the simplest among the time-dependent processes that are referred to as stochastic processes. The Poisson model assumes that the occurrence of each event is independent of the past history of performance of the technology.

Systems reliability adds another level to this analysis. A system is a technology that is composed of multiple parts. Usually it is necessary that the parts work together properly for the system as a whole to function as desired. Systems theory builds on the theory described above to consider multiple capacities and demands, and many theories and models have been developed to analyze the risks of systems (Haimes 1998). Because systems analysis can be complicated, formalized approaches such as decision tree analysis (Clemen 1996) and event tree and fault tree analysis have been developed (Page 1989). Approximate analyses use the concepts of systems reaching a discrete number of undesirable states that are referred to as limit states. One then evaluates the probability of reaching those states by using approximate analyses such as the first-order, second-moment (FOSM) method, in which the limit state is approximated by a straight line and the full probability descriptors of the demands and capacities are approximated by the first and second moments of the probability function, which usually are the average and the standard deviation (Melchers 1999).

Software reliability can be used to illustrate some of the issues mentioned here. Newly engineered software is notoriously unreliable. After in-house testing and even after beta (user) testing in the field or market, "patches" regularly have to be introduced as new problems arise. Sometimes those problems arise because of a lack of correctness in the underlying code, and at other times because of a lack of robustness in the overall design. Software engineers also can fail to appreciate the ways users may choose to utilize a particular piece of software, and hackers and others may try to exploit weaknesses in ways that undermine reliability. As software illustrates, the pursuit of functional reliability in engineering and technology is a never-ending quest with ethical implications.

Ethics of Reliability

Despite its ethical importance in science and technology reliability has been subject to little extended ethical analysis. With regard to persons, in which case the virtue of reliability manifests itself as trustworthiness, there has been more discussion. However, the following comments on the ethics of reliability in general are only preliminary observations.

First, as has been suggested in this entry, technological reliability is what makes engineered artifice the basis for improved material well-being. It is for this reason that a few technical professional ethics codes include the promotion of reliability as an explicit obligation. For example, in the Code of Ethics (developed 1948) of the American Society for Quality (founded in 1946), the third fundamental principle commits a member to promote "the safety and reliability of products for public use." However, although in some instances unreliability in products may be attributed to a failure of intention, in other cases it is caused by evolutionary changes in nature (e.g., the evolution of antibiotic-resistant bacteria), economic change (as occurs when parts cease to be available for cars or other vehicles) or unintended consequences. Indeed, unintended consequences are one of the most common ways to conceptualize breakdowns in technological reliability as engineered devices bring about unexpected scenarios. This both raises questions about the degree to which reliability can be an ethical obligation and suggests the need for engineers to consider the wider ramifications of technology in their analyses of reliability and to build flexibility into their designs.

Another instance in which reliability has been adopted explicitly as an ethical concept related to technology occurred at a Poynter Journalism Values and Ethics in New Media Conference in 1997. That conference drafted an ethics code that included the following recommended "Online Reliability Statement":

> This site strives to provide accurate, reliable information to its users. We pledge to:
>
> Ensure information on our Web site has been edited to a standard equal to our print or broadcast standards.
>
> Notify our online users if newsworthy materials are posted from outside our site and may not have been edited or reviewed to meet our standards for reliability.
>
> Update all our databases for timeliness, accuracy and relevance.
>
> Warn users when they are leaving our site that they may be entering a site that has not embraced the content reliability protocol.

The idea here is that professional standards of reliability in the print media need to be transported consciously into a new technological media framework. Similar statements about the need for commitment to reliability in information delivery related in one way or another to technology have been discussed with regard to both medicine and computers.

With regard to science replicability generally is thought of as a self-regulating process that serves both as a method for epistemological quality control and as a way to prevent scientific misconduct, including fabrication, falsification, and plagiarism. Thus, it is a mechanism for nurturing trust within the scientific community. The dominant perception that scientists deal with absolute certainties often undermines public trust in science when scientists openly communicate uncertainties in their research or when a scientific finding of high public concern is disputed and eventually overturned ("In Science We Trust" 2001).

The notion of reliability as replicability also manifests a certain hierarchy of values or axiology in the pursuit of knowledge. Alvin Weinberg (1971) has noted that physics serves as the ideal science (of which other sciences are more or less distorted images) because of the universalizability and replicability of its findings. It most closely approximates deeply entrenched Western beliefs about truth as timeless and noncontextual. However, this ingrained cultural deference to this ideal of science can lead to misunderstandings of science and unrealistic expectations about its contributions to complex political decisions.

Questions also might be raised about the issue of reliability in ethics itself. The human sciences, including ethical inquiry, proceed by means of dialectical and hermeneutical processes that are different from the models of the engineering construction of reliable artifacts or the scientific construction of reliable knowledge claims. In the popular imagination ethical and other value claims often are treated as matters of religious commitment, subjective preference, or legalistic requirements. However, a more nuanced appreciation of the process of ethical argumentation can point to possibilities for reliability.

Substantive agreement and reliability can be found, for instance, in some common documents, such as the Universal Declaration of Human Rights of 1948. Procedural reliability is manifested in the democratic considerations of ethics and other values that also are able to proceed toward common interest solutions through reasonable argumentation, tolerance, compromise, and openness of mind, procedures not dissimilar to those involved in the pursuit of an always provisional scientific truth.

Thus, the test for reliability in ethics may not be replicability, but it also may not be as distant from the actual workings of science as is maintained by many people. Indeed, when it comes to practical affairs, the desirable trait for both science and ethics may not be replicability so much as something more akin to the functional reliability of technology. That is, reliable science and ethics, much like reliable technologies, help human beings navigate toward common goods within complex situations marked by uncertainties and pluralities.

RESEARCH ETHICS: OVERVIEW

Research ethics is typically divided into two categories: those issues inherent in the practice of research, and those that arise in the application or use of research findings. In the United States, ethical practice has come to be known as the responsible conduct of research (RCR); outside the United States another common term is good scientific practice (GSP). Ethical issues associated with the application of research findings deal with their use in the support of legal, social, or economic policy as well as their technological applications (e.g., genetic engineering in therapy and agriculture, bioweapons development, and dam siting and construction).

Many entries in the *Encyclopedia of Science, Technology, and Ethics* cover different aspects of research ethics in more detail. Prime examples include the entries on "Responsible Conduct of Research" and "Scientific Integrity," the composite on "Misconduct in Science," and the series dealing with various aspects of genetics. The focus here is on a more synthetic overview that also highlights some points missing elsewhere.

Background

Both aspects of research ethics came to the forefront of public attention at the end of World War II and have developed more fully over the mid-twentieth century. Leading discussions have often but not always taken place in the United States.

RESEARCH PRACTICE. Initially ethical concerns regarding research practice emphasized the use of humans as research subjects. The revelation of Nazi atrocities at the close of World War II focused international attention on research that subjected individuals to high altitude experiments in low-pressure chambers, freezing due to exposure or submersion in ice water, starvation or seawater as their primary source of fluids, and infection with malaria, typhoid, streptococcus, and tetanus. Judges presiding over the trial of Nazi physicians drafted the Nuremberg Code (1946), which has since been followed by additional ethical codes most prominently the World Medical Association Declaration of Helsinki (1964; most recently revised in 2002). For further depth on these issues see the entries on "Nazi Medicine" and "Human Subjects Research."

In the early 1970s the U.S. Tuskegee Syphilis studies came to light (see "Tuskegee Experiment) and focused national attention on human subjects treatment in the United States. This research, carried out from 1932 to 1972, recruited disadvantaged, rural black males who had contracted syphilis to participate in the study of the course of untreated disease. Although no clearly effective treatment was initially available, when it became apparent that penicillin was effective, participants were not given this medication. When these studies were made known, the U.S. Congress mandated a commission to identify, develop, and articulate the ethical principles that underlie and must guide the acceptable use of human volunteers and subjects in biomedical research. The commission's work resulted in the Belmont Report (National Commission 1978) that serves as the foundational document for research involving humans in the United States.

In the 1980s other egregious examples of scientific misconduct were exposed, including the fabrication and falsification of data, and plagiarism (Broad and Wade 1982, LaFollette 1992). While these were not the first instances of misconduct in science—the Piltdown Man fraud was initiated in 1912—they raised serious concerns not only within but beyond the scientific community. Indeed the U.S. Congress began to demand more consistent oversight of the process of research funding which led to establishment of the Office of Scientific Integrity within the National Institutes of Health that ultimately became the Office of Research Integrity (ORI) in the Department of Health and Human Services.

Moreover, within the scientific community, it became clear that concerns regarding serious scientific misconduct were only the tip of the iceberg in the sense that the professional standards, expectations of colleagues, and ethical values of the research community with regard to many aspects of research practice were not clearly articulated nor widely understood. There was, and is, a wide range of accepted practices without much discussion of the underlying assumptions and wider implications that place those practices along the continuum of preferred, acceptable, discouraged, and prohibited practices. As a result, trainees and even more established researchers are not always clear about the acceptability of established or ongoing practices within the community.

For example, while plagiarism (the misrepresentation of the writings or ideas of another as one's own) is clearly deceptive and unacceptable, other publication practices can also be problematic. The practice of "honorary" authorship—that is, including in the list of authors individuals who have not made a clear and significant intellectual contribution to the published work—became increasingly widespread over the latter part of the twentieth century. The practice of adding names to the list of authors (sometimes without the knowledge or consent of the individual "honored") in exchange for a reagent, a strain of mice, laboratory space, or past tutelage not only tends to "dilute" the apparent contribution of other authors (depending on a reader's assumptions), but also to deny honorary authors any opportunity to make fully informed decisions about their associations with the work.

APPLICATION OF RESEARCH FINDINGS. The end of World War II also brought greater awareness of the ethical implications of the uses of science and technology. The use of the atomic bomb by the United States on Japan raised a host of questions regarding the social responsibility of scientists and engineers for the consequences of their work. The Manhattan Project reflected a national priority to devote all resources, including scientific expertise to winning the war. Yet those working on the project could only speculate on the immediate and long-term health and environmental effects of an atomic explosion. Moreover, as scientist J. Robert Oppenheimer mused, the science was so "technically sweet" that its appeal overrode concerns about the creation of an enormously destructive bomb so unlike the conventional weapons with which people were already familiar.

In the 1960s Rachel Carson and others called attention to the dangers of chemical pollutants in the environment, and reactions took place against some of the kinds of chemicals being used in many agricultural, industrial, and military activities. In the 1970s developments in molecular biology (specifically techniques with recombinant DNA) led researchers to convene a conference in Asilomar, California, to discuss the implications and potential hazards of genetic engineering. This is often identified as the first widespread, proactive effort on the part of the scientific community to acknowledge and address its social responsibility.

The discussion has become more nuanced and complex as the impact of human activity on the environment and on other species as well as other human populations has become more apparent. Whether in the construction of large engineering projects such as dams that dramatically alter the landscape, inundate archaeological treasures, and displace the local population, or in the oftentimes poorly executed use of genetically engineered crops in developing nations, or in many other technological applications, their larger ethical and social implications have become the focus of increasing examination, debate, and institutional reform.

The Responsible Conduct of Research and Good Scientific Practice

Progress in science depends on trust between scientists that results have been honestly presented. It also depends on members of society trusting the honesty and motives of scientists and the integrity of their results (European Science Foundation 2000). Fostering this trust requires clear and strong ethical principles to guide the conduct of scientific research. In the United States, ethical research practice is generally referred to as RCR or the responsible conduct of research. The ORI, the U.S. federal agency primarily concerned with education in RCR, has identified nine core instructional areas in RCR (Office of Research Integrity 2005, Steneck 2004). Areas (1) through (5) deal with the actual conduct of research while areas (6) through (9) are associated with interactions between members of the scientific community.

1. Data Acquisition, Management, Sharing, and Ownership. This area focuses on the ways in which data are recorded, whether in notebooks or in other formats (such as electronic records, photographs, slides, etc.), and how and for how long they should be stored. It explores as well the question of who owns the data, who is responsible for storing them, and who has access to them. Issues of privacy and confidentiality of patient information as well as intellectual property issues and copyright laws are included.
2. Conflict of Interest and Commitments. Discussion of conflicting interests and commitments acknowledges the potential for interference in objective evaluation of research findings as a result of financial interests, obligations to other constituencies, personal and professional relationships, and other potential sources of conflict. It also considers strategies for managing such conflicts in order to prevent or control inappropriate bias in research design, data collection, and interpretation.
3. Human Subjects. Ethical treatment of human research subjects references the requirements of the Office of Human Research Protections (OHRP), which are based on the ethical principles outlined in the Belmont Report (National Commission 1978). These principles include especially (a) respect for persons as expressed in the requirement for informed consent to participate and protection of vulnerable populations such as children and those with limited mental capacity; (b) emphasis on beneficence that maximizes the potential benefits of the research and minimizes risks; and (c) attention to considerations of justice in the form of equitable distribution of the benefits and burdens of the research across populations. Adequate attention to patient privacy and the variety of potential harms including psychological, social, and, economic is essential.
4. Animal Welfare. Research involving animals emphasizes animal welfare in accordance with the regulations of the Office of Laboratory Animal Welfare (OLAW). Principles here emphasize respect for animals used in research (Russell and

Burch 1959) in the form of "the three Rs": reduction of the number of animals used, replacement of the use of animals with tissue or cell culture or computer models or with animals lower on the phylogenetic scale whenever appropriate and possible, and refinement of the research techniques to decrease or eliminate pain and stress.

5. Research Misconduct. Dealing with allegations of research misconduct is essential given its potential for derailing a research career. Definitions of scientific misconduct, including fabrication, falsification, and plagiarism as well as other serious deviations from accepted practice that may qualify as scientific misconduct, as distinguished from error, and protections for whistleblowers are important components of this topic.
6. Publication Practices and Responsible Authorship. Publication practices and responsible authorship examine the purpose of publication and how that is reflected in proper citation practice, criteria for authorship, multiple, duplicate and fragmentary publication, and the pressure to publish. This area also considers allocation of credit, the implications and assumptions reflected in the order of authors, and the responsibility of authorship.
7. Mentor/Trainee Responsibilities. The mentor/trainee relationship encompasses the responsibilities of both the mentor and the trainee, collaboration and competition, possible conflicts and potential challenges. It also covers the hierarchy of power and potential for the abuse of power in the relationship.
8. Peer Review. The tension between collaboration and competition is embodied in the peer review process for both publication and funding. In this area of RCR issues associated with competition, impartiality and confidentiality are explored along with the specifics of the structure and function of editorial and review boards and the *ad hoc* review process.
9. Collaborative Science. Not only does research build on the work of others, but more and more investigators from disparate fields work together. The collaborative nature of science requires that often implicit assumptions about common practices such as authorship and data sharing need to be made explicit in order to avoid disputes.

In Europe, the term of art for discussion of research ethics is GSP or good scientific practice (European Science Foundation 2000). However, unlike RCR, which emphasizes guidelines for positive research behaviors, there is a tendency in other countries to emphasize the avoidance of negative behaviors. This means that despite the name (good scientific practices) discussion focuses on scientific misconduct. For instance, it the pursuit of GSP, the U.K. Office of Science and Technology (OST), the oversight body of the U.K. Research Councils, categorizes scientific misconduct into two broad groups. The first pertains to the fabrication and falsification of research results. The second category pertains to plagiarism, misquoting, or other misappropriation of the work of other researchers. The OST statement "Safeguarding Good Scientific Practice" (1998) stresses the need to avoid misconduct by means of self regulation of and by the research community, arguing that "Integrity cannot be prescribed" (Office of Science and Technology).

With the creation of the Danish Committee on Scientific Dishonesty in 1992, Denmark became the first European country to form a national body to handle cases of scientific dishonesty—again with the aim of promoting GSP. This has prompted similar practices in other Scandinavian countries (Vuckovic-Dekic 2000).

A serious case of scientific misconduct in Germany in 1998 sparked the creation of the international Commission on Professional Self Regulation in Science. This Commission was charged to explore causes of dishonesty in the science system, discuss preventive measures, examine the existing mechanisms of professional self regulation in science, and make recommendations on how to safeguard them. It published a report titled "Proposals for Safeguarding Good Scientific Practice," which advised relevant institutions (universities, research institutes, and funding organizations) to establish guidelines of scientific conduct, policies for handling allegations, and rules and norms of good practice (Commission on the Professional Self Regulation in Science 1998). Fearing over-regulation, the commission recommended that institutions retain authority for establishing misconduct policies (rather than establishing a centralized committee as in the United States and Denmark).

Ethical Issues in the Application of Research

The Enlightenment creed *Sapere aude!* (Dare to know!) symbolized the distinctively modern belief that scientific research is an ethical responsibility, indeed a moral obligation of the highest order. Ancient or premodern thinkers generally maintained that there were limits to the quest for knowledge, beyond which lay spiritual and physical dangers. Although there is a long tradition of critiques of this foundational modern commitment (e.g., Wolfgang von Goethe's *Faust* and Mary Shelly's *Frankenstein*), they have become more refined, extended, and institutionalized in the latter half of the twentieth century as science and technology began to profoundly alter both society and individual lives. The ramifications of various technological developments (e.g., atomic energy, genetic engineering) have demonstrated that unfettered research will not automatically bring unqualified goods to society.

Daniel Callahan (2003) has argued that there is a widespread assumption of the "research imperative," especially in the area of biomedicine and health care. Though a complex concept, it refers to the way in which research creates its own momentum and justification for gaining knowledge and developing technological responses to diverse medical conditions. It can pertain to the ethically dubious rationale of pursuing research goals that are hazardous or of doubtful human value, or the rationale that the ends of research justify the means (no matter how abhorrent). It can also pertain to the seemingly noble goal of relieving pain and suffering. Yet this commitment to medical progress has raised health care costs and distracted attention from the ultimate ends of individual happiness and the common good. Research, no matter how honorable the intent of those performing and supporting it, must be assessed within the context of other goods, rather than elevated as an overriding moral imperative (Jonas 1969, Rescher 1987).

As is considered in entries on "Science Policy" and "Governance of Science," the core assumption of the inherent value of research was operationalized in post-World War II U.S governmental policies for the funding of scientific research. What came to be known as the "linear model" of science-society relations posited that investments in "basic" research would automatically lead to societal benefits (Price 1965). However, the framers of this policy never specified how this "central alchemy" would occur, and they did not adequately address the need to mitigate negative consequences of scientific research (Holton 1979). The economic decline of the late 1970s and 1980s, the end of the cold war in the early 1990s, and the growing federal budget deficits of the same period combined to stimulate doubts about the identity of purpose between the scientific community and society (Mitcham and Frodeman 2004).

The very fact that societal resources are limited for the funding of scientific research has stimulated questions about what kind of science should be pursued. For instance, physicist and science administrator Alvin Weinberg argued in the 1960s that internal assessments of the quality of scientific projects and scientific researchers should be complemented by evaluation of scientific merit as judged by scientists in other disciplines, of technological merit, and of social merit. For Weinberg, because of the limited perspective of those within the community, "the most valid criteria for assessing scientific fields come from without rather than from within the scientific discipline that is being rated" (1967, p. 82).

Put simply, while the internal ethics of research asks: "How should we do science?" the external ethics of research takes up a suite of questions involving participants beyond the immediate scientific community and addressing more fundamental ends. As Daniel Sarewitz (1996) noted the pertinent questions are "What types of scientific knowledge should society choose to pursue? How should such choices be made and by whom? How should society apply this knowledge, once gained? How can "progress" in science and technology be defined and measured in the context of broader social and political goals?" (p. ix).

Myriad attempts have been made to reformulate the relationship between scientific research and political purposes, where the criteria for assessing science derive partially from without rather than from within a particular scientific discipline. Models include Philip Kitcher's ideal of "well-ordered science" (2001) and the concept of "use inspired basic research" put forward by Donald Stokes (1997). Such revised social contracts for science shift the focus from maximizing investments in research to devising mechanisms for directing research toward societal benefits; a shift from "how much?" to "toward what ends and why?" Legislation such as the 1993 U.S. Government Performance and Results Act (GPRA) reflects this focus on the social accountability of publicly funded science, as do technology assessment institutions and ethical, legal, and social implications research performed in conjunction with genome and nanotechnology research.

The prioritization of research projects is another important area in this regard, including the issue of how much money to allocate to the study of different diseases, which often raises ethical concerns about systematic discrimination. The effective use of scientific research and technologies in development policies intended to decrease poverty and improve the health of those in developing countries is a related topic. Diverse experiences with the Green Revolution, for example, show the importance of context in directing research toward common interests and away from negative outcomes such as ecological harms and the exacerbation of wealth disparities. Both of these topics raise the important issue of the role of various publics in guiding and informing scientific research and technological applications.

Although it is still largely true that "more money for more science is the commanding passion of the politics of science" (Greenberg 2001, p. 3), a number of critics and policy makers understand that more is not necessarily better. Scientific progress does not always equate to societal or personal progress in terms of goals such as safety, health, and happiness (Lightman, Sarewitz, and Desser 2003). The potential unintended physical harms that may result from scientific research have long been recognized and debated in terms of the roles of scientists and non-scientists in risk assessment. More recent developments, especially in bio- and nanotechnology research, and the growing specter of catastrophic terrorist attacks have lent a more urgent tone to questions about "subversive truths" and "forbidden knowledge" (e.g., Johnson 1996).

Limiting scientific research raises practical questions such as "Who should establish and administer controls?" and "At what level should the controls be imposed?" (Graham 1979). Some (e.g., McKibben 2003) have advocated the large scale relinquishment of whole sectors of research such as nanotechnology. Others, including the innovator Ray Kurzweil, argue for a more fine-grained relinquishment and the prioritizing of funding for research on defensive technologies to counteract potential misuses of science. This view holds that the optimal response to the potential for bioterrorism, for example, is to lessen restrictions on and increase funding for bioweapons research so that preventive measures and cures can be developed.

Discussion of the ethical implications of the use of scientific research is, at its core, about procedures for democratic decisions and the allocation of authority and voice among competing societal groups. This can be construed in broad terms ranging from criticisms of Western science as a dominant even hegemonic way of knowing that drowns out other voices, to defenses of science as an inherently democratizing force where truth speaks to power. These vague issues take on importance in concrete contexts that concern judgments about the appropriate degree of scientific freedom and autonomy within democratic societies. The most important area in which these issues arise is the use of scientific knowledge in formulating public policies.

Although bureaucratic political decision-making has come to rely heavily on scientific input, it is not obvious how the borders and interstices between science and policy should be managed. On the one hand, it seems appropriate that research undertaken by scientific advisory panels (as distinct from research in general) be somehow connected to the needs of decision makers. On the other hand, sound procedures for generating and assessing knowledge require a degree of independence from political (and corporate) pressures. Failure in the first instance leads to generation of irrelevant information and often delayed or uninformed action. Failure in the second case leads to conflicts of interest or the inappropriate distortion of scientific facts to support preexisting political agendas (Lysenkoism is an extreme example) or corporate policies.

The latter instance is often couched in terms of the "politicization of science," which is a perennial theme in science-society relationships (e.g., Union of Concerned Scientists 2004). Yet in order to attain the democratic ideal of being responsive to the desires and fears of all citizens, the politicization of science in the sense of explicitly integrating it into the larger matrix of goods (and evaluating it from that standpoint) is proper. Scientific research can be "misused" when it is inappropriately mischaracterized (e.g., to over-hype the promise of research to justify funding) or delegitimized (Pielke 2004) and it is important to enforce ethical guidelines against these practices. However, the more common misuse of science that ranges from intentional to unconscious, is the practice of arguing moral or political stands through science (Longino, 1990). This can inhibit the ethical bases of disputes from being fully articulated and adjudicated, which often prevents science from playing an effective role in policy making (Sarewitz 2004).

Teaching Research Ethics

Science educators and researchers have generally believed their responsibility was to teach scientific concepts and laboratory techniques, and it was expected that professional values and ethical standards would be picked up by observing good examples. However, as a result of well-publicized and serious instances of scientific misconduct in the 1980s, the research community has become aware of the need to address the responsible conduct of research explicitly. Thus in 1989 the U.S. National Institutes of Health (NIH) began calling for formal instruction for NIH funded pre- and post-doctoral trainees in the responsible conduct and reporting of research (National Institutes of Health 1989). Moreover, in support of expanding the NIH requirement, both the report of the Commission on Research Integrity, "Integrity and Misconduct in Research" (1995) and the report of the international Commission on Professional Self Regulation in Science, "Proposals for Safeguarding Good Scientific Practice" (1998), highlighted the fact that education in RCR /GSP has been largely neglected worldwide and should be addressed for both trainees and senior scientists. In addition, recognition of the ethical implications of science and technology has led to the incorporation of these topics into many courses and programs aimed at teaching research and engineering ethics. It is widely appreciated that students need to understand that science and technology are not value free and that scientific information can be used for good or ill, misused or abused.

While it is widely believed that "by the time students enter graduate school, their values and ethical standards are so firmly established that they are difficult to change" (Swazey 1993, pp. 237–38) there is a solid body of evidence that supports the view that in fact adults *can* be taught to behave ethically through specific educational programs introduced at the undergraduate and postgraduate level (Rest et al. 1986; Bebeau et al. 1995). This is closely linked to the individual's reconceptualization of his or her professional role and relationship to society. Educational programs can affect awareness of moral problems and moral reasoning and judgment. Moreover, studies show that moral perception and judgment influence behavior.

There is some controversy regarding the emphasis of research ethics education, that is, whether to focus on the rules and regulations, expectations and standards of the research community, or to emphasize moral development. However in reality, teaching research ethics entails both communicating the standards and values of the community and promoting moral development through increased ethical sensitivity and ethical reasoning. Thus the goals of education in research ethics are to:

1. Increase awareness and knowledge of professional standards. Toward this end, professional standards and ethical values of scientific research and conventions are identified and clarified, as is the range of acceptable practices along the continuum of preferred, acceptable, discouraged, and prohibited. In the process, the assumptions that underlie accepted practices are examined and the immediate and long-term implications of these practices are assessed.

2. Increase awareness of ethical dimensions of science. This includes examination of the issues associated with both research practice and the application of research findings.

3. Provide experience in making and defending decisions about ethical issues. Case studies designed to illustrate common research practices and situations are generally used. Discussion of these cases invariably entails in-depth analysis of affected parties, points of conflict, implications of various courses of action, and examination of the expectations, needs and responsibilities of the different characters in the scenario.

4. Promote a sense of professional responsibility to be proactive in recognizing and addressing ethical issues associated with research.

A number of key characteristics of educational programs in research ethics have been identified (Bird 1999, Institute of Medicine 2002). These reflect principles of effective adult education as well as common sense. Programs that are *required* emphasize the view that ethical issues are inherent in research and that awareness of the ethical values and standards of the research community are an essential component of professional education. *Interactive* discussion of ethical issues and concerns raised by a realistic case provides participants with an opportunity to share their experience and solve problems in a context. This approach employs principles of learning science that have been identified through research on how people learn (Bransford et al. 1999). *Broad faculty involvement* in educational programs in research ethics demonstrates that this is valued by professionals across the discipline and incorporates a variety of experience and a range of perspectives with regard to accepted practices. Programs should *begin early* in research education (e.g., undergraduate science laboratory courses) and *continue* throughout college and graduate or other professional education. In so doing, individuals can reflect on their own experience, and their understanding and appreciation of ethical concerns and strategies for problem solving can evolve. When the various components of graduate education (i.e., courses, seminars, laboratory meetings, etc.) address ethical issues they *reinforce and complement* each other.

A variety of formats and strategies have been developed to teach research ethics. The most effective are case-based and integrate discussion of research ethics into all of the various elements of research education: as modules in core courses, stand-alone full semester or short courses on research ethics, departmental seminars, workshops, laboratory and research team meetings, one-on-one interactions between trainees and research supervisors, and computer-based instruction (Swazey and Bird 1997, Institute of Medicine 2002). Each approach has strengths and weaknesses.

Through explicit discussion of ethical issues associated with the practice of research and the application of research findings the research community acknowledges the complexity of the issues and the need to address them. Specifically addressing RCR reaffirms the responsibility of the research community for research integrity, individually and collectively, and the necessity of providing this information to its members. Identifying and examining the ethical issues associated with the application (or misapplication) of research findings emphasizes the responsibility of researchers and of citizens in general to examine and assess the ramifications of science and technology for society.

Bush have suppressed or distorted research findings and undermined the quality and integrity of the appointment process.

RESEARCH INTEGRITY

Integrity (from the Latin *integritas*, meaning *whole* or *complete*) refers in ethics to adherence to a code or a usually high standard of conduct. Research integrity thus indicates doing research in accord with standards that properly inform and guide that activity—without deviance under any inappropriate influences. Integrity in this sense has close correlates with authenticity and accountability. Research integrity is also often considered the flip side of research misconduct. Whereas the topic of research misconduct concentrates on the definition, identification, adjudication, and consequences of malfeasance committed by scientists in the course of their research; research integrity concentrates on, as the Institute of Medicine's 2002 report, *Integrity in Scientific Research*, was subtitled: "creating an environment that promotes responsible conduct" of research (Institute of Medicine, p. x). Having received considerable public attention since the 1980s, however, research integrity is a contested issue both within the scientific community and between the community and its patrons.

Public and Professional Tensions

Part of the conflict over research integrity occurs over identifying the appropriate code or standard. Sociologist Robert K. Merton (1973) described four norms of science—communalism (or communism), universalism, disinterestedness, and organized skepticism—that are often cited as antecedent to codes to which scientists are supposed to adhere. But other scholars argue that such norms are not well recognized among all scientists

(Mitroff 1974), or that they are merely self-serving *vocabularies of justification* for scientific autonomy (Mulkay 1975), or that they might have served as guideposts historically but that they are being supplanted by counter-norms that are more bureaucratic and commercially oriented (Ziman 1990).

Many professional societies have written or revised codes of ethics or guidelines for research integrity that encompass normative issues ranging from formal, regulatory definitions of research misconduct (for example fabrication, falsification, and plagiarism) to more subtle professional behavior such as authorship practices and mentorship. In the early-twenty-first century, professional bodies such as the Accrediting Board for Engineering and Technology (ABET) require training in ethics and research integrity for accredited undergraduate engineering programs. Scientific journals have also assumed an active role in defining integrity for their authors around topics such as credit for authorship, conflict of interest, and responsibility for corrections and retractions.

Research integrity is often connected not only with the attempt of the scientific community to encourage ethical behavior within its own ranks, but also with its attempt to maintain professional autonomy from public interference. As such, it is an aspect of the social contract for science in which the scientific community implicitly promised to maintain the integrity of its research in exchange for an unusual lack of oversight—despite public patronage. This tacit agreement was substantially reconfigured during the 1980s and 1990s, as both parties recognized that the promotion and assurance of research integrity must be a collaborative, rather than an autonomous, enterprise (Guston 2000).

The public patrons of research in liberal democracies have a special interest in research integrity not only because of the instrumental use of science and technology for public purposes (for example, only good science can lead to the promises of health, economic advancement, environmental quality, and military security, among others), but also because of the ideological support that good science offers the state by demonstrating its effectiveness and by reifying the concepts of representation and causality upon which representative government is based (Ezrahi 1990). In the United States, research integrity has become a pressing issue to the funding agencies and professional societies that mediate between public patrons and practicing scientists. A driving force for attention to research integrity was the promulgation of rules in 1990 by the National Institutes of Health (NIH) to require institutions participating in training grants to provide training in the responsible conduct of research. Such training often includes discussions not only of misconduct, but also of whistle-blowing, the protection of human and animal research subjects, the mentoring relationship, and the consequences of recently emergent economic relations in research including conflicts of interest and intellectual property rights. In 2000 the Office of Research Integrity (ORI) of the U.S. Public Health Service proposed more specific and broadly applicable rules for training in the responsible conduct of research, but as of 2004 these rules had not been implemented.

Because of the increasing recognition that the effects of research—for good or for ill—go beyond the scientific community, there is increasing attention as well to what some (particularly in engineering ethics) call *macroethics*, or the responsibility that scientists and engineers have to behave with integrity not just toward each other and toward their direct patrons but to society more broadly conceived (Herkert 2001). This agenda includes helping to craft private and public policies that make appropriate use of science and its products, assuring that the knowledge-based innovations to which they contribute are not only technically virtuous but socially benign, and even accepting greater involvement of non-scientists in some aspects of technical decision making. This agenda has historical roots, for example, in the characterization of activism by atomic physicists in nuclear weapons policy or molecular biologists in recombinant DNA policy as *scientific responsibility*.

Unresolved Questions

Despite increasing recognition of the importance of research integrity to both the scientific community and the broader society, and the consequent need for collaboration to assure it, several questions remain. One is whether the primary responsibility for assuring the integrity of research lies with individual researchers; research institutions such as universities, professional societies and the community of science; or public patrons of research. The Institute of Medicine (2002) concludes that research institutions should have the primary role, but that public patrons of research have an important oversight role and that individual integrity is still the backbone of the system.

A second question is, given the importance of some institutional role in research integrity, why so few exist. As one such institution, ORI—initially created to investigate allegations of research misconduct—has, in the early-twenty-first century, been changing its agenda toward encouraging training in research integrity and even sponsoring *research on research integrity*. The National Science Foundation (NSF) has also sponsored projects on research integrity, including the On-Line Ethics Center.

A third question is whether greater collaboration between science and society may legitimate an increasingly malign political interference, rather than a benign influence, on public science. The Waxman report, which issued from the U.S. House of Representatives, and a similar report from the Union of Concerned Scientists in 2004, for example, claim to document dozens of threats to research integrity from the intrusion of political agendas into scientific and technical decision making in the bureaucracy.

A fourth question, which makes the others all the more difficult to manage, is—as the Institute of Medicine (2002) concluded—how to create reliable ways to assess the overall integrity of the research environment, as well as the efficacy of any particular interventions (including educational ones). The lack of empirical evidence means that the scientific community can legitimately call for additional research on research integrity, but it also means that political demands for action may be met with less than satisfactory responses.

RESPONSIBILITY

Overview
Anglo-American Perspectives
German Perspectives

OVERVIEW

Ethical responsibility is one of the most commonly employed concepts in discussing the ethics of science and technology. Scientists have obligations for the "responsible conduct of research." The professional responsibility of engineers calls for attending to the public safety, health, and welfare consequences of their work. Entrepreneurs have responsibilities to commercialize science and technology for public benefit, and the public itself is often called on for the responsible support of science and technology. Consumers are admonished to be responsible users of technology. Yet the abstract noun *responsibility* is no more than 300 years old and has emerged to cultural and ethical prominence in association with modern science and technology from diverse legal, social, professional, religious, and philosophical perspectives.

Legal Responsibility

The legal term for responsibility is *liability*. Law makes explicit certain customary understandings of liability in two areas: criminal law and civil law. Criminal law deals with those offenses prosecuted and punished by the state. Civil law includes breaches of explicit or implicit contract in which injured parties may sue for compensation or damages.

Criminal liability was originally construed to follow simply from a transgression of the external forum of the law—doing something the law proscribes or not doing something it prescribes. But as it developed in Europe under the influence of a Christian theology of sin, which stresses the importance of inner consent, criminal liability was modified to include appreciation of the internal forum of intent. The result is a distinction between unintended transgressions such as accidental homicide and intentional acts such as first-degree murder; punishments for the former are less severe than for the latter.

In contrast to the historical development of restrictions on criminal liability, civil liability has expanded in scope through delimitions on the requirements for intentionality. Civil liability can be incurred by contract or it can be what is called "strict liability." In the case of explicit or implicit contract, intentional fault or negligence (a kind of failure of intention) must be proved. In the case of strict liability there need be no fault or negligence per se.

The concept of strict or no-faulty liability as a special kind of tort for which the civil law provides redress developed in parallel with modern industrial technology. In premodern Roman law, for instance, an individual could sue for damages only when losses resulted from intentional interference with person or property, or negligence. By contrast, in the English common law case of *Rylands v. Fletcher*, decided on appeal by the House of Lords in 1868, Thomas Fletcher was held liable for damages caused by his industrial undertakings despite their unintentional and nonnegligent character. Fletcher, a mill owner, had constructed a water reservoir to support his mills. Water from the reservoir inadvertently leaked through an abandoned mine shaft to flood John Rylands's adjacent mine. Although he admitted Fletcher did not and perhaps could not have known about the abandoned mine shaft, Rylands sued for damages. The eventual ruling in his favor argued that the building of a dam, which raised the water above its "natural condition," in itself posed a hazard for which Fletcher must accept responsibility.

In the early twenty-first century, the most common kinds of civil liability are just such no-fault or prima facie liabilities related to "nonnatural" industrial workplaces and consumer products in which activities or artifacts in themselves, independent of intent, pose special hazards. In the United States one of the key cases establishing this principle was that of *Greenman v. Yuba Power Products, Inc.*, decided on appeal by the California Supreme Court in 1963. In the words of Chief Justice Roger Traynor, in support of the majority:

> A manufacturer is strictly liable in tort when an article he places on the market . . . proves to have a defect that causes injury to a human being. . . . The purpose of such liability is to insure that the costs of injuries resulting from defective products are borne by the manufacturers . . . rather than by the injured persons who are powerless to protect themselves.

Religious Responsibility

The term *responsibility* derives from the Latin *respondēre*, meaning "to promise in return" or "to answer." As such it readily applies to what is perhaps the primordial experience of the Judeo-Christian-Islamic tradition: a call from God that human beings accept or reject. Given this reference—together with its regular embodiment in the "responsorials" of liturgical practice—it is remarkable that the term did not, until the twentieth century, play any serious role in European religious-ethical traditions.

The discovery and development of religious responsibility has again paralleled rising appreciation of the ethical issues emerging from science and technology. It is in opposition, for instance, to notions of secularization and control over nature that the Protestant theologian Karl Barth (1886–1968) distinguished between worldly and transcendent relationships. God is the wholly other, the one who cannot be reached by scientific knowledge. There is thus a radical difference between the human attempt to reach God (which Barth calls religion) and the human response to God's divine revelation (a response Barth identifies as faith). In his *Church Dogmatics* (1932) Barth goes so far as to identify goodness with responsibility in the sense of responding to God.

Catholic theologians have been no less ready to make responsibility central to ethics. For the Canadian Jesuit Bernard Lonergan (1904–1984), "Be responsible" is a transcendental precept coordinate with duties to "Be attentive," "Be intelligent," and "Be reasonable." Responsibility also plays a prominent role in the documents of Vatican II. At one point, after referencing the achievements of science and technology, *Gaudium et Spes* (1965) adds that, "With an increase in human powers comes a broadening of responsibility of the part of individuals and communities" (no. 34). Later, this same document on the church in the modern world suggests that, "We are witnesses of the birth of a new humanism, one in which man is defined first of all by his responsibility toward his brothers and toward history" (no. 55).

The most sustained effort to articulate a Christian ethics of responsibility is, however, that of H. Richard Niebuhr's *The Responsible Self* (1963). In this work Niebuhr contrasts the Christian anthropology of the human-as-answerer to the secular anthropologies of human-as-maker and human-as-citizen. For human-as-maker, moral action is essentially consequentialist and technological. For human-as-citizen, morality takes on a distinctly deontological character. With human-as-answerer, the tension between consequentialism and deontology is bridged by responsiveness to a complex reality, by an interpretation of the nature of this reality—and by an attempt to fit in, to act in harmony with what is already going on. "What is implicit in the idea of responsibility is the image of man-the-answerer, man engaged in dialogue, man acting in response to action upon him" (p. 56). Niebuhr's ethics of responsibility is what might now be called an ecological ethics.

Responsibility in Philosophy

The turn to responsibility in philosophy, like that in theology, exhibits two faces: first, a reaction to the challenge posed by the dominance of scientific and technological ways of thinking; and second, an attempt to take into account the rich and problematic complexity of technological practice. The first is prominent in Anglo-American analysis discourse, the second in European phenomenological traditions of thought.

According to Richard McKeon (1957), interest in the concept of responsibility can be traced to diverse philosophical backgrounds, one of which is the Greek analysis of causality (or imputability) and punishment (or accountability) for actions. As McKeon initially notes: "Whereas the modern formulation of the problem [of responsibility] begins with a conception of cause derived from the natural sciences and raises questions concerning the causality of moral agents, the Greek word for cause, *aitia* (like the Latin word *causa*), began as a legal term and was then extended to include natural motions" (pp. 8–9). But it was in efforts to defend moral agency against threats from various forms of scientific materialism that the term became prevalent in analytic philosophy. For instance, H. L. A. Hart's distinctions between four kinds of responsibility—role, causal, liability, and capacity—(Hart 1968) are all related to issues of accountability as they arise in a legal framework, where they can help articulate a theory of punishment to meet the challenges posed by modern psychology.

McKeon's general thesis is that the term *responsibility* appeared in late-eighteenth and early-nineteenth-century moral and political discourse—as an abstract noun derived from the adjective *responsible*—in coordination with the expansion of democracy. But there are also numerous historical connections between the rise of democracy and the development of modern technology. On the theoretical level, the possessive individualism of *homo faber*, developed by Thomas Hobbes and John Locke, prepared the way for democracy and the new industrial order. On the practical level, democratic equality and technology clearly feed off one another.

But the connection goes deeper. According to McKeon, responsibility was introduced into the political context because of the breakdown of the old social order based on hierarchy and duty, and the inability of a new one to function based strictly on equality and self-interest. Whereas the former was no longer supported by the scientific worldview, the latter led to the worst exploitative excesses of the Industrial Revolution. To address this crisis there developed the ideal of relationship, in which individuals not only pursued their own self-interest but also tried to recognize and take into account the interests of others.

Something similar was called for by industrial technology. Good artisans, who dutifully followed the ancient craft traditions, were no longer enough, yet neither should they just be turned loose to invent as they pleased. Thomas Edison, after creating a vote register machine for a legislature, in which he subsequently discovered the legislature had no interest, resolved never again to invent simply what he thought the world needed without first consulting the world about what it wanted. The new artisan must learn to respond to a variety of factors—the material world, the economy, consumer demand, and more. This is what turns good artisans into responsible inventors and engineers. As their technological powers increase, so will their need to respond to an increasing spectrum of factors, to take more into account. Carl Mitcham (1994) has described this as a duty *plus respicere*, from the Latin to include more in one's circumspection.

Another argument to this effect is provided by John Ladd (1981) who, in considering the situation of physicians, argues that the expansion of biomedical technology has increased the private practitioner's dependence on technical services and undermined professional autonomy. Moral problems concerning physicians and society can no longer rest on an ethics of roles but involve the ethics of power, "the ethical side of [which] is responsibility" (p. 42).

The metaphysical elaboration of responsibility has taken place primarily in European philosophy. Lucien Levy-Bruhl's treatise titled *The Idea of Responsibility* (1884) is its starting point. After sketching a history of the idea from antiquity to the late nineteenth century, Levy-Bruhl argues surprise that a concept so basic to morality and ethical theory had not previously been subject to systematic investigation, especially since it is also manifested in a variety of ways across the whole spectrum of reality. There is responsibility or responsiveness at the level of physical matter, as atoms and molecules interact or respond to each other. Living organisms are further characterized by a distinctive kind of interaction or responsiveness to their environments and each other.

Extending this metaphysical interpretation Hans Jonas (1984), another philosopher in the European tradition, explored implications for science and technology. Responsibility is not a central category in previous ethical theory, Jonas argued, because of the narrow compass in premodern scientific knowledge and technological power. "The fact is that the *concept* of responsibility nowhere plays a conspicuous role in the moral systems of the past or in the philosophical theories of ethics." The reason is that "responsibility ... is a function of power and knowledge," which "were formerly so limited" that consequences at any distance "had to be left to fate and the constancy of the natural order, and all attention focused on doing right what had to be done now" (p. 123).

> All this has decisively changed. Modern technology has introduced actions of such novel scale, objects, and consequences that the framework of former ethics can no longer contain them.... No previous ethics had to consider the global condition of human life and the far-off future, even existence, of the race. These now being an issue demands ... a new conception of duties and rights, for which previous ethics and metaphysics provide not even the principles, let alone a ready doctrine. (pp. 6 and 8)

The new principle thus made necessary by technological power is responsibility, and especially a responsibility toward the future.

What for Jonas functions as a deontological principle, Caroline Whitbeck (1998) has argued may also name a virtue. When children are described as reaching "an age of responsibility," this indicates that they are able to "exercise judgment and care to achieve or maintain a desirable state of affairs" (p. 37). Acquiring the ability to exercise such judgment is to become responsible. At the same time, the term *responsibility* continues to name distributed obligations to practice such a virtue derived either from interpersonal relationships or from special knowledge and powers. "Since few relationships and knowledge are shared by everyone, most moral responsibilities are special moral responsibilities, that is, they belong to some people and not others" (p. 39).

Consideration of the special responsibilities that belong to scientists and engineers has been a major theme in advancing discussions of science, technology, and ethics. Although overlapping, these two discussions have nevertheless mostly taken place among different professional groups.

Scientific Responsibility

Efforts to define the social responsibility of scientists have involved an refinement of the representative Enlightenment view that science has the best handle on truth and is thus essentially and under all conditions beneficial to society. From such a perspective, the primary responsibility for scientists is thus to pursue and extend their disciplines.

Historically this responsibility found expression in Isaac Newton's hope for science as theological insight, Voltaire's belief in its absolute utility, and Benedict de Spinoza's thought that in science one possesses something pure, unselfish, self-sufficient, and blessed. A classic manifestation is the great French *Encyclopédie* (1751–1772), which sought "to collect all the knowledge that now lies scattered over the face of the earth, to make known its general structure to the men among whom we live, and to transmit it to those who will come after us." Such a project, wrote Denis Diderot, demands "intellectual courage."

The questioning of this tradition has roots in the Romantic critique of scientific epistemology and industrial practice, but did not receive a serious hearing among scientists themselves until after World War II. Since then one may distinguish three phases.

PHASE ONE: RECOGNIZING RESPONSIBILITIES. In December 1945 the first issue of the *Bulletin of the Atomic Scientists* led off with a statement of the goals of the newly formed Federation of Atomic (later American) Scientists. Members should "clarify . . . the . . . responsibilities of scientists in regard to the problems brought about by the release of nuclear energy" and "educate the public [about] the scientific, technological, and social problems arising from the release of nuclear energy." Previously scientists would have described their responsibilities as restricted to doing good science, not falsifying experiments, and cooperating with other scientists. Now, because of the potentially disastrous implications of at least one branch of science, scientists felt their responsibilities enlarge. They were called on to take into account more than the procedures of science; they must respond to an expanded situation.

The primary way that atomic scientists responded over the next decade to the new situation created by scientific weapons technology was to work for placing nuclear research under civilian control in the United States and to further subordinate national to international control. They did not, however, oppose the unprecedented growth of science. As Edward Teller wrote in 1947, the responsibility of the atomic scientists was not just to educate the public and help it establish a civilian control that would "not place unnecessary restrictions on the scientist," it was also to continue to pursue scientific progress. "Our responsibility," in Teller's words, "is [also] to continue to work for the successful and rapid development of atomic energy" (p. 355).

PHASE TWO: QUESTIONING RESPONSIBILITY. During the mid-1960s and early 1970s, a second-stage questioning of scientific responsibility emerged. Initially this questioning arose in response to the growing recognition of the problem of environmental pollution—a phenomenon that cannot be imagined as alleviated by simple demilitarization of science or increases in democratic control. Some of the worst environmental problems are caused precisely by democratic availability and use—as with pollution from automobiles, agricultural chemicals, and aerosol sprays, not to mention the mounting burden of consumer waste disposal. Rachel Carson's *Silent Spring* (1962) was an early statement of the problem that called for an internal transformation of science itself. But an equally focal experience during this second-stage movement toward an internal restructuring of science was the Asilomar Conference of 1975, which addressed the dangers of recombinant DNA research.

After Asilomar, the dangers of recombinant DNA research turned out to be not as immediate or as great as feared, and some members of the scientific community became resentful of post-Asilomar agitation—although others actually argued for even more stringent guidelines than those proposed (Sinsheimer 1976, 1978). Increased possible consequences nevertheless again broadened the scope of what could be debated as the proper responsibility of scientists. Robert L. Sinsheimer, for instance, himself a respected biological researcher and chancellor of the University of California, Santa Cruz, argued that modern science was based on two faiths. One is "a faith in the resilience of our social institutions . . . to adapt the knowledge gained by science . . . to the benefit of man and society more than the detriment"—a faith that "is increasingly strained by the acceleration of technical change and the magnitude of the powers deployed" (Sinsheimer 1978, p. 24). But even more telling is

> a faith in the resilience, even in the benevolence, of Nature as we have probed it, dissected it, rearranged its components in novel configurations, bent its forms, and diverted its forces to human purpose. The faith that our scientific probing and our technological ventures will not displace some key element of our protective environment, and thereby collapse our ecological niche. A faith that Nature does not set booby traps for unwary species. (Sinsheimer 1978, p. 23)

This new argument was commensurate with the development of what Jerome R. Ravetz (1971) saw as the replacement of "academic science" by "critical science"—which is in turn related to what others have termed public interest science. Or as William W. Lowrance (1985) argued, beyond responsibility in the first-stage sense, there is a need to incorporate in science itself what he referred to as principles of "stewardship."

PHASE THREE: REEMPHASIZING ETHICS. The attempt to transform science from within was overtaken in the mid-1980s by a new external criticism not of scientific products (knowledge) but of scientific processes (methods). A number of high-profile cases of scientific misconduct raised questions about whether public investments in science were being wisely spent. Were scientists simply abusing a public trust? Moreover, some economists began to question whether, even insofar as scientists did not abuse the public trust, but followed ethical research practices—which was surely mostly the case—scientific research was as much of a stimulus to economic progress as had been thought.

The upshot was that the scientific community undertook a self-examination of its ethics and its efficiency. Efforts to increase ethics education, or education in what became known as the responsible conduct of research, became required parts of science education programs, especially in the biomedical sciences at the graduate level. And increased efficiency in grant administration and management became issues for critical assessment. Since the 1990s scientists have increasingly been understood to possess social responsibilities that include the promotion of ethics and efficiency in the processes of doing science.

At the same time, scientists have also attempted to reemphasize the importance of science to national health care, the economy, environmental management, and defense. In the face of the AIDS epidemic, biomedical research presents itself as the only answer. Computers and biotechnologies are offered as gateways to new international competitive advantage and the creation of whole new sectors of jobs. Global climate change, it is argued, can be adequately assessed only by means of computer models and the science of complexity. Finally, especially since 9/11, new claims have been made for science as a means to develop protections against the dangers of international terrorism. The social responsibility of science is defended as the ethically guided production of knowledge that addresses a broad portfolio of social needs: the promotion of health, the creation of jobs, the protection of the environment, and the defending of Western civilization.

Engineering Responsibility

Applied science professionals such as technologists and engineers are more subject than scientists to both external (legal, political, or economic) and internal (ethical) regulation. Indeed, engineers have since the early twentieth century attempted to formulate explicit principles of professional responsibility—precisely because of the technological powers they wield. Historically, similar discussions did not originate among scientists until the second half of the twentieth century, and scientific organizations remain in the early twenty-first century less likely to have formal codes of conduct than engineering associations.

Engineering associations aspire to the formulation of codes of conduct similar to those found in medicine or law. But unlike medicine, which is ordered toward health, or law, the end of which is justice, it is less obvious precisely what constitutes the engineering ideal that could serve as the basis for a distinctive internalist ethics of responsibility. The original engineer (Latin *ingeniator*) was the builder and operator of battering rams, catapults, and other "engines of war." Engineering was originally military engineering. As such, the power of engineers, no matter how great, was significantly less than the organized strength of the army as a whole. Moreover, as with all other soldiers, their behavior was guided primarily by their obligations to obey hierarchical authority.

The eighteenth-century emergence of civil engineering in the design of public works such as roads, water supply and sanitation systems, lighthouses, and other nonmilitary infrastructures did not initially alter this situation. Civil engineers were only small contributors to larger processes. But as technological powers in the hands of engineers began to enlarge, and the number of engineers increased, tensions mounted between subordinate engineers and their superiors. The manifestation of this tension is what Edwin T. Layton Jr. (1971) called the "revolt of the engineers," which occurred during the late nineteenth and early twentieth centuries. It is in association with this revolt and its aftermath that *responsibility* enters the engineering ethics vocabulary.

One influential if failed effort at formulating engineering responsibility led to what was known as the technocracy movement and its idea that engineers more than politicians should wield political power. Henry Goslee Prout, a former military engineer who had become general manager of the Union Switch and Signal Company, speaking before the Cornell Association of Civil Engineers in 1906, described the profession in just such leadership terms: "The engineers more than all other men, will guide humanity forward.... On the engineers ... rests a responsibility such as men have never before been called upon to face" (quoted in Akin 1977, p. 8). At the height of this dream of expanded engineering responsibility, Herbert Hoover became the first civil engineer to be elected president of the United States, and an explicit technocracy movement fielded its own candidates for elective office. The ideology of technocracy sought to make engineering efficiency an ideal analogous to medical health and legal justice.

During World War II a different shift took place in the engineering conception of responsibility: not from company and client loyalty to technocratic efficiency but from private to public loyalty. A chastened version of responsibility nevertheless emphasized the potential for opposition between social and corporate interests. Having failed in trying to be responsible for everything, engineers came to debate the scope of more limited responsibilities—to themselves, to employers, and to the public. The need for this debate is still clearly dictated by the powers at their command and the problems such powers pose, even though it is not obvious that engineering entails responsibilities of any specific character.

With engineering under attack as a cause of environmental pollution, for the design of defective consumer goods, and as too willing to feed at the trough of the defense contract, one American engineer writing in the mid-1970s summed up the situation as follows. He first admitted that,

> Unlike scientists, who can claim to escape responsibility because the end results of their basic research can not be easily predicted, the purposes of engineering are usually highly visible. Because engineers have been claiming full credit for the achievements of technology for many years, it is natural that the public should now blame engineers for the newly perceived aberrations of technology. (Collins 1973, p. 448)

In other words, engineers had oversold their responsibilities and were being justly criticized. The responsibilities of engineers are in fact quite limited. They have no general responsibilities, only specific or special ones:

> There are three ways in which the special responsibility of engineers for the uses and effects of technology may be exercised. The first is as individuals in the daily practice of their work. The second is as a group through the technical societies. The third is to bring a special competence to the public debate on the threatening problems arising from destructive uses of technology. (Collins 1973, p. 449)

This debate, formalized in various technology assessment methodologies and governmental agencies, can be read as a means of subordinating engineers to the larger social order. In comparing responsibility in engineering with responsibility in science, it may thus appear that there has been more of a contraction than an expansion. Yet the issue of responsibility has so intensified that engineers now consciously debate the scope of their responsibilities in relationship to issues not previously acknowledged.

Too Much Responsibility?

One common worry about certain technologies is that they undermine human responsibility. For instance, reliance on computers in medical diagnostic processes or strategic missile defense systems transfers some decision making responsibilities from human beings to computers. But the same computer systems that assume practical responsibility for diagnosis or defense call for the exercise of a higher ideal of responsibility in their design and deployment. It is precisely because modern technology calls for so much responsibility at the ideal level that observers can be so sensitive to the issue at the practical level. It is not at all clear, for instance, that computers have in any way deprived human beings of responsibilities they formerly had. What physicians of the early nineteenth-century would have been responsible for diagnosing and then treating the array of obscure diseases for which twenty-first-century physicians are held accountable? It is more likely that new technologies make possible certain responsibilities which they can also be configured to assist.

But this raises a question: Are the responsibilities thus called forth truly reasonable? From the perspective of prudence, one should not take on or give to another too much responsibility. To do so is to invite failure if not disaster. Although exact boundaries are not easy to determine in advance, once overstepped they are difficult to recover. In light of this principle of prudence, then, one must ask: Can the principle of responsibility, and those who are called to live up to it, really bear the added burden being placed on it and them by contemporary science and technology?

ANGLO-AMERICAN PERSPECTIVES

In the English language *responsibility* is generally defined as a quality or state of being answerable or accountable for acts or decisions. However, the term *responsibility* and its cognatex *responsible* are used in a variety of ways. H .L. A. Hart illustrated that variety with the following story of a drunken sea captain who lost his ship at sea.

> As captain of the ship, X was responsible for the safety of his passengers and crew. But on his last voyage he got drunk every night and was responsible for the loss of the ship with all aboard. It was rumoured that he was insane, but the doctors considered that he was responsible for his actions. Throughout the voyage he behaved quite irresponsibly, and various incidents in his career showed that he was not a responsible person. He always maintained that the exceptional winter storms were responsible for the loss of the ship, but in the legal proceedings brought against him he was found criminally responsible for his negligent conduct, and in separate civil proceedings he was held legally responsible for the loss of life and property. He is still alive and he is morally responsible for the deaths of many women and children" (Hart 1968, p. 211).

Four Types of Responsibility

Hart uses this story to identify four different senses of responsibility: role responsibility, causal responsibility, liability responsibility, and capacity responsibility. Role responsibility refers to the duties and obligations a person has by virtue of occupying a role such as mother, doctor, or captain of a ship. When a person occupies a role, others expect certain kinds of behavior and hold that person accountable for failure to do what is expected. In this context individuals have duties to behave in certain ways that can be referred to as role responsibilities. Causal responsibility is attributed to things and events as well as persons. In the case of events one might say of the terrorist attack on September 11, 2001, that the event has been causally responsible for instilling fear in many U.S. citizens. In the case of persons a particular action by a person is specified as the cause of or the major causal contribution to an untoward event or occurrence. For example, a person's failure to stop at a stop sign may be said to be causally responsible for the ensuing accident. Causal responsibility may or may not be connected to blameworthiness. Thus, if the person failed to stop at the stop sign because she had a heart attack, she may not be blameworthy but her failure to stop is still causally responsible for the accident. Similarly, even if a person unknowingly or under coercion pressed a button that detonated a bomb, that person would be causally responsible for the resulting damage.

Liability responsibility often refers to legal liability and identifies the person or group that is expected to pay damages or make compensation or sometimes explain (give an account of what happened) in situations in which harm is done. Liability often but not always accompanies causal responsibility or blameworthiness. Strict liability refers to holding an individual liable—to pay damages, make compensation, or give an explanation of what happened—when that individual is not causally connected to the event and has done nothing wrong. An example would be holding a company liable for harm that resulted from a defect in one of its products despite the fact that the company did everything possible to make the product safe. Capacity responsibility refers to the capability (generally psychological) a person must possess to be considered morally responsible for his or her behavior. For example, if an individual lacked the ability to reason and to understand and control his or her behavior, it would be inappropriate to hold that person responsible for his or her actions.

In describing this fourfold distinction it is helpful to bring in the notion of blameworthiness. Being blameworthy or at fault is another sense of responsibility that depends on the other uses of that term. A person typically is considered blameworthy when (1) the person had capacity responsibility (that is, had the ability to understand and control his or her behavior); (2) the person did something he or she was not supposed to do (such as fail to perform a role-responsibility); and (3) the person's act or omission was causally responsible for an untoward event or harm. For example, a person would be blameworthy if while working as a night security person for a bank (and having the capacities of most human beings) he or she forgot to check to see if a door was properly locked and consequently allowed a burglar to get into the bank and steal money.

In addition to Hart's fourfold distinction and the concept of blameworthiness, moral philosophers have distinguished many different kinds of responsibility, including personal, collective, moral, legal, diminished, prospective, and retrospective responsibility. Thus, discussions of responsibility must attend carefully to the differing meanings of the term.

Analytic moral philosophers have focused largely on capacity responsibility and especially the connection between freedom and responsibility. For individuals to be responsible for their behavior, it would seem that they must be free to act as they do. If individual behavior were entirely determined, say, because it is predetermined by God or results from external causal forces such as genetics, upbringing, and circumstances, it would seem that individuals could not be held responsible for what they do: Their behavior is not in their control.

With this in mind, moral philosophers have focused on giving an account of human freedom without denying the various factors that influence human behavior. Often scholarship on this topic has focused on what it means to say that a person is free or "could have done otherwise."

By contrast, some philosophers have argued that ascriptions of responsibility should be seen as forward-looking (prospective) social practices. In this context human freedom is not a requirement. For example, ascriptions of responsibility can be understood to be mechanisms for exerting pressure on individuals to behave in certain ways. Society holds individuals responsible for their behavior to exert pressure on them to behave in socially desirable ways. When individuals behave in socially undesirable ways, society disapproves and tells them they are bad. Society uses the law to threaten and actually punish individuals when they engage in undesirable behavior. This is done to instill in individuals a sense of responsibility for their actions, a sense of responsibility that influences how they behave. Understanding responsibility in this way gives responsibility ascriptions a utilitarian and deterministic foundation. Responsibility ascriptions are utilitarian practices aimed at achieving good results. This account eliminates an element at the heart of notions of responsibility and at the core of the connection between freedom and being human: a sense that what it means to be human involves carrying the weight of responsibility for one's actions.

Responsibility in Science and Technology

A host of important responsibility issues arise in the fields of science, engineering, and technology. The issue that has received the most attention involves the responsibilities of scientists and engineers for the production of scientific knowledge and technological products. Because science and engineering give human beings enormous power for good and ill, questions about the responsibility of scientists and engineers, both individually and collectively, have always surrounded scientific and technological endeavors. The question became particularly prominent in the twentieth century with the creation and use of the first atomic bomb and later with the production of civilian nuclear power. The question persists in the early twenty-first century in regard to genetic engineering, surveillance technologies, cloning, and biological weapons. Are scientists and engineers considering the social and moral implications of what they are doing? Do they have a responsibility to stop what they are doing or to speak out when they think the risks of their work or that of their colleagues are too great?

Evidence of concern about the scientists' or engineers' responsibility for their work is seen, for example, in the ongoing fascination with Mary Shelley's *Frankenstein* (1818), a science fiction story in which a doctor-scientist uses scientific and technical prowess to bring a humanlike monster composed of separately acquired body parts to life. Doctor Frankenstein is horrified at the sight of his creation and immediately flees his laboratory; he does nothing until the beast begins to interfere in his life. Left to its own devices the beast wreaks havoc on the lives of Doctor Frankenstein and others.

The Frankenstein story is an indictment of those who fail to think about the implications of their attempts to create new knowledge, products, and techniques; it is an indictment of those who refuse to take responsibility for what they create. Whatever Mary Shelley's intentions were in writing *Frankenstein,* the story serves as a morality tale for a technoscientific world. Its relevance to a world in which biological weapons, clones, and powerful surveillance technologies have already been created is evident.

Failure and Disaster

The Frankenstein story suggests that scientists and engineers should consider the implications of their work before they do it and take responsibility for that work after it is done. More often than not responsibility issues arise after knowledge has been created and technological endeavors have been undertaken and some sort of failure subsequently leads to a disaster. Then attempts are made to trace back role responsibilities and identify who is to blame. For example, when the *Challenger* spaceship and more recently the *Columbia* crashed, public attention turned to figuring out what went wrong and who was responsible. Engineers, as well as managers, were put on the spot. Who made the decision to launch? Were there not signs that a problem existed? Who had failed to fulfill their responsibilities?

Similar questions arise for all technological failures, especially those which have catastrophic results, such as the Three Mile Island accident; the disaster at Bhopal, India; the DC10 airplane crash; and the Hyatt Regency hotel collapse. After September 11, 2001, questions were raised about the structural design of the World Trade Center as well as the failure of American intelligence organizations.

Although responsibility issues can and do arise independent of science and technology, the issues surrounding technological disasters seem particularly daunting because of their complexity. Modern technologies are so complex that the individuals involved in their development, production, distribution, and use often cannot understand fully the projects to which they are contributing. Because of that complexity there must be a division of labor, and this means that engineers and scientists often work on pieces of a larger project. This challenges traditional notions of responsibility, for how can individuals be responsible for what they are doing when they cannot fully comprehend what they are doing?

Information technology is a good example of this issue. Many computer programs consist of millions of lines of computer code. Can a single individual be responsible for all the lines of code in a program? No one can be expected to understand the entire program, and so how can particular individuals be held responsible for the program? Computer scientists develop testing procedures and standards for reliability, but there are limits to what they can be expected to do. Moreover, when projects are divided into parts, there is a danger of something falling into the cracks or of error being introduced when the parts are put together. The complexity of modern technologies poses daunting challenges both retrospectively in tracing back failure and prospectively in assigning responsibilities for large projects in a way that minimizes the likelihood of failure.

Many scientific and engineering professional associations acknowledge that their members have social and professional responsibilities both individually and collectively. Professional organizations are an important means of addressing some of those responsibilities. One method professional societies use is to adopt and promulgate codes of ethical and professional conduct.

GERMAN PERSPECTIVES

In the German philosophical tradition the concept of responsibility (*Verantwortung*) has been accorded special and extensive treatment, especially in relation to science and technology. The following introduction to this tradition begins with a description of responsibility as a relational construct and then distinguishes three basic levels of responsibility: action responsibility, role responsibility, and universal moral responsibility.

Basic Concept

The German word *Verantwortung* derives from the Middle High German and originally meant simply "to answer," probably in response to an accusative question such as "Did you do X?" The concept of responsibility is thus evaluative and attributive as well as descriptive. A person can be *held* (to be) responsible, which introduces the normative or ethical dimension into human experience.

The concept of responsibility implies a multidimensional structure linked to assignment, attribution, and imputation, in ways that may be analyzed and interpreted with respect to the following model:

Someone S (the subject or bearer of responsibility, which can be a person or a corporation)

is responsible for A (actions, consequences, situations, tasks)

to O (addressees or "objects" of responsibility)

under the supervision or judgment of J (some judging or sanctioning agent)

in relation to N (a prescriptive or normative criterion of attribution)

and accountable within context C (a sphere or realm of human activity).

For example, a person (S) is responsible to other motorists and pedestrians (O) for stopping at traffic lights (A) under the supervision of the police or courts (J) in relation to the traffic laws (N) when driving an automobile (C). This makes responsibility a five- or six-place relation, although some of the relations may overlap. For instance, it is possible for an addressee (O) and supervisor (J) to be the same.

Following work in the development of attribution theory by the social psychologist Fritz Heider (1896–1988) and the social phenomenologist Alfred Schutz (1899–1959), it was the Polish logician I. M. Bochenski (1987 [1947]) who first defined responsibility in terms of the logic of relations. For Bochenski, however, responsibility was a two- or perhaps a three-place relation: Someone (S) is responsible for action (A) to another person (O).

As an attributive, relational construct, responsibility is also an interpretative concept with social functions. It can be expressed as an attributive, relational norm (controlling expectations regarding action and behavior). Responsibility further implies that a person (S) must justify actions, action consequences, situations, tasks, and so forth (A) in front of an addressee (O) and before an agent (J) in respect to which the responsible party has obligations or duties in accordance with standards, criteria, or laws (N). Responsible parties are accountable for their own actions or under specified conditions for the actions of others. Parents, for example, are liable for certain behaviors of their children, and corporations for certain behaviors of their employees. (This tends to apply more to wrongdoings than to achievements.) The concept of responsibility thus structures social reality and social relations.

One may further differentiate between the typical bearers of responsibility in terms of active roles and observer roles. Specifically, one may impute or attribute a particular responsibility to oneself as an actor or to others from the multiple perspectives of a participant, observer, or scientist, in relation to general rules and norms. Particular cases of attribution instantiate general patterns of responsibility. The attribution of responsibility is an active process both in self-interpretation and in the interpretation of the actions of others. The concept of responsibility is thus implicated in self-understandings and projections of ideals for social order.

Types and Levels of Responsibility

Types of responsibility occur at three basic levels: individual actions, social roles, and universal moral principles. Such distinctions are justified by appeal to "ideal typ(ic)al" prevalence, similar but not identical to Max Weber's *Idealtypen* or ideal types. In what follows, diagrammatic schema are used to condense and illustrate hierarchical models of different types of responsibility, with different levels or strata referring to different dimensions of interpretation. The first diagram is more abstract and calls for more interpretative constructs, such as particular kinds of responsibilities, than the others.

QUALIFICATIONS. In general, the three levels are constituted by analytic and perspectival constructs that may overlap and all apply (although in different ways) to a single real case of responsibility. That is, concrete instances of responsibility attribution may be analyzed not only on a formal or abstract level (as illustrated in the first diagram) but also from a more concrete point of view (as with role or moral responsibility). Although usually any one analysis on a specific level is tied to a certain interpretation (e.g., some particular role), this does not preclude another interpretation (from, say, the moral point of view).

Within the different levels of these schematic constructs are further analytic constructs that are also able to be attributed to individuals or groups. Even in their more concrete forms, constructs are to be understood as analytic distinctions. That is, collective or group responsibility seldom precludes individual or personal responsibility, although collective responsibility cannot be reduced to or derived from individual or personal responsibility alone. The same applies to institutional responsibility. Moreover, there are conceptual connections or analytic relations between some juxtaposed or subordinated subtypes.

ACTION RESPONSIBILITY. The most obvious and general level of responsibility is that which involves being responsible for the results or consequences of one's own actions. This may be termed the prototyp(ic)al case of (causally oriented) action responsibility. A subject is held responsible for the outcomes of his or her actions in an instance for which he or she is accountable. An engineer designing a bridge or a dam is responsible to the supervisor, employer, client, and/or general public for his or her design in terms of technical correctness, safety, cost, feasibility, and more. A scientist is not responsible for the outcome of an experiment or research project but is responsible for the conduct of the research and the reporting of its results.

Frequently, accountability questions are raised in negative cases, when one or more of these criteria are not fulfilled. The breaking of a dam may be the result of such factors as honest mistakes in statics or dynamics analyses; careless, negligent, or even criminal misconduct; incompetence; and the use of substandard materials. The need to withdraw or revise technical reports in science may likewise be attributable to honest mistakes or malfeasance. In any particular case it is important to identify the particular negative action responsibility. Professional scientists and engineers have responsibilities to the public to ensure high standards in their work, to avoid risks of disasters insofar as this is compatible with reasonable costs, and to report results fully and completely without fabricating or falsifying data. The responsibility to avoid mistakes, failures, and poor quality products, processes, systems, and so on is part and parcel of action responsibility. Different types of action responsibility are shown in Figure 1.

The most commonly discussed cases of action responsibility are individual action responsibility. But if a group is acting collectively or if individuals participate in joint group action, then what may be called coresponsibility arises as a distinctive phenomenon. Coresponsibility is the sharing of responsibility by participating members in a group action. Responsibility for group actions is also sometimes called collective or group responsibility, and the circumstances in which this can be legitimately attributed to groups—especially large ones such as a nation-state or ethnic classification—are highly contentious. Mostly such attributions are rejected or justified only under very special cases on the grounds that groups should not be punished (or rewarded) for the actions of individuals. In practice, however, such punishments are quite common (as in warfare where they may be apologized for as "collateral damage").

ROLE RESPONSIBILITY. A second level of responsibility is constituted by role and universal moral responsibility. In accepting a role or fulfilling a task (e.g., by taking on a well-defined job) a role holder usually bears some responsibility for acceptable or optimal role fulfillment. Role responsibility is not opposed to or fundamentally different than individual action responsibility, but manifests action responsibility at a level other than that of human action as such. Indeed, as the examples already cited in discussing action responsibility indicate, most of these roles will entail individual action responsibilities, or can be thought of as constituting particular instances of individual action responsibility.

These roles or duties might be assigned in a formal way or be more or less informal. They can even be legally ascribed or at least legally relevant. Different types of roles and responsibilities, including legal responsibilities, are presented in diagrammatic form in Figure 2.

In corporate or institutional settings, role patterns include leadership responsibility (with respect to external and internal instances, addressees, and agents) as a special form of associated institutional role responsibility. In addition, there is the corporate responsibility of firms, corporations, or other social institutions such as government agencies and even nongovernmental organizations insofar as these have special tasks to perform or obligations to fulfill with respect to clients, the public, or members of the organization or corporation. This type of responsibility can also have a legal, moral, or neutral character, which may or may not coincide with group or institutional responsibility.

Other examples of role responsibility that deserve explicit mention include not only legal responsibility but also pedagogical responsibility, religious responsibility, political (citizen) responsibility, and more. In an

advanced scientific and technological society one might also speak of consumer responsibility.

UNIVERSAL MORAL RESPONSIBILITY. Universal moral responsibility provides a different specification for the functioning of individual action responsibility than that associated with role responsibility. Not all action responsibility and role responsibility is specifically moral in character or moral to the same degree. To have a responsibility to be on time for an appointment because of a particular role has more an efficiency than a moral character; it is a responsibility that keeps some particular organizational system functioning more smoothly than would otherwise be the case.

Action responsibility and role responsibility take on a specifically moral character when an agent's actions and the results of those actions are directed toward persons or living beings (including even the agent) whose well-being is directly affected by the agent's activity. With regard to others such affects can be direct or indirect, can be defined by contractual or formal duties, and can inhere in institutions or corporations. By way of diagrammatic summary, see Figure 3.

For Hans Jonas (1984) universal moral responsibility can become pronounced with regard to the uses of technology that have the potential for environmental or human destruction such as nuclear weapons or genetic engineering. Caring responsibility is not only role related (with different kinds of scientists or engineers exhibiting it in different degrees) but also general for those who inhabit a highly scientific and technological society—that is, those who promote and benefit from advanced scientific and technological activities. According to Jonas's argument, members of a scientific and technological society, by virtue of participating in such a society, and because of the tremendous potential for intentional and nonintentional destruction present in the society, become responsible for ensuring the well-being of all persons and other living beings affected by their specific actions in the form of a general and permanent obligation.

A few more restricted observations on various types of universal moral responsibility related especially to science and technology are as follows:

- The remote consequences of an agent's activity—possibly combined with the impacts of other people's commissions or omissions—may create an indirect moral (co-) responsibility. For instance, neglecting a safety check or wrongly certifying the airworthiness of an airplane could contribute to loss of life when coupled with a less than expert pilot or other crew member.
- Corporate moral responsibility frequently coincides with, but need not be identical to, the moral cor-

esponsibility of members of a decision-making board. Therefore corporate moral responsibility is not to be analytically confused with the moral coresponsibility of group members partaking in a collective action or decision-making process. (Questions of responsibility distribution are increasingly important in assessing responsibility in the virtual environments created by computers and information systems, where teams of programmers have created web-based utilities in which people differentially interact to produce multiple types of products.)

- To abide by the ethics code of a professional society is a combination of indirect responsibilities. As such it is certainly a moral obligation. Thus beside immediate action- or impact-oriented responsibilities, scientists and especially engineers take on, through their professions, higher-level moral responsibilities to fulfill contractual or role duties and promises and to live up to the ethical standards of their professional organizations, not to infringe established laws, and more, inasmuch as the fulfillment of a task, contract, or role does not contradict another overriding moral norm or right. In engineering ethics codes the responsibility to protect public safety, health, and welfare has (since World War II) increasingly been considered paramount.

General Commentary

The previous review aims to summarize in somewhat schematic or outline form the consensus of an extended tradition of critical reflection on responsibility in the German philosophical traditions. These traditions run at least from Gottfried Wilhelm Leibniz (theodicy) through Immanuel Kant (categorical responsibility) and G. W. F. Hegel (idealist responsibility) and Karl Marx (economic responsibility) to the phenomenological tradition (Edmund Husserl through Martin Heidegger to Schutz) and critical social theory versus systems theory (Jürgen Habermas versus Niklas Luhmann). Since World War II, discussions within the Verein Deutscher Ingenieure (Society of German Engineers) have been especially concerned with conceptualizing responsibility in relation to science and technology. The 2002 "Fundamentals of Engineering Ethics" highlights the topic of responsibility in its first major paragraph. The most general discussion of responsibility in this context has occurred in the work of such philosophers as Karl Jaspers, Günther Anders, and Hans Jonas—drawing attention to new moral responsibilities engendered by nuclear weapons, environmental pollution, and genetic engineering. Hans Lenk and Matthias Maring have since the 1980s worked to synthesize the many achievements within these traditions.

One of the important notes to emphasize about this schematic synthesis is that there exists a differentiated interplay among the identified levels and types of responsibilities, universal moral obligations being but one case. Moral responsibility may be activated by a special type of action and in connection with a special role, but its key characteristic is universality. Moral responsibility as such is not peculiar to a specific person or role but applies to everyone in a similar situation or role. Moral responsibility is nevertheless individualized in the sense that it cannot be delegated, substituted, displaced, replaced, or off-loaded by the respective person, corporation, or organization. Neither can it be diminished, divided, dissolved, or done away with by being shared by a number of people. Moral responsibility is both irreplaceable and unable to be diminished.

With regard to conflicts between different responsibilities or types, priority rules have been developed for adjudicating, regulating, or at least mitigating conflicts and for combining different responsibilities when they are present at the same time. In the last analysis, the presence of a situation- and context-dependent responsibility under the auspices of practical (concrete) humanity should, from the moral point of view, prevail or override any partial and nonmoral responsibility. That is, human rights trump role responsibility rights. One of the challenges of a technoscientific society is to explore ways in which such a priority can be operationalized in and through scientific and technological developments, not just among technical professionals but in society as a whole.

RESPONSIBLE CONDUCT OF RESEARCH

The *responsible conduct of research* (RCR) is one of two major components of research ethics. The essence of the concept is that RCR is central to the practice of science: " [T]he responsible conduct of research is not distinct from research; on the contrary, competency in research *encompasses* the responsible conduct of that research and the capacity for ethical decision making" (Institute of Medicine 2002, p. 9). The emphasis is on professional responsibilities and the extent to which the scientific research community and its members, as a profession, determine, recognize, and adhere to professional standards and values (Carr-Saunders and Wilson 1933). RCR assumes that: (1) there are identifiable, shared standards of practice and behavior that can and should be made explicit; (2) these standards are, consciously or unconsciously, acknowledged by members of the community; and (3) they are standards that research supervisors are expected to instill in trainees.

History

The term RCR is closely related to that of *research integrity*, which it tended to replace as a term of art in the 1990s. It is probably derived from the 1989 Institute of Medicine document *Responsible Conduct of Research in the Health Sciences* (1989) and the concept is further reinforced and reflected in the National Institutes of Health (NIH) requirement that pre- and post-doctoral trainees funded by the NIH receive some formal education in the proper conduct and reporting of research (NIH 1989). However its roots no doubt date from the 1980s when various professional scientific societies, including, for example, the American Chemical Society and Sigma Xi, developed and promulgated codes of conduct for their members (Sigma Xi 1984, Jorgensen 1995, Johnson 1999). In the 1990s the NIH requirement is credited with motivating the biomedical research community to develop educational programs to formalize and make explicit to trainees the expectations of the scientific community with regard to the procedures and processes involved in carrying out and publicizing the results of scientific investigation.

Although inherent in the notion of RCR is professional competence and integrity, education and training in RCR includes many other aspects of scientific research practice. Common usage of the term RCR is a bit of a misnomer because, in point of fact, it includes a wide range of elements beyond the conduct of research that are fundamental to the practice of scientific research. It encompasses not only the experimental process itself, but also closely associated processes such as the dissemination of research findings, the implications of competition among colleagues and its potential impact on the evaluation of research results, and the training of future scientists. As the leading agency emphasizing the importance of education in RCR, the Office of Research Integrity (ORI) in the Office of Public Health and Science in the U.S. Department of Health and Human Services (DHHS) has identified elements central to research practice and appropriate for explicit discussion in the context of RCR (Office of Research Integrity 2005). These topics are:

- data acquisition, management, sharing, and ownership;
- humane treatment of research subjects including both humans and laboratory or other non-human animals;
- allegations of research misconduct;
- recognition of, and management or elimination of, conflicts of interest and conflicts of commitment;

- the mentor/trainee relationship and associated responsibilities;
- publication practices and the responsibilities of authorship;
- the peer review process;
- the expectations of collaborators regarding the nature of collaborative research, appropriate recognition of contributions to the work, and the allocation of responsibility.

Assessment

RCR, in contrast to most formulations of scientific misconduct and integrity, does not solely nor primarily focus on the more egregious and unacceptable practices of fabrication, falsification, and plagiarism (FFP). Instead the notion of RCR implies that there are less responsible, as well as irresponsible, practices. Put another way, there are a range of research practices from the preferred, through accepted but discouraged to prohibited practices. Serious deviation from accepted practices in carrying out research, or in reporting the results of research, may be considered unacceptable by some members of the scientific research community.

A major emphasis of RCR is education in the form of making explicit for both trainees and peers what is often implicit in research practice. However debate continues over how best to assess the efficacy of that education. This stems in part from a lack of consensus on the extent to which the goals of RCR education should include not only explicit understanding of the standards and values of the community and the expectations of both colleagues and society regarding professional behavior, but also training in ethical decision making (Institute of Medicine 2002).

RHETORIC OF SCIENCE AND TECHNOLOGY

Rhetorical inquiry is a multidisciplinary field of study devoted to the critical examination of discourse. Initiated in classical times, it cultivates an "ability, in each [particular] case, to see the available means of persuasion" (Aristotle 1991, p. 36). As an academic field, rhetoric of science and technology is the study of how scientists and non-scientists use arguments to advance claims about science and technology.

The idea that there is a *rhetoric* of science and technology may strike some as perverse and others as obvious. In popular parlance, the term rhetoric connotes something less than truthful, the ranting of politicians who evade substantive dialogue. When tied to science and technology, rhetoric can sound like a curse, staining the purity of certain knowledge and precise measurement with the mark of ideological bias and political maneuvering. But to those who study the rhetoric of science and technology, the term has no such connotation. Instead it is steeped in its ancient tradition and denotes the careful study of how texts are designed to seek the assent of an audience. When those texts are from the realm of science and technology, the means of persuasion utilized include such factors as appeals to disciplinary assumptions and values, the demonstration of methodological rigor, and the selection of language that suggest the neutral observation of nature.

Historical Development

The negative connotations attached to rhetoric are largely the result of a lengthy conflict with philosophy, in which the latter claimed the more valued side of oppositions between opinion and truth, form and content, passion and reason. Yet recent developments in philosophy and other fields recognize these dichotomies as problematic, resulting in a general resurgence of interest in the tradition of rhetorical inquiry, a tradition maintained by enclaves of scholars working mostly in departments of Speech Communication and English in the United States.

Developments in the philosophy, sociology, and history of science have also contributed to the rise of scholarship on the rhetoric of science and technology. Science studies scholars have shown that what one era recognizes as the truth of a scientific theory is seen by a later era as mere opinion, supplanted when an authorizing scientific community accepts a new truth claim. The fact that this transformation occurs by way of arguments addressed to a particular audience, that it often entails a significant shift in values and beliefs by people with an investment in the outcome of those arguments, and that it is frequently marked by controversy, makes rhetorical inquiry a natural approach to the study of such moments.

The idea that communication between scientists and the public might have a rhetorical dimension, or that new technologies may be promoted through rhetorical means, is rarely disputed. Thus the rhetorical examinations of these aspects of science and technology are likewise promising scholarly pursuits in an age when science and technology play such an important role in the development of public attitudes and policies.

The first hint that rhetorical inquiry might be applied to scientific discourse began appearing in the journals of rhetoricians in the 1970s. There were theoretical essays exploring the developments in philosophy and sociology of science that contributed to the possibility for a rhetoric of science (Weimer 1977; Overington 1977), research that began to examine the persuasive nature of specific scientific texts (Campbell 1975), and a general call for scholarship in this new area (Wander 1976). The birth of the field was announced when two books appeared almost simultaneously with nearly identical titles: Lawrence J. Prelli's *A Rhetoric of Science* (1989) and Alan G. Gross's *The Rhetoric of Science* (1990). Both fruitfully applied classical rhetorical concepts to the study of scientific truth claims.

In 1991 Randy Allen Harris wrote a thorough review of the nascent field, defining its relationship to other fields and organizing the scattered research into useful taxonomic categories. In 1993 the American Association for the Rhetoric of Science and Technology held its inaugural meeting at the National Communication Association convention, where it continues to meet annually. The field has continued to develop with the aid of such professional supports as the University of Iowa's Project on the Rhetoric of Inquiry, graduate programs specializing in the study of rhetoric in science and technology at the University of Pittsburgh and the University of Minnesota, and a series of books on the Rhetoric of the Human Sciences published by the University of Wisconsin Press. Research has generally grown along two paths: studies of the arguments made by scientists when they address other scientists, and scholarship that focuses on the relationship between science or technology and the public.

Internal Rhetorics of Science

The most heavily researched area in this growing field is the internal rhetoric of scientists, that is, the discourse scientists use when addressing other scientists, either within their own discipline or across disciplines. Because most people think the internal discourse of scientists is resistant to rhetorical scrutiny, scholars blazing the trail have focused on establishing that even the most specialized communication can be examined usefully through the lens of rhetorical analysis. The prototypical scientific research article has been the subject of much research. For example Watson and Crick's famous 1953 *Nature* report, "A Structure for Deoxyribose Nucleic Acid," has been examined in several unrelated studies that explain its persuasive design through rhetorical theories pertaining to voice, ethos, irony, kairos, stasis, and narrative (Bazerman 1988, Halloran 1984, Gross 1990, Miller 1992, Prelli 1989, Fisher 1994). An entire volume of essays has been written on the rhetoric of a single journal article by Stephen Jay Gould and Richard Lewontin (Selzer 1993).

More evidence that the research report was the primary focus for early rhetoricians of science is the fact that some of the first books in the field were devoted to illuminating writing practices in this genre. For example Charles Bazerman's *Shaping Written Knowledge* (1988) contrasts the scientific article with other forms of academic discourse and traces historical changes and disciplinary differences in the design of the experimental report. It shows how even scientists "use, transform, and invent tools and tricks of the symbolic trade" to shape claims so that they are judged novel and truthful by other scientists (p. 318). In *Writing Biology* (1990), Greg Myers looks at the review process to examine the way authors and editors, operating with different interests, negotiate the status of a scientific claim in a journal article. His book further traces the way two controversies are played out in scientific journals, where scientists interpret their own words and those of their opponents as freely and expertly as any debater in the public forum.

In addition to the rhetoric of the experimental article, landmark scientific monographs such as Newton's *Opticks* (1704) and Darwin's *On the Origin of Species* (1859) and have received sustained attention from scholars of rhetoric seeking to understand how scientists persuade their colleagues to accept radical new theories. The most successful scientists are often the ones who are also master rhetors, capable of adapting new ideas to the presuppositions of their audiences rather than making a frontal assault on a standard paradigm with the irresistible force of a revolutionary theory.

Rhetorical studies have done a particularly good job of showing how the style in which a scientific claim is communicated has an influence on how a scientific community thinks about that claim, and vice versa. Jeanne Fahnestock's careful account of rhetorical figures in science demonstrates that language does "much of our thinking for us, even in the sciences, and rather than being an unfortunate contamination, its influence has been productive historically, helping individual thinkers generate concepts and theories that can then be put to the test" (Fahnestock 1999, p. xi).

Because facilitating the growth of knowledge is the central activity of scientists, the way in which scientists use the tools of language and argument to advance knowledge claims has received the most attention from scholars of the rhetoric of science. Another internal rhetoric of science that receives less attention, either because it is considered less central or because its character is less contested and thus less shocking when discovered, is the way in which scientists persuade one another that a particular line of research holds future promise. Myers devotes a chapter of his book to the rhetoric of the grant proposal, a genre of scientific writing that must convince reviewers a research program deserves funding because of its potential interest to the scientific community and the professional ethos of the authors. Leah Ceccarelli (2001) examines motivational texts of science to show that scientists who employ a strategic ambiguity of language are better able to persuade colleagues from different disciplines to overcome barriers separating their fields and engage in new interdisciplinary lines of research. These internal discourses of science that do not seek the assent of colleagues to a particular truth claim, but instead seek future action from fellow scientists, have been less studied by rhetoricians, but may be just as important to the ultimate development of science.

For the most part, research on internal rhetorics of science tends to be descriptive and explanatory in nature, uncovering the rhetorical practices at the heart of scientific activity. But some of it has an implicit prescriptive character, suggesting other resources of language and argument that scientists might use to shape science in more useful or ethical ways. In contrast research on external rhetorics of science and technology tends to be more explicit in its criticism of current communication practices and more direct in its recommendations for change.

External Rhetorics of Science and Technology

The ways in which scientists communicate with the public and the ways in which nonscientists communicate about scientific or technological issues are more obviously rhetorical in nature, and ripe for critical commentary. Popularization is one genre of scientific writing that is a natural subject for rhetorical analysis. By contrasting journal articles written for specialists with popularizations on the same topics, rhetorical inquiry has shown that popular accounts remove hedges and qualifications for scientific claims while emphasizing the uniqueness of observations (Fahnestock 1986). Because of these changes, the public may get a distorted view of the certainty and significance of a scientific knowledge claim, something that can be dangerous when the subject has important social implications. Rhetorical analysis contrasting internal rhetorics of science with popularizations has also demonstrated that while the former emphasize the activities of the scientists and the conceptual structure of the discipline in which they are working, the latter emphasize the activities of the objects being studied (Myers 1990). Again distortion may result, with public audiences developing an image of science as the unmediated observation of external nature, without the interference of scientists who employ theoretical apparatus or make methodological decisions.

Rhetorical inquiry has also brought critical attention to the situation in which an expert takes a new scientific theory away from its disciplinary origins and argues before public audiences, thus eluding accountability to the controls of a specialized scientific community (Lyne and Howe 1990). Popularization may be the genre of science writing that does the most to break down the barrier that exists between the two cultures of scientists and nonscientists, but its tendency to misrepresent science as a non-controversial activity of observation by disinterested individuals has ethical consequences, especially when the public is asked to make decisions about matters for which science and technology do not have indisputable answers.

Situations in which the public must act on technical matters despite a lack of scientific consensus have been the subject of several case studies in the rhetoric of science and technology. Examining cases as diverse as the recombinant DNA controversy of the 1970s (Gross 1990, Waddell 1990) and disputes over the accuracy of missile defense technology in the 1980s and 1990s (Mitchell 2000), rhetorical critics have analyzed debates about the public control of contemporary scientific and technological developments. Most have supported the findings of an early study of the discourse surrounding the Three Mile Island incident (Farrell and Goodnight 1981). When technical reason usurps the place of more appropriate modes of public deliberation about matters of social or political import, a crisis of communication is the result. In each case study, rhetorical patterns that promote democratic participation are endorsed as an alternative to the dysfunctional assumption that people can rely on science and technology to solve their most serious public problems.

Another type of scholarship on external rhetorics of science and technology takes a more historical approach, scrutinizing the documentary evidence surrounding a particular scientific field or technological development to uncover the specific discursive forms that reflect and shape public attitudes. The scope of such rhetorical histories can be broad, as it is in Celeste Condit's 1999 study of public debates about human heredity from 1900–1995, or narrow, as in Charles Bazerman's 1999 study of how Thomas Edison and the people around him represented light to the public from 1878–1882. In both cases though, the purpose of the rhetorical study is not to critique the oversimplification of popularizations, nor to valorize public deliberation over technological decision making, but to demonstrate the complicated ways in which science, technology, and culture interact in the public mind.

Conclusion

Although the rhetorical study of science and technology can be broadly divided into the examination of internal and external communication, there is work within the field that breaks out of this neat mold. For example the rhetoric of technology typically makes no distinction between internal and external genres, but examines both in the patterns of communication unique to "enterprises concerned with the development, production, and marketing of artifacts and practices" (Miller 1994, p. 92). There also are various fields of rhetorical study that intersect with the rhetoric of science and technology, but are not typically considered a part of it, such as the rhetorical study of medicine, mathematics, economics, or communication technologies.

Study of rhetoric in science and technology is an important but young field that sometimes suffers lack of confidence in communicating outside its peer group. A scan of citation practices in the literature demonstrates that most rhetoricians of science and technology are familiar with related research done in philosophy, history, and sociology of science, but the reverse is rarely true. Publishing mostly in journals read by other rhetoricians, or in books that are marketed to Speech Communication and English departments, they do little to communicate their findings to other science studies scholars or to scientists and the public. This is unfortunate, as the rhetorical critic's tools of close reading and argument analysis illuminate aspects of texts and debates that would benefit scholars in other fields. Perhaps with time, the rhetoric of science and technology will mature into a field that acts as a full and equal participant in the community of science studies scholars. At that point perhaps it will also do more to export its findings especially to scientists and citizens who must evaluate scientific discourse to make fully informed ethical decisions about science and technology.

RIGHTS AND REPRODUCTION

It is in the context of reproduction, interpreted broadly, that many of the issues concerning the ethics of science and technology have arisen. The birth of the first so-called "test tube" baby in 1978 set in motion an ongoing process of questioning interventions such as assisted reproduction, embryo research, and cloning.

The notion that human beings possess a legitimate inclination to conceive and bear children is part of traditional natural law teaching. For instance, Thomas Aquinas (1225–1274) argued that human beings share those inclinations "which nature has taught to all animals," such as sexual intercourse, education of offspring, and so forth (*Summa theologiae* I–II, Q. 94, a.2). As traditional natural law was transformed into modern natural right, and human sexuality became increasingly mediated by science and technology so as to become both more productive and subject to human control, the intersection of human rights and having children (termed variously both reproduction and procreation) became increasingly contentious.

One contention centers around what are termed *reproductive rights*, generally indicating women's right to control whether, when, and how they bear children. There is clearly an important gender dimension to the issues. The right to be free from interference such as sterilization, on the one hand, and the right to abortion, on the other, have been important historical landmarks in women's control over their fertility.

Historically, the content of the reproductive rights has gradually increased, however, beyond freedom from interference to include a right with a much wider scope, such as the right to positive assistance in reproduction (that is, the use of technology in the case of infertility); and also to choice of the *kind* of children one has (for example, sex selection and genetic factors). Reproductive rights in this sense remain hotly contested at least to some degree: While there is widespread acceptance of in vitro fertilization, some potential means of assisted reproduction continue to be regarded by many as unacceptable, such as reproductive cloning. The right to choose to avoid preventable genetic disorder in one's children is also regarded as problematic by those who find such choices expressive of intolerance towards difference.

Disagreements depend to a considerable extent on different views on what the fundamental basis of the right is—for example, on whether the right to reproduce is claimed a natural right, or as an aspect of autonomy—and on how these concepts themselves are understood. For example, it might appear strained to argue for a *natural* right to reproduce by *artificial* means, unless it is argued that the artificial is necessary in order to fulfill a natural purpose of human life. Should infertility be regarded as a disease that needs treatment, or just an unfortunate inability to satisfy one's wishes? Again, while on the one hand an autonomy argument might be deployed to suggest that the right to reproduce is an aspect of doing as one wants with one's body, on the other hand, in so far as reproduction has effects on others and requires the allocation of health care resources, it is difficult to see how the argument can, by itself, provide an argument for the cooperation of others. The welfare of future children is a consideration that may compete with that of the reproductive rights of adults.

RIGHTS THEORY

Rights are generally defined as justified claims for the protection of general interests. In this sense, human beings have been described as having rights to property, "to life, liberty, and the pursuit happiness" (United States Declaration of Independence, 1776), as "free and equal in rights" (Declaration of the Rights of Man and Citizen, 1789), and as having rights "to share in scientific advancement and its benefits" (Universal Declaration of Human Rights, 1948). More recently civil rights or liberties to freedom of speech and assembly have been complemented by proposals for social, economic, and welfare rights to minimum levels of shelter, food, and medical care. What was initially a quite limited relation of rights to science and technology, insofar as their advancement rested on the protection of intellectual property rights, has become increasingly a question of consumer rights to certain levels of material benefit and safety related especially to technology. The assessment of such diverse claims nevertheless requires appreciation of the broader philosophical discussion of rights and various analytic distinctions introduced to clarify numerous complications.

Fundamental Distinctions

As initial observations have already indicated, the notion of rights has become deeply embedded in modern societies, but it has critics precisely because of its origin in particular socio-cultural contexts and because of its relationship to individualism. "Rights express the idea that respect for a given interest is to be understood from the point of view of the individual whose interest it is" (Waldron 1993, p. 576). While this statement arguably overlooks the fact that it is not only individuals but also groups that may be held to have rights, as seen in debates about rights of particular minorities, it soon becomes clear that this does not avoid questions of individual rights: Some of the most difficult issues with group rights concern relationships of the individual *to* the group.

The classic and most systematic attempt to delineate different kinds of rights was that of Wesley Hohfeld (1919), who identified a number of distinct categories. Some of the ways in which the term *rights* would be used, he argued, would be more accurately captured by the term *privileges*. These are to be contrasted with rights "in a strict sense," which Hohfeld categorized as claim-rights.

If a person X has a claim-right, in Hohfeld's sense, there must be at least one person who has a duty to X with regard to that claim. This is the thesis of correlativity of rights and duties: A claim can normally be met only through the efforts, or at least the non-interference, of others. This thesis has come to be regarded as definitive of rights.

To say that X has a privilege, however, has no such implication. A privilege is a liberty to do something, which may be either of a general or a special kind. In the general sense a privilege to act in a certain way is simply the absence of a duty to avoid doing it. No one is in a position to make a counter-claim against the person. In the special sense, however, a privilege is a liberty that is *exceptional,* that is, it is not enjoyed by other persons—for example, informed consent on the part of patients allows health care professionals certain liberties to do things to them which may be invasive, which would not be permissible in other circumstances. Hohfeld also distinguished claim-rights from other terms such as powers and immunities.

Questioning Correlativity

The thesis of the correlativity of rights and duties is problematic. First, different aspects of correlativity have been distinguished: the moral and the logical (Feinberg 1973). The moral correlativity thesis states that in order to have rights individuals must have and accept duties themselves. This is controversial because it would rule out the rights of persons with mental incapacity. Some would argue that all human beings have rights, pre- as well as postnatally, even if it is not possible to hold them to be subject to duties.

The logical correlativity thesis is concerned with what X's rights imply for others' duties. In terms of Hohfeld's claim-rights, which are *defined* in terms of the duties they imply for others, then questions arise about what those duties are, for where rights *do* imply duties, these may be of different kinds. For example, if X has a right to something, while it may not be the case that there is any person Y in particular who has a duty to do anything to help X to get that something, it may yet be appropriate to say that everyone has a duty not to *prevent* X from getting it.

More generally, however, the question has to be asked whether the correlativity thesis is true of all rights. The term *rights* has certain uses in political discourse, which go beyond claim-rights. This is described as the rhetorical or "manifesto" use. Thus Onora O'Neill writes: "A 'right to food' could be satisfied by earning enough money to buy food, by having enough land to grow it or by having friends and family with obligations to provide it; in each case there would be an entitlement to food . . . But without one or other determinate institutional structure, these supposed economic rights amount to rhetoric rather than entitlement" (O'Neill 2000, p. 125). Such "rights" arguably do not imply duties on the part of anyone in particular.

Furthermore, even where rights imply duties, it does not appear to be the case that the converse applies: That where there are duties there are always corresponding rights. If one accepts that X has a right to the fulfilment of a promise, there must be someone who has a duty to fulfil it, and if Y has a duty to fulfil a promise, there must presumably be someone who has a right to have that duty fulfilled. Promising involves correlativity of this kind. Other duties, however, such as those involved in scientific inquiry, for example, are not of this type. Duties to pursue truth, avoid fraud, and publish results are arguably not best explained in terms of other people's rights, but arise from the nature and purpose of the activity itself.

Claim Elements

If one accepts that in addition to claim-rights in the strict sense there are also wider uses of the term, it is still possible nevertheless to regard rights as including a claim *element*. In order for a claim to be a right, however, it must be justified. The two elements, a claim and a justification, are common to both Hohfeldian claim-rights and manifesto rights. Different moral theories will attempt to justify rights in different ways, however, and it is the type of justification to which appeal is made that categorizes a right as of one sort or another. In the case of a claim-right to the fulfilment of a promise, that the promise was made, and thus a duty incurred, will form part of the justification. In the case of a manifesto right, however, the justification could be in terms of moral judgments about what should be the case, and may be based more on moral ideals of principles of justice than on duties.

There are at least two further distinctions it is important to consider in thinking about the claim element of a right: the contrast between *negative* and *positive* and the importance of rights of *voice* and rights of *exit*. The distinction between negative and positive rights depends on what they imply for others—either non-interference or positive action, respectively. The right to freedom of scientific inquiry, for example, might be construed negatively as a freedom right not to be prevented from pursuing a particular line of research. At the same time, it might be argued that freedom of scientific inquiry is meaningless unless research is funded, which might imply positive action on the part of others such as governments and research councils.

Claim-rights may change their content over time from negative to positive, depending on the social context. Thus at one time the right to reproduce was construed as a negative right to be free from interference: the right to choose whether or not to reproduce. Over time, however, it has been argued to include not only the right to decide on the number and spacing of one's children, but also, by some, the type of children one has. This has led to arguments about the extent of the different duties for others, including the provision of contraception advice, assisted reproduction where necessary, and sex selection. Again, X's right to life implies a duty on everyone not to kill X, but might also require, in a certain circumstance, that a bystander who has the ability to save X from drowning has a duty to do so.

The distinction between *rights of voice* and *rights of exit* (see Hirschman 1970) is particularly prominent in discussions of group rights. Rights of exit include the right not to participate—that is, the right to choose not to accept traditional practices of the group, such as practicing a certain religion. There is a view that the individual's right to exit from a group is essential if groups are to claim rights. A formal right of exit, however, may be insufficient to protect some oppressed group members, such as in the case of women traumatized by domestic violence. Rights of voice, as the name implies, involve the ability to participate in decision-making and to express one's preferences in, for example, political decision-making. The relationship between the two is complex: Arguably individuals should not need to exit if they have a right to exercise their voice within the group so that things can be changed from within.

The debate about rights of voice and rights of exit demonstrates the close association of rights talk with liberalism. Historically rights emerged in the context of liberalism, being concerned with essential freedoms and limiting government power, but there is an issue concerning the extent to which they should be limited to freedoms *to* do certain things, such as freedom of speech and movement, or whether they also embrace freedoms *from* such conditions as poverty. The distinction between negative and positive rights, describable as a distinction between freedom rights (liberal, freedom *to* rights) and rights of recipience or welfare rights, reflects underlying differences in political philosophy and justification.

Natural Rights

In moral and political argument, rights are used sometimes as starting points, sometimes as conclusions. A prominent example of the use of rights as starting points is to be found in Robert Nozick's *Anarchy, State and Utopia* (1974), the first sentence of which states: "Individuals have rights, and there are things no person or group may do to them (without violating their rights)." Nozick sees himself as operating in the tradition of the seventeenth-century philosopher John Locke (1632–1704), arguing that human beings have certain "natural" rights.

The notion depends on state of nature theory and natural law. The idea of a state of nature is a hypothetical state external to society, in which human individuals are unaffected by social conditioning, and which operates as a device for critical reflection on existing societies. The laws of different societies assign to their citizens or subjects different rights and duties. But beyond this, it is argued, there are natural laws and natural rights, which provide a point from which to criticize the laws in any particular society (such as laws that allow for institutions such as slavery). Locke argued that in a state of nature there would be a natural law that "no-one should harm another in his life, liberty or property" (*Two Treatises of Government*, ed. Peter Laslett, 2nd edition, Cambridge University Press, 1967).

The idea of natural rights has been heavily criticized, most notably by Jeremy Bentham (1748–1832) who described it as "nonsense upon stilts." Bentham argued: "From real laws come real rights; from imaginary laws come imaginary rights." ("Anarchical Fallacies" in *The Works of Jeremy Bentham*, Vol. II, ed. J. Bowring; Edinburgh: William Tait 1843). The doctrine of natural law confuses the questions of what the law is and what the law ought to be. While one can criticize the law from a moral point of view, in order to do this one needs a perspective such as that of utilitarianism, not the notion of natural law.

The idea of the state of nature has also been criticized as ahistorical by Marxist and feminist critics. The objection is that there is no universal human nature, no pre-social state of nature. What people are like, as well as their values and expectations, are the products of the society in which they live. There is a strand in natural law thinking that natural rights should be *evident* to everyone. But even those philosophers who employ the notion of a state of nature differ over how it is to be understood, and there is further disagreement over what rights there are. Property, for example, is high on the list of Locke and Nozick, but it is by no means evident to all that it is a *natural* right. From an opposing point of view the so-called "natural" right to property is a historically conditioned expression of the interest of those who have it. Rights are seen as institutionalizing certain interests at the expense of others. The debate about property rights has been particularly pertinent in science and technology, in the context of intellectual property and patenting, for example in relation to the human genome. The distinction between what is discovered and what is invented relies on a notion of what exists by nature, but controversy continues over what can legitimately be patented.

Human Rights

Nevertheless the idea that there are universal and timeless rights grounded in enduring features of human nature has persisted. The United Nations Declaration of Human Rights (1948) and the European Convention on Human Rights (1950) are expressions of this idea, although dispute has raged over how many of the rights contained in these documents are real rather than manifesto rights.

Despite traditional criticisms of natural rights, Tom Campbell (1983) has argued that socialists need not object to the notion of human rights as protectors of fundamental human interests, if this notion is divorced from the ahistorical concept of a state of nature and from the traditional view about what rights human beings have. On this view, the problem with the tradition of liberal western democracy in which the notion of natural rights flourished has been the concentration of thinkers in that tradition on "freedom" rights at the expense of "welfare" rights. To focus on freedom rights can seem callous when people's basic food needs are not being met.

The objection to this from those who favor freedom rights is that welfare rights cost money, and therefore are not always feasible. In order to count as a genuine human right, any given right must be "practicable, universal, and paramount." Consider again the example of the right to reproduce. If this is understood as the right to be free from interference, then it might appear to cost nothing. If it is interpreted as a right to in vitro fertilization (IVF), however, the costs could spiral out of control. Nevertheless, the so-called freedom rights also cost money and it might be better to think in terms of basic rights rather than accepting the negative-positive distinction (see Shue 1980). The right to freedom from interference in one's private life, for example, might require the provision of some machinery of justice, including a police force.

Thus the idea of natural rights as starting points runs into difficulties, while the notion of human rights has become a site of political struggle between competing political ideologies. So on what basis can an argument for rights be put forward? It is possible to put forward arguments on utilitarian grounds, giving reasons why people should be free to do certain things or why they should receive particular goods and services: in other words, that they should have rights to do x and y or to receive p and q because to do so leads to good consequence. In this sense the term *right* is quite vulnerable to being trumped by other considerations, as this way of reasoning does not regard rights as attaching to individuals in quite the same way as in the natural rights tradition: as integral to what is understood by a human being.

Rights as Conclusions

Ronald Dworkin (1977) has argued that rights themselves should be regarded as trumps over some background justification for political decisions that state a goal (such as one based on utilitarian reasoning) for the community as a whole. An example would be that if someone has a right to publish pornography, this means that it is for some reason wrong for officials to act in violation of that right, even if they (correctly) believe that the community as a whole would be better off if they did.

Dworkin argues for a "rights-based morality" in contrast to one based on either duties or goals. His arguments started with the claim that government must treat those whom it governs with equal concern and respect. He identified his aim as that of examining how far a theory of rights can be constructed from the abstract idea that government must treat people as equals. It was Dworkin's contention that utilitarianism does not do this. Despite its claim that "each counts for one and no one for more than one," he argued that utilitarianism is corrupted by external preferences, where external preferences are preferences we have regarding other people. An example might be that people who are homophobic do not only have a preference regarding their own sexuality but also have an external preference that others should not be free to embrace homosexuality. If the majority shared these external preferences the minority could experience discrimination and hardship. In the context of science and technology, some people object so strongly to possibilities such as human reproductive cloning that they not only wish not to engage in it themselves, but want it to be universally prohibited, although others argue that it could be contemplated as an application of the individual's right to reproduce.

Therefore in a society where the background justification is utilitarian, rights are needed to act as trumps over the outcome of utilitarian calculations. It is important to note that Dworkin does not want to exclude all external preferences (for example, charitable ones), but only those that fail to treat human beings with equal concern and respect. Thus he argues for basing political morality around a fundamental right to equal concern and respect.

Objections to Rights-Based Morality

Rights-based morality nevertheless overlooks crucial features of the moral landscape (see, for example, O'Neill 2000). Rights are adversarial, and may be useful when opposing oppressive governments—perhaps particularly in drawing attention to the plight of particular groups—but apart from such situations it may be more appropriate to look to another framework, such as that of duties. This way of looking at things, drawing more on the thought of Immanuel Kant (1724–1804), directs attention to what people ought to *do* rather than what they ought to get. Duties "formulate the requirements to which Declarations of Rights merely gesture," but rights have acquired popularity, argues O'Neill, because they appear to offer something to everyone (O'Neill 2000) without focusing on the associated and varied costs. While rights-talk is pervasive, it is important always to be alert to the question of justification of any particular rights claim.

As should be clear from the present discussion, although rights are easily asserted with regard to many aspects of science and technology, the full legitimization of such assertions is much more difficult. It may be that individuals have rights to intellectual property in particular forms of scientific inquiry, and that consumers have rights to be protected from invasions of privacy by means of surveillance technologies. It may be that individuals have a right to exit certain aspects of scientific and technological development, and that different publics have the right to a voice in the governance of science. However, for what are often no more than manifesto rights to become fully warranted claims will in many instances require further reflective consideration than has to date been achieved.

RIGHT TO DIE

For literally hundreds of thousands of years, human beings recognized death as inevitable feature of the human condition—to be avoided when possible, but ultimately accepted as necessity. Indeed, one of the distinctive features of moral reflection involved considerations of how properly to approach death. The idea that one had a right to die rather than a necessity to accept death with grace would have been inconceivable. In the last half of the twentieth century, however, advances in scientific medicine and technology fundamentally altered the traditional framework of reflection on death. As it becomes increasingly possible to prolong death and to extend the life span, it becomes necessary not simply to accept death but to consider a possible right and in some cases even responsibility to die.

The claim that the individual has a right to die presupposes not only advances in science and technology however but also individualism: It requires a view about the individual having control over his or her own life. This is by no means a claim that has won universal support. In some societies the individual life has been regarded as belonging to the king or ruler who could command its sacrifice; another view is that it is for a divine being either to bestow or to take away life.

Even within an individualistic framework, however, the basis and limits of a right to die are not always clear. First, as rights are commonly supposed to impose duties on others, a right to die may require others at least to refrain from interfering, and possibly also to provide assistance, so speaking of a right to die may have a number of meanings, such as death through assisted suicide; rejection of treatment, food, and hydration; and euthanasia. Common to all these may be an argument that the individuals should be free, where possible, to choose the timing and manner of their death. They differ in their implications for other people involved (that is, what exactly other people have to do or refrain from doing in order to allow the individual to exercise their right).

Arguments for a Right to Die

To be free to choose to die, when life has ceased to hold any attraction or meaning, might be supported on the basis of a respect for autonomy. The simplest case appears to be that of the individual who both wants, and has the means, to commit suicide. The implications for third parties in this case are simply to refrain from interference. The German philosopher Immanuel Kant (1724–1804), however, argued that the rational agent could not consistently will to end one's own life, for this would mean that the same will that naturally wanted to extend life at the same time wanted to end it, and this involved a contradiction. He also argued that to commit suicide involved failing to treat rationality in one's own person as an end. There are clearly difficulties with this Kantian argument, because it fails to recognize any circumstances in which ending one's own life would be a rational course of action. It is significant, however, that mental health legislation has commonly regarded suicidal impulses as evidence of lack of rationality.

If autonomy is interpreted in the manner of the English philosopher John Stuart Mill (1806–1873), then there are strong grounds supportive of a right to die. Mill argued that when people interfere on paternalistic grounds to prevent persons from harming themselves, it is likely they will interfere wrongly, because individuals are in general the best judges of what is in their own interests. This suggests that an individual may very well be in a good position to know when life no longer has any meaning or value for the individual whose life it is. The onlooker may try to engage in rational argument, but should not forcibly interfere.

The issues become more complicated when the duties that the right implies for others involve positive assistance, such as in assisted suicide, which is distinguished from voluntary euthanasia on the grounds that the patient remains the agent. Apart from the legal requirements that may apply in different jurisdictions, there are questions about what obligations, if any, there are to assist. This is particularly problematic where individuals who wish to die do not have the means or ability to take their own life—for example, when they are incapacitated to the extent that they cannot help themselves. The assistance required may be providing the means, such as administering a drug, or withdrawing of food and fluids. There are issues here, also, about *who* is being asked to provide assistance—whether it is a friend, or family member, or a health professional. There are special questions about professional roles and the extent to which the obligations of professionals differ from those of others. Withdrawal of food and fluids may be regarded not as treatment, which an individual is entitled to refuse, but as a basic human right that is inalienable, or as basic care that should never be withdrawn.

Several key cases have addressed the issues of the right to die in the absence of the capacity for autonomous decision-making. The 1976 Karen Quinlan case (In re Quinlan, 70 NJ 10, 355 A.2d 647 [1976]) in the United States decided that Quinlan's right to privacy supported her right to be removed from a ventilator. In the United Kingdom, the 1993 Tony Bland case (Airedale NHS Trust *v.* Bland [1998] HL) concerned a patient who had been in a persistent vegetative state for more than three years when the hospital sought a declaration that it could lawfully withdraw all forms of life support. The case went up to the House of Lords, who argued not that it was in Bland's best interests to die but that it was not in his best interests to prolong his life in those circumstances, and that it was lawful to withdraw feeding.

In 2005 the case of Terri Schiavo, a Florida woman in a persistent vegetative state for more than a decade, became a cause célèbre because of basic disagreements between her husband and her parents over whether a feeding tube should be removed. For the husband, consistently supported by the courts, this would allow her to die in accord with previously expressed desires not to become dependent on extraordinary technological means. For the parents and many religious supporters, this was tantamount to murder.

The sense that individualism, and individual choice, need to be mediated by a sense of natural limits, also has the potential to facilitate acceptance of a responsibility to die, especially at a time of ever increasing possibilities for intervention.

RIGHT TO LIFE

What was once considered fate or a gift, that is, human life, is increasingly thought of as subject to manipulation or control by means of scientific research and biomedical technology. The ability to regulate fertility and pregnancy on the basis of knowledge and desire, along with psychological studies of child development and the potentials of genetic engineering—not to mention the potential of nuclear weapons and other runaway technologies to destroy all life on the Earth—have conspired to promote consideration of possible rights to existence of those forms of life that have become increasingly subject to the unintended impacts or conscious manipulation of others.

The Right to Life: The Narrow Sense

When the right to life is spoken of, it is normally human life that is meant, although there are arguments for extending the scope of the right to other life forms. To restrict the right to the human species may attract the charge of speciesism. For present purposes, however, the discussion will be confined to humans.

The force of the right to life, insofar as it imposes obligations on others, is normally to stress the wrongness of killing, rather than a positive right to be brought into existence. This is because it is difficult if not impossible to identify someone who would be wronged by not being brought into existence. There is also controversy over whether someone can be wronged *through* being brought into existence, as in the debate about "wrongful life." It does not follow, however, that the right to life has no implications for positive aid. There are differences of opinion about the extent to which a right to life could impose obligations to *save* another's life.

One of the most difficult problems facing a right to life, however, concerns the definition of human life—especially with regard to its beginning and ending. There is disagreement both about when life begins and about when it ends. Some would say that the question of when life begins is not the right question, because life is ongoing. The germ cells are alive and life continues from generation to generation. What is normally meant, however, is the life of an identifiable individual—but even this is not clear-cut, with some putting more emphasis on the concept of the person than on that of human being. There is a similar issue at the end of life—whether what is important is the death of the organism or the end of everything one recognizes as personhood.

Arguments for a Right to Life

Not all arguments for the view that killing a human being is wrong use the terminology of rights. It might depend upon a view about the sanctity of human life. The doctrine of the sanctity of human life might be religiously informed: Life is a gift from God and therefore sacred. It is a way of expressing the view that life has intrinsic value—it is valuable in itself, from beginning to end, and it is wrong to destroy it.

Those who support the sanctity of life doctrine typically also take a conservative view about the beginning and ending of life, the presumption being that there is something of intrinsic value from the moment of conception, and that while there is life there is a being worthy of respect at the end of life. On the sanctity of human life view there can be no trade-offs. In other words, it would not be permissible to kill one innocent person in order to raise the quality of life of others, or even because of the opinion that a person's quality of life is no longer worth living. Critics point out that this has implications for social policy. How can there be justification for taking money away from life-saving enterprises and giving it to those that can at best only improve quality of life for some people? Upholders of the sanctity of life doctrine here fall back on a distinction between negative and positive, holding that the doctrine imposes the obligation not to kill, but not necessarily to save at all costs.

Ronald Dworkin has stressed the importance of distinguishing the sanctity of life view from the view that the individual is a person with rights and interests. According to the doctrine of the sanctity of life, life has intrinsic value even if it is not in a person's own interests to continue living, and even if the focus of discussion is not a person with interests of its own. Thus the sanctity of life doctrine provides an objection to abortion even if is not presumed that the fetus is a person.

Arguments that do depend on rights, however, have to face the problem that different rights of different individuals may conflict, and it is not always clear how they are to be balanced against each other. Utilitarianism offers a way in which to balance the interests of different persons. It is sometimes criticized for being willing to sacrifice one life to save more, because the individual life is not regarded as sacred. Although killing is directly wrong, it is not *absolutely* wrong on this view. For a utilitarian, killing is wrong because of its consequences, both for the person concerned and for third parties. It is wrong to the extent that it prevents happiness, destroys a "worthwhile life," or creates misery. The person killed loses the chance of any future happiness. Third parties may suffer side effects such as distress at the loss of the person and fear for their own fate if the protection against killing is weakened.

A potential killer may nevertheless judge that the person in question does not have a life worth living. While side effects provide some protection against someone carrying out this sort of calculation, there is still a problem in hypothetical situations where adverse side effects can be ruled out. A further argument is that if someone wants to go on living, that is evidence that they have a life that is worthwhile.

If what is valued is the *amount* of happiness or worthwhile life, rather than the intrinsic value of the individual life, then in some circumstances this can be maximized by killing one person to save five. In many cases, again, this objection can be met by pointing to the undesirable side effects of a policy that is willing to sacrifice individuals. At the same time, because utilitarians see consequences as more important than the means of arriving at those consequences, they are less impressed by the distinction between killing and failing to save. Failing to help a person when help is available can be just as bad.

Hard Cases

For some, the right to life is inalienable—it cannot be given up. Others take the view that it can be forfeited; for example, by murderers, so that capital punishment becomes a justifiable form of killing. The greatest controversy, however, occurs over the issues of euthanasia, embryo experimentation, and abortion. In the latter two cases the disagreement is not so much over the right to life *per se* as over the status of the embryo and fetus. What some regard as the possessor of rights, others regard as a collection of cells and the issue has to be resolved by social decision-making, such as laws permitting embryo experimentation for a certain limited time.

Broader Views

A wider interpretation of the right to life could embrace notions of the right to survival of the human species overall. Concerns about environmental degradation and human conflict have led to calls for a balance between the quality of the environment and the sanctity of the dollar, rather than a focus on quality of life and sanctity of life in medical interventions. Such a global bioethics stresses the importance of acceptable survival for the human species. Others go beyond the survival of the human species, expanding the circle of morality to include other species, and respect for all life.

RIGHT TO REPRODUCE

SEE *Rights and Reproduction.*

RISK AND EMOTION

Technologies, particularly if they are new, often give rise to emotional reactions that are based on perceived risks. Recent examples of such technological risks involve cloning and genetically modified food; the use of nuclear energy continues to spark heated and emotional debates. Empirical research has shown that people rely on emotions in making judgments about what constitutes an acceptable risk (Slovic 1999). However, this does not answer the question of whether judgments that are based on emotions can provide a better understanding of the moral acceptability of risks than do judgments that do not take the emotions into consideration. Many scientists dismiss the emotions of the public as a sign of irrationality. Should engineers, scientists, and policy makers involved in developing risk regulation take the emotions of the public seriously?

Emotions and Moral Judgments

There are two major traditions in modern moral theory that deal with the role of emotions, going back to the Enlightenment thinkers David Hume (1711–1776) and

Immanuel Kant (1724–1804). For the Scottish philosopher Hume ethics is based not on reason but on the emotions, particularly the sentiment of benevolence, which reason assists in achieving its goals. In opposition to that view the German philosopher Kant maintained that ethics depends on the rational determination of human conduct, with the emotions tending to function as distractions. In neither case, however, are the emotions understood to function in a cognitive manner to reveal something about the world. They are either the noncognitive source of moral value or a noncognitive distraction from moral rationality.

A quite different minority tradition in moral theory, however, grants the emotions cognitive value. This line of thought goes back to Aristotle (1925) who argued that through emotions we perceive morally salient features of concrete situations. In Hume's time the economist Adam Smith (1723–1790) suggested in *Theory of the Moral Sentiments* (1759) that emotional sympathies for others through imaginative identification with their pleasures and pains can provide knowledge about how other people experience the world. For Max Scheler the emotions are the motivators of decent behavior; they reveal the basic moral facts of life (Scheler 1913–1916).

In the 1970s such theories of the cognitive power of the emotions were given new support by developments in neurobiology, psychology, and the philosophy of the emotions. For scholars as diverse as Ronald De Sousa (1987), Robert Solomon (1993), Antonio Damasio (1994), and Martha Nussbaum (2001) emotions and cognitions are not mutually exclusive. Rather, to have moral knowledge, it is necessary to experience certain emotional states.

To be able to have moral knowledge, a person has to know or be able to imagine how it feels to be in a certain situation and to be treated by others in certain ways as well as how it feels when one is humiliated and hurt or cherished and embraced. These emotions are fundamental features of human life that point to what morality is really about. It is not possible to understand moral life without knowing these emotions and without having the ability to feel sympathy and compassion for others. Hence, only beings with the ability to have emotions can make justified moral judgments. The moral point of view implies that people can feel with others or at least imagine what their emotions might be like and that people care about morally important aspects of the lives of others (Schopenhauer 1969, Scheler 1970).

Emotions and Judging the Acceptability of Risks

A cognitive theory of emotions provides new insights about emotions toward acceptable risks. With the traditional picture one would have to choose between the horns of the Hume-Kant dilemma: either take emotions seriously but forfeit claims to rationality or emphasize rationality at the expense of the emotions. With a cognitive theory of emotions, however, one can argue for taking emotions seriously in order to achieve a more comprehensive rationality, particularly with respect to the moral acceptability of technological risks.

As an example, if people are forced against their will to do something they consider dangerous, this is most likely to result in emotions of anger or frustration. However, that is a completely reasonable response. A prima facie injustice has been done to them, and only if they can be persuaded that there are good reasons why they should undergo this specific risk will their anger subside. In contrast, if no good explanation can be given, they will remain upset. In fact, one might find a person irrational who would not get upset by such an injustice. One would judge a person confused who said, "I know company X is not respecting my rights by building this chemical plant in my neighborhood without informing me or asking my consent, and I think it is not fair, but I don't care." A moral judgment that does not lead to an appropriate emotion is seriously flawed.

Some cognitive theories of emotions would take this analysis even further and claim that without certain feelings or emotions a person is unable to have appropriate moral judgments (e.g., De Sousa 1987, Solomon 1993, Damasio 1994, Nussbaum 2001). When people fail to become outraged in response to abridgments of their autonomy, they may not fully grasp the injustice being done to them.

Moreover, people find it morally reasonable not only for the victim of an injustice to be outraged but also for witnesses to be affected in the same way. People even expect that those who inflict an injustice on others should be forced to reassess their actions if they truly care about those they harm. When such agents are unmoved by feelings of sympathy, they are thought of as hard-hearted and egoistical. Emotions thus help assess not only one's own situation but that of others as well as one's own actions in relation to others. In such ways emotions may lead to fairer social arrangements concerning technological risks.

Evaluation of Emotions Concerning Risks

The idea that emotions are useful pathways to moral knowledge concerning risks does not entail the idea that emotions are infallible as normative guides. Emotions also can be wrongheaded or misguided. Emotions can help people focus on certain salient aspects, but they also can lead people astray. Engineers may be enthusiastic about their products and overlook certain risks. The public may be ill informed and thus focus only on risks and overlook certain benefits. Both parties may be biased, and their emotions may reinforce those biases.

In such situations followers of Hume might claim that emotions should rule. Followers of Kant, by contrast, might argue that emotions should be set aside in favor of purely rational analysis. Those who adopt a cognitive theory of the emotions would defend the emotions as a potential source of new knowledge. Not only can reason be brought to bear in a critical manner on the emotions, the emotions may be used as a basis for critical assessments of reason. Indeed, the emotions themselves may be played off against each other in pursuit of mutual emotional assessment. One example would be the development of affective appreciation through sympathy with opposing perspectives. Engineers might try to make an emotional identification with the perspectives of the public, and vice versa, and those who benefit from technology might try to appreciate the perspectives of those who incur its costs. Without emotions being brought into the mix, well-founded judgments about the moral acceptability of technological risks are unlikely.

RISK AND SAFETY: OVERVIEW

Risk and safety are polyvalent concepts with numerous and overlapping ethical complexities in relation to science and technology. As such they are dealt with in a number of different entries.

In technical terms, scientific phenomena may exhibit certainty, risk, or uncertainty. Situations of *certainty* have a probability of 1. For example, all things being equal, it is certain (probability = 1) that water freezes when cooled below 0° Celsius. Cases of *risk* have some numerical probability between 0 and 1, based on a known or assumed model of what causes the outcome under study. For instance, the risk of tossing "heads" on a fair coin has a probability of 0.5, because the model is known. In risk assessment, the risk of something is typically defined as the average annual estimated probability of causing a fatality. Cases of *uncertainty* cannot be defined *a priori* in terms of probabilities, because of inadequate knowledge. To assign legitimate or scientifically valid probabilities, one needs experimental or frequency/statistical data; an example is data on automobile accidents for drivers of a given age. In many cases of uncertainty there may simply be no adequate data.

Despite the name, "risk assessors" typically do not assess cases of risk (with known or well-established probability between 0 and 1), but situations of great uncertainty.When people have "risk" knowledge, they do not need risk assessment. In part because they address uncertainty in extremely complex situations, risk assessments usually err between four to six orders of magnitude

(Shrader-Frechette 1991). That is, fatalities predicted by risk assessments typically are (later proved to be) wrong by factors of 10,000 to 1,000,000. Most predictions are too low and exhibit an "overconfidence bias" in favor of some technology (Kahneman and Tversky 2000; Kahneman, Slovic, and Tversky 1982).

It is against this technical background that the following entries on risk need to be read: "Risk Assessment," "Risk Ethics," and "Risk Perception." Other entries—such as "Risk and Emotion" and "Risk Society"—make an effort to move beyond the more strictly technical understanding of risk.

There is no technical concept of safety analogous to that of risk. Nevertheless, according to an influential analysis by William W. Lowrance, safety can be defined in terms of risk: "A thing is safe if its risks are judged to be acceptable" (1976, p. 8). Mike W. Martin and Roland Schinzinger pointed out as early as 1983 that this definition needs a qualifier: The judgment of acceptability needs to be done with adequate knowledge. Free consent is not enough; it must be free and informed.

Langdon Winner, however, has gone further and warned against defining safety in terms of risk. According to Winner, traditional efforts to promote safety had a clear goal of eliminating certain "workplace dangers" or "health hazards." But when the promotion of safety involves assessing risks in terms of their acceptability, the goal fades into "studying, weighing, comparing, and judging circumstances about which no simple consensus is available" (1986, p. 143). It is against this critical background that the articles on "Safety Engineering: Historical Emergence," "Safety Engineering: Practices," and "Safety Factors" need to be considered.

There are also a number of articles that are related to the concepts of risk and safety. Among these it is useful to mention "Exposure Limits" and "Hazards." Even more specific topics include "Radiation" and "Regulatory Toxicology."

RISK ASSESSMENT

Many decisions involve an intuitive assessment of risk; this subjective risk assessment is usually called *risk perception*. Risk assessment is also a formalized approach to evaluating risk, often defined as a function of the probability and magnitude of loss or harm from an event. Risk assessment is often thought of as ethically obligatory, but since it can be done in more than one way, it is itself subject to ethical assessment.

Risks are routinely assessed formally for a wide variety of human endeavors, from drinking tap water to operating nuclear power plants; for natural hazards such as earthquakes, hurricanes, and floods; and for the human use of and exposure to chemicals and other substances such as arsenic or phthalates. Risks may also be defined and assessed in terms of specific harms or losses to people, for example a person's lifetime risk of dying of heart disease, or aquatic ecosystem risks from anthropogenic eutrophication (that is, being overburdened with nutrients as a result of human action). While failing to assess risk can lead to Faustian bargains with the future, risk assessments for public policy can be risky in themselves, as illustrated by the effects of transnational debates about risk assessments of genetically modified organisms, vaccines, and terrorism.

Methods

As described in *Risk Assessment in the Federal Government* (known as the "Red Book," 1983), risk assessment consists of four steps: hazard identification, dose-response assessment, exposure assessment, and risk characterization. More broadly, risk assessment entails identifying and characterizing an underlying hazard—including its sources, pathways, effects for given exposures, and mitigating factors, and estimating the associated contingent probabilities. In effect, formal risk assessment requirements are intended to insure that human and even ecological health is considered in decisions with other primary objectives.

For example, product risk assessment may be required by law, as in the case of new pharmaceuticals in the United States. In the United States, the Food and Drug Administration (FDA) assesses the adequacy of new drug risk assessments, including how they are conducted. The FDA also determines what constitutes permissible risk for a licensed product. As risk assessments are generally conducted in the service of specific risk management objectives, the two are mutually dependent (Committee on Risk Assessment of Hazardous Air Pollutants 1994). In some venues separation of risk assessment and risk management is considered critical to protect the science of risk assessment from contamination by management or political pressures. However, many formal risk assessment processes now include participation by multiple stakeholders to deliberate about risk management objectives and values, in addition to experts' technical analyses (Stern and Fineburg 1996).

Human health risk assessments are of necessity carried out at a population or group level—that is, for a statistical person rather than an identified individual. They are based on extrapolations from animal studies; on experimental tests of human product use, which usually involve relatively small samples; or on epidemiological studies, which rely on statistical controls. Recent developments in risk assessment have included the ability to tailor risk assessment results interactively for subpopulations, as is illustrated by online risk calculators that determine an individual's risk based on a few personal characteristics. But individual differences can make the population health risk assessments applied in policy decisions more or less applicable, for which reason minority populations may be poorly served by general risk assessments. An example in point is airbags in cars, which when designed to optimally protect average adults may harm or kill children.

Environmental risk assessment, as required for example in environmental impact statements, has focused largely on risks to human health and the economy, but increasingly addresses ecological endpoints. Because selection of assessment endpoints can determine the structure and outcome of decisions, it is inherently controversial. Assessing risks from ozone only in terms of economic loss from damage to automobile tires paints a very different picture of the size of the risks than if the assessment also takes into account acute respiratory or cardiovascular events triggered by exposure to ozone, or possible ecological effects of ozone, such as reduced growth rates and plant deformation.

Basic Issues

By focusing on probabilistic loss, risk assessment frames management choices in terms of threat reduction and loss avoidance. Common criticisms of risk assessments have included that they are based on an overly narrow conceptualization of benefits, or that the dimensions of harm included are insufficient or inappropriate. It is difficult to incorporate into a risk assessment even proxy measures for intangibles—such as quality of life—or other poorly defined or understood endpoints. In part to take into account uncertainties, risk assessments are sometimes designed to produce estimates of risk that err on the high side, for example by using upper bounds of estimated risks, rather than averages. Those risk assessment procedures that have been codified by government entities incorporate scientific procedures, including requirements for representative empirical data, statistical analyses, and quality control in the form of peer review. Some also include ethical requirements, such as human subjects review, or the participation of parties who may have a substantive interest in the value at risk.

Four issues are key to risk assessment as currently practiced. The first is what is valued, how and by whom it is valued, and the distributive implications thereof. The selection of assessment endpoints can have far-from-obvious implications, as the airbag example illustrates. Assessing values remains a methodological and ethical challenge (Fischhoff 1991, Slovic 1995).

The second is the treatment and interpretation of uncertainty—both uncertainty stemming from limits to what is known, and uncertainty stemming from inherent variability (see Morgan and Henrion 1990). Especially in the case of extremely rare and catastrophic events, the selection of a distribution function or simulation procedure with which to analyze uncertainties can influence the outcome of the assessment considerably. Similarly, choosing how to represent the results of the risk assessment and the uncertainty therein can influence how recipients interpret and use the assessment.

The third key issue is the substitutability implied or assumed by risk assessment, as it often requires comparative values. As has been illustrated in discussions of protected values and irreversible effects, in reality trade-offs are sometimes impossible or unethical.

Fourth is that technically competent risk assessment requires significant resources, is both analytically and data-intensive, and can be difficult to interpret. Risk assessments that are carried out for new drugs, for example, require expertise in toxicology and epidemiology and investments in large studies, which still may not be large enough to discover devastating rare or long-term adverse effects.

Risk assessments may produce risk characterizations that are not readily used to compare or prioritize risks. For example, ecological risk assessments may conclude simply that a specific species is at some risk of extinction, while a human health risk assessment may produce an estimated probability of a specific health endpoint within a given timeframe, for example a five percent probability of being diagnosed with breast cancer within five years. Comparing the two is difficult.

For this reason it is desirable that risk assessment outcomes be translatable to a common measure, such as an abstract measure of utility, or monetary value. Summary endpoints like the probability of human mortality or morbidity, or economic loss, can be presented in a common metric that facilitates at least some comparisons, such as disability adjusted life years, or monetary value. But choice of a common metric itself can be problematic, both because individuals may not agree on the equivalence of different forms of bodily injury or harm and because not all endpoints can be equally well represented by all measures. In addition, some measures, such as dollars, carry their own meaning, which may or may not facilitate the risk assessment depending on how that meaning is construed.

However, no single metric or endpoint necessarily constrains environmental, technological, or human health risk assessments. Although many risk assessors with economic training might prefer to use dollars as a summary endpoint, doing so is not a requirement of risk assessment, but a methodological choice with ethical implications. The identification and definition of possible endpoints to consider, the valuation of these, and the estimation of their contingent probabilities all entail some degree of judgment and choice.

RISK ETHICS

Risk ethics is an emerging branch of philosophy that investigates the moral aspects of risk and uncertainty. Although one originating motivation in the pursuit of science and technology was an effort to reduce risk and uncertainty present in the natural world, it has been increasingly appreciated that the scientific and technological world presents its own constructed risks. Recognizing that one form of risk (natural) is overcome only at the cost of another form of risk (involved with science or technology) has stimulated critical reflection on risk in ways that did not occur in the absence of technological risk.

A Brief Introduction to Risk Concepts

Risk has vernacular and technical meanings. In everyday language a risk is simply a danger. But in relation to science and technology, risk is often defined as the probability of some harm. The probability of a benefit is often called a chance. According to another common definition, risk is identified with the value obtained by multiplying the probability of some harm or injury by its magnitude. With any attempt to spell out the details of how this might be done, however, problems arise since it is not clear that there is a single measure for all harms or injuries. Attempts have been made to measure all health effects in terms of quality-adjusted life years (Nord 1999). Risk-benefit analysis goes one step further and measures all harms in monetary terms (Viscusi 1992). However, as several critics have pointed out, such unified approaches depend on controversial value assumptions and may be difficult to defend from an ethical point of view (Shrader-Frechette 1992).

Independent of methodological issues, however, are the assumptions of traditional moral philosophy, which has focused on situations in which the morally relevant properties of human actions are both well-determined and knowable. In contrast, moral problems in real life often involve risk and uncertainty. According to common moral intuitions it is unacceptable to drive a vehicle in such a way that the probability is 1 in 10 that one runs over a pedestrian, but acceptable if this probability is 1 in 1 billion. (Otherwise one could not drive at all.) It is far from clear how standard moral theories can account for the difference and explain where the line should be drawn.

Utilitarianism

In utilitarian ethics, all moral appraisals are reducible to assignments of utility, a (numerical) measure of moral value. Furthermore, the utility of human actions is assumed to depend exclusively on their consequences. According to utilitarianism one should always choose the alternative that has the highest utility, that is, the best consequences.

One utilitarian approach to risk is *actualism*, according to which the moral value of a risky situation is equal to the utility of the outcome that actually materializes. For example, suppose that an engineer decides not to reinforce a bridge in advance of it being subject to an exceptionally heavy load, although there is a 50 percent risk that the bridge will collapse under such use. If all goes well and the bridge carries the load, then according to the actualist standpoint what the engineer did was right. But examples such as this show that actualism cannot provide meaningful action guidance. Even if actualism is accepted as a method for retrospective moral assessment, another theory is needed to guide decision-making about the future.

One such theory is *expected utility maximization*, which has become the standard utilitarian approach to risk. According to this theory, the utility of the prospect that an outcome may occur is obtained by multiplying the utility of the outcome itself by its probability. Then, the action with the highest probability-weighted value should be chosen. According to this rule, an action with the probability 1 in 10 to kill a person is five times worse than an action with the probability 1 in 50 of the same outcome. This method for weighing potential outcomes is routinely used in risk analysis.

In intuitive arguments about risk, it is common to give the avoidance of very large disasters, such as a nuclear accident costing thousands of human lives, a higher priority than is warranted by probability-weighted utility calculations. For instance, people clearly worry more about the possibility of airplane crashes (low-probability but high-cost events) than automobile accident deaths (which are higher-probability but lower-cost events). Expected utility maximization disallows such cautious decision-making. Proponents of precautionary decision-making may see this as a disadvantage of utility maximization, whereas others may see it as a useful protection against costly over-cautiousness.

Just like other forms of utilitarianism, expected utility maximization is strictly impersonal. Persons have no role in the ethical calculus other than as bearers of utilities whose values are independent of those who carry them. Therefore, a disadvantage affecting one person can always be justified by a sufficiently large advantage to some other person. No moral distinction is made between the act of exposing oneself to a serious danger in order to gain some advantage and the act of exposing someone else to the same danger for the same purpose. This is a problematic feature of utilitarian theory in general that is often aggravated in problems involving risk.

Duty- and Rights-Based Theories

A moral theory that is based on duties (rather than on the consequences of actions) is called deontological or duty-based. A moral theory in which rights have the corresponding role is called rights-based.

Robert Nozick formulated the problem for rights-based theories in dealing with risks in this way: “Imposing how slight a probability of a harm that violates someone’s rights also violates his rights?” (Nozick 1974, p. 7). Similarly, one may ask the following question about deontological theories: “How large must the probability be that one's action will in fact violate a duty for that action to be prohibited?"

One possible answer to these questions is to prescribe that a (rights- or duty-based) prohibition to bring about a certain outcome implies a prohibition to cause an increase in the probability of that outcome (even if the increase is very small). But such a far-reaching extension of rights and duties is socially untenable. Human society would be impossible if people were not allowed to perform actions such as car driving that involve a small risk of developing into a violation of some prohibition.

It seems clear that rights and prohibitions may lose their force when probabilities are sufficiently small. The most obvious way to account for this is to assign to each duty or right a probability limit below which it is not valid. However, no credible way to derive such a limit has been proposed. It is also implausible to draw the line between acceptable and unacceptable probabilities of harm with no regard to the benefits involved. (In contrast, such weighing against benefits is easily accounted for in utilitarian theories.)

Contract Theories

According to contract theories, the moral principles that rule humans' dealings with each other derive from a contract between all members of society. The social contract prohibits certain actions, such as actions that lead to the death of another person. Under what conditions should it also prohibit actions with a low but nonzero probability of leading to the death of another person? The most obvious response to this question is to extend the criterion that contract theory offers for the determinate case, namely consent among all those involved, to cases involving risk and uncertainty. This can be done in two ways because consent, as conceived in contract theories, can be either actual or hypothetical.

According to the criterion of actual consent, all members of society would have a veto over actions that expose them to risks. This would make it virtually impossible, for example, to site industries that are socially necessary but give rise to emissions that may disturb those living nearby. With a rule of actual consent, a small number of nonconsenting persons would be able to create a society of stalemates, to the detriment of everyone else. Therefore, actual consent is not a realistic criterion in a complex society in which everyone performs actions with marginal effects on the lives of many others.

Contract theory has a long tradition of operating with the hypothetical consent that is presumed to be given by every hypothetical participant in an ideal decision situation such as described in John Rawls's "original position." Unfortunately, none of the ideal situations constructed by contract theorists seems to have made the moral appraisal of risk and uncertainty easier or less dependent on controversial values than the corresponding appraisals in the real world.

Widening the Issue

Many discussions of risk have been limited by an implicit assumption that excludes important ethical aspects. It is assumed that once we have moral appraisals of actions with determinate outcomes, we can more or less automatically derive moral appraisals of actions whose outcomes are "probabilistic mixtures" of such determinate outcomes. Suppose, for instance, that moral considerations have led us to attach well-determined values to two outcomes *X* and *Y*. Then we are supposed to have the means needed to derive the values of mixed options such as 70 percent chance of *X* and 30 percent chance of *Y*. The crucial assumption is that the probabilities and values of nonprobabilistic alternatives completely determine the values of probabilistic alternatives.

In real life, however, there are always other factors in addition to probabilities and utilities that properly influence our moral appraisals of an uncertain or risky situation. We need to know not only the values and probabilities of potential outcomes, but also who exposes whom to risk and with what intentions, the extent to which the exposed person was informed, whether or not the person consented, and more.

Perhaps the most important foundational problem in risk ethics is the conflict between two principles that both have intuitive appeal. They can be called the collectivist and the individualist principles in risk ethics (Hansson 2004). According to the collectivist principle of risk ethics, exposure of a person to a risk is acceptable if and only if this exposure is outweighed by a greater benefit either for that person or others. According to the individualist principle, exposure of a person to a risk is acceptable if and only if this exposure is outweighed by a greater benefit for that person only.

The collectivist principle dominates traditional risk analysis, but if carried to extremes it will lead to neglect of individual rights. The individualist principle is equally problematic, because it allows minorities to prevent social progress. It is a major challenge for risk ethics to find a reasonable and principled compromise between these two extreme positions.

RISK PERCEPTION

Risk perception has been defined variously as perceived or subjective probability estimates of death, other judgments of probable harm or loss, psychological states such as fear or traumatic stress, beliefs about causal processes resulting in harm or loss—that is, mental models of hazardous processes, or attitudes toward the activity, event, product, or substance in question. Risk perception, in which risk is assessed subjectively, often without formal decomposition into probability and harm, is frequently treated as folk or lay *risk assessment*.

When elicited as subjective probability or frequency of mortality, risk perceptions can agree or disagree with actuarial information, where such exists, and can in some instances be validated or invalidated by science. Comparisons of lay and expert risk perceptions, together with research on the effects of risk communication, illustrate that expertise and information can have large effects on risk perceptions. Such comparisons have been used to make the ethical claim that non-experts are irrational when they fear risks that experts deem acceptable, such as risks from genetically modified organisms. Shrader-Frechette points out that those framing risk questions control the answers, and suggests that to deal with the great uncertainties surrounding, for example, ecological risks, the burden of proof should fall on those proposing that a risk is acceptable. Shrader-Frechette also proposes a three-category framework for risk, as an alternative applying the effect-no effect (or acceptable-unacceptable) dichotomized view of science to risks. In her view, serious risks for which the complexities and uncertainties are so great that we lack sufficient information to make a decision fall into a third category (e.g., Shrader-Frechette, 1994). However, as intuitive statisticians, both experts and non-experts are subject to predictable judgmental biases (Fischhoff, Bostrom, and Jacobs Quadrel 2002; Gilovich, Griffin, and Kahneman 2001; Kahneman, Slovic, and Tversky 1982). Personal experiences also affect risk perceptions, though if not repeated their effects may disappear over time. That communities enact policies to reduce their seismic risks following large earthquakes and resist or ignore them at other times testifies to this, as do differences between life scientists and other scientists in their risk perceptions.

Schools of Thought

Risk perception research since the 1970s has been characterized by several schools of thought, each of which is associated with particular disciplinary backgrounds and methodological predilections. Psychometric research and cultural theory are among the most widely acknowledged.

Psychometric research on risk perception proceeded by analogy with measurements of physical perceptions—such as light, weight, or heat—in attempting to establish reliable, validated psychological scales for perceived risk. By eliciting people's judgments on dimensions such as dread, familiarity, catastrophic potential, and control, researchers were able to predict, to some extent, risk acceptance judgments. This research produced a risk factor space, the two dimensions of which were how familiar, controllable, and understood risks are, and how much people dread them, including judgments of catastrophic potential. For example, the risks from nuclear power are typically perceived as highly unknown and dreaded, landing in the upper right quadrant of those two dimensions, where as the risks from bicycles are perceived as known and are not dreaded, putting them in the lower left quadrant. This vein of research is best characterized in works by Paul Slovic, Baruch Fischhoff, Sarah Lichtenstein, and colleagues (Slovic 2000).

Cultural theory stems from anthropologist Mary Douglas's writings on risk and culture. Among the best-known tests of cultural theory are those that employ grid/group theory, in which it has been shown that people's attitudes toward risks are a product of their degree of individualism, egalitarianism, and hierarchy or collectivism. Related research on worldviews posits that risk perceptions are a function of attitudes toward science and technology in particular, but also other attitudes.

Another approach is to treat risk perception as an instance of information processing. Information processing is cognitive, social, and affective (Damasio 1994). Cognitive processes such as categorization, similarity judgments, and inference from mental models are, from an information processing perspective, all components of risk perception. Recent research shows that there is a strong relationship between affect and perceived risk. There is a commonly observed inverse relationship between perceived risk and perceived benefit. Under time pressure, which limits analytic thought and increases reliance on affect, this inverse relationship strengthens (Finucane, Alhakami, Slovic, and Johnson 2000). Further, introducing information that changes one's affective evaluation of an item, for example information that associates nuclear power with clean air and pastoral scenes, can systematically change both the related risk and benefit judgments.

People seem prone to using an "affect heuristic" that improves judgmental efficiency by deriving both risk and benefit evaluations from a common source: affective reactions to the stimulus item. The mechanisms for these effects may be hardwired in our brains, in the amygdala, through which all thought passes. Animal studies suggest that the amygdala coordinates multiple fear systems, and that fear is a potent determinant of memory, learning, and salience.

Ethical Issues

People's behavior depends on their risk perceptions. Given this dependency, whose risk perceptions should prevail to determine societal priorities is often contested. Further, technical risk assessments generally apply to a statistical person or to a population, and so are not directly applicable to an individual or that individual's perceptions of his or her own risk. Therein lies the central ethical dilemma posed by risk perceptions, exacerbated by their variability and vulnerability to judgmental biases.

In addition, overarching ethical principles conflict with manipulations of risk perceptions that may, at face value, seem in the public interest. Principles such as those in the U.S. Bill of Rights are vulnerable to perceived needs precipitated by risk perceptions. As the U.S. Public Law 107–56 (commonly known as the U.S. Patriot Act, 2001) and the U.K. Anti-Terrorism, Crime, and Security Act (also 2001) illustrate, it is easy to delimit transparency of government, judicial checks on legislative and executive branches, and civil liberties and equal treatment of citizens under the guise of reducing risks, even without evidence that the measures enacted will actually reduce risks.

The literature on risk perception across different domains of science and technology is daunting. Health, environmental, and technological risk perception, and to some extent hazard perception, are largely separate bodies of research. Health risk perception research is rooted primarily in social psychology, and has been dominated by the health belief model, the theory of reasoned action, and variants thereon. This research is influenced by the extended parallel process model, which predicts that people who believe something poses a serious risk to them personally will engage in fear control rather than risk control if they do not believe that they can control the risk effectively (Witte 1992). Environmental and technological risk perception research has drawn more broadly on social and cognitive sciences, including the theories and models cited above. Methods have varied from informal and sometimes misleading reliance on casual observations, such as of focus groups, to carefully designed and implemented surveys and experiments. Anthropology and ethnographic methods of studying risk perceptions have grown in importance, as practitioners have recognized their value in improving the design of risk interventions, as well as providing a fuller account of how people perceive risk.

Spatial and temporal dimensions of risk perceptions remain to be fully explored, and will likely provide further insights into risk behaviors.

RISK SOCIETY

The concept of risk, long associated with the language of maritime trade and insurance, has become a key term for characterizing contemporary Western societies. Important early contributions to the development of this analysis were the work of Patrick Lagadec (1981), who coined the term *risk civilization,* and that of Mary Douglas and Aaron Wildavsky (1982). However, Ulrich Beck's *Risk Society* (1992), originally published in German in 1986, was the decisive contribution to a new theory of society. Beck's conceptualization has inspired research that focuses on the implications of science and technology for the social and natural environment and on the increasing use of risk analysis in discussions of public policies related to science and technology, and which involve ethical questions.

Reflexive Modernity

Beck's theory represents a continuation of the German tradition of an ethical questioning of modernity, including science and technology, that runs from Max Weber (1864–1929) through Jürgen Habermas (b. 1929). In contrast to postmodern theories that present late twentieth-century social transformations as going beyond modernism, Beck argues that modernity is going through an unintended and unseen phase that is forcing it to confront the premises and limits of its own model. Modernization has become, in his words, "reflexive." The concept of reflexive modernization, which was introduced by Beck and developed in a subsequent work with Anthony Giddens and Scott Lash (Beck, Giddens, and Lash 1994), propounds a "radicalization" of modernity in which the dynamics of individualization, globalization, gender revolution, underemployment, and global risks undermine the foundations of classical industrial modernity and make old concepts obsolete. The internal dynamism of modernity brings it up against the previously unknown possibility of global self-destruction as a result of the risks generated by certain technologies.

Beck thus depicts the risk society as coextensive with reflexive modernity. In the same way that "simple modernity" produced goods and services that presented challenges involving just distribution, reflexive modernity is producing risks that must be distributed justly.

An Expanded Concept of Risk

Many theoretical works in other disciplines had previously analyzed the risk concept, although more narrowly: economics, behavioral theory (in particular decision making and game theory), anthropology, and technology assessment.

In economics, where the concept has always been fundamental, prevailing interpretations make a clear distinction between risk and uncertainty. Whereas risk can be assessed and calculated in terms of its numerical probabilities, uncertainty cannot be treated in that manner. Introduced at the beginning of the twentieth century by Frank Knight (1885–1972) and John Maynard Keynes (1883–1946), this distinction made possible the recognition of the ontologically contingent nature of economic behavior and its aggregate outcomes. An economic agent cannot avoid wide margins of uncertainty or eliminate it by means of the application of more information or scientific knowledge.

The anthropological work of Douglas and Wildavsky (1982) diverges from this classical approach in emphasizing the subjective aspect of risk and the ways in which risk is assessed and perceived by individuals. Their work helped significantly to shift attention away from a probabilistic approach to the cultural framework of risk perception. Variations in the understandings and perceptions of risk in different societies demonstrate the cultural relativism involved in judgments of risk.

Beck's main contribution was to build risk systematically into a theory of modern society and its dilemmas. Risk is seen as a defining feature of society itself, forming the dark side of industrial successes, technical and scientific progress, and economic growth. It has stimulated changes in social relations, family structure, political and cultural organization, and even the self.

Unlike the threats of early industrialization, the risks of "late modernity" (nuclear, chemical, genetic, ecological, etc.) are generated by techno-economic decisions and considerations of utility. The novel aspect of contemporary risk society is that people's decisions as a civilization lead to problems and dangers that radically contradict the established language of control and conventional techniques of calculation. Current risks are not socially, spatially, or temporally demarcated; there are no clear-cut solutions; and it is difficult to trace responsibility or assess compensation for those who are affected. In addition, human perception fails to notice many of the risks: they become visible only through scientific interpretation (as in the case of stratospheric ozone depletion), which in turn increases dependence on experts.

Beck focuses above all on environmental and health risks, especially genetic technology. He later extended the concept of risk to global financial crises and transnational terrorist networks (Beck 2002). Bringing together such disparate phenomena enables him to identify relevant trends in modern societies but has the drawback of implying a less fragmented world than that which Beck perceives.

Niklas Luhmann (1993 [1991]) has enriched "risk society" analysis with his theory of autopoietic systems. Here risk is a specific form of dealing with the future that has to be decided in the context of probability and improbability. The uncertain and unforeseeable nature of the future arises not only from complexity and people's cognitive limitations but also from the decision-making process itself. There is a long hiatus between when a decision is made and when its consequences are felt, with random factors affecting them. To talk of risks is to see future losses as the consequence of a decision that has been made. For Luhmann this is where "risk" differs from "danger," with danger being attributable to external causes and corresponding to those "affected" by decisions. Although the distinction is slight because "one person's risk is another person's danger," it points to the key issue of acceptance of risk decisions.

Developments and Implications

Beck's message on the relationship between science, technology, politics, and ethics in late modernity is that our language does not inform future generations of the dangers people create when they use certain technologies. As it develops technologically, society encounters the difference between two worlds: the language of quantifiable risk, in which people think and act, and that of nonquantifiable insecurity, which people also are creating. As risks become more complex and the need for precise calculations increases, there is growing doubt about the ability of science to control and foresee those risks. This situation has shaken the belief that technological and social progress go together and has forced science to acknowledge both its collateral effects and its inherent epistemological limitations. The concept of "world risk society" (Beck 1999) draws attention precisely to the limited controllability of globalized and artificially produced risks.

In these circumstances human responsibility for technological advancement is an ethical issue that is both relevant and complex. For Beck the processes and techniques of risk management block out responsibility. Modern society operates as a "laboratory" in which no one in particular must answer for the negative effects of technological experimentation. The institutions of modern society recognize the existence of risk but permit an "organized irresponsibility" (Beck 1995 [1988]). Pollution, along with its increasingly global impact in the form of climate change, graphically illustrates this paradox. The greater the environmental degradation is, the more laws and environmental regulations there are, but at the same time no institution seems to be specifically responsible.

Technologically induced risks lead to calls for the demonopolization of scientific expertise, its subjection to social scrutiny, and extension of democratic accountability to science, technology, economics, and government. For this to be achieved politics must "(re)-invent" itself and focus on issues previously regarded as apolitical. What once was the exclusive province of science has become the subject of intense political debate, as in the case of biotechnology. In this context individual citizens, movements, and interest groups participate and influence political decisions in the field that Beck describes as "sub-politics," which is located beyond the formal representative institutions of the political system.

Because the concept of risk is probabilistic in nature, it tends to deny inherent uncertainties and place greater emphasis on scientific control over randomness, contingencies, and chance. In the vast literature on risk there are authors who argue, however, that the language of uncertainty would be more appropriate for a better understanding of the current world, full of indeterminacies and contingencies, whether inherent in the world or epistemic. Underlying this argument would be lack of knowledge of the statistical probability of many of the possible outcomes, public distrust of the estimates produced by experts, potential margins of error, and the random unpredictability of nature and human behavior

(Martins 1998). This approach has affinities with the work of authors who underline the ontological nature of uncertainty that is inherent in the natural and social worlds and focus on "ignorance," "catastrophes," and "accidents" (see, for example, Perrow 1984). It differs from the work of those who stress above all the social perception of risks (such as Douglas and Wildavsky 1982).

Beck often is said to alternate between the realist and the constructivist approaches and to absorb uncertainty into the general category of risk. However, he cannot be said to limit risk to the perceptual aspect or to avoid a strong emphasis on uncertainty. There are several studies of practical situations in which risk is not limited to perceptions, such as the subpolitics of medicine. At the same time, in light of the emphasis Beck places on deregulation, uncertainty, and contingency, his "risk society" cannot properly be understood according to the probability model. In introducing the notions of "unintended consequences and unawareness" into his theory of reflexive modernity instead of emphasizing the "knowledge," as Giddens and Lash do, Beck recognizes that there are areas of unknowability, contingency, and ignorance. For this reason his theoretical approach lends itself to multiple interpretations that lie between the concepts of risk and uncertainty.

These issues are relevant because a decision based on risk or uncertainty is not neutral in its political consequences. Risk is associated with prevention, whereas uncertainty is associated with precaution (Godard et al. 2002). Risk may lead to a process of risk-mitigating negotiation and agreement, whereas uncertainty may lead to risk-avoiding prudence. The possibility of rejecting certain techno-economic decisions and actions has provoked a lively ongoing debate about the advisability of the "precautionary principle" at a time of rapid technological change.

ROADS AND HIGHWAYS

Roads and highways have been principal means by which entire economies and societies have emerged and grown over time. They have contributed positively to the spread of ideas, cultures, languages, inventions, goods, and services. Disease, enslavement, tribute, and warfare have also spread through networks of roads and highways to devastate entire peoples and areas and immeasurably alter the course of history.

Early Roads and Highways

The first roads dating back to the dawn of civilizations (c. 3000 B.C.E.) were little more than dirt paths worn down by frequent travel from one location to another via wheeled vehicles. Rivers were the main highways of this time period, as goods and people moved up and down their courses and any city that desired to rise to importance was located on a river. Yet within a period of a few hundreds of years, roads became a commonplace and began to reshape the geopolitical history of entire regions. Even during this period, rivers continued to be the most economical way to transport large quantities of goods, with roads being used to link river trade to cities and towns throughout entire regions.

The earliest roads were designed to bear the weight of wheeled traffic including carts, large wagons, and swift chariots. Within cities the main thoroughfares were paved and varied in width from two to ten meters. A series of "narrow streets" connected to these "broad streets" within cities and enabled populations within them to increase substantially in size. The Neo-Babylonians and Assyrians constructed royal roads that linked major cities across their empires. The Persians took over many of the practices of the Assyrians and maintained excellent royal roads, some as long as 2,670 kilometers (1,650 miles). These roads featured "excellent inns," as noted by the Greek historian Herodotus (c. 485–c. 425 B.C.E.), as well as special parks so that the king or his senior administrators could take their rest in leisure when traveling across the vast reaches of the Persian Empire. Similarly, in ancient Egypt roads were constructed both within large cities and linking cities and regions of Egypt and her territories to one another. The typical Egyptian road was about five meters in width. Outside of cities, most roads in the ancient Near East were unpaved but had been carefully prepared and leveled, and were regularly maintained. The ancient Greeks did not favor roads and built only a skeleton of dirt roads from one region to another until the time of Alexander the Great (356–323 B.C.E.), who saw the need for better roads linking the rapidly expanding segments of his empire.

The Romans, likely expanding upon earlier techniques of the Etruscans, took road building to new heights of engineering excellence, constructing two, four, six, and eight lane highways connecting all key parts of the Empire. Roads themselves became a symbol of the might of Rome and the certainty that if they were needed, a Roman army would arrive swiftly to deal with any sociopolitical unrest or the incursion of enemies from outside its borders. Roman surveyors determined the optimum location and direction of roads, favoring straight traces whenever possible. Roman engineers constructed roads that would last for centuries through careful attention to the underlying base materials, superb drainage to keep water away from the road and its foundation, the careful use of stones and cement, and regular repair. Many miles of these Roman roads survive throughout the former Empire and quite a few modern roads follow the exact course as their Roman predecessors. While originally designed for military purposes, the roads became the means by which Roman ideas, life, and culture spread across the Empire. All roads carried mileage markers, always delineated in terms of their distance from the imperial city of Rome, a reminder to all of the might and power of the Empire. By the time of Diocletian (245–c. 313), there were 372 main roads throughout the Empire, covering a distance of some 85,000 km (nearly 53,000 miles). The Romans went well beyond any of their predecessors in the extent and interconnectivity of the system of secondary and primary roads they created and maintained across the Empire. In Roman Britain alone, more than 9,656 km (6,000 miles) of roads were constructed and maintained. Bridges and tunnels, milestones to enable travelers to instantly know their location, wooden signposts, and many other "modern" features of roads and highways were common throughout the Empire. The roads created ideal conditions for the growth of a postal service for government use and also a private postal service employed by wealthy citizens. A series of posts were set up so that couriers only had to move from one posting station to another—a design that would later be used by the famous but short-lived Pony Express in the American West.

Roads were not a distinctly Roman and European phenomena. The Qin and Han dynasties of China created a highly integrated network of roads, mainly for military use, in the second century B.C.E. The first Qin Emperor, Qin Shihuangdi (c. 259–210 B.C.E.) constructed 7,000 km (4,350 miles) of roads radiating out from his capital city of Xianyang in northern China. One hundred years later, there were more than 35,000 km (21,750 miles) of roads in northern China serving an empire of some 4 million square kilometers (1.5 million square miles). Similarly, the Incas created an empire running from Ecuador to central Chile and held it together via a network of more than 10,000 roads built across some of the most difficult mountain terrain in the world. Remnants of these Incan royal highways still exist in the early twenty-first century, and many modern roads follow the traces of these roads as a continuing tribute to the foresight and skills of these early highway engineers in South America.

The road systems developed by the Romans throughout the western Empire declined considerably after the fall of Rome, while those in the East continued to be maintained to a reasonable degree both under the Eastern Roman emperors and their Muslim conquerors. Many medieval roads in Europe declined to little more than dirt roads and were subject to flash floods and steady deterioration.

Modern Roads and Highways

Roads in the West began to be vigorously revived in the seventeenth century with the introduction of street lighting, ferry services, and emerging regulations from local, regional, and national governments. Central governments began to assume more direct responsibility and control for roads and centralized planning and maintenance became common, supported by general tax revenues.

Pierre Trésaguet (1716–1796), director of the École des Ponts et Chaussées in Paris in the mid-eighteenth century, had studied long and well the achievements of the Romans. His department had responsibility for some 40,000 km (25,000 miles) of roads throughout France, many built in the exact traces of earlier Roman roads. Trésaguet ensured that exacting road preparation methods were employed, following earlier Roman techniques, and the road system throughout France improved dramatically under his tenure. Two Scottish engineers made similar improvements throughout Britain in the early nineteenth century. Thomas Telford (1757–1834) built an exquisite model road between London and Holyhead demonstrating the superiority of preparing a very solid and carefully constructed roadbed before providing surfacing materials. While expensive to build, it was vastly superior to other roads. John McAdam (1756–1836), his fellow Scot, pioneered the use of natural materials as the base of a roadbed and developed methods to highly compact these materials to provide the same type of firmness that Telford achieved, only with much lower production costs. The surface material used on his road and the entire type of road took its name after him—macadam. By the late nineteenth century, the use of asphalt and portland cement (first used in Scotland in 1865) also became common and the maintenance required for roads became much less labor intensive.

Roads, including early toll roads such as the Lancaster Turnpike in Pennsylvania where travelers had to pay a fee to enter and/or exit the road, were a principal means of commerce in colonial America, and traces to the American West eventually were turned into roads that enabled white settlers to push rapidly westward in search of new lands and opportunities.

The advent of trains and railroads in North America, Europe, and elsewhere provided new opportunities to create many smaller secondary roads that linked many smaller towns and farming areas to commercial nodes. Consequently, these roads became the means by which goods and services circulated far more widely than was economically feasible before with attendant mobility of goods, people, and ideas. The combination of railroads and roads during the Civil War, for example, enabled large and rapid movements of troops and influenced the outcome of many a Civil War battle.

The nineteenth century saw the introduction of steam-powered equipment to construct roads, with the most important invention being the steamroller of Louis Lemoine and Amedee Jean Ballaison. These steamrollers quickly found their way to India and other nations far from Europe and the United States. New gasoline powered vehicles provided even more powerful machines to build roads and also led to more plentiful traffic for roads, resulting in yet further expansion of networks of roads across nations. By the nineteenth century it was common for city roads to be made of portland cement, and bitumen (pitch) or concrete used for cross country routes. Rural roads in the hinterlands continued to consist of dirt and packed gravel.

The first multi-lane, limited access highway in North America was constructed during 1917–1925 as the Bronx River Parkway, a New York thoroughfare still in use in the twenty-first century. The first bona fide superhighway in the United States was the 160-mile Pennsylvania Turnpike from Middlesex to Pittsburgh that opened in 1940 and quickly outdistanced expectations as 2.4 million vehicles used it annually within the first few years. Adolf Hitler (1889–1945) and Benito Mussolini (1883–1945) were aficionados of superhighways, and under their direction, massive superhighways were constructed in Italy and Germany in the 1930s that enabled the rapid movement of troops. President Franklin Delano Roosevelt appointed a National Interregional Highway Commission in 1941 and a Federal Aid Highway Act was approved in 1944 that authorized $1.5 billion for interstate highway construction. By the time of the Eisenhower administration, the federal highway legislation resulted in the construction of more than 64,000 km (40,000 miles) of highways running across the United States in both north and south and east and west orientations. Many states, such as New York, Pennsylvania, Ohio, and Illinois, also built their own extensive toll roads that connected in networks running particularly throughout the northeast. In the early twenty-first century similar highway systems can be found throughout the world, and the proportional number of miles of such highways within a nation serves as a rough gauge of its economic status in the world. These massive networks of superhighways and their linked secondary roads enabled the massive growth of suburbs and attendant suburban "flight," substantially altering the tax base and quality of life of central cities–a situation readily observed in places such as Atlanta, Boston, Chicago, London, Los Angeles, Paris, and Philadelphia.

Highway Engineering and Ethical Issues

Highway planning in the early 2000s is a complex branch of civil engineering that is designed to move goods and people efficiently, effectively, and safely across large distances. It includes attention to forecasting demand, acquiring land from various parties, designing roads and arteries that make for safe and aesthetically pleasing experiences for highway users, moderating costs, and providing for long-term maintenance and expansion when needed. Traffic volume is generally measured in terms of annual average daily traffic, which allows for derivation of a figure that avoids the inevitable peaks and troughs of traffic flow in any given day, week, or month. An entire route is divided into zones and then estimates are made about travel between zones and the amount of travel that will be undertaken by different modes of transport (for example, trucks, cars, buses). A maximum theoretical traffic flow rate is calculated using reasonable parameters of environmental, highway, and traffic conditions. A further factor taken into account in planning is what level of service the road will need to bear that will be acceptable to its users. Travel is an inherently subjective experience, and planners attempt to find an acceptable level of service (LOS), avoiding the extremes of very good (index A) and very poor (index F).

A number of additional factors need to be considered. All human technological applications have environmental effects. Highways directly affect matters such as noise pollution from horns, tires on road surfaces, engines, the speed of traffic, and shock effects from heavy loads on road surfaces; air pollution due to carbon monoxide, nitrogen oxides, volatile hydrocarbons, sulfur oxides, and particulate matter from exhaust fumes as well as evaporation from road surfaces; water pollution due to runoff that picks up oils, trash, and other materials from road surfaces; and environmental effects from the initial siting of the highway and its continued maintenance. These latter effects can include changing migration patterns and habitats of birds, mammals, amphibians, fish, and other creatures, as well as increased road kills (which number substantially more than one million mammals per year in America alone). Sometimes road kills result in the total extinction of a species or a severe threatening of its existence, such as with the Florida panthers.

Highway design includes attention to both aesthetics and safety issues. Each highway has to surmount certain physical challenges that the land presents, and decisions have to be made about how much to use the natural features of the land in construction or to substantially alter them. Modern highways attempt to utilize natural materials and natural roadbeds as much as possible, because it is far cheaper than completely excavating and hauling away such materials and replacing them with others. Sometimes the natural material base is not conducive to the type of heavy travel a particular road will be required to bear and then such steps have to taken.

A much larger portion of land is required than just that needed for the roadway itself. Most highways require a median that is almost equal in size to the width of the one or more lanes on one side of a divided highway. Then the outer edge of the driving lane requires a shoulder so that vehicles have a space to move off the road safely when they encounter vehicular or other problems. A drainage ditch is usually found outside the shoulder to handle runoff from the driving lanes, which are sloped in such a way that water runs off the highway quickly. The ditch also serves as the means to handle runoff from surrounding land on either side of the road cut to keep water off the road surface and prevent erosion from undermining the pavement or roadbed.

Pavement materials for roads and highways have to meet technical standards in order to be used. All materials must be sufficiently strong and durable to meet the required criteria that planners have established for that particular type of road. A typical highway is a composite of many different types of materials that are laid down in a carefully defined sequence and constantly checked to verify that they meet required specifications. Materials include sand, gravel, crushed rock, portland cement, asphaltic cement, lime, and, increasingly frequently, recycled materials such as crushed glass, scraps from old roadways, and pulverized tires.

Road geometry takes account of the steepness of curves, the slope of hills and valleys (road grades), passing maneuvers on varied terrain, and the need to maximize clear lines of sight. This is further complicated by situations where two highways meet one another, where a whole series of considerations must be addressed to plan and construct effective intersections and interchanges that enable a smooth and safe flow of traffic.

The actual siting of highways is always a complex decision that involves balancing factors such as travel time, vehicle operation cost, accessibility, environmental effects, societal acceptability, safety, total cost of construction, and viable alternative routes. Increasingly, local, state, and federal governments in many countries have to use the concept of eminent domain to assert their primary claim over land held by owners reluctant to relinquish their claims, frequently because they are opposed to the siting of the highway through their property. Government agencies generally are required by law to provide a fair-market value price to the owners.

The impact of interstate highways on commerce, migration, immigration, and employment growth has been the subject of much study. The overall findings indicate that, in general, counties or administrative units that reside alongside interstate highways see an increase in net immigration, employment growth, and commercial activity, while counties that have been bypassed by the interstate suffer net migration, a loss of employment over time, and declining commercial activity. The large amounts of particulate matter generated from major roadways has been identified as a source of chronic exposure that produces negative health effects within communities, especially in children and adults suffering from various respiratory preconditions.

Roads and highways also have to be managed by agencies to ensure that traffic flow is maintained at a reasonable level and that users of the roadway obey traffic laws that are designed to maintain such flows. Traffic signals of many different varieties have been developed, and a set of international standards have been developed for signs so that drivers can travel virtually around the globe and know what they are supposed to do in particular situations. Toll booths, highway exit and entry, emergency breakdown services, quick response to traffic accidents, enforcing traffic laws, and many other facets of roads and highways are generally under-appreciated by users but essential to maintaining a working system of roads and highways. Driver error, including falling asleep at the wheel, is by far the most common source of traffic accidents and deaths and injuries to drivers, pedestrians, and wildlife.

Future Developments

Computerization is the next major innovation in roads and highways, and virtually every industrialized nation has a wide range of current applications in the area of intelligent transportation systems (ITS). These include automated toll booths where vehicles with appropriate stickers on their vehicles can pass through the booth and automatically be billed for their trip rather than having to stop and manually deliver money or tokens to a human or automated operator. Many interstates or roads in heavily congested areas of the world use computers to regulate entry into the highway as traffic lights and barriers allow only one vehicle at a time onto the highway such that mergers happen more seamlessly and the flow of traffic on the road is not impeded by entering traffic. Many cities have sophisticated computer systems that regulate traffic signals across the city with the timing of signals changing throughout the day to accommodate the daily ebb and flow of traffic to and from major zones within the city. Cameras placed in strategic positions in cities and mobile camera units elsewhere increasingly document speeding vehicles with attendant tickets being subsequently issued to the offenders. Global positioning technology makes it feasible to track vehicles anywhere in the world, and many large transport companies already utilize this technology to keep track of their vehicles both on the road and also across railroad systems in seamless global transportation networks that enable managers to ensure that their products arrive at required destinations in a timely manner and in good condition.

ITS planners have created plans for intermodal transport systems that utilize advanced telecommunications and computer systems to move goods across entire continents through underground tunnels or highways dedicated solely to the movement of freight. These intelligent systems would only require human operators on points of entry or exit within the system, and once on the network, goods could be accelerated greatly in their passage to desired destinations. Similar designs exist for automobiles of the future that would go on "autopilot" once the human operator had placed the vehicle on the superhighway. Computers would then guide the vehicle to the required exit point and then the human operator would take over control functions to move the vehicle safely off the superhighway. Such a system would alleviate the traffic jams so familiar to major interstate highway systems during peak flow times and enable resources to be used more efficiently.

The widespread use of ITS raises a host of ethical issues, many not particularly unique to these applications but part of a broad set of issues common to technological innovations. Increasingly the operators of these systems would have knowledge of one's whereabouts and be able to track the movement of a single individual across a city, state, or even potentially around the globe as these various systems come online and interconnect both operationally and informationally. Technical managers would also be able to shape human perceptions and experiences of reality by varying conditions on these systems—for example, deciding that today's optimal travel time from point A to point B will be 25.8 minutes, and programming the system to deliver these results. It should be noted, however, that highway engineers have always shaped human perceptions of the surrounding environment and influenced ways of life going back to where the first roads were constructed (all artifacts have politics, as Langdon Winner has argued), how structures actually are designed (for example, low bridges on the Wantagh Parkway in New York designed by Robert Moses (1888–1981) specifically to keep buses off the parkway), and via the distinct sociotechnical roles that engineers play in public policy making.

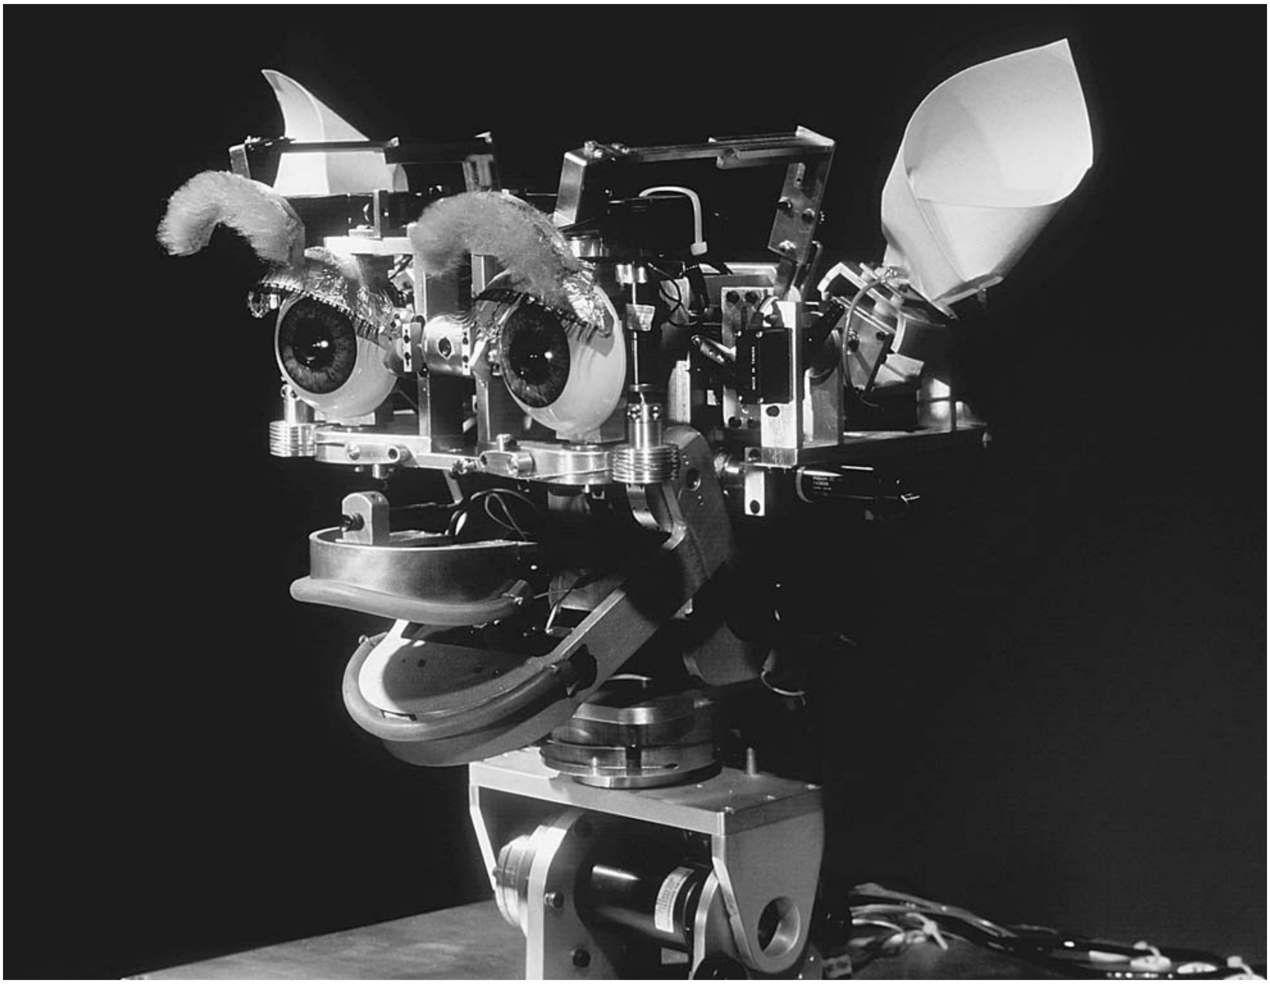
ROBOTS AND ROBOTICS

Robots are programmable machines capable of moving around in and interacting with their physical environment. The word *robot* was popularized by Karel Capek (1890–1938) in his play *R.U.R.,* where he used it to refer to a race of manufactured humanoid slaves; robots are machines that can do the work of humans. It is debatable whether merely remote-controlled devices should count as robots, although many devices popularly thought of as robots are of this nature. Similarly, computer programs such as virtual "autonomous agents" and web "'bots" are not, strictly speaking, robots as they lack the ability to manipulate the physical world.

The term *robotics* was coined by Isaac Asimov and refers to the study and use of robots. Research into robotics began in the 1940s, alongside research into cybernetics and computers. The first commercial robots were produced for industrial applications in manufacturing in the 1960s. As computing technology began to improve rapidly in the 1980s and 1990s, a number of writers such as Hans Moravec (1998) and Ray Kurzweil (1992) made arguably exaggerated claims on behalf of robots, suggesting that they would soon possess consciousness and intelligence. Major limitations on the tasks that can be performed by robots—especially in real environments—remain, largely due to a lack of success in reproducing "intelligence" and robust locomotive and sensory systems. The vast majority of existing robots



Kismet, a robot created by Dr. Cynthia Breazeal at MIT. She developed Kismet for her doctoral research in expressive social exchange between humans and humanoid robots. *(© Rick Friedman/Corbis.)*

are industrial robots, which perform a limited range of repetitive tasks in a controlled environment.

The ethical, political, and legal issues surrounding robots can be roughly grouped into two categories: those that are raised by existing technologies and a more speculative set that would arise if genuinely "intelligent" or conscious robots were to become a reality.

Existing technologies largely raise questions relating to their social impact (Weiner 1961). The main impact of robotics thus far has been to displace persons from jobs in manufacturing industries. It might be argued that by replacing workers in industries where jobs tended to be both highly paid and skilled, robots have had a negative impact on human happiness. Alternatively, it might be argued that robots have contributed to human happiness by eliminating the necessity of repetitive and occasionally dangerous work. The economies of scale and other increases in efficiency that robotics have made possible would also need to be taken into account in this calculation. Access to robots could conceivably become a source of inequality in a society where robots play a significant role.

Another area where it seems likely that robots will have dramatic social impacts is warfare. A number of types of remote control and semi-autonomous devices are already deployed by militaries around the world. It seems likely that fully autonomous robots will play a role in wars conducted by industrialized nations in the future.

The use of robots in military contexts raises many difficult ethical and legal issues. They offer to reduce casualties amongst friendly combatants, but in doing so may decrease the threshold of war. "Smart weapons" may allow commanders to attack military targets with greater precision and thus lower the risk of civilian casualties in war. However, the possession of such weapons by one side only may increase the likelihood and extent of asymmetrical warfare and consequently of increased civilian casualties. There are also ethical and legal questions surrounding the allocation of responsibility for deaths caused when such weapons go astray, resulting in attacks on targets that are not legitimate under the rules of war.

More prosaically, a number of quite advanced robots are now manufactured as entertainment devices and "robot pets." The development of robot toys suggests that there is a need to scrutinize the educative and communicative functions of these robots. There are also questions surrounding the ethics of human/robot interactions. Are robots appropriate objects of emotional attitudes? If not, then designing robots to encourage such investment may be wrong.

A much larger, more complex, but also speculative, set of issues would arise if robots were to achieve any degree of consciousness, or genuine intelligence.

At what point would such creations deserve moral concern? What rights should they have? While these questions are regularly raised by writers in the area, little serious philosophical work has been done on these subjects, perhaps reflecting a lack of faith that the technology will become a reality.

Yet much contemporary moral theory, which grounds moral status in the capacities of individuals, suggests that sentient robots would be deserving of the same moral regard as other sentient creatures. If robots can feel pain, then humans will have obligations to avoid causing them pain. If they become self-conscious, can reason, and have future-oriented desires, then they will be worthy of the same moral regard and respect as human persons. This suggests that it would be entirely appropriate to feel grief stricken by the "death" of a robot, to feel remorse for killing a robot, and even sometimes to choose to save the life of a robot over that of a human being.

This last scenario might serve as a test of the moral status of robots. Humans will know that robots are moral persons when they feel that the choice between the survival of a robot and of a person is a genuine moral dilemma. This might be called the "Turing Triage Test," after Alan Turing's famous test for when a machine can be said to think. If this test is a valid one, it suggests that what is required for robots to become persons may include the ability to express subtle and complex emotional states through their bodily appearance.

As well as the question of how people should treat robots, there is also the question of how robots are expected to treat people. What ethical precepts should they be designed to obey? Isaac Asimov's " three laws of robotics" are a famous attempt to answer some of these questions. Yet, as Asimov's stories demonstrate, much more will need to be done before humans become confident that intelligent robots could safely take their place alongside humanity. These questions would become especially urgent if artificially intelligent robots might be capable of reproducing themselves and thereby pose a threat to the human species. If robotics researchers *are* on the verge of creating entities that will be more intelligent than humans and that may compete with humanity for dominance over the planet, then this is a momentous decision, which should only be made after extensive public deliberation.

It also includes discussion of the possible social impact of the development of robots.

ROBOT TOYS

Robots combine sensors, computation, and motors to interact intelligently with their environment. Robot *toys* need to be so cheap and robust that they can be used as playthings. While there is a long history of toys that look like robots, only recently has the cost of computation dropped sufficiently to allow the sale of truly functional robotic toys. This entry focuses on three examples of this new genre of toy that should be of interest from the ethics perspective: Lego MindStorms robot construction sets and Furby interactive robotic pet by Tiger Toys, and Sony Aibo robot dog.

Lego and Furby: Some Contrasts

These two very different kinds of robotic toys were both introduced in 1998, had a large impact, and contrast in several interesting ways. Lego MindStorms and Furby represent two types of toys that Gary Cross (1997) finds typical of twentieth century U.S. toy production: the educational and the novelty toy. Lego MindStorms Robotics Invention System extended the Lego Technic construction system to include a programmable computer controller brick (the RCX), sensors and motors, and computer interface and programming environment. Lavish documentation and support (reflecting a long nurturing by educators) allowed users to build a variety of working robots, ranging from traditional light-guided rovers to static room alarms. Although MindStorms was expensive, included more than 700 pieces, and required considerable assembly and a personal computer, it was nevertheless an immediate success with both children and adults. It became widely used in schools and colleges and has remained in production for a number of years.

By contrast Furby was a plush but inexpensive, stand-alone, interactive toy. Multiple sensors (light, touch, sound, infra-red) drove a single motor, which, via a series of ingenious cams, controlled several motions of the ears, eyes, eyelids, mouth, and rear body (Pesce 2000). Enormously popular in its first season, with long lines at toy stores and price premiums featured on TV news, more than 12 million Furbys were sold in one year. Yet just as quickly the fad passed and in the early twenty-first century Furbys are no longer produced.

Robotic toys fall into two groups: the programmable and the pre-programmed. MindStorms takes programmability to the limit: One can choose which of several general purpose programming languages to use. The Furby was pre-programmed.

Another contrast is in terms of transparency and openness. MindStorms was released as a normal, closed (although very well documented) product. That is, one could run its code but not change it except in predefined ways. After a brief struggle with fans and hackers, Lego agreed to release the technical specifications and allow programming access to the RCX's ROMs. As a result MindStorms became an extensible open-source system for constructing robots. Indeed it has become a platform for a large variety of languages and operating systems. By contrast Furby remained a closed system. It was pre-programmed and an epoxy blob hid its computational abilities and electronics. Moreover its capacities were not documented but shrouded in rumour and advertising hype, so it was difficult to know what the toy could actually do. Could Furbys really learn?

Ethics

Interactive robotic toys raise special issues for ethics. First, robot toys face some special ethical requirements. As robots they interact with children in the real world, so they must be safe. Contrast virtual robot-building software such as the early Apple computer game RoboWar. Virtual battle robots can *fire projectiles* at each other in their on-screen arena without endangering people. Real robot toys are different: As programmed robots, they are capable of initiating unexpected actions; as toys they cannot be cordoned off from human contact in the way that real factory robots typically are.

Second, more subtly, robot toys face design challenges to keep contact with the real world fun and educational. The environment is a great teacher, providing feedback on feasible design for free. But the price can be costly; think of testing whether a Furby can swim or a Lego robot can navigate in sand. The ideal of a platform is helpful here (Danielson 1999). For example MindStorms pushes most electrical considerations down into the platform it provides. The connectors allow polarity to be reversed, but otherwise the user need not be aware of the electrical properties of the sensors and motors.

Third, interactive robotic toys may even change moral categories. Surprisingly Sherry Turkle has found that children categorize their Furbys in a new way: "Children describe these new toys as *sort of alive* because of the quality of their emotional attachments to the Furbies and because of their fantasies about the idea that the Furby might be emotionally attached to them" (Turkle 2000). These children appear to be assigning interactive toys to a third class, between the animate and the inanimate, because of how they interact with them. In a related development, robotic toy pets have been found useful in rehabilitation in Japan (Goodale 2001). These preliminary research results suggest that human relations with emotionally evocative and involving robotic companions will be ethically complex.

Aibo

The third example, Sony's Aibo robotic dog, raises some additional contrasts and ethical issues. Aibo was introduced in 1999 in the United States and Japan. Although very expensive, it sold out in Japan "in just 20 minutes" (Yoshida 2001). Aibo has never sold very well outside of Japan. This difference points to Japan's distinctive history and culture with respect to robots in general and robotic toys in particular. While Aibo's price and sophistication place it with the Lego system, there was an ethically interesting contrast: When Aibo owners hacked its software in order to personalize and extend its capabilities, Sony reacted to block them and protect its intellectual property. Lego, in contrast, opened MindStorms by publishing its source code. Third, Aibo's advanced capabilities allow it to function as a pet much better than the much simpler Furby. Aibos' cognitive and moral status is thus much more ambiguous (see Turkle 1995, chap 3). On one side, the animal rights organization People for the Ethical Treatment of Animals (PETA) claims "the turn toward having robotic animals in place of real animals is a step in the right direction" (MacDonald 2004). But research on actual attitudes towards Aibo find that owners "rarely attributed moral standing" (Peter Kahn, Friedman, and Hagman 2002).

Future Developments

Robotic toys will become ever more sophisticated interactively. Furby, for instance, gave rise to the more capable and expensive Aibo. Robotic toys may thus be a mechanism for increasing the pace of ethically challenging technological change. The toy industry is well known for driving down costs, in order to sell large volume blockbusters. (Furby was brought to market in less than a year and at less than one-half the expected price point.)

In the wake of Furby, there thus exists an increasing number of young new users of a technology, acquired over a short time, along with the design and industrial capacity to make more of the next version very quickly. MIT roboticist Rodney Brooks, for example, has predicted that the first robots to establish a wide household presence will be robotic toys. This is a recipe for rapid technological and attitude change and little time for ethical reflection.

ROTBLAT, JOSEPH

The physicist Sir Joseph Rotblat (b. 1908), born in Warsaw, Poland, on November 4, was a member of the Manhattan Project, which developed the atomic bomb in the United States. In November 1944, when it became clear that Nazi Germany would not be able to develop a bomb and affect the outcome of World War II, he became the only scientist working on the weapon who

Joseph Rotblat, b. 1908. Rotblat is a Polish physicist who received the Nobel Peace Prize in 1995 in conjunction with the Pugwash Conferences on Science and World Affairs, for their efforts towards nuclear disarmament. *(Hulton Archive/Getty Images)*

resigned prior to its being used against Japan. This principled stand, that the benefits of nuclear power should only be used for peaceful purposes, has been a hallmark of Rotblat's career and was instrumental in his sharing the 1995 Nobel Peace Prize with the Pugwash Conferences on Science and World Affairs, the organization he helped found in 1957 to work for the complete elimination of nuclear weapons.

After earning his doctorate in physics from the University of Warsaw in 1937, Rotblat moved to the United Kingdom in 1939 where he worked with James Chadwick at the University of Liverpool on the feasibility of atomic fission.. Having lost his family in his native Warsaw when the Nazis invaded Poland in September 1939, Rotblat soon moved with other émigré scientists to Los Alamos, New Mexico, to contribute to the Manhattan Project. Following his resignation from the project, he moved back to the United Kingdom where he took up positions as Director of Research in Nuclear Physics at the University of Liverpool (1945–1949) and then as Professor of Physics at the University of London (1950–1976), specializing in the medical applications of nuclear radiation.

From his early years working with Chadwick to his association with Bertrand Russell and Albert Einstein as a signatory of the famous 1955 Russell-Einstein Manifesto, which called on scientists to work for the abolition of warfare and nuclear weapons, Rotblat has dedicated his professional and personal life to exposing the fallacy of nuclear deterrence and arguing for the immorality and illegality of nuclear weapons. Because of the role of scientists in creating first the atomic and then the hydrogen bombs, Rotblat believed scientists had both moral and professional duties to ensure that such weapons would not be used against humanity. From the first Pugwash Conferences meeting held in Pugwash, Nova Scotia, in July 1957, to the 2003 Pugwash annual conference that returned to Nova Scotia, he worked tirelessly in calling upon the global scientific community to maximize only the beneficial applications of science and technology.

In his final speech as President of Pugwash in 1997, Rotblat reiterated the principle that led to his resignation from the Manhattan Project in 1944: "Many scientists are still not willing to face reality. Many discourage or actively hamper young scientists from being concerned with the social impact of science . . . Scientists have to realize that what we are doing has an impact . . . on the whole destiny of humankind" (Rotblat 1997, pp. 248–249). Still active in Pugwash and in the movement to eliminate nuclear weapons in his nineties, Rotblat has been a source of inspiration for several generations of scientists around the world with his fundamental belief in the promise of science and technology to improve the human condition and eliminate war as a social institution.

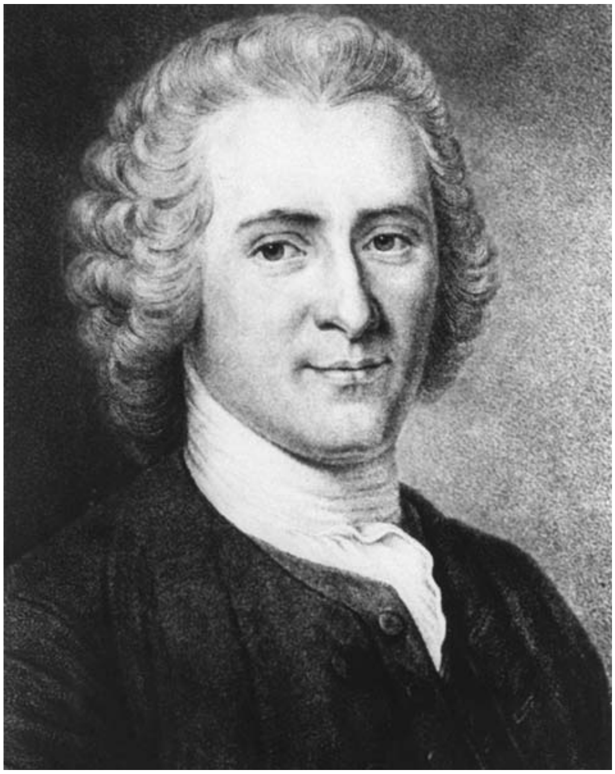
ROUSSEAU, JEAN-JACQUES

Jean-Jacques Rousseau (1712– 1778), who was born in Geneva on June 28 and died on July 2 in Paris, was a self-taught genius who became the leading critic of the Enlightenment vision of an essential harmony between science and society, technology and ethics. As a mid-century member of a circle of intellectuals working on the *Encyclopédie*, a comprehensive attempt to synthesize scientific knowledge and technological skills for social utility, Rousseau's questioning nevertheless had the effect of contributing to the French Revolution and extending modernity.

Brilliant, intellectually disciplined, independent minded, and well-educated, Rousseau arrived in Paris in 1741 and proceeded to impress and become friends with some of the notable Enlightenment intellectuals, especially Denis Diderot (1713–1784) and Jean le Rond d'Alembert (1717–1783). Yet his independent free-thinking temperament found outlet in two prize-winning essays that attacked modern science, technology, enlightenment, and early modern political philosophy as undermining virtue and happiness: *The Discourse on the Arts and Sciences* (1750) subsequently called *The First Discourse*; and *The Discourse on the Origin and Foundation of Inequality Among Men* (1753), subsequently called *The Second Discourse*.



Jean-Jacques Rousseau, 1712–1778. The Swiss-born philosopher, author, political theorist, and composer ranks as one of the greatest figures of the French Enlightenment. *(AP/Wide World Photos.)*

The First Discourse waged war against the modern project as a dangerous dream, corrupt and corrupting in its origin, means, ends, and consequences. The essential features of the dream are fundamental yet simple: The universe is matter in motion, neutral, even hostile to humankind: It was neither created by God for, nor naturally ordered to, human good. Yet knowledge of a certain kind is possible (mathematical physics) and can constitute power over nature, render it predictable and hence controllable for human ends. The pursuit of human good, in turn, is to be guided by calculative, rational, enlightened self-interest ultimately oriented to peace, health, material prosperity, comfort, and bodily pleasure. The climactic scene is to be life in healthful longevity and pleasurable prosperity. There looms on the horizon the specter of universal gratification, even if by means of the scientific manipulation of human nature itself.

The core of Rousseau's response is that because scientific knowledge can be useful, the talented few may seek it with different motives and purposes. Some will be moved by pride, seeking honor, glory, and even tyranny. Others are ultimately moved by fear, especially of death as well as of pain and suffering. Yet desires for peaceful prosperity are but vain diversions from the hard facts of life, recognition of which is required for the possible achievement of true virtue and happiness.

The Second Discourse deepens the argument by suggesting that the root of the problem is reason itself. First, reason includes the human ability to compare oneself with others. This capacity makes possible pride, the love of self over all others. Thus reason contributes to the human selfishness that engenders tyranny. Second, reason can also construct ideas, even of time, and hence of the future. This ability of reason brings the idea of one's ultimate future to mind—that is, death and its terrors—and hence breeds the fear of death. Whereas reason had been previously considered natural to human beings and good, Rousseau argues that in some way it is neither.

Rousseau's argument rests on a reinterpretation of human history. Whereas Aristotle (384 B.C.E.–322 B.C.E.), for instance, considered human history to be cyclical, believers in the Bible saw history as providentially headed toward the end-time, and the moderns argued for history as human progress, Rousseau proposed that human history is in large measure decay from the natural goodness of an early time. From Rousseau's perspective, reason itself is an accidental, artificial acquisition that separates humans from our natural goodness, so that nurture becomes opposed to nature.

In this way Rousseau raised the question, Why reason or science? After all, he claimed, the purpose of science cannot be known by science. Neither can science answer the most important questions—Is life good and What is the good life?

Rousseau's own answer to this fundamental question may be sketched as follows: Tyranny not death is the greatest preventable evil; hence issues of justice and political philosophy are more important than science. Additionally, human sociability, virtue, and happiness are rooted less in reason than in the passions, particularly sentiments such as love, beauty, romance, and pity or sympathy and compassion. Hence, Rousseau's novels and memoirs such as *Julie, Or, The New Heloise* (1761) and *Emile: Or, On Education* (1762) contain striking portraits of the loving, romantic couple; the joys of family life; the sense of community in the tribe or nation; as well as the pleasing sentiment associated with life itself.

As fundamental and coherent as Rousseau's attack on and attention to science and enlightenment may be, he was—and remains—a paradoxical, if not contradictory, teacher. Alongside attacks on reason are to be found high praise of Isaac Newton (1642–1727), René Descartes (1596–1650), and especially Francis Bacon (1561–1626) as the preceptors of the human race. Socrates (c. 470 B.C.E.–399 B.C.E.) (or Plato [428 B.C.E.–347 B.C.E.]) is his self-proclaimed master, as a genius moved by pure not vain curiosity. Moreover, Rousseau did not live the life he taught as good. He philosophized while directing others to find happiness in noble sentiments.

Perhaps these tensions may be explained by Rousseau's vision of the human as a complex being oriented to conflicting goods: the goods of the body and of the soul, of the community and the individual, of life and truth, and, moreover, of the good of the few, theoretical pursuits, and the good of all others, practical pursuits, of theory and practice. The least one can conclude is that perhaps Rousseau took his stand as a middle-man, as the in-between being, as philosopher also concerned with the happiness of humankind, and, as such, forged his own place among the future teachers of the human race. Certainly many of the questions he raised have subsequently become themes in on-going discussions of science, technology, and ethics, even when they are not always explicitly referenced to Rousseau.

ROYAL COMMISSIONS

Royal Commissions, or commissions of inquiry, are part of the executive arm of some Commonwealth governments that are rooted in the British parliamentary system. Their main function is to inform the government and often to deal with broad topics of social, cultural, or economic importance. The reports of Royal Commissions, whether interim or final, are tabled before a nation's parliament and regularly released as parliamentary papers.

Formation and Composition

In the United Kingdom a Royal Commission consists of three or more (usually five) Commissioners, including the Lord Chancellor, who are privy counselors appointed by letters patent to perform certain functions on the queen's behalf (United Kingdom Parliament 2003). Canadian or Australian counterparts sometimes produce minority reports that are more significant than the majority findings (Canadian Press Newswire 1996).

The 1868 Inquiries Act in Canada initiated a process by which Royal Commissions could be appointed by the cabinet to carry out full and impartial investigations of specific national problems. The terms of reference for the commission and the powers and names of the commissioners are stated officially in an order-in-council. The findings are reported to the cabinet and the prime minister for appropriate action. The names of commissions usually refer to the chair or commissioners. An example is the Royal Commission on National Development in the Arts, Letters, and Sciences, which was named the Massey Commission after Vincent Massey, who chaired it from 1949 to 1950 ("Index to Federal Royal Commissions" 2003).

Australia and New Zealand have implemented Royal Commissions as a means to find out facts. As in all other jurisdictions Royal Commissions in those countries are given special powers to compel the attendance of witnesses, compel the production of documents, and give special privilege to persons who give evidence before the commission so that they cannot be prosecuted or subjected to subsequent legal actions (Fitzsimmons 2003).

Scientific, Technological, and Ethical Issues

Royal Commissions have been used frequently to deal with significant scientific, technological, and ethical issues. New Zealand established the Royal Commission on Genetic Modification to develop suggestions for a new regulatory structure for its agri-food (agribusiness) sector. That commission looked for possible strategies for co-managing the range of interested parties involving new corporatist and managerial dimensions of food governance (Le Heron 2003). The Australian Aboriginal Deaths in Custody Commission, which sat from 1987 to 1991, made 339 recommendations in an attempt to prevent more deaths (Fitzsimmons 2003).

Canada's 1989 Royal Commission on New Reproductive Technologies was established to act as the official forum for public deliberation on a complex issue. According to Francesca Scala (2002), the commission showed great promise for defining questions of infertility treatment and related scientific research questions and matters of public concern. Scala argues, however, that the commission's stance in favor of reproductive technologies resulted from the government's capitulation to the powerful interests of the biomedical industry.

Controversies

At their best Royal Commissions are seen as independent bodies that allow for significant public input. They are, however, not without controversy and often are used by governments to gain breathing room on controversial issues, with costs running into the tens of millions of dollars and reports that take years to produce, with no obligation on the part of the government to act on those recommendations.

The Royal Commission on New Reproductive Technologies was launched in 1989 and released its final report in 1993. It received advice from 40,000 individuals and organizations with an interest in the matter (Wood 2002). After expenditures of more than $30 million the bottom line recommendation was that Canada needed laws to govern reproductive and genetic technologies (RGT). As a result the federal government placed a moratorium on nine controversial issues, including sex selection, human embryo cloning, and the buying and selling of eggs, sperm, and embryos. The resulting introduction of Bill C-47 died on the on the order table when the 1997 election was called. The second attempt to create RGT laws, Bill C-247, failed during its second reading in the Canadian parliament.

The Massey Commission in Canada submitted 146 recommendations under eight headings. As a result of those recommendations a federal scientific research policy was created, the National Library (now Library and Archives Canada) was created, actions were taken to create the Natural Sciences and Engineering Research Council and the Social Sciences and Humanities Research Council, and additional resources were provided to support universities as well as students. The impact of the commission's recommendations continues to affect research communities across Canada more than fifty years after the publication of its report.

The Royal Society of New Zealand considered the Royal Commission on Genetic Modification to be part of an effort "promoting excellence in science and technology" (Royal Society of New Zealand). The commission provided a forum for the submission of reports from a diverse range of sources that included the Maori

Congress, Friends of the Earth, New Zealand Biotechnology Association, Human Genetic Society, Grocery Marketers Association, Quakers, Anglicans, DuPont, CarterHolt, and Greenpeace.

Despite criticism regarding costs, political diversion, and lack of direct influence on final decisions, Royal Commissions often provide vital material for long-range policy decisions and are valuable as vehicles for consciousness-raising (O'Malley 2002). Ted Hodgetts, a retired political science professor who worked on Royal Commissions, stated that it sometimes takes years to measure a commission's value, particularly if a commission deals with longer-term arrangements. However, through the process of osmosis and seepage, the ideas enter the general discourse.

Royal Commissions maintain an arm's-length distance from the government of the day and provide impartiality and great inclusively of ideas, especially for ideas and opinions that do not correspond to the dominant political ideology. They generally avoid getting bogged down in party politics, as occurred with the hearings dealing with former U.S. President Bill Clinton's involvement in the Whitewater land deal and the raid on the Branch Davidian compound in Waco, Texas (Canadian Press Newswire 1996). Their usefulness in dealing with complex societal, scientific, technological, and ethical issues probably will continue far into the future.

ROYAL SOCIETY

Dating itself from 1660, the Royal Society of London originated with informal gatherings that began fifteen years earlier and then received its Royal Charter in 1662 as one of the first institutions devoted to the advancement of science. It has been the model for many scientific organizations formed since, not only in the United Kingdom but throughout the world. An independent charitable organization whose members have been selected for their eminence in the fields of science, technology, or medicine since the middle of the eighteenth century, the Royal Society was historically influential in establishing the processes of science and the scientific method as we understand them today.

Historical Impact

From the earliest days of the Society, religious or political affiliation was not a membership criterion. In principle, anyone could be a member; there was even a membership category for foreign nationals. In practice, however, the difficulties of travel kept many potential members from joining a group that met weekly in London, and membership fees were steep enough to exclude many others. In addition, lack of government financing spurred the Society to seek members from the upper social strata who presumably would be generous with their support. This may have inhibited lower-ranked individuals from joining a group that set a high social tone (Hunter 1982). Moreover, it has been suggested that the evolving criteria used for establishing scientific credibility deliberately excluded women and people of color (Harraway 1997). It was not until 1945 that the first woman was elected to the Fellowship. It was not until the tail end of the twentieth century that programs addressing diversity issues were put in place.

Henry Oldenburg (1615–1677), a man of German birth, was the first secretary of the Society (from 1660 to 1677), and as such became responsible for soliciting reports from around the world for publication in the *Philosophical Transactions of the Royal Society*, the oldest science journal still in publication. He was also instrumental in devising methods to secure works against plagiarism, a common problem of the day. These processes were precursors of contemporary notions of peer review and the credit due the first to publish a result. Moreover, in assessing the credibility of reports received, the Royal Society played a central role in establishing scientific norms for impartiality and absence of bias.

The inductive method as expressed by Francis Bacon (1561–1626) was the source of inspiration for many early members of the Society, including Robert Boyle (1627–1691) and Sir Isaac Newton (1642–1727). Adherents to this method proceed by gathering facts through experimentation and observation and then using such collected facts to infer general relationships. Boyle, one of the founding members, was instrumental in defining the experimental method, developing procedures for conducting, validating, documenting, and interpreting experiments. Newton served from 1703 to 1727 as the twelfth president of the Royal Society, the first scientist to hold the title.

Given the lack of external funding and the consequent need to solicit membership from the aristocracy, it was not until the 1800s that membership became the province of professional scientists. During this timeframe the government increasingly looked to the Royal Society for advice on matters of science and technology—a relationship that continues into the twenty-first century. The Royal Society also became increasingly successful in gaining government support for scientific expeditions, particularly to the Arctic and Antarctic. In mid-century, the government initiated a yearly science research grant program, the funds of which were administered by the Royal Society.

This century also saw increasingly successful efforts by the Royal Society to influence the legislative process. One notable example was an effort to modify the proposed language of the Cruelty to Animals Act of 1876, which would have eliminated experiments using animals not directly related to "saving or prolonging human life, or alleviating human suffering." The bill in its original form would have absolutely prohibited the use of dogs or cats in research. As passed, the prohibition against experimentation on cats and dogs was removed and restrictions generally loosened, though a license and inspection process was put in place (Hall 1984).

Recent Impact

At the beginning of the twenty-first century, the goals of the Society are to "push back the frontiers of knowledge and to improve the quality of life in Britain and globally" (Royal Society 2005). The Society continues to publish the *Philosophical Transactions* as well as other peer-reviewed science publications, and rewards achievement through induction of new Fellows and by bestowing medals and other awards to deserving individuals. The Society also acts as the United Kingdom's Academy of Science, providing scientific advice on science policy issues such as funding, and on public policy issues with a scientific or technical component such as cloning. It further represents UK science internationally. The Society continues to act as a funding agency, providing grant support to researchers as well as resources for science and math teachers.

ETHICS OF SCIENCE. The Royal Society does not have a written ethics policy, though the "quality of life" clause in the Society's mission statement could be taken for the beginnings of one. The statutes of the society allow for expelling a Fellow for conduct injurious to the character or interests of the Society.

During his 2004 Anniversary Address to the Society, Lord Robert May, its president, addressed the work the Society had done over the previous year in assessing scientific rules of conduct, specifically in regards to biological research. Among a variety of other issues, May noted his concerns about the peer review process, the unwillingness of some to consider other scientific views, and publication policies.

SCIENCE IN SOCIETY. In 1985, the Royal Society published a report on the public understanding of society that took the view that the general public did not know enough about science to make informed decisions and that more education was needed to correct this. However, given the negative reaction to the handling of science issues since then, including public concerns about genetically modified foods, the Society's approach to policy issues that affect the public has changed.

One outcome of this change was the establishment of a Science in Society program. This program has several components, one of which, the Dialogue initiative, is set up as a series of workshops between scientists and people of all walks of life. The purpose of these workshops is to develop consensus recommendations on topics of science or technology. The Royal Society carries these recommendations forward to the appropriate policy makers. Recent topics included trust in science, genetic testing, and cybertrust and information security.

Another component of the Science in Society program is a scheme whereby individual Members of Parliament (MPs) and a scientist from their district are paired up and allowed to experience each other's world. The scientists are briefed on the workings of government and accompany their MP during their daily activities. The MPs reciprocate by spending time in the scientist's laboratory. The aim is to both establish mutual understanding as well as to develop relationships.

SCIENCE POLICY. Each year, the Society provides reports on a wide variety of policy issues. In early 2005, the major policy topics included animals in research, bioweapons, climate change, the military use of depleted uranium, the environment, stem cells and cloning, nanoscience and nanotechnology, infectious diseases in livestock, humans in research, and genetically modified plants.

Increasingly these reports include sections summarizing societal concerns and the various ethical viewpoints held by stakeholders. Generally these reports do not choose a specific ethical standpoint; leaving that to society and the legislative process, but there are exceptions. For example, the 2003 report *Measuring Biodiversity for Conservation* takes the view that as a minimum "each generation should pass on a set of opportunities no less than what itself inherited."

RUSSELL, BERTRAND

Bertrand Arthur William Russell (1872–1970) was a British philosopher, logician, mathematician, and essayist as well as a champion of humanitarian ideals and influential critic of nuclear weapons. Best known as one of the founders of analytic philosophy, Russell was born into an aristocratic family in Trelleck, Monmouthshire, Wales, on May 18. In 1890, he entered Trinity College, Cambridge, where he later held a professorship until he was dismissed in 1916 for writing pacifist propaganda and leading anti-war protests. Russell then traveled, lectured, and continued to write both philosophical treatises and social and moral essays. He rejoined the faculty at Trinity College in 1944 and received the Nobel Prize in Literature and the British Order of Merit in 1950. After World War II, he became a leading figure in the effort to control nuclear weapons proliferation. Russell died at Penrhyndeudraeth, Wales, on February 2.

Logic, Mathematics, and Philosophy

Through his early examination of the philosophy of G. W. Leibniz, Russell became convinced that logical analysis is the most important method for philosophical investigation. So motivated, he set about the tasks of

Bertrand Russell, 1872–1970. The Welsh mathematician, philosopher, and social reformer made original and decisive contributions to logic and mathematics and wrote with distinction in all fields of philosophy. *(The Library of Congress.)*

making logic a more robust and powerful field and clearing away conceptual difficulties that had impeded its progress. One such difficulty was posed by a paradox that Russell himself discovered in 1901: The set of all sets that are not members of themselves is a member of itself if and only if it is not a member of itself. Russell's Paradox undermined naïve set theory, which served as the foundation of mathematics. Russell's own solution to the paradox was his theory of types of sets, which led to the foundation of modern axiomatic set theory. In his seminal work, *Principia Mathematica* (1910–1913), written jointly with Alfred North Whitehead (1861–1947), he attempted to derive all of mathematics from a restricted set of logical axioms. Although undermined by Gödel's proof that some propositions in any axiomatic system of suitable complexity remain undecidable, the formal system was a major intellectual achievement.

Along with G. E. Moore (1873–1958), Russell is credited with founding analytic philosophy, which rejected idealism and what is regarded as meaningless or incoherent philosophy in favor of clear and precise propositions. For Russell the application of analytic methods to traditional philosophical problems could resolve long-standing disputes. For example, in "On the Relations of Universals and Particulars" (1911) he claimed that logical arguments could resolve the ancient problem of universals. Among his most important contributions to the philosophy of language is his "theory of descriptions" expounded in "On Denoting" (1905). Russell was also a teacher of Ludwig Wittgenstein (1889–1951), the founder of that version of analytic philosophy known as linguistic philosophy, who later eclipsed his mentor in terms of philosophical importance. Karl Popper (1902–1994) and W. V. Quine (1908–2000) were also heavily influenced by Russell, and in fact Popper once referred to him as "the greatest philosopher since Kant" (1976, p. 109).

Science and Technology in Society

In his autobiography (1967–1969), Russell divulged that he was moved by a profound sympathy for the suffering of humankind. This motivated him to write about political and moral issues and to practice social activism. His ethical writings include *Why I Am Not a Christian* (1927) and *Marriage and Morals* (1929), both of which aroused popular antipathy. In fact, he lost a lectureship at City College in New York in 1940 because he was deemed "morally unfit" to teach. Russell's experiments in social and political activism included peace protests during World War I (for which he served six months in jail), three unsuccessful campaigns for a seat in Parliament, and founding and operating an experimental school from the late 1920s to the early 1930s. He also served as president of the International War Crimes Tribunal in 1967, which investigated the conduct of the United States during the Vietnam War.

Russell's views about the role of science in society are outlined in such works as Icarus, or the Future of Science (1924), in which he fears "that science will be used to promote the power of dominant groups, rather than to make men happy. Icarus, having been taught to fly by his father Daedalus, was destroyed by his rashness. I fear that the same fate may overtake the populations whom modern men of science have taught to fly" (p. 1).

In *The Impact of Science on Society* (1951) Russell discussed the potential for science to be utilized for mass psychological propaganda, and he made an unsettling observation about the potential for biological warfare to limit human population growth. In a 1958 essay, "The Divorce between Science and 'Culture'," he argued that governments and citizens must have better science education in order to avoid the potential disasters presented by modern science and technology.

Although he maintained a general optimism about science, including some controversial applications, Russell was concerned about a cultural lag in which human knowledge was expanding more quickly than the ability to utilize it wisely. Nowhere was this concern more evident than in his efforts to fight nuclear weapons and their international proliferation. The opening lines of "The Bomb and Civilization" (1945) expressed both his faith in science and his panic about how science can be easily misused: "It is impossible to imagine a more dramatic and horrifying combination of scientific triumph with political and moral failure than has been shown to the world in the destruction of Hiroshima." It should be noted, however, that while the United States still had a monopoly on nuclear arms, Russell advocated a preemptive war against Stalin, whom he argued was as evil as Hitler (Johnson 1989).

In 1954 Russell delivered his "Man's Peril" broadcast on the BBC, condemning the hydrogen bomb test at Bikini Atoll. The following year Russell and Albert Einstein issued the Russell-Einstein Manifesto, which called for a conference of scientists to discuss "what steps can be taken to prevent a military contest of which the issue must be disastrous to all parties?" This manifesto stimulated the first Pugwash Conference on Science and World Affairs in 1957.

In 1958, Russell became the founding president of the Campaign for Nuclear Disarmament (CND), which promoted nonviolent demonstrations to eradicate nuclear weapons and other weapons of mass destruction. In 1961 (at age 89), he was imprisoned for one week in connection with anti-nuclear protests. Two years later, he established the Bertrand Russell Peace Foundation, to promote his vision of peace, human rights, and social justice. Russell's last essay, "1967," took up the immanent doom presented by nuclear weapons in the scenario of obstinate sovereign states and argued that the only solution is to realize that "peace is the paramount interest of everybody."

RUSSIAN PERSPECTIVES

Russian perspectives on science, technology, and ethics come from two sources: those outside and those inside Russia. Because of the historical impact of the Communist Revolution of 1917, the absorption of Russia into the Soviet Union (1922–1991) for much of the twentieth century, the role of Marxism as the official Soviet ideology, and a strong expatriate intellectual community, scholars outside Russia have created a substantial body of literature analyzing Russian-Soviet-Marxist-Communist perspectives on science and technology, including much related to ethics. While referencing some of this literature, the present entry nevertheless emphasizes discussions as they have developed within Russia itself.

Russian discussions of ethics in relation to science and technology have exhibited both strong positivist commitments to scientific and technological progress and equally vigorous criticisms of science and technology as destructive of traditional Russian values. A brief introduction to these discussions, emphasizing technology, may be divided into three periods: pre-Soviet, Soviet, and post-Soviet. The post-Soviet period has revived and extended some perspectives prominent during the pre-Soviet period.

Originating Discussions

Pre-Soviet Russian history may be divided from the point of view of the scientific and technological progress into three major periods. The first runs from the invasion of the legendary Scandinavian warrior Rurik in the 800s through Mongol (or Tartar) invasions in the 1200s to the rise of Ivan the Terrible in the 1500s and then to the beginning of the Romanov reign in the 1600s. The second takes place during the reign of Peter the Great (1682–1725). In his lifetime, two special schools for training engineers were established, the Engineering School in 1700, and the Mathematical-Navigation School in 1701. Peter the Great introduced engineering training into the Naval Academy, regimental schools, and even religious colleges. He founded the St. Petersburg Academy of Sciences in 1724. As the great modernizer of Russia, it was Peter who brought modern science and technology into the motherland, and thus it was during this second period that discussions relevant to science, technology, and ethics increasingly came to the fore.

The third period begins from the foundation of the first high engineering schools and runs to the Communist Revolution (1917). In 1809, the Institute of the Corps of Engineers of Rail Transport was set up in Russia for theoretical training for engineers and higher technological education. At that time, many vocational and secondary technical schools had already been transformed into higher technical schools and institutes. The Technological Institute in St. Petersburg, for example, had been created in 1862 as a school for foremen from the lower social strata, such as peasants and artisans. In Moscow, a Higher Technical School was established in 1868 following the reorganization of a vocational school (dating from 1830). These new higher educational establishments concentrated on the theoretical side of their curricula (Gorokhov 1998).

One of the most important contributors to such discussions was the Russian engineer Peter K. Engelmeyer (1855–1942). Engelmeyer's positivism is evident in the following words: "Our nineteenth, technological century is . . . the century of unprecedented conquest of the forces of nature. Technology has conquered for us space and time, matter and power, being the power itself that irrepressibly turns the wheel of progress" (Engelmeyer 1898, p. 6). For Engelmeyer the technological worldview dominated the nineteenth century because of an inward tendency of European culture to address real problems with real power. The genius of humanity over the previous two centuries had constructed a human-made microcosm within the larger natural one, making it possible for human beings to satisfy their physical needs to an extent previously unknown. Because of this Engelmeyer saw engineers as the leaders or technological elite in society, and argued for a new system of engineering education to promote the realization of this ideal. The emergence of technocracy in the twentieth century revealed how "efficient" such societal management can be. But it was difficult to anticipate the unintended consequences of this boundless scientific and technological progress, especially in the military sphere.

During this same period Russia was also home to an opposed school of religious and cultural criticism of technology. Sergei N. Bulgakov (1871–1944), in an article titled "The Main Problems of the Theory of Progress," published in 1902, emphasized that in the twentieth century technological change was becoming a kind of theology. By means of modern technology all people of the future were supposed to be happy, proud, and free. To bring happiness to as many people as possible was taking the form of a super modern religion in which society equipped with technological knowledge played the role of God. But according to Bulgakov such technological optimism, which tries to create a material heaven on Earth and even obtain cosmic power, inevitably leads to immoral practices. Technology begins to dominate human beings rather than serve them, making them not happy but miserable. The state, having become the patron of science and technology, inevitably begins to demand that science and technology serve economic and military ends.

During the Soviet Period

In the seven decades from the Communist Revolution to the collapse of the Soviet Union, science and technology were treated in two different ways. On the one hand, they were given unquestioned ideological support; socialism itself was said to be scientific and to provide the strongest support for technology. On the other, political interference in both science and technology compromised their autonomy and efficiency.

The common view in the West that this was simply a corruption of science and technology has been challenged by, for instance, Nikolai Krementsov (1997). Krementsov distinguishes the period of the initial Stalinization of science (1929–1939), its achievements during World War II and up to Joseph Stalin's death (1940–1953), and the post-Stalin consolidation. For Krementsov, Soviet science was "big science" that, as in the United States, it involved a convergence of party-state agencies and the scientific community. Its dramatic achievements—from the atomic and hydrogen bombs (1949 and 1953) to *Sputnik I* (1957)—should not be overlooked. Even in areas of health and medicine Soviet science realized important human benefits. As Vadim J. Birstein (2001) and others have documented, however, science was also used to experiment on human beings; like scientific experimentation that amounts to torture anywhere, this presents a major challenge to the ethics of the scientific community.

> Yet from the beginning of the 1930s, the general ideological atmosphere in the Soviet Union radically changed; from now on the only way to create the new human being was to be sought not in biological, but in social changes. . . . Meanwhile a lot of medical research done in the Soviet Union sometimes posed ethical and legal problems. The first attempt on the part of the authorities to regulate medical research took place in 1936. Narkomzdrav [the name of the Ministry of Health at that time] of the Russian Federation issued regulations determining the conditions of testing new medical devices and methods, which could be dangerous to the health and life of patients. . . . These rather progressive regulations, however, were issued at the same time, when in the depths of the KGB, the secret "Laboratory X" worked on the creation and testing of toxic substances. . . . There are some indications that the laboratory tried to create toxins which could be impossible to detect after victim's death; these substances were tested on prisoners." (Yudin 2004)

During the post-Stalin era impressive attempts were made to adopt cybernetics in order to deal with the emerging problems of a command model of science and technology policy. Additionally, the theory of a new Scientific Technology Revolution (STR) that integrated science and technology anticipated by decades Western European notions of technoscience—and sought to maintain a close link between technoscience and social values.

Among the most insightful non-Russian scholars of Russian science and technology in relation to questions of ethics and politics is Loren R. Graham. In *What Have We Learned about Science and Technology from the Russian Experience?* (1998), he summarizes a life of research on this topic. Although he admits that this short book is more about science and technology than Russia, it nevertheless draws useful conclusions about science and technology in Russia. According to Graham,

> The enormous Soviet scientific establishment, the world's largest, performed rather well in many areas, provided for the nation's military strength, and supplied most of the needs of heavy industry. But it did not do so well in terms of intellectual breakthroughs or outstanding achievements. . . . Political freedom may not be as necessary for the development of natural science as many of its advocates have claimed, but a combination of political freedom and generous financial support *are* necessary for the most creative achievements. One of the tragedies of Russian history is that science there has never enjoyed both financial support and political freedom, either under the Soviet system or today, although, in chronological sequence, it had first the one and then the other. (pp. 132–133)

Another tragedy, however, is the degree to which despite all the rhetoric about their socialist-humanist character under Communism, from the 1930s through the 1980s Soviet science and technology was also deeply antihuman and destructive of the environment.

Post-Soviet Discussions

One major reason for the collapse of the Soviet Union was its failures in regard to the development of an ethics of science and technology that was anything more than their simple promotion for political purposes. The ideology that science and technology might perfect the future of humanity makes no difference to the happiness of the present generation. Indeed, the contemporary squandering of natural resources and contamination of the environment are sacrifices of the future as well as the present, and call for the response of a new ethics (Danilov-Danilian 1999). It is just such a felt need to rethink the uses of science and technology that has led to a reconsideration of the ideas of some of those who were driven out of Russia by the Soviet regime.

One of these thinkers whose ideas have been resurrected is Nikolai Berdyaev (1874–1948). From the 1930s Berdyaev argued that the domination of technology would destroy the person and lead inevitably to dehumanization. To struggle against the hegemony of technology was thus necessary to save humanity. Once everything can be transformed or constructed then this power will be applied even to the human psyche. This precisely was embodied in the unprecedented program for the remolding of the people from the capitalist past in the forge of socialist reconstruction (Gorokhov 1992).

For Berdyaev technology is dehumanizing because it opposes the humanistic ideals of Renaissance culture. But Renaissance ideals also place human beings in an antagonistic relationship with the environment. The main contradiction of contemporary technological civilization is that modern technology creates unprecedented opportunities for human beings to invent needs and wants, which are then satisfied by destroying the natural world. Berdyaev sees the basic problem as a split between indifferent and apocalyptic attitudes toward technology. The former interprets technology as a personal matter of inventors and engineers, and assumes no responsibility for the results of human activity. The latter interprets technology as anathema, the triumph of the Antichrist. But neither response is satisfactory. One contemporary alternative has been the Russian "cosmicism" (Stepin 2002), which "opposes physicalist thinking in order to develop ideas of unity between human beings and the cosmos," both in religious and natural scientific terms.

Along with the work of Berdyaev, the thought of Bulgakov has also once again become important in Russia. Although he was educated initially as an economist with Marxist sympathies, Bulgakov's studies of agrarian life led him to criticize Marxist proposals for the centralization of agriculture. Then in the early 1900s, after a religious crisis, he rejected Marxism completely in favor of a "sophiological" interpretation of Russian orthodoxy and undertook studies for the priesthood. After teaching political economy and theology at a university in the Crimea, in 1922 he was exiled from Russia and eventually took part in establishing the Institute of Orthodox Theology (St. Sergius Theological Institute) in Paris, where he remained until his death.

For Bulgakov human beings must accept their own nature as well as the natural environment as given. To reject either nature is to invite disaster, personal or environmental. To live with the impression of their ever-increasing power may open boundless vistas for "cultural creativity," but it also places humans in increasing danger. The way out of the antagonism between economic activity based on scientific research into the mechanisms of nature and nature itself is the gradual "digestion" of the human-made back into the natural. Bulgakov's philosophy stimulates discussions of low-waste and environmentally friendly technology, as has indeed been the case in Russia during the early 2000s—although against the background of the triumphant march of technological civilization, such an appeal remains the voice of one crying in the wilderness. Yet contemporary efforts to develop a theory of sustainable development correlates to a great extent with the ideas of Bulgakov.

In post-Soviet Russia it is thus common to argue that there are limits to scientific and technological progress. It is not possible to realize, implement, or produce only what is planned, designed, and projected in scientific forecasts; not all the negative effects of the technological activity can be accurately projected. It is only possible to foresee certain risks with new scientific technologies. But this requires the development of moral responsibility in science and professional ethics in engineering. Yet the invention of nuclear weapons and other large-scale technologies has also revealed the limits of individual ethical responsibility for those operating in sociotechnical systems (*Inshenernaja etika* 1998). In biotechnology and genetic engineering there is also a need to develop a scientific and engineering ethics that would guide natural scientific and engineering research (Frolov and Yudin 1989).

An increasing interest in environmental ethics has thus become a significant part of Russian discussions. No longer can humans trust in the power of nature to take care of itself.

> The natural mechanisms are not sufficient at present to preserve the biosphere. New methods for regulations, based on the understanding of natural processes and to some degree also the management of such processes, are required. Anthropogenic regulation can forestall natural cataclysms and decrease the speed of dangerous processes. We must choose between immediate profit and long-term revenues in the usage of natural resources. (Marfenin 2000, p. 8)

In Russia there is concern that when human beings are too eager to dominate nature with science and technology, they may destroy nature and, at the same time, their ongoing economic growth. When humans threaten the biosphere as a whole they also threaten human society. The alternative is a new paradigm in science and technology based on an equal partnership between humans and the environment (Danilov-Danilian and Losev 2000).

Such critical reflections point toward the need for ethical assessments of science and technology. In the words of Stepin again:

> Scientific cognition and technological activity . . . involve a wide range of possible development trajectories . . . and are always faced with the problem of choosing a certain scenario out of the variety of possible scenarios of development. And

> the landmarks for this choice are not only knowledge but also the moral principles that ban the methods of experiment and transformation that are dangerous for people. More and more often contemporary complex research programs and technological projects require the social expertise that includes some ethical components.... Human society must find the way-out of the global crises, but to do this we shall have to come through an epoch of spiritual transformation and elaboration of a new system of values. (Stepin 1988, pp. 19–20)

Concern for the practical elaboration of a new paradigm of scientific and technological development, one that does not separate theory and practice nor ethical responsibilities and scientific-technological power, that respects both society and nature, thus animates current Russian perspectives on science, technology, and ethics.

SAFETY ENGINEERING

Historical Emergence
Practices

HISTORICAL EMERGENCE

The protection of people from harm increasingly has been a focus of many fields of engineering since the nineteenth century. At the dawn of the Industrial Revolution (c. 1750–1850) engineers, as the term is used today, devoted their efforts almost entirely to making devices that functioned reliably and profitably, but with little attention to safety. One notable exception is James Watt (1736–1819), the so-called inventor of the steam engine. Despite introducing numerous improvements on the Newcomen steam engine, Watt intentionally resisted building a high-pressure engine because of the dangers it posed to those working with it. In fact, when Richard Trevithick (1771–1833) began experiments with the high-pressure steam engine, which increased both efficiency and power, Watt (and his partner Matthew Boulton) petitioned Parliament to pass an act outlawing the use of such engines as a public danger.

The second generation masters of steam power for railroads and steam boats thus brought with them boiler explosions, brakeman maimings, and wrecks causing astonishing loss of life. In *Life on the Mississippi* (1883) and again in *Huckleberry Finn* (1894) Mark Twain described in vivid detail the explosion of steam ships and the resultant death and injury of passengers. Manufactories too subjected workers (and often those living nearby) to industrial accidents, toxic fumes, and loss of hearing. Although those risks were hardly unknown, they were accepted by workers and the public as a necessary concomitant to technological progress.

However, over the course of the nineteenth century the protection of human safety became an increasingly important priority for engineers, companies, and eventually federal and state governments. Indeed, the first scientific research contract from the federal government was issued to the Franklin Institute in Philadelphia in 1830 to investigate the causes of steamboat boiler explosions and to propose solutions (Burke 1966).

As each new technology matured to the point where advances in performance were incremental, a poor safety record became a barrier to increased public acceptance and use. Workers began to organize into unions and insist that they be better protected from workplace hazards. Engineering societies, whose original charters tended to stress the promotion and facilitation of the profession's work, by the mid-twentieth century began to impose safety as a primary ethical duty of the engineer. The end of the nineteenth century also witnessed the development of safety codes and standards governing the use of natural gas and electricity, the design of building and steam boilers, and the storage and use of explosives.

In the twenty-first century nearly every engineering code of ethics stresses the safety of workers and the public. The American Nuclear Society's Code of Ethics (2003) states:

> We hold paramount the safety, health, and welfare of the public and fellow workers, work to protect the environment, and strive to comply with the principles of sustainable development in the performance of our professional duties. The first commitment in the Code of Ethics for the Insti-

> tute of Electrical and Electronic Engineers mandates that members . . . accept responsibility in making engineering decisions consistent with the safety, health and welfare of the public, and to disclose promptly factors that might endanger the public or the environment (Institute of Electrical and Electronic Engineers 1990).

All licensed professional engineers are bound by the Code of Ethics for Engineers promulgated by the National Society of Professional Engineers. Both Fundamental Canon No. 1 and the first Rule of Practice impose on the engineer a duty to "hold paramount the safety, health and welfare of the public" (National Society of Professional Engineers 2003).

Apart from these commitments by long-standing communities of engineers there are many engineers whose work is devoted entirely to the protection of the public and workers from the hazards of technology and natural phenomena: Fire protection engineering, automobile safety engineering, and industrial safety engineering are a few examples. Safety engineering is itself an engineering discipline; its practitioners attempt to understand the ways in which technological systems fail and discover ways to prevent such failures. The American Society of Safety Engineers, founded in 1911 and now numbering over 30,000 members, is devoted to being "the premier organization and resource for those engaged in the practice of protecting people, property and the environment, and to lead the profession globally" (American Society of Safety Engineers 2004).

The intertwining of engineering and safety probably will intensify in the future in response to constantly rising public expectations. Two prominent engineering scholars in Lancaster University's Department of Engineering have observed the large gap between the safety expectations of today and those in the early days of modern technologies:

> Safety is rapidly becoming a means by which the public and governments judge the viability of organisations involved in safety-related processes, possibly more so than environmental issues. Many large organisations could not afford a single, large-scale incident as a result of an inferior safety culture, despite buoyant economics. This is a significant dynamic departure from past public acceptability of fatal incidents (Joyce and Seward 2004).

The dedication of the engineering profession to safety as a primary goal and an ethical duty is in accordance with this change in public expectations.

PRACTICES

Safety is one of the primary goals of engineering. In most ethical codes for engineers safety is mentioned as an essential area of professional competence and responsibility.

In everyday language, the term *safety* is often used to denote *absolute safety*, that is, certainty that accidents or other harms will not occur. In engineering practice, safety is an ideal that can be approached, but never fully attained. What can be achieved is *relative safety*, meaning that it is unlikely but not impossible that harm will occur. The safety requirements in regulations and standards represent different (and mostly high) levels of relative safety. Industries with high safety ambitions, such as airway traffic, are characterized by continuous endeavors to improve the level of safety.

The ambiguity between absolute and relative safety is a common cause of misunderstandings between experts and the public. Both concepts are useful, but it is essential to distinguish between them.

In decision theory, lack of knowledge is divided into the two major categories: "risk" and "uncertainty." In decision-making under risk, the probabilities of possible outcomes are known, whereas in decision-making under uncertainty, probabilities are either unknown or known with insufficient precision. In engineering practice, both risk and uncertainty have to be taken into account. Even when engineers have a good estimate of the probability (risk) of failure, some uncertainty remains about the correctness of this estimate.

Safety has often been defined as the antonym of risk, but that is only part of the truth. In order to achieve safety in practical applications, the dangers that originate in uncertainty are equally important to eliminate or reduce as those that can be expressed in terms of risk. Many safety measures in engineering are taken to diminish the damages that would follow from possible unknown sources of failures. Such measures protect against uncertainty rather than risk.

Several methods are used by engineers to achieve safety in the design and operation of potentially dangerous technology.

Inherently safe design. The first step in safety engineering should always be to minimize the inherent dangers in the process as far as possible. Dangerous substances or reactions can be replaced by less dangerous ones. Fireproof materials can be used instead of flammable ones. In some cases, temperature or pressure can be reduced.

Safety reserves. Constructions should be strong enough to resist loads and disturbances exceeding those that are intended. In most cases, the best way to obtain sufficient safety reserves is to employ explicitly chosen safety factors.

Negative feedback. Dangerous operations should have negative feedback mechanisms that lead to a self-shutdown in critical accident situations or when the operator loses control. Two classical examples are the safety valve that lets out steam when the pressure becomes too high in a steam boiler and the "dead man's handle" that stops the train when the driver falls asleep. One of the most important safety measures in the nuclear energy industry is to ensure that a nuclear reactor closes down automatically when a meltdown approaches.

Multiple independent safety barriers. In order to avert serious dangers, a chain of barriers is needed, each of which is independent of its predecessors so that if the first fails, then the second is still intact, and so on. Typically the first barriers are measures to prevent an accident, after which follow barriers that limit the consequences of an accident, and finally rescue services as the last resort. One of the major lessons from the *Titanic* disaster (1912) is that an improvement of the early barriers is no excuse for reducing the later barriers (such as access to lifeboats).

Maintenance and inspections. Many severe accidents have resulted from insufficient maintenance of installations or pieces of equipment that were originally in excellent shape. Regular inspections by persons with sufficient competence and mandate are an efficient means to prevent this from happening.

Educated and responsible operators. Human mistakes are an important source of accidents. An efficient countermeasure is to educate workers, authorize them to temporarily stop processes they consider to be acutely dangerous, and encourage them to take initiatives to improve safety.

Incidence reporting. Experience from air traffic and nuclear energy shows that systems for reporting and analyzing safety incidents are an efficient means to prevent accidents. Systems for anonymous reporting facilitate the reporting of human mistakes.

Safety management. Safety can be achieved only in an organization whose top management gives priority to safety and aims at continuous improvement.

SAFETY FACTORS

A safety factor (also called an uncertainty factor or assessment factor) is a number by which some variable such as load or dose is multiplied or divided in order to increase safety. Safety factors are used in engineering design, toxicology, and other disciplines to avoid various types of failure.

The sources of failure that safety factors are intended to protect against can be divided into two major categories: (a) the *variability* of conditions that influence the risk of failure, such as variations in the strength of steel and in the sensitivity of humans to toxic substances, and (b) the *uncertainty* of human knowledge, including the possibility that the models used for risk assessment may be inaccurate.

Safety factors are used to obtain a safety reserve, a margin between actual conditions and those that would lead to failure. Safety reserves can also be obtained without the use of explicitly chosen safety factors.

At least since antiquity, builders have obtained safety reserves by adding extra strength to their constructions. The earliest known use of explicit safety factors in engineering dates from the 1860s. In modern engineering, safety factors are used to compensate for five types of failure:

(1) higher loads than those foreseen,

(2) worse properties of the material than foreseen,

(3) imperfect theory of the failure mechanism in question,

(4) possibly unknown failure mechanisms, and

(5) human error in design or calculations.

The first two of these can in general be classified as variabilities, whereas the last three belong to the category of (genuine) uncertainty.

In order to be an efficient guide for safe design, safety factors should be applied to all the integrity-threatening mechanisms that can occur. For instance, one safety factor may be required for resistance to plastic deformation and another for fatigue resistance. A safety factor is most commonly expressed as the ratio between a measure of the maximal load not leading to the specified type of failure and a corresponding measure of the applied load. In some cases it may be preferable to express the safety factor as the ratio between the estimated design life and the actual service life.

The use of explicit safety factors in regulatory toxicology dates from the middle of the twentieth century. In 1954 Arnold J. Lehman and O. Garth Fitzhugh, two U.S. Food and Drug Administration (FDA) toxicologists, proposed that ADIs (acceptable daily intakes) for food additives be obtained by dividing the lowest dose causing no harm in experimental animals (counted per kilogram body weight) by 100. This value of 100 is still widely used. It is now often accounted for as being the product of two subfactors: one factor of 10 for interspecies (animal to human) variability in response to the toxicity and another factor of 10 for intraspecies (human) variability in the same respect. Higher safety factors such as 1,000, 2,000, and even 5,000 can be used in the regulation of substances believed to induce severe toxic effects in humans.

The effect of a safety factor on the actual risk depends on the dose–response relationship. If the risk is proportionate to the dose (linear dose–response relationship), then the risk reduction will be proportionate to the safety factor. If the dose–response relationship is nonlinear, then the reduction in risk can be either more or less than proportionate. Because the dose–response relationship at very low doses is always unknown, the exact effect of using a safety factor cannot be known with certainty.

Natural organisms often have safety reserves that can be described in terms of safety factors. Structural safety factors have been calculated for mammalian bones, crab claws, shells of limpets, and tree stems. Natural safety reserves make the organism better able to survive unusual conditions. Hence, the extra strength of tree stems makes it possible for them to withstand storms even if they have been damaged by insects. But safety reserves also have their costs. Trees with large safety reserves are better able to resist storms, but in the competition for light reception, they may lose out to tender and high trees with smaller safety reserves.

At least two important lessons can learned from nature in this context. First, resistance to unusual loads is essential for survival. Second, a balance will nevertheless always have to be struck between the dangers of having too little reserve capacity and the costs of having an unused reserve capacity. Perfect safety cannot be obtained, but a chosen balance between safety and costs can be implemented with the help of safety factors and other regulation instruments.

SAKHAROV, ANDREI

Theoretical physicist and the "father of the Soviet H-bomb," Andrei Sakharov (1921–1989), who was born in Moscow on May 21, became a prominent human rights

Andrei Sakharov, 1921–1989. Sakharov, one of the Soviet Union's leading theoretical physicists and regarded in scientific circles as the "father of the Soviet atomic bomb," also became Soviet Russia's most prominent political dissident in the 1970s. *(© Bettmann/ Corbis.)*

activist and the first Russian to win the Nobel Peace Prize.

Sakharov's father was a physics teacher and popular science author. World War II shortened his study of physics at Moscow University. After two years of work in a munitions factory, in 1945 he went on to graduate study in theoretical physics under Igor Tamm (1895–1971). In 1948 the Soviet government assigned Tamm's group, including Sakharov, to research the feasibility of a thermonuclear bomb. In a few months Sakharov suggested a new idea that was instrumental in the development of the first Soviet thermonuclear bomb (which was tested in 1953). In 1951 he pioneered the research of controlled thermonuclear fusion that led to the tokamak reactor. He was also the main developer of the full-fledged Soviet H-bomb tested in 1955: Unlike the 1953 design, the yield of the 1955 design was potentially unlimited. He was amply rewarded by 'the government, with membership of the Soviet Academy of Sciences (1953), three Hero of Socialist Labor medals (1954, 1956, and 1962), the Stalin Prize and Lenin prize, and a luxury dacha, or villa.

In 1958 Sakharov calculated the number of casualties that would result from an atmospheric test of the "cleanest" H-bomb: 6,600 victims per megaton for 8,000 years. "What moral and political conclusions must be drawn from these numbers?" he asked in an article published that year. He answered: "The cessation of tests will lead directly to the saving of the lives of hundreds of thousands of people and will have the more important indirect result of aiding in reducing international tensions and the danger of nuclear war" (1958, p. 576). Sakharov was proud of his contribution to the 1963 test ban treaty, which stopped atmospheric nuclear testing of the United States, the USSR, and the United Kingdom.

In the 1960s Sakharov returned to pure physics. His most important contribution was a 1966 explanation of the disparity of matter and antimatter in the universe, or baryon asymmetry. The major turn in Sakharov's political evolution took place in 1967 to 1968, when antiballistic missile (ABM) defense became a key issue in U.S.-Soviet relations. Sakharov wrote the Soviet leadership to argue that the moratorium proposed by the United States on ABM work would benefit the Soviet Union, because an arms race in this new technology would increase the likelihood of nuclear war. The government ignored his letter and refused to let him initiate a public discussion of ABM in the Soviet press.

An insider's view of how the upper echelons of the Soviet regime functioned led Sakharov to the conclusion that the goals of peace, progress, and human rights were inextricably linked. He made his views public in the 1968 essay "Reflections on Progress, Peaceful Coexistence, and Intellectual Freedom," published in samizdat (underground self-publishing in the Soviet Union) and in the West in the summer of 1968. The secret father of the Soviet H-bomb emerged as an open advocate of peace and human rights.

Sakharov was immediately dismissed from the military-scientific complex. He then concentrated on theoretical physics and human rights activity. The latter brought him the Nobel Peace Prize in 1975 and internal exile in 1980, after he had been stripped of all honors including the title of Hero of Socialist Labor. In 1985 the European Parliament established the annual Sakharov Prize for Freedom of Thought, given for outstanding contributions to human rights.

In December 1986 the new Soviet leader Mikhail Gorbachev (b. 1931) released Sakharov from internal exile. Upon his return he enjoyed three years of freedom, including seven months of professional politics as a member of the Soviet parliament. The latter were the last months of his life.

For many years Sakharov lived intoxicated by socialist idealism. He later said in his memoirs that he "had subconsciously . . . created an illusory world to justify" himself. Totalitarian control over information enabled Soviet propaganda to brainwash even the most intelligent. Sakharov wanted to make his country strong enough to ensure peace after a horrible war. Experience brought him to a "theory of symmetry": All governments are bad and all nations face common dangers. In his dissident years he realized that the symmetry "between a normal cell and a cancerous one" could not be perfect, although he kept thinking that the theory of symmetry did contain a measure of truth.

Sakharov saw "striking parallels" between his own life and the lives of the two American physicists Robert Oppenheimer (1904–1967) and Edward Teller (1908–2003), who crossed in the "Oppenheimer Affair" (1953–1954). Sakharov did not believe that he had "known sin," in Oppenheimer's expression, by creating nuclear weapons. Nor did he try to persuade the government, as did Teller, of the need for a hydrogen bomb. Having disagreed with Teller on the prominent issues of nuclear testing and antimissile defense (e.g., the "Star Wars" program), Sakharov, nevertheless, believed that American physicists had been unfair in their attitude toward Teller following his clash with Oppenheimer. Sakharov felt that in this "tragic confrontation of two outstanding people," both deserved equal respect, because "each of them was certain he had right on his side and was morally obligated to go to the end in the name of truth" (Memoirs).

For Sakharov the statement that "the future is unpredictable" was meaningful far beyond quantum physics. It supported his personal responsibility for the future of humanity. For him knowledge was not only power but also professional and moral responsibility.

SANGER, MARGARET

Margaret Sanger (1879–1966), born in Corning, New York on September 14, was an internationally renowned leader in the movement to secure reproductive rights for women. Founder of the first birth-control clinic in the United States and later, of the Planned Parenthood Federation of America and the International Planned Parenthood Federation, Sanger was a controversial figure with militant feminist and socialist views, working for change in areas of strong traditional values and cultural resistance.

Sanger was the sixth of eleven children born to a devout Catholic Irish-American family. To escape what she saw as a grim class heritage, she worked her way through school and chose a career in nursing. Although she married and had three children, Sanger maintained an intellectual and professional independence. She immersed herself in the radical bohemian culture of intellectuals and artists that flourished in New York City's Greenwich Village. She also joined the Women's

Margaret Sanger, 1879–1966. The pioneering work of this American crusader for scientific contraception, family planning, and population control, made her a world-renowned figure. *(The Library of Congress.)*

Committee of the New York Socialist Party and participated in labor strikes organized by the Industrial Workers of the World.

Working with poor families on the Lower East Side of New York City, Sanger increasingly focused her attention on sex education and women's health and reproductive rights. She argued that a woman's right to control her own body was the foundation of her human rights, that limiting family size would liberate working-class women from the economic burdens associated with unwanted pregnancies, and that women are as much entitled to sexual pleasure and fulfillment as men.

Sanger's ideas have remained controversial. Those who oppose family planning point to her adherence to certain popular ideas of her time as proof that the movement is fundamentally flawed. Sanger advocated birth control as a means of reducing genetically transmitted mental and physical defects, even going so far as to call for the sterilization of the mentally incompetent. But her thinking differed significantly from the reactionary eugenics that eventually became the centerpiece of the Nazi party platform. Sanger never condoned eugenics based on race, class, or ethnicity, and in fact her writings were among the first banned and burned in Adolf Hitler's Germany.

Sanger called for the reversal of the Comstock Law and related state laws banning the dissemination of information on human sexuality and contraception. In 1914, indicted for distributing a publication that violated postal obscenity laws, she fled to England, where she was deeply influenced by the social and economic theories of Britain's radical feminist and neo-Malthusian intelligentsia. Separated from her husband and exploring her own sexual liberation, Sanger had affairs with several men including the psychologist Havelock Ellis (1859–1939) and the author and historian H. G. Wells (1866–1946). She returned to the United States in 1915 to face the charges against her, hoping to use her trial to capture media attention. But the sudden death of her five-year-old daughter generated public sympathy, and the government dropped the charges. She then embarked on a national tour and was arrested in several cities, attracting even greater publicity for herself and the birth-control movement.

Sanger founded a number of important organizations and institutions to advance the cause of reproductive rights. In 1916 she opened the first birth-control clinic in the United States in the Brownsville section of Brooklyn, New York. Nine days later, Sanger and her staff were arrested. She then opened a second clinic, the Birth Control Clinical Research Bureau, staffed by female doctors and social workers, which became important in collecting clinical data on the effectiveness of contraceptives. In 1921 Sanger founded the American Birth Control League, which later merged with the Birth Control Clinical Research Bureau to form the Birth Control Federation of American, forerunner of the Planned Parenthood Federation of America. In 1930 she founded a clinic in Harlem, and she later founded "the Negro Project," serving African Americans in the rural South. Of Sanger's work, Martin Luther King Jr. (1929–1968) said, "the struggle for equality by nonviolent direct action may not have been so resolute without the tradition established by Margaret Sanger and people like her."

After World War II, Sanger shifted her concerns to global population growth, especially in the Third World. She helped found the International Planned Parenthood Federation, serving as its president until 1959. Sanger helped find critical development funding for the birth-control pill and fostered a variety of other research efforts including the development of spermicidal jellies and spring-form diaphragms. She died only a few months after birth control became legal for married couples, a 1965 decision that reflected the influence of Sanger's long years of dedication to radical, visionary social reform.

SCANDINAVIAN AND NORDIC PERSPECTIVES

The term "Scandinavia" traditionally includes the so-called Scandinavian countries Denmark, Norway and Sweden. Sometimes "Scandinavia" is given a broader definition that also covers the two remaining "Nordic" countries Finland and Iceland. The Scandinavian and Nordic countries are highly industrialized countries that have attempted to combine economic development with social welfare and democratic planning. Technological change has been considered in relation to competing values and interests, and ethics has played a role in this context.

The development of technology and ethics in Scandinavian and Nordic countries is characterised by some general trends that are very similar to Denmark, Norway, Sweden, Finland and Iceland. Traditionally there has been a lot of scientific and cultural exchange among these countries and therefore one finds similar theoretical trends and movements among the Nordic countries. In particular can be mentioned positivistic and instrumental positions, Marxistic postions, positions from applied ethics traditions, critical environmental positions, and positions from postmodern continental philosophy.

Historical Background

The most famous case of science and technology ethics in the Nordic countries is the criticism of the Danish physicist and Nobel Prize winner Niels Bohr (1885–1962). Bohr was paradoxically one of the physicians participating in the "Manhattan Project" during World War II that lead to the creation of the nuclear bomb. Bohr has said that it was only after that the United States dropped the bomb on Hiroshima and Nagasaki that he fully became aware of the ethical responsibility of science (Rendtorff 2003). After he realized the deadly consequences of the use of nuclear bombs Bohr became an active opponent of nuclear arms and he sent several letters to the United Nations urging avoidance spread of nuclear mass destruction weapons and prevention of a nuclear war.

Although many Nordic scientists joined Bohr in his criticism of the military use of science and technology, the spirit of science and technology during the first part of the twentieth century was in general determined by a belief in the norms of science as universal and neutral creation of knowledge for the benefit of humankind.

During the 1960s there was a general belief in technology in the Scandinavian and Nordic countries. This period was characterized by a strong belief in the progress of science and technology. The spirit of research was instrumental, pragmatic and positivistic. In the 1970s, however, many critical movements emerged. In particular, many Marxist criticisms of technology were published. Marxist critiques treated technology as an aspect of the increasing oppression of people by a capitalist society. Marxist positions were influential because they contributed to the establishment of classes on society and technology in many universities.

The well known Finnish philosopher Georg Henrik von Wright published a path-breaking critical work in technology ethics in 1986, one of the most important contributions to technology ethics in Finland and perhaps also in the rest of the Nordic countries. In his book about science and rationality the basic argument is a deep scepticism towards the possibilities of humanity to deal with technological progress and its problems. A true humanism must be based on a deep understanding of human nature and the acceptance of the natural limits on human activities and the interventions of beings in their natural and cultural environment (von Wright 1986).

In Denmark there have also been many publications on the limits of growth. The theologian Ole Jensen (1976) wrote *I Vækstens Vold* (Submitted to growth) on that subject and the philosopher Villy Sørensen and colleagues (1978) proposed a discussion aimed at overcoming the Marxist opposition to the role of technology in society and proposing a new vision of a society in harmony with technology.

In addition to Marxist positions there emerged a strong ecological movement focusing on the negative environmental consequences of science and technology in an industrial society. Discussions of environmental ethics were extensive, and in Norway the deep ecology movement represented by the philosopher Arne Næss (1976) proposed a paradigm of the relationship between humankind and nature that became influential worldwide.

During the 1980s the Danish philosopher Peter Kemp attempted to integrate the humanities and technology. Drawing on the philosophies of Hans Jonas (1903–1993), Paul Ricoeur (b. 1913) and Emmanuel Levinas (1906–1995), he argued for a symbiotic relationship between the two cultures and an ethics of technology in *The Irreplacable* (1991), which was his second doctoral habilitation at the university of Göteborg.

Bioethics

During the 1990s the focus shifted from technology ethics to bioethics and medical ethics. In Norway a debate on principles resulted from discussions about the national biotechnology legislation that was enacted at the beginning of the decade. The Norwegian parliament invented the concept of "mixed ethics," a collection of deontological, utilitarian, and cultural approaches, as the basis for biotechnology legislation. Sweden discussed these matters in the framework of the Swedish Council for medical ethics, an advisory body to the Swedish government.

In Norway technology ethics and bioethics were integrated in the so-called Ethics Research program of the Norwegian Government, which opened opportunities for many doctoral candidates to start a carrier in technology ethics. That program also involved strengthening bioethics research. The professor of medical ethics Jan Helge Solbakk (1994) was influential in developing medical ethics in that country on the basis of the work of one of the founders of Norwegian medical ethics, Knud-Erik Tranøy (1992).

In Sweden utilitarian bioethics was defended by the consequentialist Torbjörn Tjansöe, who became a professor of philosophy in Stockholm. Tjansöe has radical views on bioethics and once was a dogmatic Marxist. A Kantian position in favor of human dignity has been defended by Matts Hannson (1991), who is the director of the Swedish ELSA program (Ethical, Legal, and Social Aspects of genetic technologies) based in Uppsala. In addition, there is an influential interdisciplinary research unit on bioethics and technology ethics at Linköping University, where the Danish professor Thomas Achen has worked on gene technology and law in Scandinavia (Achen 1997).

In Denmark discussions of bioethics emerged from debates in the Danish Council of Ethics, which was established in 1987. Two research programs that were sponsored by five Danish Research Councils in 1993 were especially important in the development of the bioethics research environment in that country.

The first program, Gran (Foundations and Applications of Bioethics) explored the foundations and applications of ethics and collaborated closely with the Danish Council of Ethics by arranging hearings about bioethics issues. Svend Andersen, a professor of theology at the University of Aarhus, who had been one of the first members of the Danish National Council of Ethics, directed this research project. The Danish philosopher and theologian Knud Ejler Løgstrup was the inspiration for Andersen's position on theoretical ethics. Andersen had also been responsible for an important report on research ethics for the ministry of research in 1994 (Andersen 1994, Rendtorff 2003). However, Andersen also collaborated with Peter Sandøe, a consequentialist who later worked on animal bioethics and in 1998 established a Center for Risk Assessment for Human and Animal Biotechnology based in the Royal Danish Vetenary School.

The second project, which was based in the Center for Ethics and Law at the University of Copenhagen, explored the relationship between biotechnology, ethics, and the law. It also collaborated with the Danish Council of Ethics in the organization of international conferences on bioethics and biolaw. Peter Kemp, a technology ethicist who in the 1980s had done work on medical ethics, became the director of the center, which published several works on bioethics and law. This project applied a phenomenological approach to the ethics of biotechnology (Rendtorff 1999). In addition, the

Center for Ethics and Law was responsible for a European research project sponsored by the BIOMED-II program of the European Commission, Basic Ethical Principles in European Bioethcis and Biolaw, that led to the publication of a two-volume research report (Rendtorff and Kemp 2000). The report investigated the ideas of autonomy, dignity, integrity, and vulnerability as guiding ideas for future European bioethics and biolaw.

In Finland there has also been much public debate about different issues of bioethics: abortion, euthanasia, genetic engineering, inequalities in health, decline of the natural environment, overpopulation, and scarcity of medical resources. Like many European countries, Finland has established a national council of ethics to advise government about ethical issues in health care, science, and technology. Academic debates about bioethics in Finland has mostly been inspired by the Anglo-American approaches in the field. The discussions are characterized by confrontations between consequentialist and deontological and right-based approaches to applied ethics (Rendtorff and Kemp 2000).

Icelandic approaches to bioethics follow the same patterns of confrontation between principles and pragmaticism. Recent discussions have been focussed on the development of an Icelandic biotechnology industry. A thought-provoking case is the fact that the Icelandic government has allowed a privately-owned enterprise to make a bio-bank with blood samples and genetic information from the 280,000 citizens of Iceland (Rendtorff 2003). The Icelandic genetic patrimony is unique because of the small genetic variation within a homogenous population; therefore there might be opportunities to discover new knowledge about genetics. The firm "decode" collaborates with international biotechnology companies; they have procured a number of patents and other rights to the genetic samples that constitute a unique opportunity to do research in genetic basis of disease and possible improvement of medicines for treatment of genetic diseases. Critical voices in the public debate have argued that this common gene pool poses serious problems of data protection, privacy, and anonymity. Moreover, it is stated that the Icelandic government has been too quick in allowing extended commercialization of genetic information and private ownership of blood samples from human bodies. However, this debate about bio-banks and uses of genetic technologies represent features that seems to be fairly common among all the Nordic countries.

Technology Ethics

Parallel to the discussions in bioethics, a scholarly literature has evolved that is concerned with the relationship of technology and society. In this literature attempts are made to understand the interrelationships between technological change and social concerns. The concept of ethics also is important in this context, but it is not always used in the strict philosophical sense of the word.

The Scandinavian and Nordic countries all have a tradition of social planning. All three countries were industrialized at a relatively late stage and at a slow pace. This has allowed for peaceful processes of industrialization with attention paid to the welfare state and social welfare. As a consequence, labor unions, among other groups, have played a crucial role in social development and various traditions of democracy and welfare planning have evolved that have a strong influence on Scandinavian societies.

This may explain why several issues in ethics, social policy, and technology have been formulated in a relatively constructive and formative rather than reactive way. In the initial stages two scholarly traditions seemed important: working life science and a critique of technology.

WORKING LIFE SCIENCE. This tradition began in the late 1960s. In 1971 the Norwegian Iron and Metal Workers' Union initiated an important project with Kresten Nygaard that dealt with planning methods for the trade unions (Fuglsang 1993). The aim of the project was to strengthen the trade unions' influence on new computer technologies. In 1975 the Swedish National Federation of Labour Unions (LO) sponsored a similar project, DEMOS, which dealt with democratic control and planning in working life. The aim of the project was to support workers' influence on the new technology. In Denmark Project DUE, which dealt with democracy, development, and data processing, was initiated. Some of these projects were inspired in part by Harry Braverman's work on the degrading and controlling aspects of work (Braverman 1976), but their aim clearly went beyond Braverman's objectives. They were not limited to studying the negative consequences of technology but instead were intended to formulate an approach to a constructive development of technology.

One of the computer scientists who took part in those discussions, Pelle Ehn, published a book explaining these aims (Ehn 1988). In that book the Scandinavian approach was seen as standing in opposition to the so-called sociotechnical approach, a functional approach in which social and technical systems were understood as being interdependent. By contrast, in Ehn's view workers should be able to participate directly in the development of computer systems.

CRITIQUE OF TECHNOLOGY. This tradition evolved from a combination of philosophical and sociological approaches. In Norway, Arne Næss developed his ecophilosophy, which was concerned, among other things, with the inability of engineers to take into consideration the wholeness of humankind and nature in which they were situated (Næss 1976). Sigmund Kvaløy (1976) developed a critique of the complexity of industrialism. The sociologist Dag Østerberg (1974) was concerned with the way in which technology could be understood as materialized social relations interacting with human activity.

In Denmark, Hans Siggard Jensen and Ole Skovsmose published a critique of technology in which they argued for a nonteleological or deontological ethical approach to technology (Jensen and Skovmose 1986). They positioned themselves in relation to the work of the philosophers Immanuel Kant (1724–1804) and Jürgen Habermas (b. 1929). Anker Brink Lund, Robin Cheesman, and Oluf Danielsen published a book in which they criticized technocratic approaches, particularly in the area of electronic media, and pointed to possibilities for a more democratic model of technological change (Lund et al. 1981).

Tarja Cronberg (1987) has developed a distinct approach to technology that focuses on the relationship of technology and everyday life. Cronberg came to see Danish social experiments with technology as a kind of laboratory for dialogue and research inspired by phenomenological approaches and critical theories of communication (Habermas 1984).

In Sweden, Andrew Jamison and Aant Elzinga have tried to work out historical perspectives on science and technology policy. They also stress the impact of culture (Elzinga and Jamison 1981). Jamison (1982) has been interested in the concept of "national styles" in an attempt to determine how national culture plays a formative role in relation to science and technology; this is implicitly a deontological approach.

The two initial traditions of working life science and technology critique have been conducted in various ways in small scholarly communities. In computer science the tradition of working life science has involved differing understandings of computer design and human-computer interactions. The journal *Computer Supported Cooperative Work* has been important in this work. An influential semiethical orientation in Scandinavian computer design is "activity theory," which is present in the work of the Danish working life scientist Susanne Bødker. Technology is seen as a tool that mediates between an individual and a social object or social role in an organization. For this relationship to become meaningful, it is necessary to design and integrate computer programs in an artful way. In Finland, this tradition of activity theory has become a very important contribution to work development research through the work of Yrjö Engeström (Engeström et al. 1999) and his Centre for Activity Theory and Developmental Work Research at the University of Helsinki.

A critique of technology seems not to have developed in a systematic way in Scandinavian philosophy. Some works have been published, but they have not led to the development of distinct philosophical traditions. At the Department of Management, Politics and Philosophy in the Copenhagen Business School in Denmark some scholars have developed the notion of "ethical budgets" and values-driven management for firms, which seems to be related to technology and ethics (Ole Thyssen 1997), and other philosophical contributions in the areas of ethics, innovation, and technology have been produced.

In Finland, a tradition of engineering ethics and responsibility of scientists has developed through such organizations as the Finish nongovernmental organization Technology for Life, and the Association of Swedish-Speaking Engineers in Finland, which has created a code of ethics for its members. Attempts are here made to sustain civil courage and find ways for engineers to demonstrate loyalty to third party (the future, the nature, humankind) rather than merely to business or within professions. Engineering ethics is taught in some engineering schools and technical universities in the Scandinavian countries even though these courses are not, or at most are seldom, compulsory. At the Helsinki University of Technology, a one-year course has been created with the help of Technology for Life.

Science, Technology, and Society Studies

A small tradition of science and technology studies (STS) has developed primarily in the three Scandinavian countries (Denmark, Norway, Sweden). It has, in parallel with working life science, attempted to focus more on the development of than on the impact of technology. In Norway two STS institutions have been created that serve as examples of this work.

One is the Center for Technology and Human Values (now the Centre for Technology, Innovation and Culture), which was headed by Francis Sejersted in the period 1988–1998. Sejerstedt (1993) examined how a special form of capitalism has developed in Norway that is anchored in democratic, egalitarian, and local values in contrast to Chandler's (1990) notions of corporate and competitive capitalism in Germany and United States. Other researchers at this institution have shown how the transfer of technology to Norway as well as innovation processes can be seen as being intertwined with regional social structures and local values, leading to special forms of localized innovation (Wicken 1998).

A second STS institution is at the Norwegian University of Science and Technology in Trondheim, headed by Knut H. Sørensen. In his research Sørensen has been occupied with studying what he calls the domestication and cultural appropriation of technology in everyday life, which may be seen as part of a deontological, nonteleological tradition (Lie and Sørensen 1996, Sørensen 1994, Andersen and Sørensen 1992).

In Sweden several STS units have been created, such as Tema T in Linköping and Science and Technology Studies at Göteborg University. Those groups conduct research on various aspects of technology and ethics, such as the role of expertise, technology in everyday life, technology and gender, technology and identity, technology and large technological systems, and public engagements with science.

These institutions focus largely on technology *development* rather than the *consequences* of technology, and in terms of ethics they may be seen to underline mostly a deontological approach in which social values come first and technology comes second.

In Denmark and later in Norway a tradition of technology *assessment* has developed. The most important contribution in this field is probably the Danish "consensus conference," which involves laypeople in the ethical assessment of technology. The laypeople are appointed much as a jury is appointed in a court. They question experts during a three-day session. Afterward they withdraw and formulate a verdict in the form of a consensus report. This approach can be associated with a nonteleological or deontological approach to ethics and technology.

Ethics of Science

In Scandinavia debates on the ethics of science have involved research on both ethics in technology and bioethics research. However, only with the establishment of specific committees for the ethics of science has this become an integrated part of work on the ethics of technology.

In Denmark the ethics of science was prominently present in the medical research community, which had to deal with serious problems with scientific fraud. The central committee on the ethics of science was influential in resolving problems among scientists with regard to this issue.

In 1998 the Danish Committee on Scientific Fraud and Integrity in Science (Udvalgene Vedrørende Videnskabelig Redelighed) was established as a subcommittee to the national committee for medical research. This committee formulated a number of rules for the ethics of science and publication ethics. The committee was allowed to process individual complaints against scientists (Rendtorff 2003, p. 63).

In this context, an intense debate about the ethics of science emerged as a reaction to the work of the political scientist Bjørn Lomborg (2002), director of a newly established Institute for Assessment of Environmental Protection. Lomborg had argued that most of the environmental sciences had been too pessimistic with regard to their conceptions of the dangers of an environmental crisis. Lomborg's work was brought to the committee in 2002 by a number of scientists who complained that Lomborg was guilty on scientific fraud because they did not believe in his methods and research results. It was argued that Lomborg did not work with a satisfactory scientific method. Lomborg had illustrated his argument with statistical material, and many ecological scientists thought that this constituted scientific fraud because he used statistical material to illustrate arguments that, according to the ecologists, could not be defended on those grounds. Lomborg's opponents argued that Lomborg's book could not be regarded as science, but rather as a contribution to the public debate. Moreover, it was argued that Lomborg as a social scientist did not have sufficient knowledge, which led to incorrect and hasty conclusions. The Committee on Scientific Rraud and Integrity investigated the issue, based on dialogue with international experts, and in spring 2003 (Rendtorff 2003, p. 9–10) Lomborg was judged by the committee to have committed not subjective but objective scientific fraud; according to the committee, he did not understand his research subject. This led to a violent debate about environmental technology in Denmark, and after that time the ethics of science became a very widely discussed subject.

In January 2004 the Ministery for Research of the Danish liberal-conservative government intervened. They came up with a very critical assessment of the decision in the Lomborg case. However, the Ministery wanted to protect people who were charged of scientific fraud; it therefore did not accept the decision of the Committee for Scientific Fraud in the Lomborg case. So Lomborg, in the end, was not convicted of scientific fraud and the official inquiry ended in January 2002. But even though the case of Lomborg did not get a clear closing and decision about whether it really was a case of scientific fraud, it illustrates many of the basic dilemmas of the ethics of science in Scandinavian countries: problems of the definition of scientific fraud and the integration of the public in scientific debates.

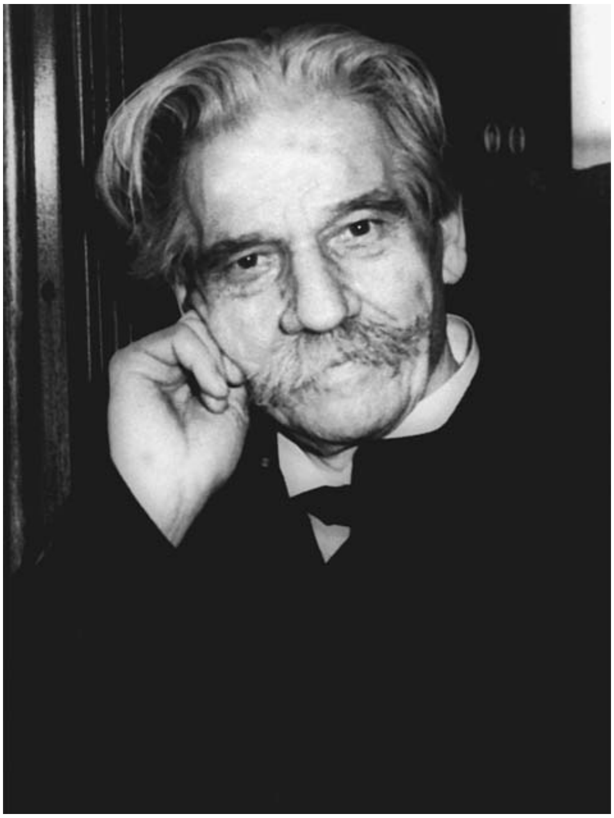
SCHWEITZER, ALBERT

Albert Schweitzer (1875–1965) was born in Kaysersberg, Germany (now part of France) on January 14, and became a theologian, physician, musician, and philosopher whose ethical theory argued the centrality of reverence for life. After a doctorate in philosophy from the University of Strasbourg (1899), Schweitzer received his licentiate in theology (1900), and from 1901 to 1912 held administrative posts in the Theological College of St. Thomas. In 1913, having earned an M.D. degree, he founded a hospital at Lambaréné, French Equatorial Africa (now Gabon). As a German citizen, he became a French prisoner during World War I, but returned to Lambaréné in 1924, where he spent the remainder of his life expanding, administering, and improving the hospital. Recipient of the 1952 Nobel Peace Prize, Schweitzer worked during his later years in the struggle to end the proliferation and testing of nuclear weapons. He died on September 4 and was buried at Lambaréné.

From Music to Philosophy

In 1905 Schweitzer, an accomplished organist, wrote a biography of Johann Sebastian Bach (1685–1750), and in 1906 *The Quest of the Historical Jesus* established him as a theological scholar. As a Christian, his faith guided his life as a physician at Lambaréné, where he unselfishly treated thousands of patients, including lepers. Although successful in diverse fields, Schweitzer considered his contributions to philosophy to be his most important achievements.



Albert Schweitzer, 1875–1965. Schweitzer was a German religious philosopher, musicologist, and medical missionary in Africa. He was known especially for founding the Schweitzer Hospital, which provided unprecedented medical care for the natives of Lambaréné in Gabon. *(AP/NYWTS/The Library of Congress.)*

Schweitzer's philosophy of culture and ethics sought to reorient material progress toward humanity as a normative ideal. In his *The Decay and the Restoration of Civilization* (1923) and *Civilization and Ethics* (1923)—brought together in *The Philosophy of Civilization* (1949)—Schweitzer interpreted World War I as the sign of a deep-rooted crisis of European culture. The Enlightenment ideals of progress and rationality had decayed and lost their ability to control the trajectory of science and technology. Philosophy and religion no longer provided intellectual and spiritual guidance. Human powers had outstripped human capacities for reason.

This asymmetry between human powers and the ability to wisely constrain and channel those powers for compassionate action underpinned Schweitzer's ethics. In *Civilization and Ethics*, he writes:

> The disastrous feature of our civilization is that it is far more developed materially than spiritually. . . . Through the discoveries which now place the forces of Nature at our disposal in such an unprecedented way, the relations to each other of individuals, of social groups, and of States have undergone a revolutionary change. . . . Advances in knowledge and power work out their effects on us almost as if they were natural occurrences. . . . Paradoxical as it may seem, our progress in knowledge and power makes true civilization not easier but more difficult. (pp. 86–87)

He did not conceive of his own ethical theory as completely novel, but rather as the revitalization and reformation of the ethical legacy of humanity in the twentieth century. His goal was to restore the binding character of humanity and humanitarianism as the common assets of world civilizations. Schweitzer drew not only from the Christian commandment of love but also from Asian philosophies. He held that his main principle of "devotion toward life born from reverence for life" was a plausible ethical guideline for any individual regardless of his or her culture or religion.

In contrast to the rational a priori approach of Immanuel Kant (1724–1804), Schweitzer grounded his ethics in the experience of life as an empirical hypothesis, and is in this sense closely related to Friedrich Nietzsche (1844–1900) and Arthur Schopenhauer (1788–1860). Reflecting upon life in this way, Schweitzer believed, would lead to the perspectives of reverence and responsibility. An experience of one's own "will to life," and the effort to avoid pain and seek pleasure, rationally compels an individual, under the auspices of a quasi-Kantian truthfulness, to acknowledge the same volition in others (see Meyer and Bergel 2002). This consciousness of being connected with other lives demands that people respect the moral rights of others, including plants and animals.

Schweitzer's ethics is contextual and situation-oriented and leads to a practical law that serves "concrete" humanity. He does not require an unbounded ethical responsibility beyond one's capability, but rather insists that it is most important to practice reverence for life within one's scope of action. He believed "abstraction is the demise of ethics" and that concrete humanity should always be promoted.

Ethics and Technology

Schweitzer was aware that life presented conflicting demands and that technological and scientific developments in modern civilization posed difficult challenges for practical responsibility. Yet he did not believe that this warranted the construction of dubious hierarchies and theoretical rankings of values that only solve problems in the abstract. His ethics does not promise a methodical and self-evident solution to difficult problems. Instead, the principle of reverence for life should be used as a general guideline for the process of critical thinking.

Schweitzer's ethics serves as a compass in the complex geography of modern problems to orient practical action toward responsibility and reverence for life. In his autobiography, *Out of My Life and Thought* (1990), Schweitzer describes the moment when the concept of reverence for life dawned upon him as he traveled through an African jungle in September 1915. He remembers, "Late on the third day, at the very moment when, at sunset, we were making our way through a herd of hippopotamuses, there flashed upon my mind, unforeseen and unsought, the phrase 'reverence for life.' . . . Now I had found my way to the principle in which affirmation of the world and ethics are joined together!" (p. 155).

Although he did not develop a special ethics for science and technology, Schweitzer's humanitarianism and reverence for life can be easily transferred to the moral problems in this field. For instance, he argued that because nuclear technology could not be controlled, it could by the same token not be responsibly used—a position that would, of course, have to be qualified by specific situations and contexts (Schweitzer 1958). In general, Schweitzer's advice for solving ethical problems, including those presented by science and technology, was to rely on and use practical reasoning, individual responsibility, and the ideal of concrete humanity.

SCIENCE AND ENGINEERING INDICATORS

Science and Engineering Indicators is a term referring to efforts to measure the pursuit, support, and performance of science and engineering on scales that geographically extend from the local to the international. Their goal is usually to help direct policy programs in research, education, and industrial support.. The most prominent and celebrated of these is Science and Engineering Indicators (referred from here on as *Indicators*) published every two years in the United States by the National Science Board (NSB). NSB is the body that oversees the budget and policies of the National Science Foundation (NSF) and the report itself is prepared by NSF's Science and Resources Directorate.

As an NSF publication, *Indicators* was conceived after Congress, in 1968, broadened the NSF Charter to include more engineering and social sciences in the agency's support portfolio. Legislators desired a sense of the impact government support for research was having on the "health" of the national research system, and NSF, which already had an active statistics branch, broadened its ambitions to large-scale endeavors.

The first *Indicators* report was issued in 1972 as simply "Science Indicators" and ever since it has been the worldwide standard reference and model for the statistical treatment of science, engineering, and technology. *Engineering* appeared in its name in 1986 when the NSF, under Congressional pressure, sharply raised its budget for engineering research and elevated its interest in supporting partnerships between U.S. universities and industry.

No mandate, however, was established for assessing the social and economic impact of science and engineering. Editors of *Indicators* have been conscious of and curious about returns on government research investment. But they believe the report is already extensive enough and that performance indicators that assess such outcomes are, and always were, imposingly difficult areas to measure. Quantified data will probably always constitute the core of the *Indicators* endeavor.

As the research system has grown and changed over the years, *Indicators* has evolved in style, content, and presentation. The 1976 edition, reflecting a relatively simple time in the measurement of science and technology for policy, contained chapters titled "International Indicators of Science and Technology," "Resources for Research and Development," "Resources for Basic Research, Industrial R&D and Innovation," "Science and Engineering Personnel," and "Public Attitudes toward Science and Technology."

By comparison, the more voluminous and finely rendered 2002 edition mirrored the rise of new technologies, the increasing globalization of science and technology, and the wider mingling of corporate, university and government interests. Its chapters included "Elementary and Secondary Education," "Higher Education Science and Engineering," "Science and Engineering Workforce," "Funding and Alliances in U.S. and International Research and Development," "Academic Research and Development," "Industry, Technology, and the Global Marketplace," "Public Attitudes and Public Understanding of Science and Technology," and a special chapter entitled "Significance of Information Technology." By the increasing specificity of the chapter titles it was becoming clear that the *Indicators* editors were being nudged toward treating the facts and figures of science and engineering as more than self-referential measures of the enterprise.

The 2004 edition extended the publication's reach by introducing a chapter on state-by-state research and development statistics, mainly to reflect the importance states place on science and engineering for their economic development. But as to actual state-by-state outcomes, *Indicators* once more begged off entering with any sense of resoluteness an area in which statistics are, to them, impossible to gather.

The era of the Internet has improved the currency and relevance of *Indicators*. NSF has taken advantage of Internet technology by continually updating the data in its interactive online version. Thus, readers can no longer object, as they would in the past, that the publication's data were too out of date to be useful. Their objection was a valid one for scholarship: Upon the date of publication, many of *Indicators* data were often more than a year out of date.

Identifying exactly what science, engineering, and technology ought to indicate is a subject that is without a consensus but is ripe for speculation, especially in the ethical dimensions of the technical universe. Its chapters draw conclusions and projections, but the publication largely leaves it to the readers to interpret what the numbers mean. One certainty is that *Indicators* confirms that science and technology have shown huge growth both in complexity and scope since the report was first issued, raising issues related to how scientific and technological change affect, and indeed can improve on, human life.

As an information tool for ethical studies of science and technology, the best that can be said is that *Indicators* offers mountains of data for the taking—levels of funding by field of study, patent activity by universities, size of university department, and so on. But if the ethical subject is conflict of interest by scientists in universities, for example, *Indicators* will provide enough data on the extent of private funding for academic research, but offer nothing in the way of, for example, numbers of universities that require their faculties to adhere to a code of behavior in dealings with industry. If the query is numbers of litigation cases between universities and corporations over intellectual property, again, *Indicators* fails the test.

But on balance, a point can be reached where too much is asked of a report that was always meant to be statistical. *Indicators* is widely praised, universally used, and admiringly emulated. The problem for users with an interest in ethics and the social sciences is that the publication does not address societal and economic outcomes, leaving the reader with the sense that science mainly looks inward while growing in size and importance worldwide. As for technological growth, the reader has no guidance for judging its relative social benefits.

Science and engineering are such powerful forces for change that their statistical treatment will continue to evolve. Very little systematic research, however, has been done to better reflect the vast ramifications of science and technology on society and economies, raising the issue of what *Indicators* is in fact supposed to indicate. The Organization of Economic Cooperation and Development in Paris, established after World War II, began such metrics as part of the post-war reconstruction of Europe. The work of that organization continues with its periodic reports on various fields of technology, and their social and economic importance. And, of course, other countries, as mentioned, confidently persist in attempting to measure the social impact of science and technology.

By 2005 every industrial country as well as the twenty-five-member European Union (EU) had issued its own science and engineering indicators. The EU, Japan, and most of the large but less developed countries such as Brazil, India, and China tended to stress the societal dimensions as well as the purely statistical treatment of science and technology. The popularity of *Indicators* seems to support the notion that science and technology are increasingly indispensable tools of economic progress and that countries more than ever feel the need to keep pace with one another.

SCIENCE FICTION

From its beginnings as a literary genre science fiction has displayed ambivalence toward the ethical implications of scientific discovery and technological development. As a form of literature devoted in large part to evoking the potential futures and possible worlds engendered by mechanical innovation, science fiction (SF) has emerged over the last century as the preeminent site within Euro-American popular culture where the social consequences of modern technology may be explored creatively and interrogated critically.

As Brooks Landon has argued, SF "considers the impact of science and technology on humanity" by constructing "zones of possibility" where that impact can be represented and narratively extrapolated (Landon 1997, pp. 31, 17). Landon's understanding of the genre builds on James Gunn's definition of SF as the "literature of change," a mode of writing that investigates the outcome of technological progress at a level "greater than the individual or the community; often civilization or the race itself is in danger" (Gunn 1979, p. 1). This broad focus on the promises and perils of techno-scientific transformation requires a degree of concern, however implicit, for its moral repercussions, and the best SF has not shrunk from ethical engagement.

From *Frankenstein* to *Brave New World*

If, as several critics have argued, Mary Shelley's *Frankenstein, or the Modern Prometheus* (1816) was the first true SF novel, the genre's founding text provides a paradigm of moral ambivalence toward the processes and products of scientific inquiry. Driven by an urge to unlock the secrets of nature, Victor Frankenstein is at once the genre's first heroic visionary and its first mad scientist. Indeed, these roles are inseparable: Frankenstein's bold commitment to unfettered experimentation makes him capable of both wondrous accomplishment—the creation of an artificial person endowed with superhuman strength and intelligence—and blinkered amorality. Unable to contain or control his creation, whose prodigious powers have been turned toward destructive ends, Frankenstein comes to fear that he has unleashed "a race of devils … upon the earth, who might make the very existence of the species of man a condition precarious and full of terror" (Shelley 1982, p. 163). *Frankenstein,* through its many cinematic incarnations, has bequeathed to contemporary popular culture an enduring myth of science as an epochal threat for humanity and a source of moral corruption.

Throughout the nineteenth century the maturing genre continued to manifest that dualistic response: on the one hand limning a world transformed by the relentless advance of modern science and industry and on the other hand depicting the corrosive effects of that transformation on traditional values and forms of life. Jules Verne's popular series of "Extraordinary Voyages," with their celebration of the wonders of technology, represented the former trend, whereas H.G. Wells's darker and more skeptical series of scientific romances, beginning with *The Time Machine* (1895), epitomized the latter response. Although Verne's *Twenty Thousand Leagues Under the Sea* (1870) contains a kind of mad scientist, Captain Nemo, he is more a misunderstood genius than a figure of Frankensteinian evil, and his futuristic submarine, the *Nautilus,* is more a marvel of invention than a lurking monster. That powerful machine may inspire fear, but this is the result of ignorance rather than intrinsic threat. By contrast, the eponymous character in Wells's *The Island of Dr. Moreau* (1896) is a power-mad fanatic whose creations, a horde of human-animal hybrids, clearly descend from Frankenstein's fiendish invention. Twisted parodies of natural forms, they point up the moral limitations of experimental science: Moreau's brilliance can mold a beast into a human semblance, but it cannot endow the result with virtue or a functioning conscience.

Emblematic though he may be of the ethical predicament of modern science, Dr. Moreau, like Victor Frankenstein, is just one man, and an isolated one, exiled on his island. In the twentieth century SF began to explore the possibility that individual overreaching might be generalized, wedding scientific novelty with industrial mass production to generate in the ironic title of Aldous Huxley's novel, a *Brave New World* (1932). Huxley's satirical vision of a future in which babies are grown in vats and emotions are managed technocratically by drugs and the mass media offers a wide-ranging

Scene from the 1954 science-fiction film "Gog." The human-vs.-robots theme is common in science fiction. *(The Kobal Collection.)*

indictment of a regimented society from which morality has been purged in favor of a coldly instrumental scientism. A triumph of scientific and social engineering, filled with technological marvels, that false utopia is ethically atrophied and spiritually void. Huxley's depiction of the dystopian implications of techno-scientific development in the capitalist west were echoed in Yvgeny Zamiatin's *We* (1924), which projected a future socialist Russia dominated by a grim totalitarianism. Though capable of tremendous feats of industrial engineering, this regime dehumanized its citizens, ruthlessly suppressing their artistic impulses, their sexual drives, and their moral aspirations.

A similar vision of simultaneous technological achievement and moral impoverishment is offered in Karel Çapek's *R.U.R.* (1920). That popular play coined the term *robots* to describe the mass-produced workers who, like Frankenstein's monster, finally rebel against their creators in an orgy of destruction. Çapek's robots, like the test-tube babies in Huxley's novel, are actually synthetic humans rather than the clanking machines their name implies. More conventional mechanical creatures figure in SF texts of the 1920s and 1930s, the most famous being the humanoid robot in Fritz Lang's *Metropolis* (1927), a sinister automaton used to manipulate and control the masses. In all its varieties the artificial person, following in the wake of *Frankenstein*, continued to provide a potent icon of moral ambivalence within the genre: Physically and intellectually superior creatures that symbolize at once the titanic capacities of modern technology and the potential perfectibility of humanity, they are ultimately soulless, wholly lacking in moral will.

An American Affirmation

Not all SF produced during that period was equally pessimistic, however. In the United States a more technophilic strain developed, associated with popular pulp magazines whose titles—*Amazing*, *Astounding*, *Won-*

der—suggest their wide-eyed enthusiasm for technological innovation. However, despite the celebratory tone of much of that material, a more cautionary note sometimes was sounded; indeed, the best pulp SF carried forward the ambivalence toward the moral implications of scientific progress that the European tradition had pioneered.

This attitude is especially visible in pulp SF depictions of artificial persons, such as Isaac Asimov's influential series of robot stories, published during the 1930s and 1940s and eventually gathered into his book *I, Robot* (1950). A large part of Asimov's purpose in the series is to overcome popular anxieties about mechanical beings as uncontrollable Frankenstein's monsters; to this end he develops an ethical code—"The Three Laws of Robotics"—that, hardwired into his robots' brains, ensures their virtuous behavior as protectors and servants of humanity. However, much of the narrative suspense of the stories lies in the various contraventions of the laws, with disobedient robots taking advantage of conflicts within the moral norms governing their operation. Clearly, if left to their own devices (i.e., if not programmed with ethical precepts), the robots would, as in Çapek's play, turn against humanity or at least refuse to accept their own servile status. Another pulp writer, Jack Williamson, pursued the logic of Asimov's Three Laws as moral safeguards to their *reductio ad absurdam* in his story "With Folded Hands" (1947), in which robots take their charge of protecting human beings from harm so seriously that they prohibit all risk taking, mandating comfort and safety through a regime of moralistic totalitarianism.

Still, within American pulp SF these moments of doubt about the ethical consequences of technological advancement were far outweighed by a resolutely affirmative vision of the overall role of science in reordering human life. John W. Campbell, Jr., who became the editor of *Astounding* in 1937 and presided over what has come to be known as SF's Golden Age in the subsequent decade, was famous for championing scientific literacy within the genre and embracing technocratic solutions to social problems. In the pages of *Astounding* and other SF pulps scientists and engineers emerged as an intellectual elite; as John Huntington has argued, a "myth of genius" (1989, p. 44) predominates, with readers encouraged to identify with superior, powerful technocrats whose expertise and pragmatic skill presumably transcend ethical doubts and hesitations. The writers most closely associated with this upbeat vision were Asimov, Robert A. Heinlein, and L. Sprague de Camp, all of whom were trained scientists.

In Heinlein's collection *The Man Who Sold the Moon* (1950) an entrepreneurial genius single-handedly pioneers space travel as a commercial venture, bypassing government control. The ethical-political complications surrounding this move into space are neatly evaded by associating moral questioning with bureaucratic inertia, a collective stagnation the confident capitalist transcends through bold individual action. De Camp's classic alternative-history novel *Lest Darkness Fall* (1941) contains a similar portrait of intrepid genius as a technologically adept time traveler from the twentieth century visits ancient Rome, deploying his expert knowledge to forestall the Dark Ages.

Such sweeping visions of techno-scientific accomplishment seemingly untroubled by ethical qualms were characteristic of much Golden Age SF, although, as Asimov's robot stories showed, a lurking anxiety about the potential perils of technological breakthrough could not be dispelled entirely.

The Return to Questions

That lingering subtext rose to the surface in American SF during the 1950s as the global repercussions of the atomic bombings that ended World War II began to be perceived fully. New SF magazines such as *Galaxy* and *Fantasy and Science Fiction* emerged as rivals to *Astounding,* and the stories they featured began to question, if not openly reject, Campbell's staunch commitment to the technocratic ideal. Although *Astounding* had published stories dealing with the coming dangers of atomic energy such as Lester Del Rey's tense novella "Nerves" (1942), which described an accident in a nuclear power plant, those tales generally had depicted enlightened engineers steadily learning to master the technology. After the horrors of Hiroshima and in the throes of a looming confrontation between rival superpowers armed with high-tech weapons, American SF began to doubt not only the moral competence of technocrats in their stewardship of the atomic age but also the very capacity of humanity to avert its self-destruction.

Still, as Paul Brians has argued, science seldom was blamed for that awful crisis: "Many science fiction writers understood that the power of the new weapon threatened civilization and perhaps human survival, but they placed the responsibility for the coming holocaust on the shoulders of politicians or military men and argued that science still provided humanity's best hope for the future" (Brians 1987, p. 29).

Nonetheless, by showing the likelihood as well as the catastrophic effects of global war, tales of nuclear holocaust strongly suggested that humans lacked the ethical resources needed to control this powerful new technology. For example, Judith Merril's novel *Shadow on the Hearth* (1950) focuses on the personal costs of atomic devastation for one typical American family, whose moral strength, although admirable, is insufficient in the face of a breakdown of civilized order. On a broader scale *A Canticle for Leibowitz* (1960) by Walter M. Miller, Jr., depicts a postholocaust culture governed by a Catholic Church unable to forestall, because of to the inherent sinfulness of human nature, a cyclical repetition of nuclear disaster.

At the same time such stories were appearing popular SF films began to deal with the nuclear menace, offering a series of alarmist portraits of the imagined effects of atomic radiation that ranged from giant mutant insects (e.g., *Them* [1954]) to *The Incredible Shrinking Man* (1957). Even the most optimistic cinematic handling of the postwar atomic threat, *The Day the Earth Stood Still* (1951), in which an alien representative of a cosmic civilization intervenes to prevent global war, suggests that human beings, if left to their own devices, are not fit to govern their planet or themselves.

During the 1960s and 1970s that downbeat attitude, in which humanity's technological reach is seen to escape its moral grasp, gained strength as a new generation of writers began to challenge the technophilia of their pulp forebears. The technocratic legacy of Campbell was interrogated skeptically, and in some cases definitively rejected, by what came to be known as SF's New Wave, a loosely affiliated cohort of authors, many writing for the British magazine *New Worlds*, who began to question if not the core values of scientific inquiry the larger social processes to which they had been conjoined in the service of state and corporate power. New Wave SF arraigned technocracy from a perspective influenced by the counterculture discourses of that period, such as student activism, second-wave feminism, anticolonial struggles, and ecological causes and in the process developed a more radical ethical-political agenda—as well as a more sophisticated aesthetic approach—than the genre had featured previously. As a result the New Wave established a crucial benchmark for modern SF's engagement with the serious moral issues surrounding science and technology.

New Wave stories with feminist, ecological, or antiwar agendas were often dire in their predictions of future developments, but their critiques of technocracy were guided by implicit ethics of gender equity, natural balance, and nonviolence. Often those different agendas were wedded, as in Ursula K. Le Guin's short novel *The Word for World Is Forest* (1976), in which the brutal military occupation of another planet directly involves the devastation of its physical environment by hypermacho men, and Thomas M. Disch's *Camp Concentration* (1968), which explores the roots of high-tech warfare in the flaws and insecurities of masculinity. The work of Alice Sheldon, most of it published under the pseudonym James Tiptree, Jr., also probes the nexus of gender hierarchy and militarist and ecological violence, seeming at times to endorse a despairing sociobiological vision in which male sexuality expresses itself through technologically augmented aggression.

The New Wave's ethical idealism thus often was tempered by pessimism, a grim assessment of the dystopian futures portended by out-of-control technology. A key New Wave theme involved the extrapolation of contemporary urban problems to hypertrophied extremes as humans find themselves immured in vast concrete prisons of their own making. Novels such as David R. Bunch's *Moderan* (1971) and Robert Silverberg's *The World Inside* (1971) present such grim portraits of claustrophobic environments that they verge on the Gothic: In these texts the universal triumph of technology predicted and celebrated in Golden Age SF has culminated in a brutal cityscape where beleaguered, stunted spirits struggle to preserve the tattered shreds of conscience and dignity. In the work of the British author J. G. Ballard the modern city emerges as a psychic disaster area. His controversial 1973 novel *Crash*, for example, depicts a denatured humanity bleakly coupling with machines, with the enveloping landscape of metal and concrete having unleashed a perverse eroticism that seeks fulfillment in violent auto wrecks. SF films of that period, such as *THX 1138* (1971), contained similarly harsh indictments of regimented megalopolises that have co-opted or paralyzed ethical judgment.

The Future of Humankind

Long-standing anxieties regarding high technology were amplified during that period by the new science of cybernetics, which claimed that no meaningful distinctions could be drawn between humans and complex machines. The emergence of so-called artificial intelligence posed a challenge to humanity's presumed supremacy, and SF took up that challenge largely by emphasizing the moral superiority of human beings over their intellectually advanced creations. Ernst Jünger's *The Glass Bees* (1957), for example, derives its satirical power from a pointed contrast between the eponymous robots, who dutifully pursue their assigned tasks, and the skeptical narrator, whose ethical questioning suggests a cognitive and spiritual autonomy denied to mere machines, however skillful or complex.

The work of the British author Arthur C. Clarke, such as his story "The Nine Billion Names of God" (1953), had long engaged the possibility that humanity might have spawned its betters in the form of powerful information machines. In 1969 Clarke collaborated with the director Stanley Kubrick to produce the popular film *2001: A Space Odyssey,* in which a sentient computer, the HAL 9000, displays at once its cognitive power and its ethical limitations, conspiring to take over an interplanetary mission, only to be foiled by human pluck and ingenuity. *2001* established a cinematic trend in which the supercomputer emerged as an instrument driven by an urge to domination, as in *Colossus: The Forbin Project* (1970).

If computers threatened to supplant human mental functions, sophisticated new forms of artificial persons seemed poised to replace humanity entirely. Philip K. Dick's novel *Do Androids Dream of Electric Sheep?* (1968) deals with this imminent danger as its policeman protagonist hunts down a group of renegade androids, synthetic duplicates that are indistinguishable on the surface from normal people. However, there is a crucial difference, and it is essentially an ethical one: Androids are incapable of genuine empathy for others. The moral quandary in the novel is that humans are seldom empathetic; moreover, the protagonist's job requires that he be efficient and ruthless—"something merciless that carried a printed list and a gun, that moved machine-like through the flat, bureaucratic job of killing" (Dick 1996, p. 158)—making him as coldly unfeeling as the androids he seeks to slay. Thus, even when a bright moral line seems to distinguish humans from machines, a technocratically regimented social system serves to obscure if not efface it.

Androids was filmed by Ridley Scott as *Blade Runner* (1982), a film that effectively captures the novel's morally ambiguous tone while pointing forward to subsequent "cyberpunk" treatments. The movie's bleak urban milieu, populated by cynical humans and idealistic machines, offers essentially the same fraught moral landscape that would be featured in novels such as William Gibson's *Neuromancer* (1984), in which artificial intelligences and other cybernetic entities seem more deeply invested with values such as freedom and autonomy than do the human characters.

Cyberpunk fictions of the 1980s and 1990s by Gibson, Bruce Sterling, Pat Cadigan, and others brought to a potent climax the trend toward ethical ambivalence that has marked SF's engagement with new technologies. Extrapolating the social futures portended by the proliferation of computers and their spin-off appliances, cyberpunk displays a humanity so morally compromised by high-tech interfaces—including powerful "wetware," machinic implants that radically alter the body and mind—that the capacity for ethical judgment has perhaps been lost. Yet even amid this spiritual collapse cyberpunk's antiheroes manage to salvage scraps of the decaying moral order, as occurs when the protagonist of *Neuromancer* refuses the quasisatanic lure of cybernetic immortality, affirming the finitude of the mortal self as an enduring ethical center, preserved somehow against the sweetest blandishments and the sternest threats of technology.

For nearly 200 years science fiction has provided windows onto futures transformed by modern science and technology. In that process it has shown both the resiliency and the limitations of ethical consciousness in confronting these potentially overwhelming changes.

SCIENCE: OVERVIEW

Science looms as large as any aspect of the contemporary world, with multiple moral and political engagements on its own as well as through its associations with technology. Both as a positive feature of the human world and as a phenomenon against which there are many reactions, science is a distinguishing feature of the contemporary ethical and political landscape. An overview of this landscape is facilitated by distinctions between science as a body of knowledge and as a human activity. As an activity science may be further examined as both a cognitive and a social process. Ethics is implicated in all three senses: knowledge, cognitive activity, and social process.

Body of Knowledge

In the public mind relations between science and ethics are commonly associated with the ethical and religious challenges from certain types of scientific knowledge—about the origins of life or the cosmos, about brain chemistry as the basis of mind, and more. But scientific knowledge can also be adopted to support received religious traditions and basic ethical assumptions—as when the Big Bang theory is interpreted as evidence of divine creation or quantum indeterminacy as the basis of free will.

RELIGIOUS ISSUES. Historically there have been persistent tensions between claims to revelation and knowledge acquired by natural means. During the Middle Ages Christian theology at one point sought to delimit Aristotelian natural science; specific propositions from Thomas Aquinas's effort to synthesize revelation and Aristotelian science were condemned by the bishop of Paris in 1277 (and not formally revoked until 1325). The trial of Galileo Galilei for his support of Copernican astronomy is another widely cited example. (The 1633 edict of the Inquisition was not formally revoked until 1992.) The 1925 trial of *Tennessee v. John Thomas Scopes* concerned with the teaching of Darwinian evolution in the public schools is yet another celebrated case, as is mentioned in an entry on its contemporary echo, the "Evolution–Creationism Debate."

Analyzing these and related cases scholars have distinguished a spectrum of possible interactions between science and religion, some focusing more on theological issues, others on ethics. No one has done more to parse these debates than the physicist and theologian Ian G. Barbour, winner of the 1999 Templeton Prize for Progress in Religion. According to Barbour (2000), there are at least four distinctive relations between science and religion: conflict, independence, dialogue, and integration. In a series of books published over a forty-year period, Barbour explores such relations across history, in different theological communities, and in diverse branches of science such as astronomy and cosmology, quantum physics, evolutionary biology, and genetics. At the same time, in contrast to evolutionary biologist Stephen J. Gould (1999) who argues for the independence of "non-overlapping magisterial (NOMA)" between science and religion, Barbour defends a relationship of dialogue and integration. The entry on "Christian Perspectives" makes further use of a version of this range of possibilities. Similar alternatives are also exemplified in entries on other religious traditions such as "Buddhist Perspectives" and "Jewish Perspectives."

ETHICAL ISSUES. As with religion, relations between scientific knowledge and ethics fall out into a number of different possible models: opposition (substantive ethical criticisms of science), separation (as in the fact/value dichotomy), reductionism (of ethics to science), and cooperation or partnership (in efforts to develop a scientific ethics or to use scientific knowledge to achieve ethical ends). A host of *Encyclopedia of Science, Technology, and Ethics* entries illustrate and deepen each of these models. Entries on particular branches of science, from "Astronomy" to "Psychology," tend to stress opportunities for syntheses. Entries on concepts such as "Determinism" and the "Fact/Value Dichotomy" highlight separations. Entries on "Evolutionary Ethics" and "Scientific Ethics" argue possibilities for basing ethics on science.

Increasing recognition within the scientific community of the importance of issues related to the human interpretation of scientific knowledge is reflected in the founding by the American Association for the Advancement of Science of a special Dialogue on Science, Ethics, and Religion, as described in the entry on the "American Association for the Advancement of Science." Substantive interpretations of the meaning of scientific knowledge remain an ongoing concern that has not been fully met by either scientific humanism, religious apologetics, or humanities reflection on the achievements of science—all of which are approaches represented in the present encyclopedia.

Cognitive Activity

Assessing science as a cognitive activity is the primary task of the philosophy of science and obviously overlaps with critical reflections on science as a body of knowledge. Yet in the philosophy of science the emphasis is less on the human or social meanings of scientific knowledge and more on examining the structure of such knowledge and analyzing its epistemological claims. Analyses of the structure of scientific knowledge involve three broad problem sets dealing with demarcation, confirmation, and explanation. How is scientific knowledge distinguished from pretensions to science (that is, pseudoscience) and other types of knowledge (using appeals to certainty, objectivity, reproducibility, predictive power)? What are the methods of scientific knowledge production (deduction, induction, verification, confirmation, falsification)? How do scientific explanations function (in their integration of observations, laws, and theories)?

With regard to epistemological claims, there are two major views of science: realism and instrumentalism. Realism argues that scientific propositions in some manner reflect the way the world really is, meaning they correspond to reality. By contrast, instrumentalism argues that scientific propositions are simply tools for explaining or manipulating phenomena. For the realist, the model of the atom provides a picture of what atoms actually look like. For the instrumentalist or antirealist, the differential equations used to predict the path of the Moon around Earth have no direct correspondence to the forces that actually move the Moon.

All basic philosophy of science texts cover these topic sets, as well as the debate between Thomas Kuhn and Karl Popper over the historical character of science that has been so prominent since the mid-1960s (see, e.g., the entries on "Kuhn, Thomas" and "Popper, Karl"). Increasingly there are also modest inclusions of arguments about values, especially the way gender bias may be operative in science. But in respect to values and ethics in science as a cognitive or knowledge-producing activity, it is discussions of fraud and misconduct in science, as covered by entries on "Scientific Integrity" and "Responsible Conduct of Research," that are most relevant. The most widely used introduction to these issues is the pamphlet *On Being a Scientist* (2nd edition, 1995), prepared by the U.S. National Academy of Sciences, National Academy of Engineering, and Institute of Medicine.

Social Process

Science is not only a cognitive activity but also a social process involving interactions on several levels from individual laboratories to academic disciplines and from corporations to national and international science policymaking organizations. Examination of these interactions has taken on increased importance as science has grown from a small community of practitioners to an abundant and widely dispersed "metropolis"—from small science to big technoscience. The focus of early modern philosophers, however, was on cognitive at the expense of social activities, and it was not until the 1930s that Robert Merton undertook to pursue the sociology of science.

According to Merton (as considered in the entry on "Merton, Robert"), science as a social institution rests on a normative structure that best flourishes in a democratic society because of a common ethos. Moreover, scientists ought to participate in the social order rather than pretend to a "sanguine isolationism." Indeed, World War II brought about a new era of increased participation by scientists in military and political affairs. Not only did this raise questions about their responsibility for the knowledge they produced and the products, processes, and systems such knowledge made possible, but it also posed dilemmas about the appropriate roles for scientists in political controversies. It was in the midst of such dilemmas that the "scientists' movement" (as described in Mitcham 2003) arose to help direct scientific developments toward particular ends.

Social disillusionment with science and technology in the 1960s and 1970s spurred the public understanding of science movement, which has made common cause with older traditions in the popularization of science. (See the entry on "Public Understanding of Science.") It was also related to developments in the history and philosophy of science. Against more rational reconstructionist arguments such as those of Popper, Kuhn argued that science does not progress toward reality or truth simply by the accretion of new discoveries. Rather scientific knowledge is best viewed as the product of a historically contingent group of practitioners operating from shared rules applied to a certain range of acceptable problems.

Though not his intention, Kuhn's work stimulated theories about the socially constructed nature of scientific knowledge, which in its strong form leads to relativism or antirealism, because scientific facts are deemed to be the result of network building and negotiating rather than approximating reality. But in its weak form the contextualization of science leads to the rather noncontroversial notion that knowledge is a product both of nature (a reality "out there") and human cultural and theoretical interests that condition particular trajectories of research. The move from internalist studies of science to contextual interpretations has given rise to interdisciplinary fields including science, technology, and society (STS) studies, the sociology of scientific knowledge (SSK), and rhetoric of science, all of which challenge the Mertonian ideals as fully adequate descriptions of the real social processes in science. (For more details, see the entries on "Science, Technology, and Society Studies" and "Rhetoric of Science and Technology.")

A perennial theme of science as a social process is the extent to which planning the agenda of (especially publicly funded) scientific research to meet explicit social and economic goals is feasible or desirable. In the United Kingdom during the 1930s this debate flared between supporters of Michael Polanyi and those who backed J. D. Bernal. (The encyclopedia has entries on both men.) Polanyi argued that autonomy and self-governance by science was the best way to meet social goals, whereas Bernal held that autonomous science was inefficient and needed external guidance. The same debate occurred in the United States after World War II between Vannevar Bush and Senator Harley Kilgore regarding the appropriate relationship between science and the federal government during peacetime. (See the entry on "Bush, Vannevar," as well as that on "Science Policy.") At issue are the criteria by which to judge scientific success and whether they should be internalist (e.g., peer review) or some external measure based on societal concerns.

Pressure to increase the social and fiscal accountability of publicly funded science emerged at the end of the Cold War. Related developments included science shops in Europe and other efforts to democratize science. In the United States, examples included the Office of Technology Assessment, the Ethical, Legal, and Social Implications (ELSI) research as part of the Human Genome Project and federally funded nanotechnology research, and the "broader impacts" criterion implemented by the National Science Foundation in 1997. (Further discussion can be found in entries on "Human Genome Organization," "Science Shops," "U.S. National Science Foundation," and related entries.)

Many of these developments are reactions to the fact that scientific research, despite its numerous benefits, does not yield unmitigated goods. Health and environmental risks as well as escalating arms races are familiar unintended consequences. Additionally, scientific knowledge can complicate decision making without always improving it, and has made its own share of mistakes with regard to recommendations of public interest. But the possibility of new "subversive truths" from genomic research, uncharacterized risks from nanotechnology, and the global threat of terrorism all raise the stakes of seeking new knowledge and crafting arrangements for directing it toward common goods.

Assessment

Throughout discussions of the relationship between science and ethics one core issue that remains is the proper extent and nature of scientific autonomy. David H. Guston (2000) has identified four reasons why science is often defended as special, each of which requires a degree of autonomy for its protection. Epistemological specialness refers to the notion that science searches for objective truth. Sociological specialness is the claim that science has a unique normative order that provides for self-governance. Platonic specialness refers to its esoteric, technical nature far removed from the knowledge of common citizens. Economic specialness is the claim that investments in science are crucial for productivity.

In each case there is some truth to the claims of specialness, which require the recognition of science as a unique enterprise needing some degree of separation from other social activities to ensure its smooth functioning. But as scientists as diverse as the physicist Alvin M. Weinberg (1967) and the geologist Daniel Sarewitz (1996) have argued, none of these cases should be taken as a license for absolute autonomy. Indeed the big science of the twenty-first century is so dependent on corporate and public investments that isolation is not a real option. More fundamentally, scientific knowledge is just one good to be considered among many competing goods. The ambiguity about the right level of autonomy has led to several interpretations about the proper role of science in society within various contexts, as well as criticisms of the ways in which scientific disciplines sometimes reinforce the self-perpetuating pursuit of new knowledge in the form of what Daniel Callahan (2003) has criticized as a "research imperative."

SCIENCE POLICY

Science policy involves considerations of two fundamental human activities: science and policy. People make decisions in pursuit of valued outcomes, so thinking about science policy necessarily implicates science, its close associate science-based technology, and ethics. Although science policy is a topic central to all societies, particularly developed countries that devote significant public resources to science, for two reasons the focus here is on the United States. First, the United States is responsible for the largest share of global spending on science and technology. Second, for better or worse, the budgetary leadership role of the United States in science and technology since World War II has shaped how people around the world think about science, policy, and politics.

To place United States science and technology expenditures into context, consider that according to the Organisation for Economic Co-operation and Development (OECD) in 2003 the United States provided 38 percent of the approximately $740 billion world total (public and private) investment in research and development. The next largest funders were Japan with 15 percent, China with 8 percent, and Germany with 7 percent of the world total. Measured as a fraction of national economic activities, in 2001 total (public and private) expenditures on research and development varied from more than 4 percent in Sweden to 1.93 percent for the European Union (EU) to 2.82 percent in the United States. No country invests more than 1 percent of public funds in research and development, with Sweden investing 0.90 percent, the EU 0.65 percent, and the United States 0.81 percent.

Of course science policy is more than science budgets. The institutional structures and purposes of science are also issues of science policy. If science refers to the systematic pursuit of knowledge, and policy refers to a particular type of decision making, then the phrase science policy involves all decision making related to the systematic pursuit of knowledge. Harvey Brooks (1964) characterized this relation as twofold: *Science for policy* refers to the use of knowledge to facilitate or improve decision making; *policy for science* refers to decision making about how to fund or structure the systematic pursuit of knowledge.

Brooks's characterization of science policy as including both policy for science and science for policy has shaped thinking about science policy ever since, reinforcing a perception that science and policy are separate activities subject to multiple relations. But while Brooks's distinction has proved useful, reality is more complex, because the way society views science policy itself shapes the sorts of questions that arise in science policy debates. Science for policy and policy for science are each activities that shape the other—in academic jargon they are *coproduced*. Policy for science decisions about the structure, functions, and priorities of science directly influence the kind of science that will be available in science for policy applications, and the ways science is used in policy formation will influence in turn the policies formulated for science. Policy for science and science for policy are subsets of what might be more accurately described as a *policy for science for policy* (Pielke and Betsill 1997). To the extent that thinking about science policy separates decisions about knowledge from the role of knowledge in decision making, it reinforces a practical separation of science from policy.

From such a perspective, David Guston (2000) has argued the need to develop a new language to talk about science policy, one that recognizes how science and policy are in important respects inextricably intertwined; separation is impossible. Instead, however, the artificial separation of science from policy is frequently reinforced with calls for a new *social contract* between science and society. As Guston notes, "Based on a misapprehension of the recent history of science policy and on a failed model of the interaction between politics and science, such evocations insist on a pious rededication of the polity to science, a numbing rearticulation of the rationale for the public support of research, or an obscurantist resystemization of research nomenclature" (Guston 2000 Internet site)

The present analysis of science policy in the United States, with a particular focus on federally-funded science, thus begins by examining the value structure that underlies science and its relationship to decision making, and focuses on how science and policy have come to be viewed as separate enterprises in need of connection. This will set the stage for a discussion of an ongoing revolution in science policy that challenges conventional understandings of science in society. In the early years of the twenty-first century it is unclear how this revolution will play out. But a few trends seem well established. First, the science policies that have shaped thinking and action over the past fifty years are unlikely to continue for the next fifty years. Second, decision makers and society more generally have elevated expectations about the role that science ought to play in contributing to the challenges facing the world. Third, the scientific community nevertheless struggles to manage and meet these expectations. Together these trends suggest that more than ever society needs systematic thinking about science policy—that is research on science policy itself. And such research should center on issues of ethics and values.

Axiology of Science

A value structure is part of any culture, and the culture of science is no different. Alvin Weinberg (1970) suggests four explicitly normative *axiological attitudes*—statements of value—which scientists hold about their profession. Whereas Weinberg's concern was the physical sciences, such perspectives are broadly applicable to all aspects of science:

- Pure is better than applied.
- General is better than particular.
- Search is better than codification.
- Paradigm breaking is better than spectroscopy.

For Weinberg, these attitudes are "so deeply a part of the scientist's prejudices as hardly to be recognized as implying" a theory of value (Weinberg 1970, p. 613). But these values are critical factors for understanding both thinking about and the practice of science policy in the United States. And understanding why science policy is currently undergoing dramatic change requires an understanding of how Weinberg's theory of value, if not breaking down, is currently being challenged by an alternative axiology of science.

Understanding the contemporary context of science in the United States requires a brief sojourn into the history of science. In the latter part of the 1800s, scientists began to resent "dependence on values extraneous to science," (Daniels 1967, p. 1699) in what has been called "the rise of the pure science ideal" (Daniels 1967, p. 1703). The period saw such resentment come to a head.

> The decade, in a word, witnessed the development, as a generally shared ideology, of the notion of science for science's sake. Science was no longer to be pursued as a means of solving some material problem or illustrating some Biblical text; it was to be pursued simply because the truth—which was what science was thought to be uniquely about—was lovely in itself, and because it was praiseworthy to add what one could to the always developing cathedral of knowledge. (Daniels 1967, p. 1699)

Like many other groups during this era, the scientific community began to organize in ways that would facilitate making demands on the federal government for public resources. Science had become an interest group. Scientists who approached the federal government for support of research activities clashed with a federal government expressing the need for any such investments to be associated with practical benefits to society.

Expressing a value structure that goes back at least to Aristotle, U.S. scientists of the late-nineteenth century believed that the pursuit of knowledge associated with the pursuit of unfettered curiosity represented a higher calling than the development of tools and techniques associated with the use of knowledge. Hence, the phrase *pure research* came to refer to this higher calling with *purity* serving as a euphemism for the lack of attention to practical, real-world concerns (Daniels 1967). The first editorial published in *Science* magazine in 1883 clearly expressed a value structure:

> Research is none the less genuine, investigation none the less worthy, because the truth it discovers is utilizable for the benefit of mankind. Granting, even, that the discovery of truth for its own sake is a nobler pursuit. It may readily be conceded that the man who discovers nothing himself, but only applies to useful purposes the principle which others have discovered, stands upon a lower plane than the investigator (Editorial 1883, p. 1).

Some scientists of the period, including Thomas Henry Huxley and Louis Pasteur, resisted what they saw as a false distinction between *pure* and *applied* science (Huxley 1882, Stokes 1995). Some policy makers of the period also rejected such a distinction. For them, utility was the ultimate test of the value of science (Dupree 1957). The late 1800s saw different perspectives on the role of science and society coexisting simultaneously. But Weinberg's axiology of science emerged from the period as the value structure that would shape the further development of U.S. science policies in the first half of the twentieth century.

From Pure to Basic Research

In a well-documented transition, Weinberg's axiology of science stressed the primacy not so much of pure as of *basic* research. The term basic research was not in frequent use prior to the 1930s. But after World War II the concept became so fundamental to science policy that it is difficult to discuss the subject without invoking the corresponding axiology. The notion of basic research arose in parallel with both the growing significance of science in policy and the growing sophistication of scientists in politics. By the end of World War II and the detonation of the first nuclear weapons the acceleration of the development of science-based technology was inescapable. Throughout society science was recognized as a source of change and progress whose benefits, even if not always equally shared, were hard to dismiss.

The new context of science in society provided both opportunity and challenge. Members of the scientific community, often valuing the pursuit of pure science for itself alone, found themselves in a bind. The government valued science almost exclusively for the practical benefits that were somehow connected to research and development. Policymakers had little interest in funding science simply for the sake of knowledge production at a level desired by the scientific community, which itself had become considerably larger as a result of wartime investments. Support for pure research was unthinkable.

Congressional reticence to invest in pure science frustrated those in the scientific community who believed that, historically, advances in knowledge had been important, if not determining, factors in many practical advances. Therefore the scientific community began to develop a two-birds-with-one-stone argument to justify its desire to pursue truth and the demands of politics for practical benefits. The argument held that pure research was the basis for many practical benefits, but that those benefits (expected or realized) ought not to be the standard for evaluating scientific work. Because if practical benefits were used as the standard of scientific accountability under the U.S. system of government, then science could easily be steered away from its ideal—the pursuit of knowledge.

The scientific community took advantage of the window of opportunity presented by the demonstrable contributions of science to the war effort and successfully altered science policy perspectives. The effect was to replace the view held by most policymakers that science for knowledge's sake was of no use, and replaced it with the idea that *all research* could potentially lead to practical benefits. In the words of Vannevar Bush, the leading formulator of this postwar science policy perspective: "Statistically it is certain that important and highly useful discoveries will result from some fraction of the work undertaken [by pure scientists]; but the results of any one particular investigation cannot be predicted with accuracy" (Bush 1945, p. 81).

Central to this change in perspective was acceptance of the phrase basic research and, at least in policy and political settings, the gradual obsolescence of the term pure research. The term basic came without the pejorative notion associated with lack of purity imputed to practically focused work. More importantly, the term basic means in a dictionary-definition sense *fundamental, essential,* or *a starting point*. Research that was basic could easily be interpreted by a policymaker as being fundamental to practical benefits.

The Linear/Reservoir Model

Basic research would be connected to societal benefits through what has become frequently called the *linear model* of science. The linear model holds that basic research leads to applied research, which in turn leads to development and application (Pielke and Byerly 1998). To increase the output (that is, societal benefits) of the linear model, it is necessary to increase the input (support for science).

Bush's seminal report *Science—The Endless Frontier* (1945) "implied that in return for the privilege of receiving federal support, the researcher was obligated to produce and share knowledge freely to benefit—in mostly unspecified and long-term ways—the public good" (Office of Technology Assessment 1991, p. 4). One of the fundamental assumptions of postwar science policy is that science provides a reservoir or fund of knowledge that can be tapped and applied to national needs. According to Bush:

> The centers of basic research . . . are the wellsprings of knowledge and understanding. As long as they are vigorous and healthy and their scientists are free to pursue the truth wherever it may lead, there will be a flow of new scientific knowledge to those who can apply it to practical problems in Government, in industry, or elsewhere. (Bush 1945, p. 12)

Implicit in Bush's metaphor is a linear model of the relationship between science and the rest of society: basic-applied-development-societal benefit. This model posits that societal benefits are to be found *downstream* from the reservoir of knowledge. Others have described the liner model as a *ladder,* an *assembly line,* and a *linked-chain* (Gomory 1990, Wise 1985, Kline 1985).

The linear/reservoir model is a metaphor explaining the relationship of science and technology to societal needs. It is used *descriptively* to explain how the relation actually works and *normatively* to argue how the relation ought to work. The linear model appears in discussions of both science policy, where it is used to describe the relation of research and societal needs (Brown 1992), and in technology policy, where it is used to describe the relation of research and innovation (Branscomb 1992). The linear model was based on assumptions of efficacy, and not comparisons with possible alternatives. In 1974 Congressman Emilio Daddario (D-CT), a member of the Science Committee of the U.S. House of Representatives (Science Committee), observed that members of Congress defer to the claims of scientists that basic research is fundamental to societal benefits "and *for that reason, if for no other,* they have supported basic research in the past" (Daddario 1974, p. 140; emphasis added). So long as policymakers and scientists felt that science was meeting social needs, the linear model was unquestioned.

The notion of basic research and the linear model of which it was a part has been tremendously successful from the standpoint of the values of the scientific community. Indeed the terms basic and applied have thus become fundamental to discussions of science and society. For example, the National Science Foundation (NSF) in its annual report *Science and Engineering Indicators* uses precisely these terms to structure its taxonomy of science. Not only did the basic-applied distinction present a compelling, utilitarian case for government support of the pursuit of knowledge, it also explicitly justified why pure research "deserves and requires special protection and specially assured support" (Bush 1945, p. 83). The special protections included relative autonomy from political control and standards of accountability determined through the internal criteria of science. In a classic piece, Michael Polanyi (1962) sketched in idealized fashion how a *republic of science* structured according to the values of pure science provides an *invisible hand* pushing scientific progress toward discovering knowledge which would have inevitable benefits for society.

Seeds of Conflict: Freedom versus Accountability

From the perspective of the scientific community, from the prewar to postwar periods, the concepts of pure research and basic research remained one and the same: the unfettered pursuit of knowledge. For the community of policymakers, however, there was an important distinction—pure research had little to do with practical benefits but basic research representing the "fund from which the practical applications of knowledge must be drawn" (Bush 1945, p. 19). From the perspective of policymakers, there was little reason to be concerned about science for the sale of knowledge alone; they had faith that just about all science would prove useful.

TABLE 1

Four Definitions of Basic Research

By product:	Basic research refers to those activities that *produce* new data and theories, representing an increase in our understanding and knowledge of nature generally rather than particularly (National Science Board 1996, Armstrong 1994).
By motive:	Basic research is conducted by an investigator with a *desire* to know and understand nature generally, to explain a wide range of observations, with no thought of practical application (National Science Board 1996).
By goal:	Basic research *aims* at greater knowledge and mastery of nature (White 1967, Bode 1964).
By standard of accountability:	Basic researchers are free to follow their own intellectual interests in order to gain a deeper understanding of nature, and are *accountable* to scientific peers (Polanyi 1962, Bozeman 1977).

SOURCE: Courtesy of Roger A. Pielke, Jr.

The different interpretations by scientists and policymakers of the meaning of the term basic research have always been somewhat troubling (Kidd 1959). A brief review of the use of the term basic research by the scientific community finds at least four interrelated definitions of the phrase, as summarized in Table 1.

From the standpoint of policymakers, basic research is defined through what it enables, rather than by any particular characteristic of the researcher or research process. These different interpretations of basic research by policymakers and scientists have coexisted largely unreconciled for much of the postwar era, even as for decades observers of science policy have documented the logical and practical inconsistencies. René Dubos (1961) identified a *schizophrenic attitude* among scientists, succinctly described as follows: "while scientists claim among themselves that their primary interest is in the conceptual aspects of their subject, they continue to publicly justify basic research by asserting that it always leads to 'useful' results" (Daniels 1967, p. 1700) It is this schizophrenia that has allowed postwar science policy to operate successfully under the paradigm of the linear model, apparently satisfying the ends of both scientists and politicians. *Basic research* was the term used to describe the work conducted in that overlap. The situation worked so long as both parties—society (patron) and scientists (recipient of funds)—were largely satisfied with the relationship.

The Changing Context

In the 1990s both scientists and politicians began to express dissatisfaction with the science policy of the post-World War II era. For instance, in 1998 the Science Committee undertook a major study of U.S. science policy under the following charge:

> The United States has been operating under a model developed by Vannevar Bush in his 1945 report to the President entitled *Science: The Endless Frontier*. It continues to operate under that model with little change. This approach served us very well during the Cold War, because Bush's science policy was predicated upon serving the military needs of our nation, ensuring national pride in our scientific and technological accomplishments, and developing a strong scientific, technological, and manufacturing enterprise that would serve us well not only in peace but also would be essential for this country in both the Cold War and potential hot wars. With the collapse of the Soviet Union, and the de facto end of the Cold War, the Vannevar Bush approach is no longer valid. (U.S. Congress 1998)

While the congressional report acknowledged the need for a new science policy, it did not address what that new policy might entail. However an understanding of the tensions leading to calls for change point in various directions.

These tensions have been long recognized. George Daniels (1967) sketches those underlying contemporary science policy: "The pure science ideal demands that science be as thoroughly separated from the political as it is from the religious or utilitarian. Democratic politics demands that no expenditure of public funds be separated from political . . . accountability. With such diametrically opposed assumptions, a conflict is inevitable" (Daniels 1967, p. 1704) Such tensions were recognized even earlier, in 1960, by the Committee on Science in the Promotion of Human Welfare of the American Association for the Advancement of Science (AAAS): "Science is inseparably bound up with many troublesome questions of public policy. That science is more valued for these uses than for its fundamental purpose—the free inquiry into nature—leads to pressures which have begun to threaten the integrity of science itself" (AAAS 1960, p. 69). For many years under growing budgets in the context of the Cold War, postwar science policy successfully and parsimoniously evaded this conflict. Given pressures for accountability and more return on federal spending, conflict is unavoidable.

Why, more specifically, did postwar science policy remain largely unchallenged for a half century? From the point of view of society, it solved problems. First, science and technology were key contributors to victory in World War II. Infectious diseases were *conquered*. Nuclear technology ended the war and promised power *too cheap to meter*. From the point of view of the scientific community, most good ideas received federal funding. The U.S. economy dominated the world. In such contexts, there was less pressure from the public and its representatives on scientists for demonstrable results; there was less accountability. Scientists, policymakers, and the broader public were largely satisfied with national science policies.

But at the beginning of the twenty-first century new challenges arose. Some infectious diseases rebounded through resistance to antibiotics, and new diseases, such as severe acute respiratory syndrome (SARS), threatened health. For many, the cost of healthcare made world-leading medical technologies unaffordable. The events of September 11, 2001, demonstrated the risks to modern society at the intersection of fanaticism and technology. The availability of weapons of mass destruction makes these risks even more significant. New technologies, in areas such as biotechnology and nanotechnology, created new opportunities but also threatened people and the environment. Many problems of the past have been solved, but new ones are emerging, and science and technology are often part of both the problem and possible solutions. The question of how to govern science and technology to realize their benefits is thus increasingly important.

In addition, many scientists were unhappy as budgets failed to keep pace with research opportunities: As the scientific community has grown and as knowledge has expanded, more research ideas are proposed than there is funding to support. Strong global competition and demands for political accountability create incentives for policymakers to support research with measurable payoffs on relatively short timescales, while within the scientific community competition for tenure and other forms of professional recognition demand rigorous, long-term fundamental research. As the context of science changes, scientists share anxieties with others disrupted by global economic and social changes.

New Science Policy Debates

While scientists perceive their abilities to conduct pure research constrained by increasing demands for practical benefits, policymakers simultaneously worry that basic research may not address practical needs. Insofar as postwar science policy has weakened, discussion of science policy has moved beyond the partial overlap of motives that helped sustain postwar science policy. Scientists now speak of their expectation of support for pure research, and policymakers increasingly ask for direct contributions to the solution of pressing social problems.

In this situation the differing views of scientist and policymaker can create conflict as the shared misunderstanding of the term basic research threatens to become pathological. In the words of Donald Stokes:

> The policy community easily hears requests for research funding as claims to entitlement to support for pure research by a scientific community that can sound like most other interest groups. Equally, the scientific community easily hears requests by the policy community for the conduct of "strategic research" as calls for a purely applied research that is narrowly targeted on short-term goals. (Stokes 1995, p. 26)

For their part, scientists seek to demonstrate the value of research to the public, often through increasing skill in public relations and contracting with consultants to provide cost-benefit studies that show the positive benefits of research investments. With few exceptions, the result of such concerns has not been constructive change, but rather defense of the status quo. In 1994 the National Research Council (NRC) convened scientists and informed members of the broader community to begin a constructive dialogue on the changing environment for science. The group found the public policy problem to be primarily the amount of federal funds devoted to research. A later National Academy report, *Allocating Federal Funds for Science and Technology* (1995), recommended that U.S. science should be at least world-class in all major fields, in effect recommending an entitlement for research. Similarly the 1998 "Science Policy Study" of the Science Committee similarly concluded, "The United States of America must maintain and improve its pre-eminent position in science and technology in order to advance human understanding of the universe and all it contains, and to improve the lives, health, and freedom of all peoples" (U.S. Congress 1998 Internet site)

Other approaches relate research and national needs. The Government Performance and Results Act of 1993 legislates formal accountability by requiring all government programs, including research, to quantitatively measure progress against established goals. Yet experience shows that asking for performance measures and actually developing and applying meaningful measures can be difficult. Daniel Sarewitz offers a penetrating critique of current policy and general steps that would pull research closer to society without sacrificing critical values of science. In particular he recommends research on research: "how it can be directed in a manner most consistent with social and cultural norms and goals, and how it actually influences society" (Sarewitz 1996, p. 180). Donald Stokes (1995) resolves the dichotomy between research driven by purely scientific criteria and research responsive to societal needs by changing the single basic-versus-applied axis into a two-dimensional plane, with one dimension indicating the degree to which research is guided by a desire to understand nature, and the other indicating the degree it is guided by practical considerations. This conceptual advance demonstrates that *good science* can be compatible with practical application, but does not point to specific policy-relevant steps.

There is great potential for nations that have followed the Bush model, such as the United States, to learn from the experiences of those nations that have implemented differing science policies. What change will entail is not entirely clear, however, some trends are apparent. First, overall investments in science and technology show no signs of stagnation. If anything the world is investing more in science and technology, an amount that will in the near future exceed $1 trillion per year. These substantial investments are accompanied by increasing demands for accountability, relevance, and practicality. Such demands increasingly shape the context and practice of science in society. How science will shape and be shaped by these trends will undoubtedly mark a critical transition in science policy in the United States, and perhaps in the world.

SCIENCE SHOPS

Science shops provide independent, participatory research support in response to concerns experienced by civil society (Gnaiger and Martin 2001). Science in this context refers to all organized investigation, including the social and human sciences and arts, as well as the natural, physical, engineering, and technological sciences.

The concept of science shops was developed by students at universities in the Netherlands during the 1970s. This development was assisted by faculty and staff seeking to *democratize* the disciplinary hierarchies of the traditional university system. But arguably science shops are a manifestation of a movement stemming at least as far back as Thomas Jefferson's defense of the principle that "ideas should freely spread from one to another over the globe" (Jefferson 1813, Internet page).

The science shop concept spread worldwide in two waves. The first, in the late-1970s and early-1980s, was triggered by articles in *Nature* (Ades 1979) and *Science* (Dickson 1984) and led to initiatives in Australia, Austria, Belgium, Denmark, Northern Ireland, France, and Germany. The mid-1990s saw a resurgence based in large part on fast, inexpensive, and reliable communication technologies, such as the Internet. This growth led to new activities in England, Israel, South Korea, Malaysia, and New Zealand. Similar types of organizations have also been founded in Australia, Canada, South Africa and the United States but are referred to by other terms—Community-University Research Alliances, Community-based Research Centers, or Tecknikons.

There is significant variation in organizational structure among science shops, although three models dominate. The first is the university department model, where the science shop is attached to a disciplinary framework such as chemistry, biology, law, or physics. The second, most common model is the independent civil society organization, housing technical experts or brokering relationships with university or government researchers. The third model is the virtual alliance between partners in public, private, and not-for-profit sector institutions that jointly work on issues of mutual concern and benefit.

Despite differences in structure, Andrea Gnaiger and Eileen Martin point to six common elements found in all science shops. These include providing civil society with knowledge and skills through research and education; providing services on an affordable basis; promoting and supporting public access to and influence on science and technology; creating equitable and supportive partnerships with civil society organizations; enhancing understanding among policymakers and education and research institutions regarding the research and education needs of civil society; and enhancing the transferable skills and knowledge of students, community representatives, and researchers.

Science shops are closely associated with social justice, environmental, and community activist movements. The dominant research methodologies used include research mediation, participatory research, and participatory action research. The strengths of these approaches allow for the inclusion of the unique understanding of individuals and communities of their own local contexts, which helps establish causality of problems in a complex and diverse framework rather than in a reductionist manner. There is great adaptability and flexibility that allows for quick turnaround in problem identification and solving. The methods give people strong influence over both policy and practice at the local level. Local to global focus allows for scaling up of issues, providing grounded perspectives for national and international policies.

The principle weaknesses of the science shop methods are fourfold. Despite being a cost effective way of generating research, science shops suffer from chronic funding and resource shortfalls. With very few exceptions, unless funded through a philanthropic organization, government agency, or university, they spend almost as much effort on raising funds as they do performing research and advocacy work. Second, given their strong social justice tendencies, there appears to be institutional prejudice against working with corporations, governments, and intergovernmental agencies, or other organizations perceived to have a large *foot print*. This gap results in the absence of community partner and science shop perspectives in policy negotiations. Third, with the exception of the Netherlands, the lack of coordination among science shops and their relative absence from the dominant scientific communication streams means that there is a lack of comparability and a failure to generate commensurable information. This is currently being addressed by the creation of an International Science Shop Network, funded largely by the European Union. Finally, science shops have been accused of producing biased science, constructed to support the arguments of the clients they serve, a critique which is also aimed at scientists performing research for corporate clients. This criticism has been met by submitting research outputs to the same peer-review firewall that all scientific publication undergoes.

Science shops have proven to be an efficient and effective model for generating small-scale scientific and technological knowledge on issues of immediate and local concern. They provide a gateway for communities in gaining access to specialized data, information, and knowledge at a relatively low transaction cost. There are high residual effects within participating communities, leading to better understanding of science and technology as well as a critical capacity to assess the impact of scientific and technological issues on local social, economic, cultural, and environmental circumstances.

SCIENCE, TECHNOLOGY, AND LAW

Law plays a growing critical role in the regulation of science and technology, including the ethical consequences of scientific research and new technologies. The relatively new field of *law, science, and technology* seeks to study systematically the diverse ways law interacts with science and technology. Law, science, and technology has been defined as "the discipline that deals with how our legal system can and must adjust to accommodate the problems created by the ever more urgent and ubiquitous impact of technology on society" (Wessel 1989, p. 260), and as seeking "to determine how the various processes of law—primarily judicial and legislative—respond to changes brought about by scientific advances" (Green 1990, p. 375).

Few law schools or legal scholars focused on the intersection of law with science and technology before the later part of the twentieth century. With advances in the computer, the Internet, biotechnology, genomics, telecommunications, and nanotechnology, technology has assumed an ever-increasing role in economic and daily life, and the law has struggled to keep pace. In the words of U.S. Supreme Court Justice Stephen Breyer, "[s]cientific issues [now] permeate the law" (Breyer 1998, p. 537). This has led to a proliferation in the study of law, science and technology interactions, including academic centers, textbooks (Sutton 2001, Areen et al. 1996), courses, specialized journals, conferences, and bar association sections (Merges 1988). There is also a growing awareness of the importance of scientific and technological developments by legal practitioners and scholars, with increased recognition among those outside the legal profession for the central importance of law in mediating the risks, benefits, and ethics of technology.

The field of law, science, and technology is premised on the belief that "[s]cience is a distinctive institution worthy of distinctive treatment by lawyers" (Goldberg 1986, p. 380). Despite increased awareness that science and technology present unique issues for the law, different formulations exist for examining law, science, and technology interactions. Here the field is divided into three primary strands. The first concerns the role of the law in managing the impacts of science and technology, including controlling the risks, promoting the benefits, and addressing ethical implications. The second concerns the institutions of law and science, examining how law affects the practice of scientific research, as well as the reciprocal relationship of how science and technology influence the law. The third involves a more generic inquiry into the problems and tensions that arise from the intersection of law with science and technology.

The Role of Law in Managing the Impacts of Science and Technology

Law plays a primary role in managing the impacts of science and technology. In the words of one prominent jurist, "[l]aw is the only tool that society has to tame and channel science and technology" (Markey 1984, p. 527). The impacts of science and technology that law seeks to manage can be subdivided into (a) risks, (b) benefits, and (c) ethical implications.

CONTROLLING RISKS OF NEW TECHNOLOGIES. New and existing technologies create many known and potential health, safety, environmental, and socioeconomic risks. Law is the principal societal institution for controlling these risks, through legislatures, regulators, and the judiciary (Jasanoff 1995). In developing such controls, the law relies on science to assess the relevant risks. Risk regulation thus involves two levels of science-law interactions: the role of law in regulating risks from science and technology; and the use of science by law to assess risk from new and existing technologies.

Legislation and regulation seek to address and reduce risks *ex ante,* before the risks are imposed. Most industrialized nations have comprehensive statutory and/or regulatory schemes in place to prospectively regulate potential risks from technologies such as pesticides, industrial chemicals, pharmaceuticals, natural resource extraction, genetically modified foods, and automobiles. *Ex ante* legislation and regulation by agencies statutorily empowered to do so presupposes the capability to adequately predict potential harms, a challenging undertaking for most risks. Indeed much of the complexity and controversy in *ex ante* risk regulation relates to uncertainties in the identification and quantification of potential risks. Nevertheless, given the preventive purpose of *ex ante* risk regulation, regulators are generally given considerable leeway in assessing risks, including the use of *conservative* (or plausible worst case) assumptions, requiring only substantial evidence and not necessarily the weight of evidence to support risk findings, and broad judicial deference to regulators' technical expertise.

One ongoing tension in *ex ante* regulation is the respective roles of legislators and regulators. The legislature in most jurisdictions has plenary power, and typically delegates to regulatory agencies the authority to regulate, subject to the substantive and procedural requirements included in the legislation. Regulatory agencies generally have greater technical expertise, available resources, and familiarity to address most risks associated with science and technology, and in that respect are the superior institution to make most risk regulatory decisions.

The legislature may take the lead when distrust between the legislature and regulatory agencies, or an issue itself, becomes so politically controversial that the greater legitimacy and accountability of the legislature is required (Goldberg 1987). A major concern is that legislation is usually more refractory to revision and updating than regulation, and thus inflexible statutory risk requirements can quickly become obsolete in areas of rapid technological change. An example is the so-called Delaney clause (1958) in the United States, which banned all food additives found to cause cancer in animals or humans based on a 1950s-vintage *all or nothing* view of carcinogenicity that had been scientifically outdated for many years before the law was finally repealed in 1996 (Merrill 1988).

Ex ante regulation of risks associated with science and technology thus presents some unique issues and tensions in institutional choice. Given the pace of technological change and the complexity of the subject, legislatures are likely to be at a greater disadvantage compared to regulatory agencies in determining risks associated with science and technology. By contrast the fundamental social, policy, and ethical issues raised by many new scientific and technological advances call for the greater accountability and plenary power elected legislatures offer.

The other major legal mechanism for regulating risks from science and technology is *ex poste* litigation and liability. Individuals injured by technologies may bring tort or product liability lawsuits seeking compensation, and science plays a critical role in providing proof of causation in such cases. Based on concern that such litigation was vulnerable to expert testimony of dubious scientific credibility, courts have focused on ensuring that scientific evidence presented to juries is sound. A leading development in this regard is the U.S. Supreme Court's 1993 decision in *Daubert* v. *Merrell Dow Pharmaceuticals, Inc.* that requires federal courts to perform a *gatekeeping* function to ensure that scientific evidence and testimony is reliable and relevant before it can be admitted. This opinion has resulted in judges being proactive and knowledgeable in screening prospective scientific testimony, and has generated an enormous body of scholarly commentary on how judges should evaluate scientific evidence (Black et al. 1994, Beecher-Monas 2000). It has also stimulated professional scientific organizations such as the American Association for the Advancement of Science (AAAS) to seek to educate judges about science and to provide lists of qualified experts.

Unlike *ex ante* regulation that evaluates whether a particular product, process, or technology may present risks, *ex poste* regulation is directed more specifically at whether the technology caused a specific type of injury in a particular individual or group of individuals. The scientific obstacles and uncertainties in demonstrating *specific causation* are even more complex than those faced in demonstrating general causation in the regulatory context. The judicial system uses presumptions, burdens of proof, and standards of proof in reaching decisions under conditions of uncertainty.

PROMOTING THE BENEFITS OF NEW TECHNOLOGIES. The law also plays a critical role in fostering innovation and promoting the development of new technologies through several legal mechanisms and doctrines. Perhaps the most important of these relates to intellectual property, by which the law gives inventors and creators a time-limited exclusive right to commercially exploit the output of their work. Intellectual property is protected through a number of legal forms, including patents, copyright, trademarks, and trade secrets. The underlying rationale for protecting intellectual property is to promote innovation, by giving researchers and authors economic incentives to create new inventions and works. Intellectual property protection is particularly important in high technology industries such as computer software and biotechnology where ideas and innovations rather than infrastructure and machinery are primary company assets.

New technologies present fundamental challenges to traditional intellectual property doctrines. For example, digital information may not be adequately protected by traditional copyright enforcement procedures, which require the copyright owner to bring a lawsuit alleging infringement. Because unlimited numbers of perfect digital copies can be made at almost zero marginal cost by simply uploading the material onto the Internet, legislatures and courts have extended greater copyright protections for digital data. This is exemplified by the *notice and take-down* provision of the U.S. Digital Millennium Copyright Act (1998) that compels Internet service providers (ISPs) to promptly remove information that copyright holders claim is infringing their copyright.

The rapid growth and use of peer-to-peer file exchange likewise challenges the capability of copyright law to protect copyrighted digital works, and has resulted in a renewed interest in using data protection technologies such as encryption instead of, or in addition to, the law to protect copyright. This trend, in turn, has created the need for legal restrictions on anti-circumvention measures that could be used for unauthorized bypassing of data protection technologies. However restrictions on anti-circumvention technologies have also been criticized for extending copyright beyond its traditional limits, including by undermining the *fair use* of digital data and unduly restricting scientific research (Samuelson 2001).

There are similar challenges in adapting patent law to genetic discoveries. Patenting genes has raised many scientific, legal, ethical, and practical complexities that established patent law is not equipped to address. For example, the traditional distinction between non-patentable products of nature and patentable human inventions and discoveries has been blurred by technology that permits the isolation of genes (often in a slightly different form) from living organisms. How should ethical and moral concerns about patenting genes and living organisms be considered in patent decisions, if at all? Should there be exceptions from patent enforcement for patented genes and organisms used for research or clinical applications? Might gene patents actually impede research and slow innovation, contrary to the very purpose of patenting, due to overlapping and stacked patent rights that make the administrative costs of licensing prohibitive (the so-called *tragedy of the anticommons*) (Heller & Eisenberg 1998)?

In addition to its efforts to protect intellectual property, the law encourages advances in technology through antitrust doctrine. Antitrust law promotes innovation by preventing companies from exercising monopoly power or colluding together to block new market entrants and innovations. Technology industries present unique antitrust issues. On the one hand, increased antitrust concerns and scrutiny may be warranted because of the potential for network effects to result in path dependency. Specifically the positive externalities of having other users with a compatible system may create an entry barrier to new competitors that can result in a de facto monopoly for the early industry leader, because users will be reluctant to adopt a new, better technology if it is not compatible with other users. The high initial costs of creating and introducing a new product combined with the low marginal cost of many knowledge-intensive industries heavily favors superior market power for the already-established player.

On the other hand, there are factors to suggest that antitrust issues might be of less concern in high technology industries. Rapid technological progress in high-technology sectors can result in rapid changes in market position, even for a market leader. For example, WordStar was an early market leader in word processing software, but was quickly replaced by new market entrants with superior attributes. Given these conflicting factors, the role of antitrust law in regulating high technology industries and promoting technological innovation remains a major area of academic and policy debate (Hart 1998–1999, Liebowitz and Margolis 1996).

Antitrust actions brought in the United States and Europe against the Microsoft Corporation in the late 1990s and early 2000s illustrate these conflicting antitrust considerations. Government authorities claimed that Microsoft, by virtue of its Windows computer operating system, had a monopoly power with respect to other such operating systems that allowed Microsoft to suppress innovation in potentially competing products. Microsoft contended that it should be permitted to improve its products to include new functionalities (that is, a web browser), and that the antitrust enforcement actions were restraining such advances.

There are also other legal instruments for promoting innovation and advancing technology. Direct governmental funding of scientific research and development, as well as indirect subsidization through legal mechanisms such as research and development tax credits, are important stimulants. Technology-forcing regulations, such as motor vehicle emission standards, prompt technological progress in specific industries. Other standards that provide for uniformity of new technology formats, such as digital television, likewise are intended to facilitate technological development.

ADDRESSING ETHICAL IMPLICATIONS OF TECHNOLOGY. The law is the primary vehicle by which society seeks to resolve controversies raised by scientific research and new technologies. Whether the issue is surrogate motherhood, voluntary euthanasia, human cloning, genetic engineering, privacy in the workplace, online security, or any other technological advance with potential ethical consequences, society relies on legislatures and courts to develop and apply appropriate legal principles. The bioethicist Daniel Callahan has described this tendency to translate moral problems into legal problems as *legalism,* but he himself identifies a vacuum of societal institutions other than the law to resolve moral issues in a satisfactory manner (Callahan 1996). Indeed the failure to legally proscribe an activity carries an implicit message that the activity is morally acceptable.

In some cases, courts have restricted their own authority to consider the ethical aspects of controversial technological developments. For example, the U.S. Supreme Court held that living, engineered organisms such as the OncoMouse could be patented, and refused to address ethical arguments raised by such patenting, finding that those ethical objections were best addressed to the legislative arm of the government. Even when courts exclude ethical considerations, they often remain the primary motivation for litigation, which is then fought on surrogate legally-cognizable grounds.

Institutional Issues

The second major strand in the study of law-science interactions is the impact of science and technology on the practice of law, and the reciprocal effect of law on the practice of science.

EFFECTS OF SCIENCE AND TECHNOLOGY ON THE PRACTICE OF LAW. Scientific and technological advances have both substantive and procedural effects on the law. On the substantive side, new scientific evidence and techniques can change the way legal claims are resolved, including their outcomes. For example, forensic DNA evidence has fundamentally changed criminal law and paternity disputes by greatly improving the veracity of legal fact finding, while creating a plethora of new legal, ethical, and social issues (Imwinkelried and Kaye 2001). In criminal cases, forensic DNA has helped identify and convict guilty persons who might have otherwise escaped prosecution, and exonerated innocent persons accused or convicted. But this powerful forensic tool raises new issues, such as how and from whom DNA samples should be collected and stored, how genetic information may be used, and when convicted criminals should be permitted to reopen cases based on *new* DNA evidence.

Advances in technology are further revolutionizing the procedural aspects of law. The practice of law has historically been influenced by new technologies, including the printing press, telephone, photocopier, and fax (Loevinger 1985). In the early twenty-first century, digital evidence has improved the quality and availability of trial evidence, while raising concerns about tampering with digital photos and recordings. On-line databases, digital document repositories, electronic discovery, new graphics and presentation technologies, and *digital courtrooms* are changing the ways lawyers research, prepare, and present their arguments (Arkfeld 2001). On-line filing and availability of court records is increasing the convenience and availability of judicial proceedings, yet creating new privacy concerns.

EFFECTS OF LAW ON THE PRACTICE OF SCIENCE. According to Justice Breyer, "science depends on sound law—law that at a minimum supports science by offering the scientist breathing space, within which he or she may search freely for the truth on which all knowledge depends" (Breyer 1998, p. 537). Until recently, law rarely intruded into the inner sanctum of the space it created for science. Beginning in the 1980s, however, the law has steadily intruded into the practice of science. Investigations of claims of science misconduct have become more frequent and legalistic, as government investigators adopt adversarial and formal procedures approaching those used by criminal prosecutors. Individuals claiming to have been aggrieved by scientific misconduct or allegedly false claims of scientific misconduct frequently seek judicial remedies. Attorneys have even served non-party subpoenas on scientists who are doing research potentially relevant to a pending lawsuit, even if the subpoenaed scientists have no relationship to the litigation or any of the parties. This imposes a costly burden on scientists, and exposes them to intrusive searches and disclosures about their research activities.

Legislatures are also subjecting scientists to new legal requirements. Governmentally-funded researchers have long been subject to a number of requirements that are conditions of federal funding, such as requirements for human subject protection. But in 1998, the U.S. Congress passed the so-called Shelby Amendment that subjects researchers funded by the federal government to the Freedom of Information Act (FOIA), under which citizens can request and inspect all relevant documents not protected by limited exemptions. The Office of Management and Budget subsequently narrowed this legislation to federally-funded research directly relied upon in federal rulemaking, but even under such a constricted (and challengeable) interpretation, this legislation represented an unprecedented legal intrusion into the laboratory. In 2000 the U.S. Congress enacted the Data Quality Act, which imposes a series of substantive and procedural requirements on scientific evidence used by regulatory agencies. These developments indicate a trend of growing legal intrusion into the science, which was once perceived as a *self-governing republic* generally impervious to legal interventions (Goldberg 1994).

Tensions Between Law and Science

The third strand of law, science, and technology examines the tensions and conflicts that occur when law and science are juxtaposed in decision making. These tensions and conflicts generally flow from the fact that law and science have different objectives and procedures. One frequently mentioned difference is that the law focuses on process, whereas science is concerned with progress (Goldberg 1994). While both law and science are evidence-based systems for finding the truth (Kaye 1992a, Jasanoff 1995), the law is concerned with normative considerations such as fairness and justice, considerations generally outside the scientific framework. Given this difference, otherwise relevant evidence is inadmissible in law if its use or the way it was obtained is unfair, whereas the concept of excluding pertinent data is foreign to science (Loevinger 1992, Foster and Huber 1997). One U.S. federal judge described science as "mechanical, technical, value-free, and nonhumansitic," while law is "dialectical, idealistic, nontechnical, value-laden and humanistic" (Markey 1984, p. 527). Another difference is that "[c]onclusions in science are always probable and tentative," whereas "[c]onclusions in law are usually certain and dogmatic" (Loevinger 1985, p. 3). Given these and other contrasts, it is not surprising that tensions such as the following have developed.

TECHNICAL COMPETENCE. Most legal decision makers (for example legislators, judges, and juries) have very little scientific training and expertise, and yet are called upon to decide highly complex technological matters (Bazelon 1979, Faigman 1999). The result is that "amateurs end up deciding cases argued by experts" (Merges 1988, p. 324). There is therefore concern that legal decision makers will fail to reach scientifically credible decisions (Angell 1996) and will be improperly misled by *junk science* (Huber 1988).

The legal system has instituted a number of procedural and substantive innovations in an attempt to enhance the scientific merits and credibility of its decisions. One major change has been a systematic shift of decision-making authority from juries to judges, presumably because judges have greater capability and experience in distinguishing valid from invalid scientific testimony. Thus, as previously noted, judges in U.S. federal courts are required to perform a *gatekeeping* function to screen proposed scientific testimony for its reliability and relevance before it can be presented to a jury (*Daubert* v. *Merrell Dow Pharmaceuticals, Inc.* [1993]). Similarly, in patent infringement cases, the critical issue of interpreting the scope of a patent has been taken from juries and given to the trial judge pursuant to a 1996 U.S. Supreme Court decision.

Another innovation is the use of *neutral* or third party experts, appointed by the court rather than the contending parties to assist a judge or jury in understanding the scientific issues in a case. Some jurisdictions have also experimented with specialized courts better able to handle technological disputes, such as the digital court implemented by the State of Michigan. The increased use of pretrial conferences to narrow the scientific issues in dispute and the appointment of specially trained law clerks and *special masters* are other techniques courts employ to better handle complex scientific and technological cases (Breyer 1998).

In the legislative context, there is a growing recognition of the need for legislatures to have their own scientific and technological advisory bodies (Faigman 1999), with some pressures in the United States to replace the Office of Technology Assessment which was abolished in 1995. Most European governments and the European Union have established technology advisory bodies for their legislators.

LEGAL VS. SCIENTIFIC STANDARDS. Another area of dispute is whether the law should apply scientific standards and methods of proof, or apply its own standards to scientific evidence. An example is the concept of statistical significance, where the standard scientific convention is that a result will be considered statistically significant if the probability of the result being observed by chance alone is less than five percent (i.e., $p < 0.05$) (Foster and Huber 1997). Some legal experts argue that the law should apply a more lenient standard, specially in civil litigation where the standard of proof is the preponderance of the evidence (i.e., $p > 0.5$), because while science focuses primarily on preventing false positives, the law is equally if not more concerned about false negatives (Cranor 1995, Shrader-Frechette 1991). Other experts caution against equating the scientific standard of statistical significance with the legal standard of proof, because the two measures perform different functions and are like comparing *apples and oranges* (Kaye 1992b, Kaye 1987).

Judge Howard Markey, while sitting as Chief Judge of the U.S. Court of Appeals for the Federal Circuit, wrote that "[n]o court . . . should base a decision solely on science if doing so would exclude the transcendental ethical values of the law" (Markey 1984, p. 525). He warned that "juriscience might displace jurisprudence" as a result of the tendency to "scientize the law" (Markey 1984, p. 525). In contrast, the U.S. Supreme Court's *Daubert* decision held that courts must ensure that scientific testimony have a "grounding in the methods and procedures of science," that is, be "derived by the scientific method" before it can admitted, which imports scientific standards of evidence into the law (*Daubert* v. *Merrell Dow Pharmaceuticals, Inc.* [1993], p. 590). Similarly Justice Breyer has argued "an increasingly important need for law to reflect sound science" (Breyer 1998, p. 538). Yet "some courts remain in the prescientific age" unless and until they "embrace the scientific culture of empirical testing" (Faigman 2002, p. 340).

TIMING OF DECISIONMAKING. Science and technology are progressing at increasing rates (Carlson 2003). A classic example of the rapid acceleration of technology is Moore's law, which predicts that the number of transistors on microchips will double every two years. The law is much slower to evolve, with case law advancing incrementally and gradually, and legislation advancing only sporadically. Statutes, in particular, can quickly become outdated as legislatures are limited, as a practical matter, to revisiting most issues every few years at best, and for some issues every few decades. Case law is also slow to adapt to advances in science and technology due to the binding effect of past precedents (*stare decisis*), something that does not impede science and technology. The result is that the law is often based on outdated scientific assumptions or fails to adapt to new technologies or scientific knowledge. Many experts argue that more flexible and adaptive legal regimes are needed to keep pace with advancing technological systems (Green 1990).

By contrast, there are situations where the law must address a question prematurely, before adequate scientific data are available (Faigman 1999). Science is in no rush to come to a final decision on any specific issue, and can afford to suspend judgment until *all the evidence is in*, even if that takes decades or centuries. Law does not always have the luxury of waiting (Goldberg 1994, Jasanoff 1995). When a defendant is charged with a crime, or a product manufacturer is sued for allegedly harming a citizen, the court must reach a final decision promptly without waiting for additional research to further clarify the issues. The bounded timeline of the law increases the risk of the legal system reaching decisions that may later be deemed scientifically invalid.

NEW TECHNOLOGIES VS. OLD LAWS. Another issue is whether new technologies require new laws or can be addressed by existing legal frameworks. One colorful articulation of this issue is the debate about whether there is any more need for the *law of cyberspace* than for the *law of the horse* (Easterbrook 1996, Lessig 1999). The analogy refers to the fact that there were no major legal doctrinal changes introduced to address the horse as it became a major part of commerce in earlier times, but rather existing doctrines were applied to the horse with only minor modifications. Thus there is a question about the need for new legal doctrines to address the Internet on issues such as privacy, copyright, pornography, and gambling. The passage of specialized laws such as the Digital Millennium Copyright Act and the Child Online Protection Act (1998) indicate a pattern of adopting new laws to address at least some cyberspace issues.

The same general issue arises in other technological contexts. One major debate in the regulation of genetically modified organisms is whether such products should be governed by existing environmental and food safety laws, or alternatively whether a new statutory regime created specifically for biotechnology products is required (Marchant 1988). Existing laws have generally been applied in the United States, while new enactments have been promulgated in Europe and other jurisdictions.

Another example is patent law, where to date existing patent rules have been applied to new technologies such as genes and other biomedical discoveries. Some commentators have argued that new laws, in particular new approaches that move away from the *one-size-fits-all* approach of current law, are needed to provide optimal patent protection for certain new and emerging technologies (Thurow 1997, Burk and Lemley 2002).

LEGAL INTERVENTION VS. MARKET FORCES. A final recurring issue is the respective roles of law and market in regulating new technologies. Specifically, under what circumstances is legal intervention (in the form of legislation or liability) appropriate, and when should the law pull back and leave the market to operate? Major disagreements on this fundamental issue exist. For example, there are conflicting views on whether government should restrict science funding to basic research, or also fund more applied research and development of new technologies.

This same basic tension between legal intervention and market forces underlay disagreements about whether Microsoft should have been subjected to antitrust enforcement because of its Windows operating system or whether market forces were adequate to prevent the company from unfairly exploiting its near monopoly. Another example is Internet privacy, where some commentators assert that technology and the market can provide adequate assurances of privacy, while others argue that a regulatory approach is needed. A third example is whether the government should set standards for technologies such as digital television and wireless communications, or leave it to the market to develop a de facto standard. These disputes rest on conflicting economic and political perspectives that are unlikely to be resolved in the foreseeable future.

Conclusion

The law interacts with science and technology in diverse ways. These interactions will proliferate in the future with advancing technologies that present novel risk, benefit, and ethical scenarios. The nascent legal field of law, science, and technology seeks to provide a systematic treatment of these actions, and will grow and evolve in parallel and apace with its subject matter.

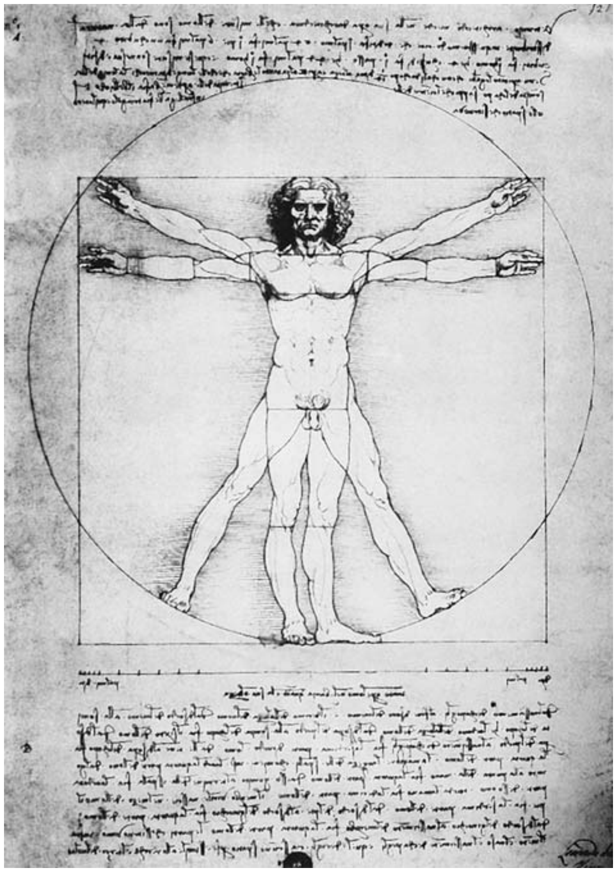
Wessel, Milton R. (1989). "What Is *Law, Science and Technology* Anyway?" *Jurimetrics* 29: 259–266.

SCIENCE, TECHNOLOGY, AND LITERATURE

The ethical implications of science and technology found in literaturre are varied and often implicit as well as explicit. A beginning survey may reasonably include the following non-exhaustive set of topics: the content of narratives that make asseissments of science and technology; orality, writing , printing, and electronic communication as technologies involving certain cultural contexts; and scientific theaories, experiments, and practices as sociocultural influences on literature. (Assessment of the stylistic and rhetorical strategies of science and technology, while also related, are treated in a separate entry.) Scholars in traditional disciplines have often touched on these topics, but only in the 1970s did interdisciplinary fields—the history of the book, science and technology studies, literature and science studies, and cultural studies—begin to give such concerns extensive attention. Tracing ethical aspects of science, technology, and literature calls for examining oratory, writing, printing, and electronic communication as technologies developed in cultural contexts; studying scientific theories, experiments, and practices as sociocultural influences on literature; assessing stylistic and narrative strategies in scientific discourse, including histories and philosophies of science, and elucidating how literary works and theories interpret and reconfigure science and technology as human endeavors. Scholars in traditional disciplines have touched on these topics for many years, but only in since the late 1970s have interdisciplinary fields—the history of the book, science and technology studies (STS), literature and science studies, and cultural studies—flourished to focus on such concerns.

Ancient and Early Modern Myths of Science and Technology

European classical representations of science and technology invoking ethical dilemmas appear in dramatic and didactic poetry. Greek and Roman myths describe Prometheus creating humans with Athena's consent and stealing fire for mortals from Zeus, actions that inspired John Ferguson's characterization of Prometheus as a master inventor and trickster whose rebellious intelligence helps humans rise above animals. Aeschylus's fifth-century *Prometheus Bound* posits that Zeus grew angry at human achievements and at Prometheus's theft, punishing the latter by chaining him to a rock. Hesiod's *Theogony* (c.700 B.C.E.) notes that Prometheus's brother Epimetheus married the beautiful Pandora, who was created as a punishment by Zeus. Pandora opens a container, releasing a host of miseries on humanity; however her curiosity inhibits human progress instead of encouraging innovation and invention. Biblical accounts imputing ethical aspects of science and technology include Genesis 6, which details the building of an ark by Noah, under God's direction, to protect animal species, including Noah's family, from the flood. Genesis 11, in the story of the Tower of Babel, relates how people built a tower and a city, thus prompting God to create different languages in order to constrain human achievement. These classical and Biblical texts represent scientific and technical projects as enhancing human life at the risk of alienating God.



"The Vitruvian Man," 1490 drawing by Leonardo da Vinci. Made as a study of the proportions of the human body, the drawing is often used as an implied symbol of the essential symmetry of the human body, and by extension, to the universe as a whole. *(© Corbis.)*

Modern cautionary tales about Faust and the Sorcerer's Apprentice further consider the dangers of human meddling with science and technology. The Faust Chapbook of 1587 describes Dr. Faust as a master of science and sorcery who conjures the Devil and enters into a pact with him: The Devil promises to serve Faust and in exchange the doctor gives up his soul and renounces his Christian faith. Faust is celebrated for his ability to cast horoscopes but becomes increasingly debauched. The impropriety of Faust's aims and actions has inspired a range of European literary texts, including tragedies, narratives, and poetry by Christopher Marlowe, Johann Wolfgang von Goethe, Heinrich Heine, Paul Valéry, and Thomas Mann, and a number of musical works by Hector Berlioz, Charles Gounod, and Franz Liszt. Goethe's 1779 poem " The Sorcerer's Apprentice" ("*Der Zauberlehrling*") interpreted through Paul Dukas's symphonic scherzo "*L'apprenti sorcier*" (1897) served as a source for the segment of Walt Disney's film *Fantasia* in which Mickey Mouse borrows the Sorcerer's magic broom and causes chaos before he is called to account for the mess. These legends suggest that human desire to know more about the world and control nature might be hubristic and selfish. The narratives imagine how endeavors motivated by extreme ambition inevitably lead to catastrophe. A bug in a computer protocol is commonly known by the term *sorcerer's apprentice mode*, as detailed in a number of websites linked to the Google search engine.

Linking themes of egotism and passion for new knowledge with contemporary theories about electricity in *Frankenstein, or The Modern Prometheus* (1818), Mary Shelley imagined how aspirations to conquer science and ancient alchemy inspire and destroy Dr. Victor Frankenstein. Frankenstein creates life only to turn his back on the creature he belatedly recognizes as a monster. Invoked often in fiction and film, the Frankenstein myth of creation gone awry retains potency for many in the age of bioengineering. Newspapers reporting on deliberations by the U.S. Congress and President's Council on Bioethics to ban cloning and restrict fetal tissue research invoked Shelley's novel (along with Aldous Huxley's *Brave New World*). Activists employ the term *Frankenfood* to denote food modified by processes of genetic transplantation.

Referring to Pygmalion rather than Prometheus, Nathaniel Hawthorne outlines the dangers of scientific ambitions and technological tinkering in stories such as "Rappaccini's Daughter" (1846) and "The Birth-Mark" (1846), whose plots explore how male scientists used their wives or daughters as subjects for their experiments. Villiers de L'Isle-Adam's mechanical fantasy *L'Eve future* (1880) follows a modern Pygmalion character who applies scientific knowledge to engineer a Galatea, only to find that even an artificial woman's needs surpass his scientific and technological ingenuity. Given the saliency of myths pointing up the dangers of science and technology, it is not surprising that themes of hubris, technology run amok, and scientific arrogance are common in science fiction, postmodern realist literature, and expository prose.

Printing and the Reading Revolution

Although the Sumerians created clay books as early as 3000 B.C.E. and the Chinese developed printing techniques in the early-second century C.E., accounts of modern printing technology usually begin with the importation of paper from Asia to Europe (Graff 1991). Early experiments with xylography and metallographic printing were *disappointing* (Havelock 1976). Johannes Gutenberg (1390–1468), who is credited with inventing typography, also is generally understood to be the first printer to use movable type in 1436. Metal type represented an advance on woodcuts, which were time-consuming to produce and of limited use. At the end of the sixteenth century, the printing industry was well established in many European cities even though printing remained a tedious process. While most books dealt with religious subjects, dramas and fictions were also published. Censorship and political restrictions curtailed some printers; in seventeenth-century England the government limited the number of printers.

After the Renaissance, advances in type and the use of paper covers decreased the cost of books while promoting a diversity of written materials. At the end of the eighteenth century, the invention of lithography and innovations in the power press advanced the printing industry, while improvements in papermaking and stereotyping decreased costs in the early-nineteenth century. By then reading had become a necessary part of everyday life for North Americans and Western Europeans in that work, worship, and social relations encouraged the activity and education became a fundamental goal of democracy (Graff 1991). In the United States during the antebellum period, children, prisoners, and freed slaves were taught to read as a means of socialization and economic empowerment, principles enunciated in didactic literature (Colatrella 2002).

Oral-Literacy Transformation

Developing scientific schema and philosophical theories, post-Enlightenment scholars demonstrated wide-ranging interests in linguistic, rhetorical, and narrative forms associated with oral and written texts. Linguists and philologists in the late-eighteenth and nineteenth centuries traced connections among Indo-European languages, studied classical rhetorical modes, and collected folktales from various regions. Romantics, who had an interest in ordinary people and their texts, celebrated the vernacular; James McPherson in Scotland, Thomas Percy in England, Jacob and Wilhelm Grimm in Germany, and Francis James Child in the United States collected examples from the oral traditions of those countries (Ong 1982). The work of these writers influenced twentieth-century formalists and structuralists, who melded textual and cultural analyses in their work on the periphery of the social sciences, notably in the fields of psychology and anthropology.

In the early-twentieth century, Andrew Lang demonstrated that oral folklore offered *sophisticated verbal art forms* (Ong 1982). Lang's work encouraged others to analyze techniques employed in classical poetry, particularly Homer's *Iliad* and *Odyssey*, and reinvigorated a debate begun in the seventeenth century concerning evolution and authorship of these works. In the twentieth century, Milman Parry viewed each Homeric epic as the culmination of orally delivered formulaic phrases used by bards. Building on Parry, Albert Lord hypothesized that "the idea of recording the Homeric poems, and the Cyclic epics [the Epic of Creation and the Epic of Gilgamesh], and the works of Hesiod, came from observations of or hearing about similar activity going on further to the East," specifically early versions of the Old Testament in ninth-century Palestine (Lord 1978, p. 156). Eric Havelock claimed the written versions of the *Iliad* and the *Odyssey* were the first products of the new Greek alphabet developed around 700–650 B.C.E. (Ong 1982).

Parry made phonographic recordings of working poets in 1930s Yugoslavia as a means of studying the composition of oral poems that might shed light on the development of the Homeric epics. After Parry's death, Lord continued the project, publishing *The Singer of Tales* in 1960, a book based on recordings and transcriptions. He argued that the Yugoslavian poets, who were generally illiterate, typically composed their songs during their performances according to mechanisms likely used in formulating the Homeric epics. Novice poets were able to create new songs because they had learned stories and formulaic phrases by watching the performances of others, a prerequisite for developing the special technique of composing by combining well-known formulas. Building on Parry, Lord argued that Homer composed oral narrative poetry through the same method, based on "intricate schematization of formulas" in Greek hexameter (Lord 1978, p. 142).

At the end of the twentieth century, the orality-literacy distinction drew the attention of theorists such as Jacques Derrida, J. L. Austin, John Searle, and Mary Louise Pratt, whose arguments influenced post-structuralist theories about literature. Derrida questioned the privileging of orality over writing, calling the practice phonocentrism and connecting it to logocentrism. He provoked speech act theorists Austin and Searle in pointing out that "the uses of language could not be determined as exclusively either normal or parasitic" (Halion 2003, Internet site). Suggesting the possibility of a unified theory of discourse, Pratt argued against the idea that the discourse of literature is functionally distinct from other verbal expressions.

Media Literacy

Contemporary interest in literacy shifts peaked in the the twentieth century as a transformation from print to new media developed. A number of non-fiction writers, including Marshall McLuhan, Ivan Illich, and Alvin and Heidi Toffler, addressed social issues concerning electronic media. The Tofflers conceived a popular theory of history describing three successive eras—the agricultural age, the age of the Industrial Revolution, and the Information Age, becoming famous as consultants to Newt Gingrich, who served as Speaker of the House in the U.S. Congress in the early 1990s. The Tofflers's work celebrates technological advances as progress. In contrast, Illich's writings question the assumed superiority of industrialized nations, the centralization of political authority, and faith in technology. He analyzed issues in medicine that denaturalize human control for the sake of technology.

Recognizing that consumers are bombarded with hundreds of advertisements, Illich criticized the reversal of the relation of needs and wants by materialist culture and argued that more technology does not produce greater leisure, freedom, or satisfaction; that what many think of as schooling is more properly termed *deschooling*; and that literacy can constrain rather than enable one's prospects in a culture. Some late-twentieth-century writers were inspired to apply Illich's theories in books such as *ABC: The Alphabetization of the Popular Mind* (1988) and *In the Vineyard of the Text* (1993), to projects associating literacy with technological change in the *convivial society*. Illich's concept of the convivial society in which technologies serve individuals rather than managers might have helped convince Lee Felsenstein, a founder of *Community Memory*—regarded by many as the world's first public computerized bulletin board system—to use the computer, which had been primarily promoted as having industrial applications, for artistic expression. English teacher Allan Luke positively characterizes literacy as *a communications technology* engaging individuals with real and fantastic worlds, creating a *simultaneous universe*, akin to McLuhan's *global village*, while Howard Rheingold describes *smart mobs* of individuals linked by electronic technologies.

McLuhan described his argument in *The Gutenberg Galaxy*, published in 1962 as *complementary* to those of Parry and Lord in dealing with cultural shifts affected by changing media; whereas their work accounted for the orality-literacy transformation, his provided trenchant analysis of the transformation from print to digital literacy. McLuhan resisted evaluating cultural change, instead concentrating on delineating connections among sociopolitics, culture, and media. In an interview, he explained how printing influenced nationalism: "Nationalism didn't exist in Europe until the Renaissance, when typography enabled every literate man to *see* his mother tongue analytically as a uniform entity. The printing press, by spreading mass-produced books and printed matter across Europe, turned the vernacular regional languages of the day into uniform closed systems of national languages . . . gave birth to the entire concept of nationalism" (McLuhan 1995, pp. 243–244). McLuhan recognized that while technologies and media inevitably produce changes, such shifts could often be uncomfortable for those experiencing them and ought to be considered critically, as Illich and Neil Postman argue.

McLuhan's work allusively comments on cultures, texts, and media technologies, often through aphorisms attesting to diverse influences. His celebrated statement

"The medium is the message" from *Understanding Media* published in 1964, described technological consequences as continuous: "the personal and social consequences of any medium—that is, of any extension of ourselves—result from the new scale that is introduced into our affairs by each extension of ourselves, or by any new technology" (McLuhan 1995, p. 151). He recognized differences among media, distinguishing *cool* and *hot* media as media requiring engagement (telephone) or passivity (radio) on the part of the user. He described the inevitable constraints associated with technological progress; for example, that the alphabet can "alter the ratio among our senses and change mental processes" as "an aggressive and militant absorber and transformer of cultures" (McLuhan 1995, pp. 119, 144).

Digital Literacy

Many language and technology theorists have developed McLuhan's insights, extending them to other technical developments and evaluating their applicability to revisionist histories of literacy and cognition. Adopting some of McLuhan's ideas about the power of media to influence human perceptions in *Orality and Literacy* (1982), Walter Ong characterizes writing as a technology that changes human consciousness. Investigations in cognition formed the basis for the development of electronic communication media. In *How We Became Posthuman* (1999), Katherine Hayles describes Norbert Wiener's cybernetics, Claude Shannon's information theory, and the fictional contributions of Philip K. Dick to ideas of distributed consciousness and thereby offers a history of disembodiment in cybernetics. Brian Massumi reviews philosophies of perception, including those of Henri Bergson, William James, Gilles Deleuze, Felix Guattari, and Michel Foucault, to argue that new ways of reading are necessary to understand the body and media (film, television, and the Internet) as cultural formations.

Janet Murray argues that late-twentieth-century forms of media changed storytelling conventions to require interactivity. She acknowledges earlier narrative forms and strategies that provide precedents and points of comparison for such media, especially the epic, the picaresque, and the drama of Shakespeare, forcefully arguing that movies, computer games, and hypertext novels are new narrative forms requiring new ways of appreciating a story. Hypertext fiction, poetics, and history, and new media criticism by Michael Joyce, Stuart Moulthrop, George Landow, and Jay Bolter also proffer the argument that hypertextual narrative forms revise notions of interactivity and change perception in representing reality in new, perhaps dangerous, ways. In their joint work, Bolter and Richard Grusin detail changes in Internet media reflecting the remediation of different media forms and their effects on users, particularly in the way that the Internet has become another, albeit more interactive (cool), medium. Greg Ulmer considers electronic communication in teaching composition in universities, arguing that students accustomed to interactive technologies benefit from a constructivist rather than instrumentalist approach.

Authorship, Technology, and Ethics in the Information Age

Post-structuralists theorists Roland Barthes, Derrida, and Foucault questioned traditional notions of authorship. Their critiques suggest that it is impossible for anyone, even another author, to divine a writer's intentions and that readers provide intertextual and contextual information that expands the text. Barthes acknowledges in "The Death of the Author," which first appeared in 1968, that the plurality of voices in the text inevitably produce many possible meanings for readers. Foucault also questioned to what extent biographical information should affect consideration of an author's literary output in "What Is an Author?, first published in 1969, positing *the author function* and emphasizing the value of studying discourse rather than biography. The Internet complicates ideas of authorship. Each search produces a list of sites that could be one person's work, that of a group, or the official page of a company or institution, while many web pages have no identified authors. Contributors to an electronic forum collaborate as multiple authors to a boundless text.

In this way, electronic writing further reduces the distance between reader and text (a shift previously noted by Walter Benjamin), and increases the ephemerality of a text. The fixity of the printed text has transformed into the fluidity of electronic content. Scholars present electronic archives of canonical writers such as Emily Dickinson, Herman Melville, and Walt Whitman that incorporate all versions of particular texts, while hyperlinks organize text to present fluid documents with multiple reading pathways. Electronic sites also recuperate once-popular writers whose works appear on the Internet along with those never-before-published.

Although Internet communication enhances many aspects of social life, its boundlessness also creates ethical problems. Free speech advocates resist filtering information. Satisfactory technical solutions preventing electronic mail spam, plagiarism, identity theft, and pornography aimed at juveniles have not yet been developed. Free electronic distribution of music and film appeals to many users but chips away at intellectual property rights, as is argued by artists and producers in the recording and film industries. Ethical standards regarding authorship, as cases of plagiarism and false documentation of sources suggest, call into question the name on the book or the claims within it, but generally the production process appears to be opaque to a reader, who could easily assume, for instance, that a biography was researched and written by the author noted on the cover or that a reporter whose byline appears on an article witnessed an event, while there may in fact have been contributions from numerous research assistants or virtual research may have substituted for an on the scene account.

Critical Paradigms of Taste and Technology

Literary criticism has a long history of valuing some genres, writers, or works over others for ethical reasons. Plato characterized poetry as too dangerous to exist in the ideal republic because it inspired political critique, and Jonathan Swift satirized the seventeenth-century Battle of the Ancients and the Moderns that provoked many French and English critics to debate the merits of classical versus contemporary literature. Training in modern languages and literatures is a product of the post-Romantic age. Earlier education in liberal arts was dominated by study of classical texts; but by the early-twentieth century, ideas of canonicity transformed to include certain modern texts. Cultural tastes change over time; for example, the novels of Herman Melville gained popular attention in the late 1840s and 1850s, but his critical reputation then diminished before critics in the 1920s rediscovered his work. In the late-twentieth century the literary canon of Great Books expanded to include works from non-European or North American cultures and by women and minorities. Thus, while the high versus popular culture distinction has had particular resiliency, it has been applied to shifting sets of literary works.

The effects of technology on standards of literary taste have primarily concerned issues of reproduction associated with electronic media. In "The Work of Art in the Age of Mechanical Reproduction" (1936), Benjamin argues that advances in printing changed the status of art in making woodcut graphics reproducible in lithography, thereby enabling "graphic art to illustrate everyday life" (Benjamin 1985, p. 219). Benjamin notes the inverse relation of accessibility and quality of works of art that accounts for the popularity of a Chaplin film versus "the reactionary attitude toward a Picasso painting" (p. 234): "The greater the decrease in the social significance of an art form, the sharper the distinction between criticism and enjoyment of the public" (p. 234). His essay ends by suggesting the dangerous capacities of film to support totalitarianism.

Frederick Kittler also analyzes how the functions of literature depend upon contextual shifts of discourse systems and on changing technical capacities of media. Like Foucault, he organizes history into eras based on paradigms of how literature is read in relation to other discourses, and, like Benjamin, he is concerned about determining effects of technology on literature. Saul Ostrow references McLuhan's idea that technology extends the human body in remarking that "Kittler is not stimulated by the notion that we are becoming cyborgs, but instead by the subtler issues of how we conceptually become reflections of our information systems" (Kittler 1997, p. x). In an essay considering Bram Stoker's *Dracula* (1982), as a commentary on the reproducibility of technology, Kittler notes that communication systems determine modern interpretations and forecast the death of literature: "Under the conditions of technology, literature disappears . . ."(Kittler 1997, p. 83).

Building on elements of Jacques Lacan, Foucault, and Derrida, Kittler theorizes about the discourse networks of 1800 and 1900. He identifies the classical romantic discourse network of 1800 according to its fundamental formulation of mothers socializing children through phonetic reading (*universal alphabetization*) and that of the modernist discourse network of 1900 by the influence of technologies such as the typewriter on writing and reading (*technological data storage*). Kittler recalibrates literary works and theories by representing them as media: "literature . . . processes, stores, and transmits data" (Kittler 1990, p. 370). He argues that a transformed literary criticism ought to understand literature as an information network, thereby classifying literary study as a type of media studies. In representing literature as technology, Kittler's theories encourage literary criticism that connects works of art to scientific practices and theories.

Futurism

Agreeing with progressive thinkers who argued the benefits of modern technology, the early-twentieth-century Futurism movement recognized literature to be a form of imaginative anticipation of and stimulation toward scientific and technological change. Futurists reacted against Romantic conceptions of literature as a sentimental retreat from technology. In a 1909 manifesto, Italian futurists such as Filippo Tommaso Marinetti proposed that products of the machine age might be celebrated alongside nature: "We will sing of the vibrant nightly fervour of arsenals and shipyards blazing with violent electric moons; greedy railway stations that devour smoke-plumed serpents; factories hung from clouds by the crooked lines of their smoke; bridges that stride the rivers like giant gymnasts ... adventurous steamers that sniff the horizon; deep-chested locomotives whose wheels paw the tracks like the hooves of enormous steel horses ..." (Tisdall and Bozzola 1978, p. 7). Marinetti excelled in performing manifestoes, designed to incite the crowd, at Futurist evenings; his arguments characterized "man as the conqueror of the universe, destined to impose change with the aid of science" (Tisdall and Bozzolla 1978, p. 89). Futurist painters concentrated on depicting dynamic forces, especially those of urban life. Photographers and filmmakers applied principles of Photodynamism to integrate light and line into action. Futurism encouraged poets, dramatists, and other writers to describe the life of matter without imposing versions of Romantic or pantheistic ego on material conditions.

Composers, architects, and activists were similarly drawn to the utopian promise of futurism. Antonio Gramsci, co-founder of the Italian Communist party, expressed sympathy for the Futurist attempts to destroy the foundations of bourgeois civilization because "they had a precise and clear conception that our era, the era of big industry, of the great workers' cities, of intense and tumultuous life, had to have new forms of art, philosophy, customs, language ..." (Tisdall and Bozzolla 1978, p. 201). In contrast, in "The Work of Art in the Age of Mechanical Reproduction," Benjamin pointed to how such radicalism, encouraged by technological change and promoting self-alienation, aestheticized destruction and contributed to Fascism.

Literature, Science, Technology, and Culture

Matthew Arnold in "Literature and Science" (1882) outlined a distinction between the disciplines later represented by C. P. Snow as *the two cultures* in his 1959 Rede lecture. Literary and cultural critics in the late-twentieth century changed the terms of such classification schemes in interpreting a range of texts—written, dramatized, ritualized, and so on—as cultural products. Clifford Geertz, Raymond Williams, and Victor Turner contributed fundamental concepts supporting the linguistic, or narrative, turn in anthropology and cultural studies. Geertz and Turner unpacked social events as cultural texts affecting individuals as community rituals, while Williams looked at the symbolism of ordinary life that had previously been excluded from scholarly consideration. Sociologists Bruno Latour and Sharon Traweek examined laboratory life and scientists's networks and discourse. Their work, along with that of Stuart Hall and Frederic Jameson, among other cultural critics, effaced previously set boundaries dividing high and low culture, linked art and life, and blurred disciplinary divisions concerning methodologies.

Like writers and artists, scientists and technologists are subject to cultural ideologies and conditions, and they produce literature as well as a body of knowledge. Cultural critics understand literature and science as discursive, epistemological practices with reciprocal influence. Tracing the representations of scientists and scientific ideas in literature can be a critical step in confronting scientific theories and practices because literary genres entertain and educate. Scientific hypotheses and inventions in fictions and ethical issues represented in literature inspire scientists. Given the increasing imbrication of science and technology in everyday life, it is not surprising that many literary and artistic works weave such references into their discourse and offer some ethical commentary on their development and implementation.

Just as science and technology are constructed out of and influence social values, literary works reflect and refract cultural ideas and events, as Maurice Agulhon noted of the Rougon-Macquart novels by Emile Zola and their Darwinian intertexts. But the forms of engagement are not formulaic, with writers using literature to offer ethical arguments about science and technology. Romantic works privilege nature over technology, yet they inspire the individual to become a close observer of the natural world and thereby give some impetus to scientific study. Nineteenth-century campaigns against hunting for leisure and fashion and anti-vivisection movements, along with an appreciation for species developed post-Darwin and support for women's suffrage, inspired British women to write about nature (Gates 2002). U.S. writers such as Ralph Waldo Emerson and Henry David Thoreau promoted scientific observation of nature and reacted against the dehumanizing effects of technology. Melville's *Moby-Dick* (1851) describes the tools and techniques of whaling in telling the story of the doomed Ahab, who is willing to sacrifice his life and his crew to pursue the white whale. In his journals *Household Words* (1850–1859) and *All the Year Round* (1859–1870) and in a number of novels published serially in the mid-nineteenth century, Charles Dickens stimulated ethically inspired social reforms associated with technological changes of the Industrial Revolution; for example, he criticized how utilitarianism associated with factories crushes the human spirit in *Hard Times* (1854), how bureaucratic selfishness results in unjust incarceration in *Little Dorrit* (1855–1857), and how the law inexorably grinds on while ignoring human need in *Bleak House* (1852–1853).

Some feminist tales of science and technology suggest that ethical motivations inspire the creation of scientific knowledge and demonstrate how technology can be applied to effect social improvement. In the short story "Hilda Silfverling: A Fantasy" (1845), Lydia Maria Child depicts a conflict between scientific knowledge and domesticity but optimistically resolves it by technological means when the title character is preserved by a chemist experimenting with cryogenics rather than being executed for a crime she did not commit. Stories by Charlotte Perkins Gilman written between 1890 and 1916 in various magazines celebrate similar examples of women who escape from painful domestic situations by working, often by entrepreneurially employing an innovative management technique or adopting a new technology (Colatrella 2000). Gilman's utopian novel *Herland* (1915) imagines a matriarchal society that can alleviate psychic and social problems for women.

As scientists, particularly defenders of Charles Darwin from T. H. Huxley to Stephen Jay Gould, have appreciated, fiction and non-fiction literature helps people comprehend, digest, and accept scientific principles and applications. Although professional discourse in some fields can be too esoteric for non-scientists to appreciate, essays in newspapers and journals aimed at a broad range of scientists and/or the general public accessibly convey technical information, disseminating new ideas and articulating ethical issues of significance to scientists, technologists, and the public. Literary works of fiction, poetry, and drama also contextualize ethical dilemmas in pointed ways. Recent medical examples of how public understanding can influence scientific and technological processes include efforts to maintain ethical standards in testing AIDS vaccines in Africa, to speed up the drug review process for orphan diseases, and to administer treatment and research studies in a humane manner; in these cases, press reports and literary works (dramas, films, and novels) contributed to informing the public about science in public policy. The fiftieth anniversary of the atomic bombing of Japan inspired a number of books, novels, and films representing the scientific researchers and politicans involved. The fiftieth anniversary of the discovery of DNA also brought historical reconsiderations in film and in print, in this case documenting Rosalind Franklin's contributions to James Watson's and Francis Crick's double helix model. While some considerations of science suggest the limitations of scientists and engineers, others verge on the hagiographical in representing their heroic dimensions. Whether one adopts Gould's ideal of literature as assisting in the process of scientific dissemination or Arnold's assumption that literature has an obligation to criticize science, almost everyone accepts that while researchers pursue knowledge for its own sake, it is impossible to disentangle scientific theory and practice and technological applications from morality and culture.

In conclusion, the interrelationships of ethics, science, and technology have often been represented in literature and other discursive media. Scientific and technical means have also sometimes been utilized to analyze literature, whether as tools of reproduction or as specific cultural circumstances affecting the production and reception of texts. While many literary works explore unpredictable and dangerous outcomes of scientific and technological experimentation, others consider the optimistic potentials of such work. Similarly, the enabling possibilities for humanity offered by computing and information technologies in recent decades have been invoked alongside constraints and problems that harm individuals and society. In studying technologies of representation such as writing, scholars connect humanistic study with scientific and technical research. Some critics and artists bring ethical perspectives to bear on representations of scientific and technology, while cultural historians and critics consider the scientific and technical mechanisms utilized in studying types of language and discourse forms such as the orally composed epic. In the Information Age, we recognize that media forms help structure our understanding and that out culturally constructed assumptions help develop and deploy technologies. Yet as questions concerning fetal tissue research and assisted reproduction testify, we have difficulty in believing that science and technology inevitably lead to progressive outcomes and that they are always ethically motivated and directed. We struggle to make sense of which historical representation of science and technology appears more accurate, while aiming to reduce the risks associated with current technologies and to design new and better ways of doing science and innovating technologies.

SCIENCE, TECHNOLOGY, AND SOCIETY STUDIES

Science, Technology, and Society Studies, or STS, is an interdisciplinary field of academic teaching and research, with elements of a social movement, having as its primary focus the explication and analysis of science and technology as complex social constructs with attendant societal influences entailing myriad epistemological, political, and ethical questions. As such it entails four interlinked tenets or concepts that transcend simple disciplinary boundaries and serve as a core body of STS knowledge and practice. Several useful introductions to the STS field are available (Sismondo 2004, Cutcliffe and Mitcham 2001, Volti 2001, Cutcliffe 2000, Hess 1997, Jasanoff, et al. 1995).

Basic Themes

The field of Science, Technology, and Society Studies covers several basic themes.

CONSTRUCTIVISM. First and foremost, STS assumes scientific and technological developments to be socially constructed phenomena. That is, science and technology are inherently human, and hence value-laden, activities that are always approached and understood cognitively. This view does not deny the constraints imposed by nature on the physical reality of technological artifacts, but it does maintain that knowledge and understanding of nature, of science, and of technology are socially mediated processes.

CONTEXTUALISM. As a corollary to the notion of constructivism, it follows that science and technology are historically, politically, and culturally embedded, which means they can only be understood *in context*. To do otherwise would be to deny their socially constructed nature. This does not contradict *reality*, but does suggest that there are different contextualized ways of knowing. Likewise any given technological solution to a problem must be seen as contextualized within the particular socio-political-economic framework that gave rise to it.

PROBLEMATIZATION. A view of scientific knowledge and especially technological development as value-laden, and hence non-neutral, leads to the *problematization* of both. In this view science and technology have societal implications, frequently positive, but some negative, at least for some people. Thus it is not only acceptable, but, indeed, necessary to query the essence of scientific knowledge and the application of technological artifacts and processes with an eye toward evaluative and ethical prescription.

DEMOCRATIZATION. Given the *problematic* natures of science and technology, and accepting their *construction* by society, leads to the notion of enhanced democratic control of technoscience. Due to the inherent societal and ethical implications, there need to be more explicit participatory mechanisms for enhancing public participation in the shaping and control of science and technology, especially early in the decision-making process, when the opportunity for effective input is greatest. The ultimate goal is to structure science and technology in ways that are collectively the most democratically beneficial for society.

In adopting such a theoretical framework for the descriptive analysis and prescriptive evaluation of technoscience, STS serves as a location for discussing key societal and ethical issues of interest and concern to a democratic public. As such STS offers a set of conceptual tools and insights, themselves continually open to reflexive analysis and further evolution as scholars and activists gain ever more experience in understanding science and technology.

Historical Development

STS as an explicit academic field of teaching and research emerged in the United States in the mid-1960s, as scholars and academics alike raised doubts about the theretofore largely unquestioned beneficence of science and technology. Public concerns relating to such areas as consumerism, the environment, nuclear power, and the Vietnam War began to lead to a critique of the idea of technoscientific progress that many people had generally come to believe. Marked by such popular works as Rachel Carson's *Silent Spring* (1962) that raised questions about the hazards associated with chemical insecticides such as DDT and Ralph Nader's automotive industry expose, *Unsafe at Any Speed* (1965), STS reflected a widening activist and public engagement with technoscientific issues and concerns.

At approximately the same time this social movement was emerging, parallel changes within a number of traditional disciplinary academic fields were occurring. Evolving out of the work of scholars such as Thomas Kuhn, whose *The Structure of Scientific Revolutions* (1962), was tremendously influential, traditional philosophers, sociologists, and historians of science and technology, more or less independently of each other, began to move away from internalist positivist-oriented studies to reflect a more complete and nuanced understanding of the societal context of science and technology. Common to the intellectual analysis in each of these fields was criticism of the traditional notions of *objectivity* within scientific and technological knowledge and action, an examination that emphasized the value-laden contingent nature of these activities. As these fields evolved, they increasingly borrowed conceptual models and drew on case examples from each other, such that by the mid-1980s a clearly interdisciplinary academic field of study, replete with formalized departments and programs, professional societies, and scholarly journals, had emerged. Reflecting the more intellectual focus of their work, these scholars and their organizations began to use the term S&TS—Science and Technology Studies—to distinguish themselves from the more activist STS wing.

A third element or subculture within STS involves the more practice-oriented science and technology or engineering management and policy fields. Often referred to by the acronym STPP (Science, Technology and Public Policy) or SEPP (Science, Engineering, and Public Policy), this group is particularly interested in the practical policy issues surrounding science and engineering and in exposing scientific and engineering managers to the broader sociopolitical context they are likely to encounter. It too conducts research and scholarship and offers graduate education programs, but generally as part of a focused mission.

Collectively then this interdisciplinary group of scholars and sub-fields constitutes what has become known as STS or sometimes S&TS Studies. Together they examine the relationships between scientific ideas, technological machines and processes, and values and ethics from a wide range of perspectives. Independent of their specific motivations, approaches, and concerns, however, is a common appreciation for the complexities and contextual nature of science and technology in contemporary (and historical) society. Drawing on a strong base of empirical case studies by academic sociologists and historians of technoscience, more activist STSers and the STTP-oriented policy and management groups have since the 1990s been in a position to take a modest "turn toward practice" (Bijker 1993, p. 129) that should in principle, even if not always in practice, allow a more *democratic* public role in the ethical shaping and control of technoscience.

The STS Controversy

One result of this intellectual theorizing about the socially constructed nature of technoscience has been a strong, often polemical, backlash from certain quarters of the scientific community. This was unfortunate because much of the debate in what became known as the *Science Wars* appeared to miss, or ignore, the central focus and insights of STS, and was often polemical because of comments by participants on both sides. Many scientists hold tightly to the traditional ideal of objective knowledge based on reason and empirical evidence. For such individuals relativist claims that scientific knowledge is *socially constructed* and not to be found in an objective autonomous nature, but rather as the result of a set of historically and culturally elaborated set of conventions, was unsettling and struck more than a discordant note. Combined with widespread evidence of scientific illiteracy among school children and widely held pseudoscientific beliefs on the part of the general public, some scientists came to view much of STS as *anti-science* and indicative of a postmodern cultural decay.

Arguing in support of the objective nature of scientific evidence and science as a special way of knowing, a number of such individuals led by Paul Gross and Norman Levitt (1994) and Alan Sokol (1996a, 1996b,

1998) took issue with some of the more relativist-oriented STS scholars, such as Bruno Latour (1987), and launched a series of sharp attacks in print and at academic conferences. A spirited debate ensued, supposedly over the epistemological nature of scientific knowledge, but it veered into the social dynamics and political implications of science, and by association tended to indiscriminately taint all STS scholars as anti-science and engaged in a *flight from reason*.

Among the skirmishes Sokol, a physicist, wrote an article consisting of complete gibberish, but cast in post-modern constructivist language, that was published in the cultural studies journal, *Social Text* (Sokol 1996a), ironically in an issue intended as a response to the earlier work of Gross and Levitt (1994). Sokol was motivated by what he considered to be the "nonsense and sloppy thinking" that "denies the existence of objective realities" (Sokol 1996b, p. 63) and sought to expose it through his parody article, with the end result of adding fuel to the already hot fire of debate.

Without replaying the whole debate, which also included a bizarre invitation by Sokol for anyone who did not believe in scientific objectivity to come to his upper story office where they could test the law of gravity by stepping out the window, much of the dialog missed the common core of agreement that actually bound the combatants more closely together than perhaps at least science defenders realized. That is to say, most scientists, including Gross, Levitt, and Sokol, readily accept a *moderate constructivism*, one that views scientific knowledge of the natural world and its associated processes, and most certainly technological creations, to be *socially constructed* phenomena. Few moderate STS scholars or members of the public would deny the obdurate reality of nature, nor do they seek to control the underlying scientific epistemology, but it certainly is within reason for them to both understand and seek to control the sociopolitical implications of contemporary technoscientific advances. In the end then, it would appear there was probably more in common between the scientific combatants and that their *war* reflected much ado about little. Yet, at the same time, it does suggest just how difficult it may be for STS, either as a group of investigative scholars or as a social movement, to play an ethically and politically responsible role in the shaping and control of science and technology as the twenty-first century unfolds.

The Problem of Ethics

To say that incorporating an ethical awareness and normative framework into society's control and shaping of contemporary science and technology will be difficult, is not to say that it should not be attempted, nor that such attempts from within the STS community are not already occurring. Indeed that has been much of the raison d'etre of STS right from the beginning, even of those more intellectual scholars most interested in revealing the epistemological underpinnings of scientific knowledge. Thus it has been the case that STS social constructivists have often revealed the underlying values and ethical choice decisions made in scientific research and discovery, while those analyzing technological decision making, such as that surrounding the launch of the space shuttle Challenger (Vaughan 1996), similarly revealed the ethics of the decision to go forward that chilly Florida morning, even in the face of admittedly mixed evidence regarding the viability of O-rings at reduced temperatures. Other more specifically focused philosophers and ethicists have analyzed case studies of technoscientific failures or near failures, ranging from DC-10 aircraft landing gear to the San Francisco BART transportation system to the collapse of the Kansas City Hyatt Regency walkway, for what they reveal about the ethics and values subsumed in such technoscientific endeavors. Other scholars have examined such issues as the siting of toxic waste and hazardous manufacturing facilities because of what they show about environmental justice inequities.

Out of such analyses has come increased attention to the need to make scientists, engineers, and corporate managers much more socially and ethically attuned to the implications of their work. To that end, engineering education programs focus more attention on the ethics of engineering through required coursework, while organizations and groups such as the American Association for the Advancement of Science (AAAS), which established a Committee on Scientific Freedom Responsibility in 1975, and the computer science community, which created the ethics-oriented Computer Professionals for Social Responsibility in 1983, concentrate specific resources toward the effort to raise awareness of ethical issues.

Beyond this institutional level of response, increasing numbers of STS academic scholars have come to recognize and focus on normative concerns as an integral part of their work. In part this has been a response to the gauntlet thrown down by the political philosopher of technology, Langdon Winner (1993), who finds much of the largely *descriptive* constructivist analysis wanting in terms of *human well-being* and the *social consequences of technological choice*. One significant measure of the barometric shift in such matters has been the work of Wiebe Bijker, a leading constructivist scholar and the 2001–2003 President of the Society for the Social Studies of Science. In a number of works, including his 2001 pre-presidential address, Bijker explicitly argued the need for greater *political engagement* in matters technoscientific on the part of citizens and scholars alike, each drawing on the constructivist insights of STS. Such engagement in his view would entail much greater democratic participation in the technoscientific decision-making process on the part of the public and a larger role for STS scholars as *public intellectuals* who, by drawing on their STS insights, might contribute normatively to the civic enhancement of our modern technoscientific culture (Bijker 2001, 2003).

Summary

As the foregoing analysis suggests, STS, as an intellectual area of research and teaching, as applied policy analysis, and as a social movement, is not only a field well suited to explain the nature of science and technology (historically and in the contemporary world), but one that also holds out great promise for the normative and democratic enhancement of today's technoscientific society. STS both provides an analytical framework and serves as a locus of debate. Such is the potential of STS and the greatest opportunity for its application.

SCIENTIFIC ETHICS

The term *scientific ethics* may refer to the ethics of doing science (Is one free to inject unwilling subjects with a pathogen so as to gain valuable scientific insights? or What role should animal experimentation play in biology?). In that sense, scientific ethics is a branch of applied ethics. The term may also refer to whether or not the methods and assumptions of science can be applied to the subject matter of ethics. The present entry is concerned with scientific ethics in the second sense—Can there be a science of norms?

Scientific ethics in this sense is often argued to be an oxymoronic term. Science deals in empirical facts, discovering what *is* the case, while ethics deals in normative matters, uncovering what *ought* to be the case. A scientific ethics would thus commit the naturalistic fallacy of confusing what is with what ought to be. Historically speaking, however, this distinction is as much the exception as the rule. Premodern ethical systems, such as the virtue theories of Plato and Aristotle, did not couch the debate about what ought to be done in a way that made facts and norms *non-overlapping magisteria* (Gould 2002). To understand the relationships between science and ethics, it is useful to begin with some working definitions.

Defining Ethics and Science

Ethics is divided into descriptive, normative, and metaethics. *Descriptive* ethics is the study of empirical facts related to morality, such as how people think about norms, use norms in judgment, or how the norms themselves evolve. There is a rich tradition of organizing knowledge about these things scientifically, ranging from the field of moral psychology (focusing on how people reason about norms) to some forms of sociobiology (studying how norms arose on evolutionary timescales).

Normative ethics is an attempt to organize knowledge about what human beings ought to do or intend, or what kind of people they ought to be—it provides guidance and advice. The three major versions of normative ethics are virtue theory, utilitarianism, and deontology. A virtue theoretic approach, such as found in Aristotle, focuses on the nature of persons or agents. Are they flourishing—functioning effectively as human beings—or failing to flourish? Virtue theorists focus on states of character (virtuous or vicious) and how they affect the ability to live the best human life. Utilitarians, such as Jeremy Bentham (1748–1832) or John Stuart Mill (1806–1873), focus instead on the consequences of an action, rather than the character of the person committing it. Specifically they look at the amount of happiness caused (or unhappiness prevented), with the happiness of all counting equally. Deontologists, such as Immanuel Kant (1724–1804), focus on the nature of the action itself rather than its consequences. Certain actions express appreciation for, and are done in accordance with, the demands of duty, respecting that which is the foundation of morality: rationality and autonomy.

Metaethical questions consider the scope and nature of moral terms. Do ethical terms such as good and bad refer to facts about the world, or merely to states of emotion in people making judgments? Does ethics constitute *knowledge* or not; is ethical knowledge illusory? What is the structure of ethical arguments? It is less controversial that science may influence metaethical positions (although that position is also debated) than that there can be a science of normative ethics.

Science likewise comes in three forms. In the weakest sense, a science is an organized body of knowledge. If this is what is meant by science in relation to ethics, then a science of ethics certainly exists. The major moral theories just mentioned are attempts to bring some organization to what is known about morality.

Normally, though, science means something stronger and refers to a set of epistemological canons that guide inquiry. In one form, these canons are called *methodological naturalism:* the methods of inquiry used by an empirical science such as physics or biology. These include observation of the world, hypothesis formation, intervention and experiment, iterative formation and improvement of a theory, and more. Such activities are constitutive of the scientific method. If such methods can produce knowledge about norms, then a science of ethics is possible.

An even stronger form of science is *ontological naturalism:* Only those entities, events, and processes countenanced by the existing sciences may be used in theory construction. Methodological naturalism is a weaker form of science than an ontological naturalism. Consequently the possibility of an ethics grounded in ontological naturalism is more controversial.

In the weakest sense, ethics is a science if it can be organized into a coherent body of knowledge; in the moderate sense, ethics is a science if it can use the traditional epistemological canons of science to gain moral knowledge; and in the strongest sense ethics is a science if in addition to using the methods of science it also makes reference only to the entities and processes accepted by the extant, successful natural sciences. Only nihilists or radical moral particularists (those who contend that moral theory is so situation driven that general principles are impossible) would deny that there could be a science of norms in a weak sense. The moderate position is more controversial. Some would contend that moral knowledge is not gained using the empiricist methodology of the scientific method. For example, Kant's deontological theory does not require that humans reason empirically about morality; rather he maintains that they can know what they must do a priori independent of any particular experience. The strong position is the most controversial: Whether a normative theory can exist that differs neither in scope or content from the empirical sciences is debatable.

Naturalistic Fallacy

The argument offered most often against the possibility of scientific ethics in the moderate or strong senses is the naturalistic fallacy. First articulated by David Hume in *A Treatise of Human Nature* (1739), the naturalistic fallacy occurs when one moves from a list of empirical premises to a conclusion that contains a normative component. Hume is "surprised" when authors writing about ethics who were previously reasoning in the "usual way" suddenly begin to substitute "oughts" in places where before only the copula "is" had been present (Hume, Book III, Part I, Section I, Paragraph 24). Hume appears to point out a flaw in attempts to reason from the empirical to the normative—one will make reference to an unexplained term in a conclusion that was nowhere present in the empirical premises of the argument. Such an argumentative structure is invalid; the truth of the premises does not guarantee the truth of the conclusion. G. E. Moore advanced a similar argument early in the twentieth century when he argued that naturalized ethical systems fall prey to the *open question argument*. After one has identified normativity with a natural property such as avoidance of pain, for example, one can still meaningfully ask whether it is good to avoid pain. This means that utilitarians have not successfully reduced goodness to the natural property *avoiding pain*.

Whether or not the naturalistic fallacy and the open question argument provide *in principle* rationales against a moderate or strong scientific ethic is itself an open question. There are several possible responses. For example, both arguments rely on an analytic/synthetic distinction (a distinction between sentences true by definition and sentences true because of the way the world is), and many philosophers think no such distinction exists (see Casebeer 2003a). In addition, Hume's argument applies only to traditional deductive and inductive arguments. It may well be, though, that the relationship between natural ethical facts and the norms they deliver is *abductive;* one may best explain—abduction is often called *inference to the best explanation*—patterns of certain facts by assuming that they are also natural norms. Finally the open question argument probably does not generalize; it really amounts to saying that the two ethical systems Moore examines (Spencerian evolutionary ethics and hedonism) are not good natural ethical theories, and all but partisans would agree.

Why Scientific Ethics

Given disagreements about whether a scientific ethics in the moderate or strong sense is possible, why might people want such a thing? There are four possibly interrelated reasons. First science seems to some to have undermined traditional ethics, and hence human beings should use science to re-create ethics on firmer foundations. Second scientific ethics might be driven by concerns about the coherence of worldviews. Third scientific knowledge is the only real kind of knowledge. Fourth the sciences provide a prestige model, and in a highly scientific society people always try to imitate that which is of greatest prestige.

The first rationale may reflect a praiseworthy desire to reconsider long-standing issues in ethics from the perspective of contemporary science; for instance, what does contemporary cognitive science say about the existence of a free will, and what impact might this have on the conception of ethics? As another example, sociobiologists sometimes veer towards eliminativist extremes about the subject matter of ethics (morality is an illusion fobbed off on people by their genes). Strong scientific ethics thus might be a path to reconstruct what is purportedly illusory, whether it be a notion of agency compatible with the sciences or a scientific defense of the genuine objectivity of ethics.

The second rationale is closely related: Researchers may hold out hope that human knowledge can be unified. At the very least, they may ask that it be consistent across spheres of inquiry. Concerns about *consilience* can thus drive scientific ethics (Wilson 1975). The third and fourth rationales are strongly linked: If scientific knowledge is on a firmer footing than folk knowledge or nonempirical inquiry, then it is no wonder that funding and prestige would attach to scientific pursuits rather than not. Researchers in ethics may thus be attracted to the epistemic roots of science and the research support flowing from them. Sometimes this attraction leads to pseudoscientific ethics (just as it leads to pseudoscience), as in, for example, the work of Madam Vlabatsky's *theosophical scientific ethics* or in the eugenics movement. A thoughtful scientific ethics rejects pseudoscience and the pseudoethics that might follow.

Of course science advances, changing as time passes. Will attempts to connect science and ethics undermine the certainty some strive for in morality? They may, but this is no objection to the enterprise; it might be that the best one can hope for even in ethics is something like the *best guess hypothesis* offered by the practicing scientist.

Examples of Scientific Ethics

What might a moderate or strong scientific ethics look like? Herbert Spencer (1820–1903) claimed to offer such a theory in his work; he derived an evolutionary account of morality that is basically utilitarian in nature: If humans but allow the mechanisms of nature to do their work, there will be *natural social evolution* toward greater freedom. This will in turn lead to the greatest possible amount of happiness. While widely acclaimed during its time, Spencer's theory was ultimately rejected owing in part to its scientific inaccuracies, and to attacks upon it by Henry Sidgwick, Thomas Huxley, and G. E. Moore. At its worst, Spencer read repugnant norms into evolution; for example, here is what he said about Great Britain's Poor Laws, which mandated food and housing for the impoverished: "... there is an habitual neglect of the fact that the quality of a society is lowered morally and intellectually, by the artificial preservation of those who are least able to take care of themselves ... the effect is to produce, generation after generation, a greater unworthiness" (Spencer 1873 [1961], p. 313).

What might a more plausible scientific ethic look like? Such a theory might resemble that offered by the Greek philosopher Aristotle or the pragmatic philosopher John Dewey (1859–1952).

Aristotelian ethics is prescientific in the sense that the scientific revolution had not yet occurred; nonetheless, his method is empirical. For Aristotle, human flourishing is the *summum bonum* of existence; to say that an action is ethical or that a person is good is just to say that the action or the person contributes to or constitutes proper functioning. Contemporary ethicists have pursued this line of reasoning; for example, Larry Arnhart (1998) argues for a naturalized, Aristotelian ethical framework, and William Casebeer (2003a, b) argues that moral facts can be reduced to functional facts, with functions treated as an evolutionary biologist would (that is, as being fixed by evolutionary history). Leon Kass (1988) raises questions for such approaches; there are things that human passions and gut reactions say about the morality of certain actions that can never be captured with reason or the scientific method alone.

A related merging of science and ethics occurs in the work of the classic American pragmatists, such as Charles Pierce (1839–1914) and Dewey. Pierce argues that science itself is a form of ethics—it expresses respect for the values that underpin effective inquiry, and is subordinate to ethics insofar as it is human concerns about the efficacy of ideas that cause people to pursue science to begin with. Relatedly Dewey argues in his *Ethics* (1932) that the process of regulating ideas effectively—which is what science does in essence—enables human beings to become better able to express values and act upon them. This approach of replacing *preexisting value* with the creation of value and understanding what genuinely follows from that positing of value is called axiology (Casebeer 2003a).

Even if moderate and/or strong versions of scientific ethics seem implausible, almost everyone admits that scientific results may limit the possible space of normative moral theories. Only the most trenchant antinaturalist would think that facts about human beings and how they reason have absolutely no bearing on moral concerns. These facts should, at the very least, constrain moral theorizing. For instance, Owen Flanagan advocates the *principle of minimal psychological realism,* which states that the moral psychologies required by moral theories must be *possible* for humans: "Make sure when constructing a moral theory or projecting a moral ideal that the character, decision processing, and behavior prescribed are possible ... for creatures like us" (Flanagan 1991, p. 32). So the scientific study of the genesis, neurocognitive basis, and evolution of ethical behavior *is* relevant to normative moral theory *even if* the moderate and strong versions of scientific ethics are misguided or fail.

Contemporary Developments and Future Possibilities

There are five general areas in which scientific research has the potential to constrain moral theory: moral psychology, decision theory, social psychology, sociobiology, and artificial modeling of moral reasoning. Moral psychologists focus on the psychological processes involved in moral thought and action. They study such phenomena as *akrasia* (weakness of the will), moral development, the structure of moral reasoning, and the moral emotions. Some of the best known work in this area revolves around moral cognitive development; Lawrence Kohlberg, for example, has formulated an empirically robust theory of moral development whereby people progress through three stages of moral reasoning, each broken into two levels. In the first stage, one reasons by asking, What's in it for me? In the second, one asks, What does culture or society say? In the third, one asks, To what contract would I be a party? What do universal moral principles demand? Progress through these stages or schema is universal and (with some exceptions) invariant. If Kohlberg is right, then perhaps a normative moral theory that takes issues of justice seriously is more viable than one that does not (although his research has been criticized for this very reason; see Lapsley 1996 for a summary).

Other moral psychologists have been exploring the relationship between reason and moral emotions such as guilt or shame. One longstanding debate in moral theory has involved the relationship between having a moral reason to do something and whether that reason necessarily motivates an individual to take action. Internalists (such as Plato or Kant) argue that moral reasons necessarily motivate: If, morally speaking, one ought not to do something then one will, *ceteris paribus*, be motivated not to do that thing. Externalists (such as Aristotle) argue that a moral reason must be accompanied by an appropriate motivational state (such as an emotion) in order to spark action. If certain normative moral theories require either an internalist or externalist psychology in order to be plausible, then results from empirical research may constrain moral theory. For example, Adina Roskies (2003) argues persuasively that neurobiological data about the relationship between emotion and reason rules out internalism and makes a Kantian psychology implausible. Other issues in moral psychology will stand or fall with progress in the cognitive sciences; for instance, moral cognitive development and moral concept development may both be subsumed by research into cognitive and concept development in general.

Decision theorists study the determinants of human choice behavior. Traditional rational actor assumptions (such as possessing unlimited time and computational power, a well-ordered preference set, and indifference to logically equivalent descriptions of alternatives and choice sets) usually inform decision theory. Whether or not these assumptions apply to human reasoning when it is done well may affect whether normative moral theories must be essentially rational and hence whether they must respond to the same norms as those of reason traditionally construed. Much work in decision theory has revolved around either extending the predictive power of traditional rational actor assumptions, or in articulating alternative sets of rational norms to which human cognition should be responsive. For instance, Amos Kahneman and Daniel Tversky's (1982) heuristics and biases research program explores the shortcuts human beings take to achieve a reasonable result when under time pressure or when working with incomplete information. It may very well be that normative moral theories constitute sets of heuristics and biases.

Gerd Gigerenzer and the Adaptive Behavior and Cognition Research Group (2000) focus on ecological rationality, demonstrating that traditional rational canons can actually lead people astray in certain environments. While there is a rearguard action to shore up traditional rational actor driven decision theory, in all likelihood, progress on this front will require articulating a new conception of rationality that is ecologically valid and cognitively realistic. The results of this program may, in turn, affect the structure of normative moral theory in much the same way that the structure of normative rational actor theory has been and will be affected.

Social psychologists study human cognition and emotion in the social domain. Given that moral judgments are paradigmatically about how people ought to treat others, work in this area usefully constrains normative theorizing. One controversy regards whether or not the *fundamental attribution error* (the human tendency to undervalue the situational influences on behavior and overvalue the internal character-driven causes) undermines traditional approaches to virtue theory. If, as some social psychologists argue, there is no such thing as *bravery* as a general trait, but rather only such fragmented virtue-theoretic traits as *brave while standing in the checkout line at the grocery store*, then it may very well be that virtue theory will have to become much more sophisticated if it is to be plausible (see Doris 2002 for a comprehensive discussion, as well as Harman 2000; Doris and Stich 2003 also offer a useful survey). The social nature of moral reasoning means that the latest studies of social psychological behavior can, on the weakest view, usefully constrain normative theorizing, and on a stronger view can usefully coevolve with it.

Sociobiologists such as E. O. Wilson study the origin and evolution of (among other things) moral norms. They argue that genes keep moral culture on some sort of leash: At the very least, the capacities human beings use to reason about morality are evolved capacities and need clear connections to the environments in which these capacities evolved; maximally moral norms may be *nothing more* than norms that have enabled organisms and groups of organisms to increase their genetic fitness. Sociobiological approaches to human social behavior have been controversial, but have nonetheless shed much light on how both the capacity to reason morally and the structure of some moral norms came to be (Boehm 1999, for example, discusses the evolution of egalitarian norms). Game-theoretic work on the evolution of the social contract and other moral norms has illuminated aspects of ethical behavior ranging from the propensity to be altruistic to the temptation to defect on agreements in certain instances. Sociobiological study reinforces the notion that any accepted normative theory should have a describable evolution and a discernable way of maintaining its existence (see Binmore 1994).

Computer models at both the micro and macro level have usefully informed all these fields of research. Changes in technology have influenced what philosophers make of the possibility of scientific impact on ethics. For example, Rene Decartes's inability to reconcile how mental states could be identical to brain states drove, at least in part, his dualism. The advent of in vitro methods for identifying the neural machinery of cognitive activity, such as Positron Emission Tomography (PET) and functional Magnetic Resonance Imaging (MRI), may have headed off dualism at the philosophic pass if such technologies were available during his time. The spread of inexpensive and powerful computing technology has made possible everything from the simulation of artificial societies (and hence has influenced sociobiological approaches) to the simulation of moral reasoning in an individual (and hence has influenced moral psychology). On the social simulation front, promising work by Jason Alexander and Bryan Skyrms (1996) on the evolution of contracts has usefully informed moral theorizing. On the individual level, work by cognitive modelers such as Paul Thagard (2000) and Paul Churchland (2001) has highlighted areas where normative moral theory can intersect with cognitive modeling.

Assessment

Is scientific ethics possible? Appropriately enough, this is an empirical matter. Should the promise held out by the rapidly progressing cognitive, biological, and evolutionary sciences be realized, there is reason to be sanguine about the moderate and strong programs for a scientific ethic. Science could reaffirm some of the prescientific insights into the nature of morality. But even if this very possibility is a misguided hope, scientific insights into human nature and cognition can usefully constrain the possible space of normative moral theory, and in this sense the existence of scientific ethics is a foregone conclusion. Science and ethics are indeed both magisterial, but they are, ultimately, overlapping.

SCIENTIFIC INTEGRITY

SEE *Research Integrity*.

SCIENTIFIC REVOLUTION

In the first half of the twentieth century it became a commonplace notion that modern science originated in a seventeenth-century "revolution" in thought precipitated by a new methodology for studying nature. In the last third of the twentieth century, a consensus developed among historians, philosophers, and sociologists of science that the emergence of modern science was more evolutionary than revolutionary. Furthermore, while modern science for 300 years claimed that its methodology generated value-free, objective knowledge, the late-twentieth-century consensus was that, implicitly and explicitly, the practice of science incorporated moral, ethical, and social value judgments.

The Seventeenth-Century Achievement

A fundamentally new approach to the study of nature did indeed emerge in seventeenth-century western Europe. The first herald of this development was Francis Bacon (1561–1626), who argued for a renovation in the human conception of knowledge and of knowledge of nature in particular. Especially in his *Novum Organum* (1620; New instrument [for reasoning]), Bacon formulated a radically empirical, inductive, and experimental-operational methodology for discovering laws of nature that could be put to use to give humankind power over nature. Bacon was primarily a social reformer who believed that knowledge could become an engine of national prosperity and power, improving the quality of life for all. To that end, he championed widespread education for all classes of society, featuring a strong mechanical-technical component that would assure widespread ability to create and maintain technological innovations. (The island of Laputa episode in Jonathan Swift's novel *Gulliver's Travels* (1726) mocks the Baconian faith in science-based innovation as improving the quality of life.)

Bacon was strongly opposed to mathematical accounts of natural phenomena, seeing in them a continuation of Renaissance magical nature philosophy and an erroneous commitment to deductive reasoning. René Descartes (1596–1650) by contrast, especially in his *Rules for the Direction of the Mind* (written 1628, but not published until 1701) and *Discourse on Method* (1637), roughly contemporary with Bacon's *Novum Organum*, articulated a mathematical and rigorously deductive, hence rational methodology for gaining knowledge of nature that employed experiment only to a limited degree and cautiously, because experimental results are ambiguous and subject to multiple interpretations. Descartes's own theory of nature was mechanistic, materialistic, and mathematical, hence deductive and deterministic. It became the basis for the mechanical worldwiew that was incorporated into enlightenment thinking and epitomized the view of nature as a clockwork world. Unlike Bacon, Descartes was a practicing researcher and a mathematician. He introduced analytical geometry—enabling algebraic solution of geometric problems—developed a materialistic cosmology in which the solar system and Earth formed naturally, discovered the reflex arc in his anatomical researches, developed a mechanical theory of life and biological processes, and wrote influentially on mechanics and optics, formulating his own theory of light.

Galileo Galilei (1564–1642), in his *Dialogues Concerning Two New Sciences* (1638), presented a deductive mathematical-experimental methodology that he attributed to Archimedes (c. 287–212 B.C.E.), several of whose treatises were translated into Latin and circulated widely beginning in the second half of the sixteenth century. In this work Galileo founded engineering mechanics and the mathematical theory of strength of materials, and he also extended and corrected earlier contributions to the science of mechanics (while perpetuating the mistaken notion that circular motion was "natural" and hence force-free). This work supplemented his more famous discoveries in astronomy based on his pioneering application of the telescope to the study of the moon and planets, and his defense of Copernicanism, the Sun-centered cosmological theory of Nicolaus Copernicus (1473–1543).

The Newtonian Triumph

Galileo's methodology probably comes closest to what people mean when they refer to "the scientific method" and its invention in the seventeenth century. It reached its mature form in the hands of Isaac Newton (1642–1727) in the last third of the century. In all of his work, but especially in his majestic *Mathematical Principles of Natural Philosophy* (1687), considered the single most influential scientific text ever, and in *Optics* (1704), Newton synthesized induction and deduction, mathematics, and experimentation into a powerful methodology capable of revealing, in his view, the hidden "true causes" responsible for the phenomena of empirical experience. Like Descartes, whose methodology (and theories) he dismissed contemptuously, Newton made major contributions to mathematics, inventing, independently of Gottfried Wilhelm Leibniz (1646–1716), the calculus; to optics, inventing the reflecting telescope, discovering the phenomenon of diffraction and the seven-color composition of sunlight, and formulating a corpuscular, or particle, theory of light that would be dominant until the wave theory of light gained ascendance in the nineteenth century; to mechanics, in his famous three laws of motion; and to a theory of the universe based on his universal theory of gravitation, which provided a full account of the planetary orbits, confirming the validity of the earlier, scattered insights of Johannes Kepler (1571–1630).

Contrary to Descartes, who believed that matter was infinitely divisible, Newton favored an atomic theory of matter, and based physics and chemistry on a variety of forces acting nonmechanically and/or at a distance, rather than basing it only on mechanical contact forces. Newton's scientific style and his accomplishments represent the peak achievement of the seventeenth-century Scientific "Revolution." Until the mid-eighteenth century, many Continental natural philosophers—the term *scientist* was invented only in the 1830s—remained committed to Descartes's strictly mechanical model of scientific explanation while rejecting Descartes's particular theories. After that, Newtonianism effectively defined "modern" scientific study of nature until the early twentieth century and the rise of relativity and quantum theory.

By the end of the seventeenth century, then, modern science was firmly established, not only in mathematical physics and astronomy, but as a comprehensive philosophy of nature that was deterministic and materialistic, though explanations incorporated immaterial forces—such as gravity, electrical and magnetic attraction/repulsion, and selective chemical affinity—that acted according to strictly mathematical laws. This materialistic-deterministic approach to nature was broadly applied to biological and medical phenomena, especially in Italy and at the University of Padua, as reflected in William Harvey's (1578–1657) demonstration in 1628 of the closed circulation of the blood pumped by the heart and by the Galileo-influenced work of Giovanni Borelli (1608–1679) and others on the mechanics of the human skeletal and skeletal-muscular systems.

Even more than the telescope, the mid-seventeenth-century invention of the microscope by Antoni van Leeuwenhoek (1632–1723) revealed the existence of new worlds. The demonstration by Blaise Pascal (1623–1662) and Evangelista Torricelli (1608–1647) of the mechanical pressure exerted by the atmosphere using a simple barometer, which also showed that a vacuum could be created, strongly reinforced the mechanical conception of nature. A critical contribution to the new philosophy of nature was Christiaan Huygens's (1629–1695) midcentury demonstration that circular motion required a force to maintain it, contrary to the previous 2,000 years of Western thought. Descartes and Galileo both misunderstood this fact, which became a cornerstone of modern mechanics in Newton's principle of inertia. By the rise of the enlightenment in the second half of the eighteenth century, an amalgam of Descartes's mechanical worldview Cartesian mechanism and Newtonian deterministic mathematical physics was applied to society and its institutions, for example, by the Baron de Montesquieu (1689–1755), Anne-Robert-Jacques Turgot (1727–1781), and the Marquis de Condorcet (1743–1794) in France, and even to the human mind, for example, by David Hume (1711–1776) and Étienne Bonnot de Condillac (1715–1780).

Newtonianism Dethroned

In the nineteenth century, Newtonianism was severely challenged, and in the twentieth century it was displaced. The relationship between increasingly abstract mathematical models of nature and "reality" became an issue. The models worked empirically, but did they also provide a picture of reality? Meanwhile, the wave theory of light overthrew Newton's corpuscular theory and when incorporated by James Clerk Maxwell (1831–1879) into an electromagnetic field theory of energy led to attributing causal efficacy to space-filling immaterial entities. The introduction of the concept of energy on a par with matter diluted the deterministic materialism of modern science, while the new science of thermodynamics revealed that Newton's conception of time was flawed. Finally, with the kinetic theory of gases, statistical explanations were introduced into physics, which called determinism into question. With relativity and quantum theory, from 1905 on, Newtonian conceptions of space, time, matter, force, cause, and explanation, and Descartes's deductive model of rationality would all be replaced, and a fundamentally new form of science and a new, statistical conception of reality would emerge.

Seventeenth-century nature philosophy had presented itself as a body of impersonal knowledge, as simply descriptive of the way things were "out there," independent of personal, social, and cultural values. Given the religious wars of the first half of the seventeenth century, and the explicitly values-steeped character of Renaissance nature philosophy, this was a major epistemological innovation. The value-free character of the knowledge was guaranteed, it was thought, by a methodology employed in acquiring it that eliminated the influence of the subject on knowledge. However attractive such a conception of knowledge was then and continued to be through the nineteenth century, it created a gulf between facts and values, between knowledge and its applications, that in principle could not be bridged by reason, which increasingly came to be defined as reasoning in the scientific (hence objective) manner.

Bacon tacitly assumed that people would know what to do with the new mastery of nature that scientific knowledge would give them. But already by the mid-seventeenth century, the educational reformer John Amos Comenius (1592–1670) was warning that the new science was as likely to create a hell on Earth as a manmade heaven if application-relevant values were not explicitly linked to knowledge. In fact, right through the twentieth century and into the twenty-first, modernism, first in the West and then globally, has borne witness to the accuracy of Comenius's warning. While the scope and explanatory/predictive power of science in the nineteenth and twentieth centuries increased dramatically and became the basis of life-transforming technological innovations, there was no commensurate increase in conceptual "tools" for identifying which innovations to implement or how to implement them. Elimination of any influence on knowledge of the values held by the subject of knowledge eliminated any influence of knowledge on the values held by subjects!

As a result, even as science and technology became, after 1800, the primary agents of social change around the world, scientists and engineers remained outsiders to the terms of that change, which was driven overwhelmingly by scientifically nonrational political and market values. Both government funding of scientific research, especially in the United States after World War II, and industry dependence on science for technological innovations blurred the distinction between pure and applied science, reinforcing the post-1960s critique of science as in fact a value-laden ideology and not objective knowledge.

SCIENTISM

Scientism is a philosophical position that exalts the methods of the natural sciences above all other modes of human inquiry. Scientism embraces only empiricism and reason to explain phenomena of any dimension, whether physical, social, cultural, or psychological. Drawing from the general empiricism of the Enlightenment, scientism is most closely associated with the positivism of Auguste Comte (1798–1857), who held an extreme view of empiricism, insisting that true knowledge of the world arises only from perceptual experience. Comte criticized ungrounded speculations about phenomena that cannot be directly encountered by proper observation, analysis, and experiment. Such a doctrinaire stance associated with science leads to an abuse of reason that transforms a rational philosophy of science into an irrational dogma (Hayek 1952). It is this ideological dimension that is associated with the term *scientism*. In the early twenty-first century the term is used with pejorative intent to dismiss substantive arguments that appeal to scientific authority in contexts in which science might not apply. This overcommitment to science can be seen in epistemological distortions and abuse of public policy.

Epistemological scientism lays claim to an exclusive approach to knowledge. Human inquiry is reduced to matters of material reality. We can know only those things that are ascertained by experimentation through application of *the* scientific method. And because *the method* is emphasized with such great importance, the scientistic tendency is to privilege the expertise of a scientific elite who can properly implement the method. But the science philosopher Susan Haack (2003) contends that the so-called scientific method is largely a myth propped up by scientistic culture. There is no *single* method of scientific inquiry. Instead, Haack explains that "scientific inquiry is contiguous with everyday empirical inquiry" (p. 94). Everyday knowledge is supplemented by evolving aids that emerge throughout the process of honest inquiry. These include the cognitive tools of analogy and metaphor that help to frame the object of inquiry in familiar terms. They include mathematical models that enable the possibility of prediction and simulation. Such aids include crude, impromptu instruments that develop increasing sophistication with each iteration of a problem-solving activity. And everyday aids include social and institutional helps that extend to lay practitioners the distributed knowledge of the larger community. According to Haack, these everyday modes of inquiry open the scientific process to ordinary people and they demystify the epistemological claims of the scientistic gatekeepers.

The abuse of scientism is most pronounced when it finds its way into public policy. A scientistic culture privileges scientific knowledge over all other ways of knowing. It uses jargon, technical language, and technical evidence in public debate as a means to exclude the laity from participation in policy formation. Despite such obvious transgressions of democracy, common citizens yield to the dictates of scientism without a fight. The norms of science abound in popular culture, and the naturalized authority of scientific reasoning can lead, if left unchecked, to a malignancy of cultural norms. The most notorious example of this was seen in Nazi Germany where a noxious combination of scientism and utopianism led to the eugenics excesses of the Third Reich (Arendt 1951). Policy can be informed by science, and the best policies take into account the best available scientific reasoning. Lawmakers are prudent to keep an ear open to science while resisting the rhetoric of the science industry in formulating policy. It is the role of science to serve the primary interests of the polity. But government in a free society is not obliged to serve the interests of science. Jürgen Habermas (1978) warns that positivism and scientism move in where the discourse of science lacks self-reflection and where the spokespersons of science exempt themselves from public scrutiny.

SECULARIZATION

Secularization is a concept important to science, technology, and ethics, because it encapsulates influential general theories about how moral influence may be exercised over and by science and technology under different historical and social conditions.

Most societies incorporate practices, beliefs, and institutions that correspond roughly to the domain of religion in modern Western cultures. These religious features presuppose the existence of non-human entities with powers of agency (i.e., gods) or the existence of impersonal powers endowed with moral purposes (i.e., karma). Moreover they generally assume that these non-human agents or powers have an impact upon human affairs. Secularization is a process by which religion comes to have decreasing importance in society along several dimensions.

First there is a decline in the status, prestige, and power of persons, practices and institutions associated primarily with religion. Second there is a decline in the importance of religion for the exercise of non-religious roles and institutions, including those associated with politics and the economy. Third there is a decline in the number of persons who take religion seriously and the degree of seriousness with which those involved in religion continue to take it. Secularization is highly correlated with the extent of industrialization in a society and with the development of scientific practices and institutions. But there is serious disagreement regarding whether secularization is largely a consequence of the growth of science and industry; whether science, industrialization, and secularization are relatively independent features of a more general process of modernization; or whether secularization is a prerequisite rather than a consequence of the growing importance of science in a society.

Three Theories of Secularization

Though he did not use the term, Auguste Comte (1798–1857) offered the first major theory of secularization in articulating what he called his law of three stages in his Positive Philosophy, developed in the 1820s. According to Comte every domain of knowledge passes through three progressive stages—a religious phase in which aspects of the universe are anthropomorphized (that is, human attributes including will and agency are projected onto non-human entities), a metaphysical phase in which impersonal forces (such as gravitational or electrical forces) are presumed to cause effects in the world, and a positive or fully scientific stage in which abstract causal explanations of events are abandoned in favor of general descriptive laws. Within Comte's system the rise of more reliable scientific knowledge drives out inferior religious belief; so secularization is a natural and necessary consequence of the rise of science. Even some sociologists of religion at the end of the twentieth century, such as Rodney Stark, retain a strong element of this positivist vision.

A near mirror image of the positivist view combines elements from the works of Early Modern historians such as Stephen McKnight and modern historians such as Howard Murphy. In their view Christian Humanism in the Renaissance focused Christian concerns on the amelioration of the human condition, encouraging the growth of science for the purpose of manipulating nature to serve human ends. Such views were strongly supported by Tomasso Campanella (1568–1639) in Italy, Johann Andreae 1586–1654> in the Germanies, and by Francis Bacon (1561–1626) in England. Later, when many intellectuals became disillusioned with organized religion because of the religious wars on the continent or because of the failure of institutionalized religion to promote causes of social justice, they turned to science as an alternative source of values that could improve peoples lives. From this perspective, science in Europe was nurtured within a religious context and then became the beneficiary of secularizing trends that emerged first within the Christian community itself.

A third relatively simple explanation of secularization derives from an evolutionary understanding of religion prominent among anthropologists such as Roy Rappaport and David Sloan Wilson. From this perspective religions serve primarily to establish group cohesion and social solidarity by promoting altruistic rather than individualistic behaviors. The growth of commercial economies tended to break down cooperative tendencies within societies, to promote in-group competition and individualism, and simultaneously to encourage inter-group cooperation and culture contact. As a consequence the local authority of religion was undermined both internally, as egoistic, liberal, ideology increasingly governed forms of behavior, and from the outside, as it became clear that many varieties of religion existed in other societies without subverting the functioning of those societies.

Twenty-First Century Perspectives on Secularization

Most social scientists at the beginning of the twenty-first century accept variants of a more complex account of secularization developed by Peter Berger and David Martin that grew out of the ideas of Max Weber (1864–1920). Within this account there are at least three interacting strands. One is a rationalizing trend that seems to emerge in monotheistic religions, especially those which, like Christianity, incorporate a transcendent God and therefore encourage attempts to understand the natural world without reference to specific instances of divine agency, and likewise grant human agency a predominant role in human affairs. Science and technology thus become consequences of the implicit rationality of transcendent monotheism. This rationalizing strand would not necessarily by itself significantly reduce the authority of religion, but interacting with the others it does.

The second strand is a socioeconomic strand that begins from the Weberian claim that the protestant ethic promoted the rise of industrial capitalism. Industrial capitalism in turn encouraged the division of labor and promoted social differentiation into classes, breaking down the social homogeneity of pre-modern society and creating social and cultural diversity. The division of labor also transformed many social roles, which had once had important religious components, into specialized secular roles. Thus educators, health care professionals, government functionaries, and other professional groups developed specialized knowledge and institutions, creating new and non-religious sources of power and authority. Furthermore the breakdown of social homogeneity undermined the sense of communally shared values inculcated by religious practices and institutions.

Finally the Protestant Reformation promoted a sense of individualism that created a tendency for religious schism, the proliferation of competing sects, and a sense of religious relativism that was only exacerbated by culture contact with non-Christian cultures. One consequence of this relativism was the separation of Church and State, which found its most explicit separation in the first amendment to the U. S. Constitution. All of these tendencies—toward rationalization, science, and technological development; toward social differentiation and diversity; and toward religious pluralism—promoted the declining importance of religion relative to secular factors in promoting and controlling human activities. That is they all contributed to secularization.

In spite of such theories of secularization, it is clear that many issues associated with twenty-first century science and technology—from abortion to cloning, from nuclear weapons to internet piracy—are subject, even in such ostensibly secular societies as that of the United States, to religious interest-group influence. Thus the extent to which secularization adequately describes the general trend that shapes the context in which scientific, technological, and ethical interactions occur remains open to debate. There are even some proponents of cultural diversity and advocates of alternatives to modern European and North American industrial culture, who admit the importance of secularization, but who oppose the hegemony of the modern science and technology of those cultures and argue for a *re-enchant-*

ment or re-sacralization of the world. These persons point to such earth-centered spiritual traditions as those of Native Americans, as models that might promote a healthier and ultimately a more sustainable science and technology.

SECURITY

Security has many dimensions, depending on the situation. People secure boats by tying them to a dock, secure loans from financial institutions, or secure promises with a handshake. People feel less secure, or insecure, when they doubt their own abilities, when they lose their privacy, when a thief steals their wallet or purse. Thus, security is a psychological as well as a physical state of feeling—as well as being—protected from loss, breach of trust, attack, or any real or perceived threat.

The word *security* is widespread and appears in many contexts, from the United Nations Security Council and the nuclear and environmental security councils worldwide to national security, social security, and neighborhood security watch groups formed to keep homes safe from burglars. The term has become enshrined as well in the Department of Homeland Security, which describes itself as working "to keep America safe" with one program slogan of "Don't be afraid, be ready." Closely related terms include *safety* and *fear*. Fear is a feeling, not always rational, of agitation and anxiety caused by the perception of danger. In the United States, in 2001, about 1,000 people died from airliner accidents, including those who died in the crashes of September 11, 2001, while in the same year, more than 42,000 people died in automobile crashes. Yet after the September 11 attacks, many people refused to fly and opted to drive. They no longer felt secure in airliners, even though they faced greater risk on the roads.

Pursuing Security

In between self-reliance and the appeal to religion (which places ultimate "security" in the divine), the most general efforts to enhance security involve science, technology, and politics. Many scientists, for instance, argue that insofar as fear arises from ignorance, scientific explanations of phenomena reduce superstition and increase understanding, thus promoting security through knowledge.

From earliest times human beings have also depended for their very existence on the technologies of food gathering, production, and preparation, as well as those that provide clothing and shelter. Technology, especially in the form of medicine, has a long history of combating the insecurity of disease. Virtually all forms of engineering propose to render human productivity and products more secure.

To protect technological gains, however, provisions for political security are a further requirement. The rise of the first civilizations was closely associated with the development of technologies of military security. In order to obtain civil security, people have even given their allegiance and surrendered their rights to emperors, kings, and governments. According to the English philosopher Thomas Hobbes in the *Leviathan* (1651), this compact between people and leaders is necessary because people naturally lack traits that would ensure mutual security. For Hobbes, people are essentially selfish creatures with no concern for or connection to one another. Because humans are largely unsuccessful and constantly warring, they trade away their freedom and individuality in order to gain stability, law and order, a predictable future, leisure, and enjoyment. While other philosophers take a less dim view of human nature, all agree that security is essential for society, production, trade, and culture.

Hobbes and other early modern philosophers also argued that state security would not only protect technological achievement but also promote it, and that security could be enhanced by turning those desires for material welfare that might otherwise lead to warfare between nations to a general warfare against scarcity. Although the pursuit of security thus plays important roles in virtually all modern technologies, the more explicit appeals to security are undoubtedly found in the discussion of computers and the military.

Computer and information professionals are at the front line of ensuring the confidentiality, integrity, operability, and availability of information systems and data. Under the umbrella of those words come physical threats stemming from floods, hurricanes, sandstorms, and other natural disasters, as well as unintentional harm from careless use, and of course intentional harm from thieves, hackers, or terrorist attack. The focus of computer and information security often narrows to the means, such as encryption, passwords, and biometrics, rather than examining the motivations and goals of security. Among the many dimensions of this broader field are various levels of security, false senses of security, intrusive burden of security, and much more.

It is particularly important to differentiate between the *ordinary* and the *national* levels of security (Nissenbaum, Friedman, and Felten Internet article). The ordinary level comprises assurance of safety from the threats mentioned above, such as natural disasters, human error, or unwanted trespass. Computer and information professionals take what measures they can to protect from ordinary threats.

The national level, however, includes more extraordinary measures of action. In the name of national security, nations pursue extreme measures. As Helen Nissenbaum, Batya Friedman, and Edward Felten described it,

> The cause of national security can be parlayed into political measures as well: a lifting of typical restraints on government activities and powers, especially those of security agencies. We may see also a curtailing of certain freedoms (e.g. speech, movement, information), a short-circuiting of certain normal democratic processes (e.g. those in the service of openness and accessibility), and even the overriding of certain principles of justice.

Thus, in some instances, ordinary security is trumped by national security, and the individual is left with fewer rights and feeling less, not more, secure. For example, national identity cards have only limited potential to enhance security but also entail an array of serious risks and other negative characteristics (Weinstein and Neumann 2001). Governments might impose national identity cards and people might agree to them out of fear, rather than out of a rational need.

Specific Issues of Computer and Information Security

In most areas, governments, institutions, and manufacturers give people visual reassurance that they are protected from harm. Security is signified by armed guards standing at a checkpoint, childproof tops on pharmaceutical products, and locks on doors, windows, and cars. Banks are often solid structures, giving depositors the reassurance that their funds are safe. Screen savers can be password protected, although breaking through such protection is trivial. Whether effective or not, these measures calm and reassure people.

In the realm of computers and information, the physical and psychological aspects of security are more elusive, because the digital world is often devoid of the visual cues that lead people to feel secure. How can a user know that a document has not been altered, that no one has eavesdropped on a conversation, that an order comes from a real customer? Challenges include authenticating data and users, maintaining data integrity, and ensuring the confidentiality of communication.

The lack of transparency of technological devices easily renders end users both insecure and dependent. Although this is a problem associated with many technological appliances such as radios, refrigerators, and air conditioners—devices that few can repair or even explain—the lack of "transparency" is peculiarly salient in computers, which are themselves increasingly integrated into other devices—to make the DVD player, car, or toaster "smart," but leaving the users feeling powerless and "dumb." When devices make people feel dumb, they also make them feel less secure.

What about the security threats of private spyware products? Not only do people have to be worried about governments or corporations spying on them, increasingly individuals have available sophisticated technologies for spying (spouses on each other, parents on kids, and so forth).

Another (closely related) issue: False security is provided by deleting computer documents, as some criminals have discovered to their chagrin. Computer professionals can recover many deleted files, even of non-criminals.

Security measures themselves can become burdensome, as when users have too many passwords to remember. Fear focused on one area may leave another more vulnerable. Indeed, professionals who concentrate too narrowly on the machine and wires and airwaves may overlook the danger of a disgruntled employee or an electromagnetic weapon. Research by Rebecca Mercuri into the dangers of electronic voting provides a cautionary tale, for this perceived cure for election errors and interference may result in the potential for even greater fraud.

Thus computer and information security are elusive goals that professionals aim to attain through technological fixes such as encryption, firewalls, and restricted networking. Sometimes these efforts are undertaken because of actual attacks and interference, and sometimes they are applied to allay fear or provide users with a sense of security.

Basic Issues of National and Military Security

The second most common area in which questions of security play a prominent role is that of national and military security. During the Cold War (1945–1990) the primary national security issue was nuclear weapons, and spies were sent into countries to learn more about them. Attempts to enhance nuclear weapons security and safety involved both controlling scientific knowledge that might be of use to an enemy, especially by means of secrecy, and engaging scientists and engineers in the development of technologies thought to enhance national security, technologies that ranged from "fail-safe" command and control techniques to monitoring and surveillance devices. The demand for secrecy in some scientific research was nevertheless often argued to be a distortion of the scientific ideal, insofar as this ideal is committed to the production of shared knowledge. Indeed, some scientists argued that secrecy was actually counterproductive, and that greater security could be had through more openness in science.

As for spies, in the United States there were witch-hunts and other wide-ranging and over-reaching investigations by government that ruined the careers of innocent people and left many feeling insecure and vulnerable. The McCarthy hearings of the early 1950s involved telephone wiretaps and other intrusive acts used on innocent people.

With the end of the Cold War, the promotion of secrecy in science in the name of national security became less pronounced, but was sometimes replaced with the promotion of secrecy in science and technology in the name of corporate security and economic competitiveness. Then, with the advent of the so-called war on terrorism (2001–), needs for secrecy and control in science for national security reasons again became a prominent issue.

One specific example concerns biodefense and the boom in building high-security "hot labs" where the deadliest germs and potential bioterrorist weapons can be studied. Although the need for level 3 and level 4 biosafety labs and associated security measures are real, scientists such as David Ozonoff at the Boston University School of Public Health worry that there may be insufficient safeguards "to prevent work that violates the ethical standards of the scientific community" (Miller 2004). Stanley Falkow of Stanford University has even decided to destroy his own plague cultures rather than work under the new security regulations, pointing out the danger of security driving away talent (Miller 2004).

As these and other examples show, security needs will not abate, for they are deep in the human psyche and are built into the contract between people and their governments. Keeping security measures in balance with other values, such as freedom of speech and the pursuit of knowledge, poses a continuing challenge.

SELFISH GENES

Evolutionary biologists increasingly accept that genes are *selfish*. But what does this mean? Clearly genes do not have personal motivations, and even if they did, they could not achieve their designs without cooperation of the bodies in which they reside. In the most general sense, genes are merely blueprints, or, better, recipes, for the production of proteins. As such they influence the anatomy and physiology of living things including not only structural proteins but also enzymes and other factors that underlie the functioning of organisms. Genes ultimately affect the structure of kidneys, as well as the structure of nervous systems. Genes thus influence kidney function, just as they influence central nervous system function. When the central nervous system functions, behavior results. In this sense, genes are intimately connected to behavior, no less than they are to the physiology and structure of our internal organs.

Organisms are typically rather short-lived. Although they occupy the most obvious stage of the ecological and evolutionary theater, and natural selection appears to act on organisms whenever some reproduce differentially relative to others, the fact remains that natural selection among organisms is only important in the evolutionary sense insofar as it results in the disproportionate replication of some genes relative to others. Individual bodies themselves do not persist in evolutionary time; genes do. In fact genes are potentially immortal whereas bodies are not.

Selfish Genes and Modern Genetics

At the time of Charles Darwin (1809–1882), genetics was unknown, and so the focus of early evolutionary biology was on bodies. With the rise of Mendelian genetics and, subsequently, the field of population genetics, it became possible to trace the consequences of differential reproduction on their ultimate units, the genes themselves. Recognition of DNA as the genetic material, along with identification of its structure and the rise of modern genomic technology, has enhanced our understanding and also clarified the importance of focusing on these crucial units. When a hippo or a human being has a certain fitness, this means that his or her DNA is projected into the future with a given degree of success.

The term selfish, in relation to genes, is no more than a useful verbal short-hand. Selfishness simply refers to success in contributing to a particular gene's own replication. Natural selection rewards those genes that produce a *successful body* by causing more of the genes that influence the production of that body to be projected into the future. In this regard a successful body is one that metabolizes efficiently, that pumps blood successfully, that regulates its internal environment in a way conducive to life, and that also behaves in a manner that maximizes its success in reproducing, and/or in contributing to the reproduction of its component genes in the other major way available to it: by contributing to the success of genetic relatives, with the importance of each relative devalued in proportion as it is more distantly related (i.e., in direct proportion as a gene in a subject individual is likely to be present, by shared descent, in the body of another).

A key event in the development of selfish gene thinking was the recognition by British geneticist William Hamilton (1936–2000) that reproduction itself is only a special case of the more general phenomenon whereby genes contribute to their own replication. In a sexual species, reproduction occurs at some cost to the parent—in time, energy, risk—for which the sole evolutionary payoff is that each of the parent's genes has a 50 percent probability of being present in each offspring, and thereby are given a boost into succeeding generations. Hamilton observed that although reproduction is not normally considered selfish, in fact it is, at the level of genes. Moreover it is only because of the selfish payoff to the genes in question that reproduction is favored by natural selection in the first place!

Unlike the usual, negative implication of the word selfish, when applied to the attributes of genes, the term has no direct ethical implications. Living things are considered to behave in a manner that maximizes their *inclusive fitness*, which is simply the net effect of an act on identical genes present in other bodies. As a result selfish gene theory suggests that behavior that is selfish at the gene level typically involves actions that are *altruistic* at the level of bodies.

Hamilton effectively demonstrated that much seemingly altruistic behavior can be explained by this gene-centered perspective. Individual genes can promote their evolutionary success not only by helping produce offspring—new bodies within which some of these genes will reside—but also by contributing to the success of other individuals that have a probability of containing the genes in question. These other individuals are genetic relatives; indeed, a genetic relative is *defined* as an organism with an above-average probability of containing genes already present in a designated individual. For example, alarm-calling, whereby individuals who sense an approaching predator announce their discovery, that is directed preferentially toward genetic relatives. This can be selected for even if it reduces the likely survival of the alarm-caller so long as it increases the prospects that these relatives—and the alarm-calling genes within them—will survive and reproduce.

British biologist Richard Dawkins has been especially successful in explaining and popularizing this perspective, notably through his highly influential book, *The Selfish Gene* (1989). Dawkins argued that genes are essentially *replicators* whose biological role is to make additional copies of themselves. Those that succeeded in doing so went on to write the continuing history of life. Whereas early in evolutionary history replicators presumably floated freely in an *organic soup*, as natural selection continued, some discovered—quite by chance—that they were more successful by surrounding themselves with cell membranes and eventually, by aggregating together into multicellular bodies. Accordingly these bodies served, and still serve, as mere survival vehicles for the replicators.

This view is counter-intuitive because human beings subjectively experience themselves as the center of their own worlds, and therefore assume that their bodies—and not their genes—are equally the center of evolutionary concern. But bodies do not persist through evolutionary time. Although bodies can be selected for in the very short term, in that certain individuals are more reproductively successful than others, in the long term, these bodies are only vehicles for the differential success of their constituent genes, which replicate by virtue of the actions of the bodies in which they are enclosed.

Selfishness versus Altruism: A False Dichotomy

Critics of sociobiology and evolutionary psychology—both of which disciplines have been strongly influenced by the concept of selfish genes—often assume that this perspective implies that selfishness is more natural than altruism. The assumption has two significant flaws. First it suggests that identifying a trait as natural means that it is necessarily good, a view that was criticized by English philosopher David Hume (1711–1776), and, in the twentieth century, by philosopher George Edward Moore (1873–1958), who emphasized that *is* does not necessarily imply *ought*. Moore called this the *naturalistic fallacy*, and he argued that it is not philosophically or ethically defensible. Although many biologists—including Darwin—have maintained that morality is rooted in a natural moral sense, it is one thing to see morality as somehow deriving from one's biological heritage, quite another to validate behavioral tendencies simply because they are *natural*. It may be natural to respond violently to frustration, or in certain situations of competition, but is debatable whether in such cases, *naturalness* confers any ethical legitimacy.

Second, the suggestion that selfishness is somehow more natural than altruism ignores the crucial recognition that underlies all of selfish gene theory: the biological reality that genes cannot and do not behave in a vacuum, but only in the context of bodies. As such when a gene predisposes its body to behave selfishly (from the perspective of the gene), it often does so by inclining that *self* to act altruistically at the level of bodies. When parents provide food for their offspring, defend them against predators, or invest time and energy in their training, they may well be acting selfishly at the level of shared genes between parent and child, but altruistically insofar as individuals are behaving benevolently toward one another. Accordingly selfish genes need not behave selfishly!

The technology of cloning, stem cell research, and allied genomic sciences—including the identification of the human genome—has made considerations of human genes increasingly real. When developmental geneticists or evolutionary theorists speak of genes, they are increasingly able to speak authoritatively about specific DNA sequences, on identifiable chromosomes. It nonetheless does not seem likely that technology will permit the isolation of specific selfish or altruistic genes because selfish behavior does not exist as such, but rather, as a constituent of other characteristics and tendencies. For example, as discussed above, alarm-calling, which is a common textbook example of animal altruism, enhances the likely survival of others but at some increased risk to the alarm-caller. Alarm-calling need not be a result of generalized altruistic tendencies; rather it could derive from enhanced watchfulness due to anxiety, or even more acute eyesight, or a greater tendency to scan the surroundings for any number of reasons. Neither altruism nor selfishness per se, isolated as a generalized behavior trait, need be involved. The likelihood, therefore, is that advances in genetic technology will continue to elaborate genetic influences on behavior (just as they will with respect to proclivities for disease), without teasing out selfish genes as such. This, however, would not negate the scientific cogency of the concept, or even its genuine reality, because genes are selfish whenever they contribute to their own evolutionary success, without necessarily inducing their bodies to behave in an overtly self-aggrandizing manner.

Ethical Considerations Regarding Selfish Genes

Traditionally selfish behavior is considered unethical and its alternative, altruism, has been lauded as highly ethical. When biologists speak of selfish and altruistic behavior, they are simply defining these actions by their fitness consequences, and are not implying moral judgments. At the same time, one can speculate that the widespread, cross-cultural valuing of altruism and derogation of selfishness may itself derive from recognition that the living world inclines toward selfishness (at least at the level of genes) to a degree that may make exhortations to the contrary especially worthwhile.

Based on this cynics might point out that social and ethical systems may emphasize the desirability of altruism because of the payoff such behavior confers on others: Most people would be better off if others could be persuaded to be more altruistic, while they themselves remain comparatively selfish! Similarly biologists might point out that, as argued above, the boundaries between selfishness and altruism are unclear and often interpenetrating. Ethicists might emphasize that whereas evolutionary phenomena are crucially important to learn *about,* they are not suitable for learning *from*: Insofar as natural selection has produced human beings, along with other organisms, as the survival vehicles for selfish genes, the evolutionary process simply promotes whatever works. It is the responsibility of human beings to decide how they choose to assess such inclinations, and how, if at all, they elect to be influenced by that knowledge.

SEMIOTICS

OVERVIEW

Semiotics (from the Greek root *sema* [sign]) proposes to be a science of signs and symbols and how they function in both linguistic (human and culture) and nonlinguistic (natural and artificial) systems of communication. In both instances the science has ethical dimensions. With regard to language and culture, some traditions of semiotics seek to expose what they argue are illegitimate uses of signs and symbols. With regard to nature and machines, questions arise about the legitimacy of conceiving interactions between noncultural phenomena in the same terms as cultural phenomena.

LANGUAGE AND CULTURE

Linguistic and cultural semiotics investigates sign systems and the modes of representation that humans use to convey feelings, thoughts, ideas, and ideologies. Semiotic analysis is rarely considered a field of study in its own right, but is used in a broad range of disciplines, including art, literature, anthropology, sociology, and the mass media. Semiotic analysis looks for the cultural and psychological patterns that underlie language, art, and other cultural expressions. Umberto Eco jokingly suggests that semiotics is a discipline for "studying everything which can be used in order to lie" (1976, p. 7). Whether used as a tool for representing phenomena or for interpreting it, the value of semiotic analysis becomes most pronounced in highly mediated, postmodern environments where encounters with manufactured reality shift humans' grounding senses of normalcy.

Historical Development

That human thought and communication function by means of signs is an idea that runs deep in Western tradition. Prodicus, one of the Greek Sophists of the fifth century B.C.E., founded his teachings on the practical idea that properly chosen words are fundamental to effective communication. Questioning this notion that words possess some universal, objective meaning, Plato (c. 428–347 B.C.E.) explored the arbitrary nature of the linguistic sign. He suggested a separateness between an object and the name that is used to signify that object: "Any name which you give, in my opinion, is the right one, and if you change that and give another, the new name is as correct as the old," (*Cratylus* [384d]). Aristotle (384–322 B.C.E.) recognized the instrumental nature of the linguistic sign, observing that human thought proceeds by the use of signs and that "spoken words are the symbols of mental experience" (*On Interpretation* [1, 16a3]). Six centuries later Augustine of Hippo (354–430 C.E.) elaborated on this instrumental role of signs in the process of human learning. For Augustine, language was the brick and mortar with which human beings construct knowledge. "All instruction is either about things or about signs; but things are learned by means of signs" (*On Christian Doctrine* 1.2).

Semiotic consciousness became well articulated in the Middle Ages, largely because of Roger Bacon (c. 1220–1292). In his extensive tract *De Signis* (c. 1267), Bacon distinguished natural signs (for example, smoke signifies fire) from those involving human communication (both verbal and nonverbal). Bacon introduced a triadic model that describes the relationship between a sign, its object of reference, and the human interpreter. This triad remains a fundamental concept in modern semiotics. John Poinsot (John of St. Thomas, 1589–1644) elaborated on the triad, laying down a fundamental science of signs in his *Tractatus de Signis* (1632). Poinsot observed that signs are relative beings whose existence consists solely in presenting to human awareness that which they themselves are not. It was the British philosopher John Locke (1632–1704) who finally bestowed a name on the study of signs. In his *Essay Concerning Human Understanding* (1690), Locke declared that *semiotike* or doctrine of signs should be one of the three major branches of science, along with natural philosophy and practical ethics.

Modern Semiotics

There are two major traditions in modern semiotic theory. One branch is grounded in a European tradition and was led by the Swiss-French linguist Ferdinand de Saussure (1857–1913). The other branch emerged out of American pragmatic philosophy through its primary founder, Charles Sanders Peirce (1839–1914). Saussure sought to explain how all elements of a language are taken as components of a larger system of language in use. This led to a formal discipline that he called *semiology*. Peirce's interest in logical reasoning led him to investigate different categories of signs and the manner by which humans extract meaning from them. Independently, Saussure and Peirce worked to better understand the triadic relationship.

Saussure laid the foundation for the structuralist school in linguistics and social theory. A structuralist looks at the units of a system and the rules of logic that are applied to the system, without regard to any specific content. The units of human language comprise a limited set of sounds called phonemes, and these comprise an unlimited set of words and sentences, which are put together according to a set of simple rules called grammar. From simple units humans derive more complex units that are applied to new rules to form more complex structures (such as themes, characters, stories, genres, and style). The human mind organizes this structure into cognitive understanding.

The smallest unit of analysis in Saussure's semiology is the *sign*, made up of a *signifier* or sensory pattern, and a *signified*, the concept that is elicited in the mind by the signifier. Saussure emphasized that the signifier does not constitute a sign until it is interpreted. Like Plato, Saussure recognized the arbitrary association between a word and what it stands for. Word selection becomes a matter, not of identity, but of difference. Differences carry signification. A sign *is* what all other signs *are not* (Saussure 1959).

Peirce shared the Saussurian observation that most signs are *symbolic* and arbitrary, but he called attention to *iconic* signs that physically resemble their referent and *indexical* signs that possess a logical connection to their referent (Peirce 1955 [1898]). To Peirce, the relationship of the sign to the object is made in the mind of the interpreter as a mental tool that Peirce called the *interpretant*. As Peirce describes it, *semiosis* (the process of sign interpretation) is an iterative process involving multiple inferences. The signifier elicits in the mind an interpretant that is not the final signified object, but a mediating thought that promotes understanding. In other words, a thought is a sign requiring interpretation by a subsequent thought in order to achieve meaning. This mediating thought might be a schema, a mental model, or a recollection of prior experience that enables the subject to move forward toward understanding. The interpretant itself becomes a sign that can elicit yet another interpretant, leading the way toward an infinite series of *unlimited semioses* (Eco 1979). By this analysis, Peirce shifts the focus of semiotics from a relational view of signs and the objects they represent to an understanding of semiosis as an iterative, mediational process.

Charles Morris (1901–1979) was a semiotician who adapted Peirce's work to a form of behaviorism. For Morris, semiotics involves "goal-seeking behavior in which signs exercise control" (Morris 1971 [1938], p. 85). Morris identified four aspects within the process of semiosis:

(1) the sign vehicle that orients a person toward a goal;

(2) the interpreter, or the subject of the semiotic activity;

(3) the designatium, or the object to which the sign refers;

(4) the interpretant, which is the cognitive reaction elicited in the mind of the interpreter.

Morris attempted to subdivide the field of semiotics into three subfields. *Semantics* studies the affiliations between the world of signs and the world of things. *Syntactics* observes how signs relate to other signs. *Pragmatics* explains the effects of signs on human behavior (Morris 1971).

Russian Influences

Saussure's abstraction of language as a self-contained system of signs became the target of criticism by those who saw language as a socially constituted fabric of human interchange. Language is highly contextual and humans acquire language by assimilating the voices of those around them. Language is not a fixed system but it changes as it is used through interaction with peers in modes of discourse. This philosophy, known as *dialogics*, was the outgrowth of intellectual development in Soviet Russia by a group whose work centered on the writings of Mikhail Bakhtin (1895–1975). The Bakhtin Circle, which included among its members Valantine Voloshinov (1895–1936), addressed the social and cultural issues posed by the Russian Revolution and its degeneration into the Stalin dictatorship. The group dissolved in 1929 after members faced political arrest. Bakhtin himself was not a pure semiotician, but he engaged with others, most notably Voloshinov, in the investigation of how language and understanding emerges in the process of dialogue.

Voloshinov argued that all utterances have an inherently dialogic character. According to Voloshinov, dialogue is the fundamental feature of speech. In his view, signs have no independent existence outside of social practice. Signs are seen as components of human activity, and it is within human activity that signs take on their form and meaning (Voloshinov 1986).

Another Russian, Lev Semenovich Vygotsky (1896–1934), applied the instrumental notion of semiotics toward cognition and learning (the relationship suggested much earlier by Aristotle and Augustine). Vygotsky identified the pivotal role language plays during the exercise of complex mental functions. In *Mind in Society* (1978 [1930]), Vygotsky observes how planning abilities in children are developed through linguistic mediation of action. "[The child] plans how to solve the problem through speech and then carries out the prepared solution through overt activity" (p. 28). He observed the similarity between physical tools and verbal artifacts as instruments of human activity. From his extensive and detailed observations of child development, Vygotsky concluded that higher-order thinking transpires by means of what he called "inner speech," the internalized use of linguistic signs (Vygotsky 1986).

Rhetorical Techniques and Ethical Implications

Roland Barthes (1915–1980) is probably the most significant semiologist to assume the mantle of Saussure. Barthes developed a sophisticated structuralist analysis to deconstruct the excessive rhetorical maneuvers within popular culture that engulfed Europe after World War II. Anything was fair game for Barthes's structuralist critique including literature, media, art, photography, architecture, and even fashion. Barthes's most influential work, *Mythologies* (1972 [1957]) continues to have an influence on critical theory in the early twenty-first century.

Myths are signs that carry with them larger cultural meanings. In *Mythologies*, Barthes describes myth as a well-formed, sophisticated system of communication that serves the ideological aims of a dominant class. Barthes conceived of myth as a socially constructed reality that is passed off as natural. Myth is a mode of signification in which the signifier is stripped of its history, and the form is stripped of its substance and then adorned with a substance that is artificial but appears entirely natural. Through mythologies, deeply partisan meanings are made to seem well established and self-evident. The role of the mythologist is to identify the artificiality of those signs that disguise their historical and social origins.

Barthes was critical of journalistic excesses that justified the French Algerian War (1954–1962). Skillfully, he deconstructed French journalism that had perfected the art of taking sides while pretending airs of neutrality, claiming to express the voice of common sense. Barthes observes that the myth is more understandable and more believable than the story that it supplants because the myth introduces self-evident truths that conform to the dominant historical and cultural position. This naturalization lends power to such myths. They go without saying. They need no further explanation or demystification.

American journalism is no less rich with its own mythical contributions to journalistic history. Examples include the Alamo (1835–1836), the sinkings of the *Maine* (1898) and the *Lusitania* (1915), the Gulf of Tonkin incident (1964), and Iraqi weapons of mass destruction (2003). In each case, the respective signifier was stripped of its own history and replaced with a more "natural" and believable narrative. These examples underscore the ethical implications of mythologies, because each was specifically instrumental in recruiting popular support behind an offensive war by making it appear to be a defensive war.

Mythologies are not limited to the realms of journalism, advertising, and the cinema, but find their way into all aspects of modern society. Science is no exception. The science educator Jay L. Lemke (1990) speaks of a "special mystique of science, a set of harmful myths that favor the interests of a small elite" (p. 129). Lemke believes that airs of objectivity and certainty in scientific discourse lend themselves to an authoritarian culture that serves to undermine student confidence. He describes linguistic practices that place artificial barriers between the pedagogy of science and common experience. He asserts that "a belief in the objectivity and certainty of science is very useful to anyone in power who wants to use science as a justification for imposing the policy decisions they favor. Science is presented as *authoritative*, and from there it is a small step to its becoming authoritarian" (Lemke 1990, p. 31).

George Lakoff and Mark Johnson (1980) describe a "myth of *objectivism*" in science writing that portrays a world of objects possessing inherent properties and fixed relations that are entirely independent of human experience. Objectivist writing emerged in the seventeenth century and now assumes the dominant position in modern discourses of science, law, government, business, and scholarship. Postmodern critics point to objectivism's failure to account for human thoughts, experience, and language, which are largely metaphorical. Metaphors are pervasive and generally unrecognized within a culture of positivism. Highlighting the use of metaphors is a useful key to identifying whose realities are actually privileged in academic writing (Chandler 2002).

Barthes's role as France's supreme social critic has been taken over by the French cultural theorist Jean Baudrillard (b. 1929). Baudrillard argues that postmodern culture, with its rich, exotic media, is a world of signs that have made a fundamental break from reality. Contemporary mass culture experiences a world of *simulation* having lost the capacity to comprehend an unmediated world. Baudrillard coined the term *simulacra* to describe a system of objects in a consumer society distinguished by the existence of multiple copies with no original. People experience manufactured realities—carefully edited war footage, meaningless acts of terrorism, and the destruction of cultural values.

In an age of corporate consolidation in which popular culture is influenced by an elite few with very powerful voices, semiotic analysis is deemed essential for information consumers. Semiotics informs consumers about a text, its underlying assumptions, and its various dimensions of interpretation. Semiotics offers a lens into human communication. It sharpens the consumer's own consciousness surrounding a given text. It informs consumers about the cultural structures and human motivations that underlie perceptual representations. It rejects the possibility that humans can represent the world in a neutral fashion. It unmasks the deep-seated rhetorical forms and underlying codes that fundamentally shape human realities. Semiotic analysis is a critical skill for media literacy in a postmodern world.

BIBLIOGRAPHY

Barthes, Roland. (1972). *Mythologies*, trans. Annette Lavers. New York: Hill and Wang. Originally published 1957. Fifty-four short critical reflections on mass culture in France during early 1950s. A classic work using semiotics to reveal the practices and artifacts of society as signifiers of the surface meanings and deep structures of contemporary life.

Baudrillard, Jean. (1988). *Selected Writings*, ed. Mark Poster. Stanford, CA: Stanford University Press. Provocative and controversial, Baudrillard describes a culture of people disenfranchised by the impotency of politics, media, and the consumer society.

Chandler, Daniel. (2002). *Semiotics: The Basics*. London: Routledge. A comprehensive introduction to semiotic theory for students of popular culture and mass communications.

Eco, Umberto. (1976). *A Theory of Semiotics*. Bloomington: Indiana University Press. In this classic text, Eco offers a theory of sign production that centers on the process of interpretation and the relationship between sign vehicles and the reality they portray. Eco's constructivist philosophy places the interpreter of signs on equal footing with the sign producer in the process of meaning construction.

Eco, Umberto. (1979). *The Role of the Reader: Explorations in the Semiotics of Texts*. Bloomington: Indiana University Press. Nine essays that explore the differences between "open" and "closed" texts, those that hold the reader at bay and those that actively engage the reader in the co-production of meaning.

Lakoff, George, and Mark Johnson. (1980). *Metaphors We Live By*. Chicago: University of Chicago Press. Linguist George Lakoff and philosopher Mark Johnson argue that metaphor is central to language and understanding.

Lemke, Jay L. (1990). *Talking Science: Language, Learning, and Values*. Norwood, NJ: Ablex Publishing. Lemke portrays science as language, suggesting that to learn science, one must learn the language of science; and to learn the language, one must engage with others in active dialog about science.

Morris, Charles. (1971 [1938]). *Foundations of the Theory of Signs*. Chicago: University of Chicago Press. This classic monograph proposed three divisions of semiotic theory: syntactics, semantics, and pragmatics.

Peirce, Charles Sanders. (1955). "Logic as Semiotic: The Theory of Signs." In *Philosophical Writings of Peirce*, ed. Justus Buchler. New York: Dover. Essay originally published in 1898. Considered the founder of pragmatism, Peirce introduced a logical model which he termed "abduction", the iterative process of formulating inferences through the interpretation of signs and testing those inferences with other signs as a means of advancing an investigative inquiry.

Saussure, Ferdinand de. (1959). *Course in General Linguistics*, ed. Charles Bally and Albert Sechehaye; trans. Wade Baskin. New York: Philosophical Library. Originally published 1916. This is a summary of Saussure's lectures at the University of Geneva from 1906 to 1911. In this seminal work, Saussure examines the relationship between speech and the development of language as a structured system of signs.

Voloshinov, V. N. (1986). *Marxism and the Philosophy of Language*, trans. Ladislav Matejka and I. R. Titunik. Cambridge, MA: Harvard University Press. Originally published 1929. Good introduction to the ideas of the Bakhtin Circle. In a series of articles written between 1926 and 1930, Voloshinov emphasizes the social essence of language and he tracks the development of ideology and consciousness at the level of discursive practice.

Vygotsky, L. S. (1978). *Mind in Society*, ed. Michael Cole, Vera John-Steiner, Sylvia Scribner, and Ellen Souberman. Cambridge, MA: Harvard University Press. Originally published 1930. A pioneer in developmental psychology, Vygotsky argued that language is central to learning, and that the workings of the human mind can best be explained in terms of its linguistic and cultural tools.

Vygotsky, L. S. (1986). "The Genetic Roots of Thought and Speech." In *Thought and Language*, trans. and ed. Alex Kozulin. Cambridge, MA: MIT Press. Russian edition originally published 1934, then translated in 1962 to become a classic foundational work in cognitive science. Vygotsky analyzed the role of speech in the development of human consciousness, and the relationship of language to complex thinking in humans.

NATURE AND MACHINE

Semiotics (from the Greek word for sign) is the doctrine and science of signs and their use. It is thus a more comprehensive system than language itself and can therefore be used to understand language in relation to other forms of communication and interpretation such as nonverbal forms. One can trace the development of semiotics starting with its origins in the classical Greek period (from medical symptomatology), through subsequent developments during the Middle Ages (Deely 2001), and up to John Locke's introduction of the term in the seventeenth century. But contemporary semiotics has its real foundations in the nineteenth century with Charles Sanders Peirce (1839–1914) and Ferdinand de Saussure (1857–1913), who, working independently of each other, developed slightly different conceptions of the sign. The development of semiotics as a broad field is nevertheless mostly based on Peirce's framework, which is therefore adopted here.

Ever since Umberto Eco (1976) formulated the problem of the "semiotic threshold" to try to keep semiotics within the cultural sciences, semiotics—especially Peircian semiotics—has developed further into the realm of biology, crossing threshold after threshold into the sciences. Although semiotics emerged in efforts to scientifically investigate how signs function in culture, the twentieth century witnessed efforts to extend semiotic theory into the noncultural realm, primarily in relation to living systems and computers. Because Peirce's semiotics is the only one that deals systematically with nonintentional signs of the body and of nature at large, it has become the main source for semiotic theories of the similarities and differences among signs of inorganic nature, signs of living systems, signs of machines (especially computer semiotics, see Andersen 1990), and the cultural and linguistic signs of humans living together in a society that emphasizes the search for information and knowledge. Resulting developments have then been deployed to change the scope of semiotics from strictly cultural communication to a biosemiotics that encompasses the cognition and communication of all living systems from the inside of cells to the entire biosphere, and a cybersemiotics that in addition includes a theory of information systems.

Biosemiotics and Its Controversies

Semiotics is a transdisciplinary doctrine that studies how signs in general—including codes, media, and language, plus the sign systems used in parallel with language—work to produce interpretation and meaning in human and in nonhuman living systems as prelinguistic communication systems. In the founding semiotic tradition of Peirce, a *sign* is anything that stands for something or somebody in some respect or context.

Taking this further, a sign, or *representamen,* is a medium for communication of a form in a triadic (three-way) relation. The representamen refers (passively) to its object, which determines it, and to its *interpretant,* which it determines, without being itself affected. The interpretant is the interpretation in the form of a more developed sign in the mind of the interpreting and receiving mind or quasi mind. The representamen could be, for example, a moving hand that refers to an object for an interpretant; the interpretation in a person's mind materializes as the more developed sign "waving," which is a cultural convention and therefore a symbol.

All kinds of alphabets are composed of signs. Signs are mostly imbedded in a sign system based on codes, after the manner of alphabets of natural and artificial languages or of ritualized animal behaviors, where fixed action patterns such as feeding the young in gulls take on a sign character when used in the mating game.

Inspired by the work of Margaret Mead, Thomas A. Sebeok extended this last aspect to cover all animal species–specific communication systems and their signifying behaviors under the term *zoösemiotics* (Sebeok 1972). Later Sebeok concluded that zoösemiotics rests on a more comprehensive *biosemiotics* (Sebeok and Umiker-Sebeok 1992). This global conception of semiotics equates life with sign interpretation and mediation, so that semiotics encompasses all living systems including plants (Krampen 1981), bacteria, and cells in the human body (called *endosemiotics* by Uexküll, Geigges, and Herrmann 1993). Although biosemiotics has been pursued since the early 1960s, it remains controversial because many linguistic and cultural semioticians see it as requiring an illegitimate broadening of the concept of code.

A code is a set of transformation rules that convert messages from one form of representation to another. Obvious examples can be found in Morse code and cryptography. Broadly speaking, code thus includes everything of a more systematic nature (rules) that source and receiver must know a priori about a sign for it to correlate processes and structures between two different areas. This is because codes, in contrast to universal laws, work only in specific contexts, and interpretation is based on more or less conventional rules, whether cultural or (by extension) biological.

Exemplifying a biological code is DNA. In the protein production system—which includes the genome in a cell nucleus, the RNA molecules going in and out of the nucleus, and the ribosomes outside the nucleus membrane—triplet base pairs in the DNA have been translated to a messenger RNA molecule, which is then read by the ribosome as a code for amino acids to string together in a specific sequence to make a specific protein. The context is that all the parts have to be brought together in a proper space, temperature, and acidity combined with the right enzymes for the code to work. Naturally this only happens in cells. Sebeok writes of the genetic code as well as of the metabolic, neural, and verbal codes. Living systems are self-organized not only on the basis of natural laws but also using codes developed in the course of evolution. In an overall code there may also exist subcodes grouped in a hierarchy. To view something as encoded is to interpret it as-*sign*-ment (Sebeok 1992).

A symbol is a conventionally and arbitrary defined sign, usually seen as created in language and culture. In common languages it can be a word, but gestures, objects such as flags and presidents, and specific events such as a soccer match can be symbols (for example, of national pride). Biosemioticians claim the concept of symbol extends beyond cultures, because some animals have signs that are "shifters." That is, the meaning of these signs changes with situations, as for instance the head tossing of the herring gull occurs both as a precoital display and when the female is begging for food. Such a transdisciplinary broadening of the concept of a symbol is a challenge for linguists and semioticians working only with human language and culture.

To see how this challenge may be developed, consider seven different examples of signs. A sign stands for something for somebody:

(1) as the word *blue* stands for a certain range of color, but also has come to stand for an emotional state;

(2) as the flag stands for the nation;

(3) as a shaken fist can indicate anger;

(4) as red spots on the skin can be a symptom for German measles;

(5) as the wagging of a dog's tail can be a sign of friendliness for both dogs and humans;

(6) as pheromones can signal heat to the other sex of the species;

(7) as the hormone oxytocin from the pituitary can cause cells in lactating glands of the breast to release the milk.

Linguistic and cultural semioticians in the tradition of Saussure would usually not accept examples 3 to 6 as genuine signs, because they are not self-consciously intentional human acts. But those working in the tradition of Peirce also accept nonconscious intentional signs in humans (3) and between animals (5 and 6) as well as between animals and humans (4), nonintentional signs (4), and signs between organs and cells in the body (7). This last example even takes special form in *immunosemiotics*, which deals with the immunological code, immunological memory, and recognition.

There has been a well-known debate about the concepts of primary and secondary modeling systems (see for example Sebeok and Danesi 2000) in linguistics that has now been changed by biosemiotics. Originally language was seen as the primary modeling system, whereas culture comprised a secondary one. But through biosemiotics Sebeok has argued that there exists a zoösemiotic system, which has to be called primary, as the foundation of human language. From this perspective language thus becomes the secondary and culture tertiary.

Cybersemiotics and Ethics

In the formulation of a transdisciplinary theory of signification and communication in nature, humans, machines, and animals, semiotics is in competition with the information processing paradigm of cognitive science (Gardner 1985) used in computer informatics and psychology (Lindsay and Norman 1977, Fodor 2000), and library and information science (Vickery and Vickery 2004), and worked out in a general renewal of the materialistic evolutionary worldview (for example, Stonier 1997). Søren Brier (1996a, 1996b) has criticized the information processing paradigm and second-order cybernetics, including Niklas Luhmann's communication theory (1995), for not being able to produce a foundational theory of signification and meaning. Thus it is found necessary to add biosemiotics ability to encompass both nature and machine to make a theory of signification, cognition and communication that encompass the sciences, technology as well as the humanities aspect of communication and interpretation.

Life can be understood from a chemical point of view as an autocatalytic, autonomous, autopoietic system, but this does not explain how the individual biological self and awareness appear in the nervous system. In the living system, hormones and transmitters do not function only on a physical causal basis. Not even the chemical pattern fitting formal causation is enough to explain how sign molecules function, because their effect is temporally and individually contextualized. They function also on a basis of final causation to support the survival of the self-organized biological self. As Sebeok (1992) points out, the mutual coding of sign molecules from the nervous, hormone, and immune systems is an important part of the self-organizing of a biological self, which again is in constant recursive interaction with its perceived environment *Umwelt* (Uexkull 1993). This produces a view of nerve cell communication based on a Peircian worldview binding the physical efficient causation described through the concept of energy with the chemical formal causation described through the concept of information—and the final causations in biological systems being described through the concept of semiosis (Brier 2003).

From a cybersemiotic perspective, the *bit* (or basic difference) of information science becomes a sign only when it makes a difference for someone (Bateson 1972). For Pierce, a sign is something standing for something else for someone in a context. Information bits are at most pre- or quasi signs and insofar as they are involved with codes function only like keys in a lock. Information bits in a computer do not depend for their functioning on living systems with final causation to interpret them. They function simply on the basis of formal causation, as interactions dependent on differences and patterns. But when people see information bits as encoding for language in a word processing program, then the bits become signs for them.

To attempt to understand human beings—their communication and attempts through interpretation to make meaning of the world—from frameworks that at their foundation are unable to fathom basic human features such as consciousness, free will, meaning, interpretation, and understanding is unethical. To do so tries to explain away basic human conditions of existence and thereby reduce or even destroy what one is attempting to explain. Humans are not to be fitted and disciplined to work well with computers and information systems. It is the other way round. These systems must be developed with respect for the depth, multidimensional, and contextualizing abilities of human perception, language communication, and interpretation.

Behaviorism, different forms of eliminative materialism, information science, and cognitive science all attempt to explain human communication from outside, without respecting the phenomenological and hermeneutical aspects of existence. Something important about human nature is missing in these systems and the technologies developed on their basis (Fodor 2000). It is unethical to understand human communication only in the light of the computer. Terry Winograd and Fernando Flores (1987), among others, have argued for a more comprehensive framework.

But it is also unethical not to contemplate the material constraints and laws of human existence, as occurs in so many purely humanistic approaches to human cognition, communication, and signification. Life, as human embodiment, is fundamental to the understanding of human understanding, and thereby to ecological and evolutionary perspectives, including cosmology. John Deely (1990), Claus Emmeche (1998), Jesper Hoffmeyer (1996), and Brier (2003) all work with these perspectives in the new view of semiotics inspired by Peirce and Sebeok. Peircian semiotics in its contemporary biosemiotic and cybersemiotic forms is part of an ethical quest for a transdisciplinary framework for understanding humans in nature as well as in culture, in matter as well as in mind.

SENSITIVITY ANALYSES

Technically, a sensitivity analysis is a calculation or estimation, quantitative or not, in which all variables except one are held constant. This allows for a clear understanding of the effects of changes in that variable on the outcomes of the calculation or estimation. The methodologies of sensitivity analysis are well established in some areas of research, particularly those that employ methods of risk assessment and computer modeling (Satelli, Chan, and Scott 2000). However, the concept of sensitivity analysis has considerable potential for policy research, especially for understanding the role of different types of knowledge as factors contributing to particular value or ethical outcomes related to scientific research or technological change.

Potential use in Policy Making: Some Examples

In the context of research intended to support policy making a sensitivity analysis can help identify and frame the dimensions of a problem and thus clarify the potential efficacy of possible interventions. Consider a hypothetical example. There is a city in a desert that continually faces stress on its water resources. City officials invariably face finite time and budgets but have to make decisions about the community's water use. It is likely that they will hear from advocates proposing the development of new water projects such as dams and reservoirs as well as advocates who call for a reduction in water use in the community. Inevitably a question will arise: To what degree should the city consider limiting the use of water, for example, through conservation, versus increasing supply, for example, by building a new dam?

A sensitivity analysis can help policy makers understand the source of stresses on the community's water resources. Specifically, does stress result primarily from a growing population or from limited storage of water? From drought and climate? From a combination? If so, to what degree? The following idealized example shows how a sensitivity analysis might be organized in this case.

(1) A valued outcome is identified. In this instance the variable is water availability as measured by reservoir storage. Of course, other valued outcomes might be selected, and other measures might be selected.

(2) The existing literature is surveyed to assess the range of factors expected to influence the valued outcome over a period of time that is relevant to the decision context. For water resources the period of concern might be the upcoming decade. The two factors identified to be the most important influences affecting water availability might be rainfall and municipal water usage.

(3) With the two factors identified, the next step is to return to the literature to identify the distribution of views on the effects of rainfall and water use on water availability. The goal here is to identify the range of perspectives on the independent influence of (a) rainfall and (b) municipal water use on water availability.

(4) With a quantitative understanding of 3(a) and 3(b), it will be possible to compare the sensitivity of water availability to each of the two factors, with possible implications for decision making.

For example, if a sensitivity analysis showed that water use was expected to grow faster than variations in existing storage related to climate, policy makers might consider managing water use. Similarly, if a sensitivity analysis showed that reservoir storage was largely insensitive to accumulated rainfall, perhaps because there was far more rainfall than storage capacity, policy makers might consider building new reservoirs. A sensitivity analysis cannot determine what means and ends are worth pursuing, but it can shed some light on the connection of different means and ends.

The point of a sensitivity analysis is to identify factors that may be influenced by decision making in order to make desired outcomes more likely than undesired outcomes. Because the process of framing a problem (for example, using too much water versus not having enough water) necessarily implies some valued outcomes, a sensitivity analysis can help make those values explicit and demonstrate the prospects that different policy interventions might lead to desired outcomes.

More generally, in light of the multicausal nature of most phenomena that are of interest to policy makers (for instance, all the factors implicated in the supply of and demand for water in a large urban setting) and the large uncertainties typically associated with efforts to quantify the relationships between a particular cause (such as the challenges associated with projecting water supply over a period of decades) and an impact (for example, the difficulties of understanding who will be affected the most by water shortages and oversupply decades in the future), one obvious approach to guiding policy decisions is to look for areas of relative strength in relationships between causes and impacts and focus research to support decision making in those areas.

In a somewhat less idealized example Pielke et al. (2000) show that in light of scientific understanding as reported by the Intergovernmental Panel on Climate Change, demographic and socioeconomic change will be twenty to sixty times more important than climate change in contributing to economic losses related to tropical cyclones over the next fifty years. This sensitivity analysis suggests that (1) even if all losses resulting from climate change were prevented, the overall benefit would be dwarfed by increasing losses caused by the growth of populations and economies, and (2) research priorities relevant to the tropical cyclone threat could reflect those relationships by focusing on issues of preparation, planning, infrastructure, development, and resilience. The order-of-magnitude difference between these two sources of tropical cyclone impacts strongly suggests that more research on the sensitivity of tropical cyclones to climate changes is not likely to change the implications for decision making.

In another example one might consider the changing incidence and impacts of tropical diseases such as malaria to understand how predictions of the influence of climate change compare with other causal factors, such as growth in resistance to antibiotics, changes in health-care delivery systems, migration and growth of populations, and annual-to-interannual climate variability.

Goals of Sensitivity Analyses

The goal is not to predict but to provide information about the relative sensitivity of impacts to various causal factors. That information can enhance the bases for effective decision making in the context of values and ethics as well as decisions about science priorities intended to support the generation of knowledge useful in pursuing desired outcomes without additional reduction in or characterization of scientific uncertainty.

In a policy setting sensitivity analysis does not attempt to resolve scientific disputes about causes of societal impacts but to compare and assess existing quantified predictions and observations of the multiple causes of such impacts to identify strong causal links. As the examples of water resources and tropical cyclones show, a sensitivity analysis approach can lessen the perceived need for reduction of uncertainty about future behavior as a prerequisite for decision making and point toward research avenues that can provide knowledge that can be useful in addressing high-priority sources of environmental change and societal vulnerability. Thus, sensitivity analysis can be an important tool for science policy decision makers in their attempt to enhance the societal value of their portfolios.

SEX AND GENDER

Questions about the degree to which concepts of sex and gender influence science and engineering or are appropriate subjects for scientific research and technological manipulation are fundamental ethical issues. This entry discusses those issues and describes the genesis of the development of sex and gender discussions related to science and technology. The focus then shifts to the role of sex and gender in scientific knowledge and issues of inequity and their implications.

Historical Background

Gayle Rubin (1975) described the sex and gender system, distinguishing the biology of sex from the cultural and social construction of gender and revealing the male-centered social processes and practices that constrain and control women's lives. Rubin extended the implications of *The Second Sex* by Simone de Beauvoir (1947), who initiated the intellectual, theoretical foundations for the second wave of the women's movement, which itself built on the nineteenth-century first wave and took an activist turn in the United States in the context of protests and the civil rights movement of the 1960s. De Beauvoir provided the philosophical basis for existentialist feminism by suggesting that women's "otherness" and the social construction of gender rest on a social interpretation of biological differences (sex).

Rubin articulated the connection between biological sex and the social construction of masculinity and femininity that resulted in superiority being attached to what was labeled masculine and discrimination against what was defined as feminine across various societies. Although the definition of the tasks, roles, and behaviors that were considered masculine or feminine varied among societies, the lower status ascribed to the feminine and to femininity remained consistent. Rubin's articulation of the operation of the sex/gender system in a variety of contexts within a society and across societies provoked ethical questions about unequal treatment based on sex/gender in all arenas, including science and technology. That explication of the sex/gender system led to questions about whether sex/gender biases had permeated science and engineering on a variety of levels.

Sex and Gender in Scientific Knowledge

Inaccurate use of definitions and terms for sex and gender may lead to causal links that go beyond what the data warrant. As Londa Schiebinger (1993) documents, human, particularly male, interest in certain anatomic features, such as mammary glands, has even influenced the taxonomic divisions and biological definitions of animal species. Moreover, aware of the fluidity in biological sex among a variety of species in the animal kingdom, including humans, biologists have explored the definition of biological sex and inappropriate extrapolations from the simplistic binary categories of biological male and female to the gender identities of masculine and feminine as well as inappropriate assumptions of their links with particular sexual orientations.

Indeed, although at the time of birth attendants categorize newborns into the binary category of male or female, numerous clinical examples demonstrate that biological sex can be disaggregated into genetic, hormonal, internal anatomic, and external anatomic components. Typically a genetic male (XY) produces some testosterone prenatally that causes an undifferentiated fetus to develop internal organs such as testes and external structures such as the penis that normally are associated with males. Breakdowns or changes at any level may cause development to take a different path. For example, individuals who are genetic males (XY) with androgen insensitivity (testicular feminization) have testes but have female external genitalia; individuals with Turner's syndrome (genetic X0) at birth have the anatomy of females (although their genitals may remain immature after puberty and they may or may not have ovaries) but do not have the XX sex chromosomes associated with "normal" females.

It once was assumed that after birth an individual categorized as male produces increased levels of testosterone at puberty that lead to the development of secondary sex characteristics such as facial hair and a deep voice, whereas a female develops breasts and begins menstruating in the absence of testosterone and in the presence of estrogen and progesterone. Clinical conditions such as congenital adrenal hyperplasia (CAH) demonstrated further breakdown in the uniformity of biological sex. The absence of the enzyme C-21-hydroxylase in individuals with CAH results in genetic females (XX) with female internal genitalia but male external genitalia.

These breakdowns demonstrating that being a genetic male does not always result in an individual with functioning male anatomy and secondary sex characteristics not only weakened the binary sex categories of male and female but also led scientists to question biologically deterministic models that linked the male sex with male gender identity, male role development, and heterosexuality. Statistical and interview data from the Kinsey Reports, coupled with clinical studies, revealed difficulties with the use of binary categories and assumptions of causality. For example, the studies of John Money and Anke Erhardt (1972) explored so-called ambiguous sex, or babies born with external genitalia "discrepant" with their sex chromosomes and internal genitalia, that is, genetic females (XX) with ovaries but with an elongated "penoclitoris" and genetic males (XY) with testes and androgen insensitivity.

Many of the babies in those studies were genetic females who had ambiguous external genitalia at birth because their mothers had been given synthetic progestins to prevent miscarriage. Money and Erhardt concluded from those studies that operations and hormone treatments that were intended to remove ambiguity would not prevent the "normal" development of gender identity congruent with the assignment of sex based on the construction of external genitalia, regardless of genetic or internal anatomic sex, as long as that reassignment occurred before eighteen months of age. At the time of those studies some ethical questions were raised about surgical attempts to construct "normal, appropriate" external genitalia, especially in the case of male identical twins in whom an accident during circumcision resulted in the amputation of the penis in one of the twins and the surgical reconstruction of genitalia for reassignment of that twin to the female sex.

Some people questioned the assumptions that Money and Erhardt made about appropriate gender identities and roles, such as whether exposure to androgens had resulted in the higher IQ of those genetic females and whether the parents of sexually reassigned individuals treated them in ways that would influence the children to develop an "appropriate" gender identity. In recent years more emphasis has been placed on the ethics of using surgery and hormones to provide conformity between biological sex and socially constructed gender roles. As adults the patients have raised questions about who made the decision to do sexual reassignment, who decided what was appropriate gender identity, and in many cases why they had not been told that those medical and psychological interventions had been performed on them.

Described as a solution for individuals who always felt that they were trapped in a body of the wrong sex, transsexual surgery became popular in the 1970s to make the socially constructed gender identity of individuals congruent with their biological sex. Although large numbers of "dissatisfied" or "problematic cases" of individuals who had undergone transsexual surgery surfaced almost immediately, realization by the broader medical and mainstream community that sex and gender are not the same and that binary categories of male and female, as well as masculinity and femininity, may be too limited and constraining, took longer.

John Money's treatment of Bruce/Brenda Reimer, as analyzed in a study by John Colapinto (2001), was instrumental in casting doubts on Money's social constructionist theories. Although the philosopher Janice Raymond (1979) pointed out that transsexual surgery would not be needed in a society that did not force people to conform to constricted, dichotomous gender roles based on their sex, not until the late 1990s did the transgender movement begin. Leslie Feinberg (1996) discussed how the social construction of gender allows her to assume a male gender role/identity without intending to undergo transsexual surgery; Feinberg understood and wanted to challenge the notion that biological sex determines gender, which is a social construction.

Inequitable Access to Science and Engineering on the Basis of Sex/Gender

Statistical data demonstrate a dearth of women in the physical sciences and engineering, suggesting that the sex/gender system prevents equitable access to education and employment in science and engineering for women and girls. The data document that legal actions in the late 1960s and early 1970s to remove the quotas (usually set at around 7 percent) on qualified women applicants to law, medical, and graduate schools have increased the percentages to parity in most fields. The physical sciences, computing, and engineering are major exceptions.

Although the number of women majoring in scientific and technological fields increased since the 1960s to reach 49 percent in 1998, as Table 1 demonstrates, the percentage of women in computing, the physical sciences, and engineering remains low. The percentage of graduate degrees in these fields earned by women is even lower. The small number of women receiving degrees in the sciences and engineering results in an even smaller percentage of women faculty members in those fields: For example, in 2000 only 19.5 percent of science and engineering professors at four-year colleges and universities were women. Outside academia the percentage of women in the scientific and technical workforce, which includes the social sciences, hovered at approximately 23 percent.

The Dearth of Women and a Gendered Science

Evelyn Fox Keller (1982, 1985) explored whether the dearth of individuals of one sex has led to the construction of a gendered science. Keller coupled work on the

TABLE 1

Women as a Percentage of Degree Recipients in 1996 by Major Discipline and Group

	All Fields	All Science and Engineering	Psychology	Social Sciences	Biology	Physical Sciences	Geosciences	Engineering	Computer Science	Mathematics
Percentage of bachelor's degrees received by women	55.2	47.1	73.0	50.8	50.2	37.0	33.3	17.9	27.6	45.8
Percentage of master's degrees received by women	55.9	39.3	71.9	50.2	49.0	33.2	29.3	17.1	26.9	40.2
Percentage of doctoral degrees received by women	40.0	31.8	66.7	36.5	39.9	21.9	21.7	12.3	15.1	20.6

history of early modern science by David Noble (1992) and Carolyn Merchant (1979), who demonstrated that women were excluded purposely and not permitted to be valid "witnesses" to scientific experiments, with theories of object relations for gender identity development. Keller applied the work of Nancy Chodorow (1978) and Dorothy Dinnerstein (1977) on women as primary caretakers of children during gender role socialization to suggest how that might lead to more men choosing careers in science, resulting in science becoming a masculine province that excludes women and causes women to exclude themselves. Science is a masculine province not only because it is populated mostly by men but because that situation causes men to create science and technology that reflect masculine approaches, interests, and views of the world.

Biases in Research in Science and Technology

The gendered nature of science has led to biases on several levels that are best illustrated by citing examples in science and technology that have led to ethical dilemmas.

EXCLUSION OF FEMALES AS EXPERIMENTAL AND DESIGN SUBJECTS. Cardiovascular diseases are an example of the many diseases that occur in both sexes from which women were excluded from studies until androcentric bias was revealed. Research protocols for large-scale studies of cardiovascular diseases failed to assess sex differences. Women were excluded from clinical trials of drugs because of fear of litigation resulting from possible teratogenic effects on fetuses. Exclusion of women from clinical drug trials was so pervasive that a meta-analysis published in September 1992 in the *Journal of the American Medical Association* that surveyed the literature from 1960 to 1991 on clinical trials of medications used to treat acute myocardial infarction found that women had been included in less than 20 percent and the elderly in less than 40 percent of those studies (Gurwitz, Col and Avorn 1992).

Dominance of men in engineering and the creative design sectors may result in similar bias, especially design and user bias. Shirley Malcom, in a personal communication to this author, suggests that the air bag fiasco in the U.S. auto industry is as an excellent example of gender bias reflected in design. Female engineers on the design team might have prevented the fiasco, recognizing that a bag that implicitly used the larger male body as a norm would be flawed when applied to smaller individuals, killing rather than protecting children and small women.

ANDROCENTRIC BIAS IN THE CHOICE AND DEFINITION OF PROBLEMS. Some subjects that concern women receive less funding and study. Failure to include women in studies of many diseases that occur in both sexes, such as cardiovascular disease, suggested that women's health had become synonymous with reproductive health. After a 1985 U.S. Public Health Service survey recommended that the definition of women's health be expanded beyond reproductive health, in 1990 the General Accounting Office criticized the National Institutes of Health (NIH) for inadequate representation of women and minorities in federally funded studies (Taylor 1994). This resulted in the establishment of the Women's Health Initiative (Healy 1991), which was designed to collect baseline data and look at interventions to prevent cardiovascular disease, breast cancer, colorectal cancer, and osteoporosis.

Having large numbers of male engineers and creators of technologies often results in technologies that are useful from a male perspective in that they fail to address important issues for women users. In addition the military origins for the development and funding of much technology makes its civilian application less useful for women's lives (Cockburn 1983). Men who design technology for the home frequently focus on issues that are less important to women users. For example, an analysis of "smart houses" reveals that those houses do not include new technologies; instead of housework they focus on "integration, centralised control and regulation of all functions in the home" (Berg 1999, p. 306). As Ruth Schwartz Cowan (1981) suggested, the improved household technologies developed in the first half of the twentieth century increased the amount of time housewives spent on housework and reduced their role from general managers of servants, maiden aunts, grandmothers, children, and others to that of individuals who worked alone doing manual labor with the aid of household appliances.

ANDROCENTRIC BIAS IN THE FORMULATION OF SCIENTIFIC THEORIES AND METHODS. Theories and methods that coincide with the male experience of the world become the "objective" theories that define the interpretation of scientific data and the use of technology. A 1996 study that included all prospective treatment and intervention studies published in the *New England Journal of Medicine*, the *Journal of the American Medical Association*, and the *Annals of Internal Medicine* between January and June in 1990 and 1994 revealed that only 19 percent of the 1990 studies and 24 percent of the 1994 studies reported any data analysis by gender despite the fact that 40 percent of the subjects were female (Charney and Morgan 1996).

Excessive focus on male research subjects and definition of cardiovascular diseases as male led to underdiagnosis and undertreatment of those diseases in women. A 1991 study in Massachusetts and Maryland by John Z. Ayanian and Arnold M. Epstein demonstrated that women were significantly less likely than men to undergo coronary angioplasty, angiography, or surgery when admitted to the hospital with a diagnosis of myocardial infarction, angina, chronic ischemic heart disease, or chest pain. A similar study (Steingart et al. 1991) revealed that women had angina before myocardial infarction as frequently as and with more debilitating effects than men, yet women were referred for cardiac catheterization only half as often.

These and other similar studies led Bernadine Healy, a cardiologist and the first woman director of the NIH, to characterize the diagnosis of coronary heart disease in women as the Yentl syndrome: "Once a woman showed that she was just like a man, by having coronary artery disease or a myocardial infarction, then she was treated as a man should be" (Healy 1991, p. 274). The use of the male as norm in research and diagnosis was translated into bias in treatments for women: Women had higher death rates from coronary bypass surgery and angioplasty (Kelsey et al. 1993).

In equally direct ways androcentric bias has excluded women as users of technology. The policy decision by Secretary of Defense Les Aspin (1993) to increase the percentage of women pilots uncovered the gender bias in cockpit design that excluded only 10 percent of male recruits by dimensions as opposed to 70 percent of women recruits. The officers initially assumed that the technology reflected the best or only design possible and that the goal for the percentage of women pilots would have to be lowered and/or the number of tall women recruits would have to be increased. That initial reaction, representing the world viewpoint of men, changed. When political conditions reinforced the policy goal, a new cockpit design emerged that reduced the minimum sitting height from 34 to 32.8 inches, thus increasing the percentage of eligible women (Weber 1999).

Implications of the Social Construction of Gender and of Science and Technology

Awareness and understanding of sex/gender biases raise the fundamental question of the way in which androcentric biases in scientific methods and theories occur. Should biological sex simply be termed essentialist and set aside, leaving the body to be viewed as a "coatrack" on which all that is cultural hangs, as suggested by Linda Nicholson (1994)? This interpretation implies that gender and all aspects of science and technology are socially, culturally constructed and nonobjective. Can scientists and engineers be objective? More important, is good science objective and gender-free? Or, as the title of Londa Schiebinger's 1999 book asks, *Has Feminism Changed Science?*

Most scientists, feminists, and philosophers of science recognize that no individual can be entirely neutral or value-free. To some "objectivity is defined to mean independence from the value judgments of any particular individual" (Jaggar 1983, p. 357). Scientific paradigms also are far from value-free. The values of a culture both in the historical past and in the present society heavily influence the ordering of observable phenomena into a theory. The worldview of a particular society, time, and person limits the questions that can be asked and thus the answers that can be given. Acceptance of a particular paradigm that appears to cause a "scientific revolution" within a society may depend on the congruence of the theory with the institutions and beliefs of the society (Kuhn 1970).

Scholars suggest that Darwin's theory of natural selection ultimately was accepted by his contemporaries, who did not accept similar theories proposed by the naturalist Alfred Russel Wallace (1823–1913) and others, because Darwin emphasized the congruence between the values of his theory and those held by the upper classes in Victorian Britain (Rose and Rose 1980). In this manner Darwin's data and theories reinforced the social construction of both gender and class, making his theories acceptable to the leaders of English society.

The current ideas of Darwinian feminists and feminist sociobiologists such as Patricia Gowaty (1997) and Sarah Blaffer Hrdy (1981) provide a biological explanation for female-female competition, promiscuity, and other behaviors practiced in modern society. Evolutionary psychologists carry this work a step further by positing biological bases for differences in the psychology of men and women. These biological differences, such as the ability of women to experience pregnancy, birth, and lactation, may give women different voices in ethical experiences, as has been suggested by Sara Ruddick (1989).

Not only what is accepted but what is studied and how it is studied have normative features. Helen Longino (1990) has explored the extent to which methods employed by scientists can be objective (not related to individual values) and can lead to repeatable, verifiable results while contributing to hypotheses and theories that are congruent with nonobjective institutions and ideologies, such as gender, race, and class, that are socially constructed in a society: "Background assumptions are the means by which contextual values and ideology are incorporated into scientific inquiry" (Longino 1990, p. 216). The lens of the sex/gender prism reveals how the dominance of men and masculinity in Western society has masked the androcentrism and ethical bias of many scientific experiments, approaches, theories, and conclusions.

SEX SELECTION

Sex selection is an ancient and persistent practice. At some times and in some places, parents have selected the sex of their children by killing newborns or neglecting babies of the undesired sex, almost always female. In the twenty-first century, technological developments and marketing practices are bringing new attention to sex selection, and raising an array of new concerns about it.

Some bioethicists and others defend sex selection as a matter of parental choice or "procreative liberty" (Robertson 2001). Others are highly critical, arguing that sex selection reflects and reinforces misogyny and gender stereotypes, undermines the wellbeing of children by subjecting them to excessive parental disappointment or expectations, and sets the groundwork for the future accessorizing and commodifying of children. The spread of prenatal screening for sex selection has caused alarm because of increasingly skewed sex ratios in some areas. Newer technologies now being used for sex selection also raise the prospect of a high-tech "consumer eugenics," in which other traits of future children are also chosen or "engineered."

Contemporary Sex Selection Methods

The development during the 1970s of prenatal testing technologies made it possible to reliably determine the sex of a fetus developing in a woman's womb. These procedures were initially intended to detect, and usually to abort, fetuses with Down Syndrome and other genetic anomalies, some of them sex-linked. But the tests were soon being openly promoted and widely used as tools for social sex selection, especially in South and East Asian countries where a cultural preference for sons is widespread. At the turn of the twenty-first century, prenatal screening followed by abortion remained the most common sex selection method around the world.

However, newer methods of sex selection are also coming into use. Unlike prenatal testing, these procedures are applied either before an embryo is implanted in a woman's body, or before an egg is fertilized. They do not require aborting a fetus of the "wrong" sex. In the United States, these pre-pregnancy methods are being promoted for social sex selection, as ways to satisfy parental desires, and are being marketed as forms of "family balancing" or "gender balancing."

EMBRYO SCREENING. Preimplantation genetic diagnosis (PGD), introduced in 1990, is an embryo screening technique. About three days after fertilization, a single cell is removed from each embryo in a batch that has been created using in vitro fertilization (IVF). Technicians test the cells for particular chromosomal arrangements or genetic sequences; then one or more embryos that meet the specified criteria—in the case of sex selection for a boy, those with both X and Y chromosomes—

are implanted in a woman's body. As a sex selection method, PGD is fairly reliable.

Like prenatal screening, PGD was presented as a way for parents to avoid having a child affected by certain genetic conditions (a motivation that has been strongly questioned by disability rights activists, whether involving prenatal tests or PGD). Before long, some assisted reproduction practitioners and bioethicists began suggesting that PGD should be made available to parents who want to fulfill their wish for a boy or a girl.

As of 2005, about 2,000 children have been born worldwide following the use of PGD, but no one knows how many of these procedures were undertaken for purely social sex selection reasons. In fact, the notoriously minimal regulatory environment for assisted reproduction facilities means that there is no firm data on the total number of PGD procedures conducted worldwide, or even on the exact number of clinics offering them. The risks of PGD to women who must undergo the hormone treatments and egg extractions required for all IVF procedures, and to the children born from screened embryos, are likewise unclear, both because of the small numbers involved so far and because of inadequate follow-up studies.

SPERM SORTING. Separating sperm that carry X chromosomes from those with Y chromosomes is the basis for a sex selection method that is less reliable, but that can be used without in vitro fertilization. A sperm sorting technique known as MicroSort® has been available since 1995. It relies on the fact that sperm with X chromosomes contain slightly more DNA than those with Y chromosomes, and uses a process called "flow cytometry," whereby X-chromosome-carrying sperm is separated from Y-chromosome-carrying sperm. The Genetics & IVF Institute (GIVF), the company that markets this technology for the "prevention of X-linked diseases and family balancing," claims that as of 2004, about 500 babies had been born after MicroSort® procedures. The company claims success rates of 88 percent for girls and 73 percent for boys. It reports that about 15 percent of its customers say they are trying to avoid the birth of a child who has inherited a sex-linked disease from the parents; the rest just want a boy or a girl.

Sex Selection as a Global Issue

In 1992 Nobel Prize-winning economist Amartya Sen (b. 1933) estimated the number of "missing women" worldwide—lost to neglect, infanticide, and sex-specific abortions—at one hundred million. Similarly shocking figures were confirmed by others. In areas of the world where sex-selection is most widespread, sex ratios are becoming increasingly skewed. In parts of India, for example, the sex ratio of young children is as low as 766 girls per 1,000 boys.

Some observers in the global North who express distress about the pervasiveness of sex-selective abortions in South and East Asia are untroubled by sex selection in countries without strong traditions of son preference. But politically and ethically, this double standard rests on shaky grounds.

As women's rights and human rights groups point out, an increased use and acceptance of sex selection in the United States would legitimize its practice in other countries, and undermines efforts there to oppose it. A 2001 report in *Fortune* magazine recognized this dynamic, noting that "[it] is hard to overstate the outrage and indignation that MicroSort® prompts in people who spend their lives trying to improve women's lot overseas" (Wadman 2001).

In addition, large numbers of South Asians now live in European and North American countries, and sex selection ads in publications including *India Abroad* and the North American edition of *Indian Express* have specifically targeted them (Sachs 2001). South Asian feminists point to numerous ways in which sex selection reinforces and exacerbates misogyny, including violence against women who fail to give birth to boys.

SOCIAL SEX SELECTION AS CONSUMER CHOICE AND COMMERCIAL ENTERPRISE. In North America and Europe, sex selection seems driven less by preference for boys than by a consumer ideology of "choice." In fact, anecdotal evidence suggests that of North Americans trying to determine the sex of their next child, many are women who want daughters.

However, a preference for girls does not necessarily mean that sex selection and sexism are unrelated. One study found that 81 percent of women and 94 percent of men who say they would use sex selection would want their firstborn to be a boy. Another concern is whether sex selection will reinforce gender stereotyping. Parents who invest large amounts of money and effort in order to "get a girl" are likely to have a particular kind of girl in mind.

The new sex selection methods have also been criticized as a gateway to consumer eugenics, both by public interest groups and by some practitioners in the assisted reproduction field. When the American Society for Reproductive Medicine seemed to endorse using PGD for social sex selection, the *New York Times* reported that this "stunned many leading fertility specialists." One fertility doctor asked, "What's the next step? As we learn more about genetics, do we reject kids who do not have superior intelligence or who don't have the right color hair or eyes?" (Kolata 2001).

Such concerns are exacerbated by the recognition that social sex selection constitutes a potential new profit center for the assisted reproduction industry. It would open up a large new market niche of people who are healthy and fertile, but who nonetheless could be encouraged to sign up for fertility treatments. Since about 2003, several assisted reproduction facilities have begun aggressively going after that market, running ads for social sex selection on the Internet, on radio, and in mainstream publications including the *New York Times* and the in-flight magazines of several airlines. If the parents of 5 percent of the four million babies born each year in the United States were to use MicroSort® sperm sorting at the current rate of $7,500 each, annual revenues would be $1.5 billion.

PROSPECTS FOR POLITICAL AND POLICY ENGAGEMENT. In India women's rights groups have long been at the forefront of efforts to enact laws prohibiting sex-selective abortion. As early as 1986 the Forum Against Sex Determination and Sex Pre-Selection began a campaign to enact legislation to regulate the misuse of embryo screening technology. Though laws have been on the books in India since 1994, they are often not enforced. China banned "non-medical" sex selection in 2004. The Council of Europe's 1997 Convention on Human Rights and Biomedicine also prohibits it, as do a number of European countries including the United Kingdom and Germany, with no adverse impact on the availability or legality of abortion. In 2004 Canada passed comprehensive legislation regulating assisted reproduction that includes a ban on sex selection. The United States currently has no federal regulation of sex selection.

In many parts of the world, even feminists who are deeply uneasy about sex selection have been reluctant to challenge it out of fear that to do so would threaten abortion rights. However, the emergence of pre-pregnancy sex selection methods makes it easier to consider sex selection apart from abortion politics, and may encourage new political and policy thinking about it.

SHELLEY, MARY WOLLSTONECRAFT

Mary Wollstonecraft Godwin Shelley (1797–1851), author of *Frankenstein* (1818), often considered the first science fiction novel and source of the universal modern image of science gone awry, was born in London on August 30 and died there on February 1. Her father, William Godwin (1756–1836), to whom *Frankenstein* is dedicated, was an important liberal reformer now best known for *An Enquiry Concerning Political Justice, and Its Influence on General Virtue and Happiness* (1793). Her mother, Mary Wollstonecraft (1759–1797), who died four days after her daughter's birth, was an important early feminist now best known for *A Vindication of the Rights of Woman* (1792). In 1814 young Mary eloped to the European Continent with Percy Bysshe Shelley (1792–1822), considered one of the greatest Romantic poets. Two years later, having already produced two children and begun *Frankenstein*, Mary married Percy after the suicide of his first wife. They had four children before Percy drowned, but only Percy Florence survived into adulthood. Mary never remarried, devoting herself to motherhood, writing, and editing her husband's works.

Mary treated science less as a solution to practical problems or an intellectual discipline than as a means to "afford a point of view to the imagination for the delineating of human passions more comprehensive and commanding than any which the ordinary relations of existing events can yield" (Shelley 1969, p. 13) Her consistent philosophical position, expressed in science fictions, historical romances, travel books, and essays, was staunchly democratic, based on her belief that while genius must be encouraged, when the discoveries of genius impinge on others, there must be responsibility to the wider community. Frankenstein's murderous monster represents the escape of untempered genius into the world.

Her novel *The Last Man* (1826) is the first in English of the subgenre of works that imagine a global catastrophe. In this case the Percy-like protagonist, Lionel Verney, moves from England to a progressively depopulated Europe, apparently the only human with a natural immunity to a new plague. In this situation science is encouraged to tame rampant Nature. Soon after the deaths begin, a character remarks to Verney that should "this last but twelve months . . . earth will become a Paradise. The energies of man were before directed to the destruction of his species: they now aim at its liberation and preservation" (Shelley 1965, p. 159).

Mary Wollstonecraft Shelley, 1797–1851. Shelley is best known for her novel *Frankenstein; or, The Modern Prometheus*, which has transcended the Gothic and horror genres and is now recognized as a work of philosophical and psychological resonance. *(Source unknown.)*

Science always raises social and moral problems in Mary Shelley's writing. In her philosophical satire "Roger Dodsworth: The Reanimated Englishman" (1826), the fact that someone is brought back from frozen suspended animation to live out a 209 year life span, raises fundamental questions of authenticity. Was he *alive* while frozen? Is his even one *life*?

In her fiction Mary Shelley consistently articulates ethical issues related to science and technology that have since become major themes of public discussion. In Percy Bysshe Shelley's poem "Queen Mab" (1813), we see the cleft stick implicit in the progress of science: "Power, like a desolating pestilence, / Pollutes whate'er it touches; and [yet] obedience, / Bane of all genius, virtue, freedom, truth, / Makes slaves of men, and, of the human frame, / A mechanized automaton." Mary Shelley contributes to ethical thinking about science and technology by calling on society to consider how the power of scientific genius might be limited by the moral claims of the human community. Mary Shelley asks humans, by pursuing science within a community, to do better than they—and her characters—have.

SHINTŌ PERSPECTIVES

The indigenous religion of Japan, Shintō describes human existence much like the popular singer, Sting: as spirituality in the material world. This worldview is the foundation of Japanese civilization and has endured and adapted for centuries. While Shintō recognizes spirit over materiality as the basis of life, it shares something compelling with the perspective of science: the human propensity to identify that which is most powerful in nature and to harness that power for a comfortable and happy human life. Both are able to channel the raw potential of nature toward specific human aims on all levels of society, from the domestic to the national, and both regulate human control over nature through ethical standards that rely on an unquestioning belief in the value system upon which they are built.

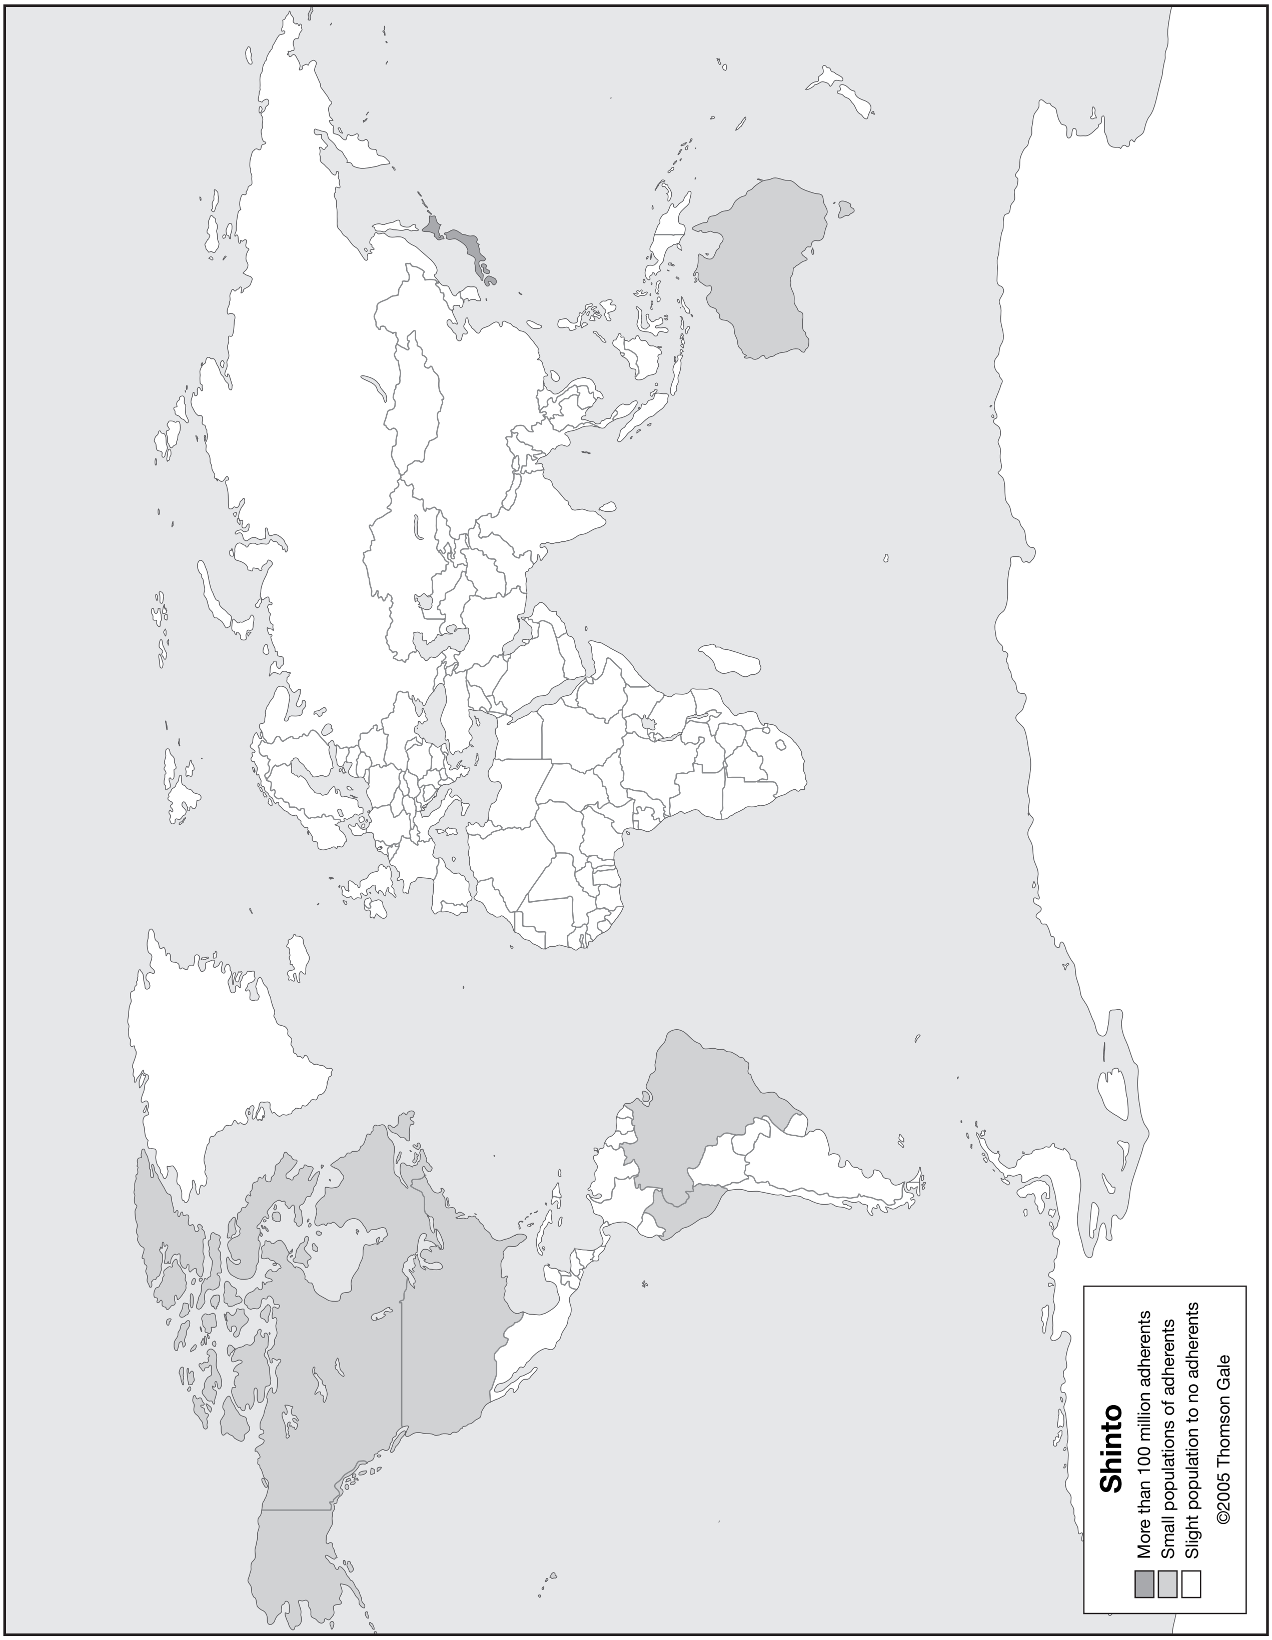
Traditional Teachings

Some of the earliest forms of science and religion sought to answer the question of the origins of living things. Practitioners of both looked to the sun for clues and based their theories and myths on its primordial role in sustaining life on Earth. The sun is the most reliable source of technology. It regulates time. Its proximity to the Earth allows life to flourish. The sun is the gravitational center of the solar system and causes all the planets to orbit it in precise yearly progressions. Hence many ancient cultures regarded the sun as a great celestial king, embodied as a human sovereign on earth.

Shintō, similarly, reveres the sun as the source of all forms of power in the world, both divine and temporal, and as the animating life force behind objective reality. The ancient Japanese personified the sun as a goddess, Amaterasu, who provided life-sustaining technologies—the cultivation of rice and wheat, the knowledge of harvesting silk from silkworms, and the invention of weaving. The goddess also allowed her grandson, Jimmu Tenno, to incarnate as the first historical mikado (emperor) of Japan. His descent to the sacred Japanese islands in 660 B.C.E. began an unbroken line in a divine solar dynasty. The mikado's chief role was to administer the life-giving force of the sun and its associated technologies within the conduct of Japanese life and ethics.

Shintō acknowledges the connection between fundamental natural processes, such as the live-giving, maintaining, and destructive nature of the sun, and the smooth function of human life lived in harmony with them. Nature is tangible power. Certain natural occurrences and objects possess more potency than others, such as the celestial bodies, mountains, rivers, fields, oceans, rain, and wind. These centralized embodiments of natural power, including also special people such as heroes and leaders, were divinized as *kami* (nature spirits) and worshipped.

Nature is very delicate; it can be disrupted easily. Of all living creatures, human beings have the unique propensity to consciously become disjointed from the balanced flow of nature. Its creative and destructive powers (*musubi*) and those objects (*kami*), both active and inert, that harness it rest on a fragile hinge. If nature's power is unleashed without a conduit, its destructive force can inhibit human happiness and survival. If the objects that house nature's power become contaminated, the creative functions of life stall or halt. The ancient Japanese regarded such obstructions as *pollution* (*tsumi*), overcome only through ritual ablution and lustration (*misogi harai*), likened to the polishing of tarnished silver. To overcome obstructions to nature's inherent balance caused by pollution, Shintō presents a threefold solution: conscious invocation of the power within a *kami,* ritual cleansing as the manner in which



Shinto
More than 100 million adherents
Small populations of adherents
Slight population to no adherents

to remove the pollution, and ethical conduct to prevent such pollution in the first place.

The Shintō tradition of the divine emperor together with the living presence of *kami* relies on the complete integration of politics, science, and religion, with Shintō, the *shen* (spirit) *tao* (the way of), as the unbroken thread connecting these three societal divisions. Even after shogun temporal authority resigned the *tenno*, the *heavenly god-king*, to symbolic status, the divinity of the emperor remained powerful in the cultural mind of Japan. The emperor would always be regarded as the true ruler of Japan, so much so that the tradition was reinstituted in 1868, ending the feudal rule of the shogun and beginning the *taikyo* (great teaching) movement of 1870 to 1884.

Modern Shintō

The Great Teaching Movement (1870–1884) brought Shintō into the modern world in the same manner as many other neoreligious and political movements—in the guise of an ancient tradition. Even though the divinity of the emperor was considered the basis of all civic and devotional duty, the ideology of the modern Western nation-state was beginning to take shape in Japan. Shintō became synonymous with the Japanese nation. The notion that Shintō, specifically with its concept of the divine emperor, was the exclusive religion of Japan made the Japanese a unique race, a belief successfully promoted through the national education system. It remained Japan's guiding ethos until the end of World War II.

Japan's entrance into the modern world involved much more than the reassertion of traditional values in a foreign governmental model. For the first time, Japan was exposed to Western technology, which led to its own industrial revolution beginning in the nineteenth century. At the same time that Japan was adopting new technologies, the emperor was restored to temporal power—achieving the modern-ancient blend that characterizes all non-Western nation-states.

Before Japan's contact with the West, Shintō did not have a code of ethics comparable to those of Western religions. Humans were regarded as fundamentally good because positive forces of nature, the gods, had created them. There is no original sin in Shintō. Salvation is deliverance from the troubles of the world, which often means the malfunction of the world. Evil is simply the lack of harmony between spirit and matter, which can be restored through ritual appeasement of the disturbed *kami*. Ethics based on the strict division between good and evil did not emerge in Shintō until the seventeenth century with the influence of Confucian dualism expressed in the war code of Bushido. The samurai who followed this code contributed the qualities of loyalty, gratitude, courage, justice, truthfulness, politeness, reserve, and honor to Shintō's system of natural ethics. From the Confucian Teachings of Kogzi, Shintō acquired its three central insignia: the mirror to symbolize wisdom, the sword to symbolize courage, and the jewel to symbolize benevolence.

By the 1890s observance of Shintō's reverence to the emperor became the secular obligation of every Japanese citizen and not a matter of personal piety. As a result, a threefold code of ethics distinguished Japan's national identity: loyalty to the country; harmony within the family; and, by extension, harmony within society as a whole through modesty, fraternity, and intellectual development. After World War II, Shintō influence was no longer part of the Japanese national identity because the post-war constitution provided for strict separation of religion and state. There is no official government support for Shintō in early twenty-first century Japan.

Contemporary Issues

Shintō beliefs continue to undergird Japanese popular culture, particularly in its relation to technology, a field that Japan has dominated since the end of World War II. Because Shintō recognizes an unseen force behind the machinery of the world, its application to the numerous human-made devices that provide conveniences to humankind is obvious. The most notable example of Shintō's interaction with modern technology was in connection with the Apollo 11 moon mission. Before the launch of Apollo 11, Shintō purification rites were offered to placate a potentially restive *kami*, the moon-brother of the sun, Amaterasu. The rites aimed to secure two goals: to avert the imbalance of the moon's natural rhythms affected by human-made machinery landing on its virgin soil, and to assure a successful journey for the spacecraft and its crew.

In the early-twenty-first century, the Japanese increasingly rely on machines to make life easier. However many unseen factors can cause mechanical malfunction. With computer viruses and their consequences rampant, Japanese high-tech businesses often invoke the favor of Shintō *kami* to prevent the damage caused by hackers. The nation's computer network sustains 35,000 cyber attacks each month and many companies believe that antiviral software will not solve the problem. From playing a role in the development of technology and the resolution of its associated problems to averting domestic disharmony by presiding over wedding unions, Shintō continues to maintain the spirit behind the material world.

SHIPS

Ships were invented before the beginning of recorded history. The Egyptians developed true sails by 3500 B.C.E., and the first sail-only boats were being used by 2000 B.C.E. For almost 4,000 years the leading technological developments involved refinements in sails and the design of larger and more powerful ships. The nineteenth century brought the development of steam power; after that time ships driven by electricity, fossil fuels, and even nuclear energy were developed.

Humans have used ships in warfare for almost the entire period of their development, first as a means of transporting soldiers and supplies, later as tactical vehicles for raids and looting expeditions, and then for strategic control of the seas. During the cold war era nuclear-equipped ships and submarines that were dispersed across the oceans to render them less vulnerable played a significant role in the nuclear deterrence strategy known as mutually assured destruction (Till 1984). Today, in a world where loose aggregations of terrorist organizations are considered the enemy, the role of a navy is being redefined again in light of incidents such as the 2000 suicide attack on the U.S.S. *Cole* by men in a small, innocuous motorboat packed with explosives.

Commerce

Throughout history ships have served as unifying forces, promoting multilateralism and cultural diversity through trade. However, ships also were used as tools of colonialism and exploitation. Some analysts have observed that the more contact Europeans made with African culture, the more contempt they manifested and the more violence they committed (Scammell 1995). Ships also served as unwitting vectors of diseases such as smallpox, which decimated the native population of the Americas. Chartered shipping companies often acted as proxies of government, carrying out policies of ruthless exploitation that went well beyond what governments could do in the face of public opinion (Jackson and Williamson).

Safety

The most common type of ship collision involves two ships heading toward each other on a course that would lead them to pass each other without incident. At the last moment one of the ships turns into and collides with the other. These accidents always involve a classic misinterpretation of visual data: The captain of one ship assumes that the other ship is going away from his or her vessel and is turning to set a course landward of the first ship (Perrow 1984).

Technology, usually improperly used, can make captains complacent and careless. Studies of ship groundings have revealed that officers did not take soundings even though they knew they were in shoal water, failed to monitor the tide and current, did not keep a proper record of bearings, did not recheck the radar, and failed to adjust a magnetic compass, which in one disastrous case deviated 20 percent from true north (Moody 1948).

Design Issues

Huge ships, like skyscrapers, present safety issues that are implicit in their design. "[L]uxury passenger liners constitute the most serious fire risk afloat. Superimpose a hotel, a cinema, and a pleasure pier onto a very large cargo vessel…" with all of the possibilities for chaos that would entail (Sullivan 1943).

After the *Titanic* disaster in 1912 it was revealed that the ship did not carry enough lifeboats to accommodate every passenger and crew member. The *Titanic* had twenty boats that could carry only a third of its total passenger and crew capacity (Jim's Titanic Website 2004). When the *Andrea Doria* sank in 1956, it listed an angle greater than that envisioned by the designers, and so the lifeboats on the uphill (port) side could not be launched ("Andrea Doria: The Life Boats" 2004).

The Environment

Ships have a significant environmental impact. They act as a vector for invasive species such as hydrilla weed and zebra mussels, which arrive attached to a ship's hull or in the ballast and are released into local environment, where they drive out native species. Ships sometimes accidentally hit and damage fragile coral reefs such as those in Pennekamp State Park, Florida, and marine mammals such as whales, dolphins, and manatees frequently are maimed or killed after colliding with ships' propellers.

The public consciousness long retains the names of ill-fated oil tankers that dump their cargoes into the marine environment. On the evening of March 23, 1989, the *Exxon Valdez,* as a result of navigational errors, grounded in Prince William Sound, Alaska, with more than 53 million gallons of oil aboard. Approximately 11 million gallons of oil were spilled, resulting in the deaths of 250,000 seabirds, 2,800 sea otters, 300 harbor seals, 250 bald eagles, up to 22 killer whales, and billions of salmon and herring eggs (Exxon Valdez Oil Spill Trustees Council 2004).

However, the quiet dumping of engine oil during normal operations accounts for a majority of the oil that pollutes marine environments (Boczek 1992). A variety of treaties provide an international regime that governs dumping and oil spills. Those treaties include the United Nations Convention on the Law of the Sea, four 1958 Geneva conventions, the 1969 Brussels Convention passed in response to the Torrey Canyon disaster, another 1969 Convention on Civil Liability for oil spills, and a December 1988 annex to the Marpol agreement that established strict controls over garbage disposal from ships at sea (Boczek 1992).

Dangerous cargoes sometimes explode in port, as occurred in the July 17, 1944, incident in Port Chicago, California, when a Pacific-bound navy ship being loaded with explosives by a work crew consisting mostly of black sailors exploded, killing 320 men. Concerned about another explosion, 258 black sailors refused an order to load ammunition on another ship and were court-martialed ("A Chronology of African-American Military Service" 2004). Later large-scale peacetime ship explosions include the April 16, 1947, explosion of the S.S. *Grandcamp* at the pier in Texas City, Texas, killing 576 people (Galvan 2004), and the May 26, 1954, explosion aboard the carrier U.S.S. *Bennington* at sea, which killed 100 sailors (Hauser 1954).

Status of Seafarers

Contrary to popular belief as reflected in movies such as *Ben Hur,* most oared ships in antiquity were not operated by slaves. Citizen rowers were less expensive because they were paid only when aboard ship and their deaths did not cost the state anything. However, Athens turned to the use of slaves at a point in the Peloponnesian War when it ran out of available citizens (Casson 1994).

In 1598 the chronicler Hakluyt wrote of sailors: "No kinde of man of any profession in the commonwealth passe their yeres in so great and continuall hazard . . . and . . . of so many so few grow to gray haires" (quoted in Scammell 1995, p. 131). Sailors faced a high mortality rate from disease, accidents, and combat. Unable to recruit enough sailors, the British government began the impressment, and essentially enslavement, of unwilling agricultural and industrial workers in the 1500s, a policy that would continue for almost three centuries (Scammell 1995). However, the sea was one of the few careers that allowed people of humble rank to move up to positions of status and power (Scammell 1995). A significant path out of the working class was blazed by engineers (Dixon 1996).

Today the lives of itinerant seamen on cargo ships are still dangerous, grindingly hard, and poorly compensated (Kummerman and Jacquinet 1979).

SIERRA CLUB

The Sierra Club is one of the leading non-governmental organizations that influence science, technology, and ethics relations from the environmental perspective.

Origins

The oldest environmental organization in the United States, the Sierra Club was founded in 1892 by a Scotsman, John Muir (1838–1914), who did not become a U.S. citizen until 1903. By 1892, however, he was already known to presidents and writers (including Ralph Waldo Emerson (1803–1882) as one of the country's most passionate advocates for the protection of wilderness.

Muir arrived in San Francisco, California, from Wisconsin in 1868 and headed to Yosemite Valley in the Sierra Nevada Mountains, which the avid outdoorsman had read about in a magazine. He spent the next seven years there, exploring, collecting plants, writing about his discoveries, and urging others to visit the high country. Those writings helped convince President Benjamin Harrison to create the Yosemite National Park in 1890.

In 1892 Muir became the first president of The Sierra Club, an association whose purpose as listed in its Articles of Incorporation was "To explore, enjoy, and render accessible the mountain regions of the Pacific Coast; to publish authentic information concerning them; and to enlist the support and cooperation of the people and government in preserving the forests and other natural features of the Sierra Nevada Mountains."

The Sierra Club-sponsored hiking and camping outings, called High Trips, that were fun but also meant to make members aware of and articulate about the preservation challenges facing the Sierra Nevadas. The education of such *activists* was important, for almost as soon as Yosemite National Park was established, efforts began to shrink it, strip it of federal protection, build a private railroad through it, and drown its beautiful Hetch Hetchy Valley behind a dam.

The park was shrunk and the proposal to build the dam passed in 1913, but all these fights—and especially the tragedy of the Hetch Hetchy defeat—helped transform the Sierra Club from a politically naive hiking club into a formidable and politically astute environmental organization. Its leaders now understood how the government worked and how important it was to win over public opinion to its causes. Outings and conservation were still integral to the Sierra Club, but so was political clout.

Contemporary Work

In the early twenty-first century, the Sierra Club is headquartered in San Francisco. With more than 750,000 members, it has lobbyists in Washington, DC, and a nationwide volunteer grassroots network striving to influence public policy on a variety of environmental issues.

Over the years, the club focus widened as environmental threats increased. Air and water pollution, urban sprawl, unsustainable logging, and the promotion of renewable energy—in addition to the protection of wilderness areas such as those in Yosemite—have emerged as some of the organization's top priorities. In recent years scientific pursuits in the areas of biotechnology—particularly as this new science relates to genetically modified organisms in agriculture and forestry—have been challenged by the club.

With regard to genetically engineered organisms, the club subscribes to a hard version of the Precautionary Principle and calls for a moratorium on the planting of all genetically engineered crops and the release of all genetically engineered organisms (GEOs) into the environment. It urges that where there are safer alternatives to the use of GEOs, these technologies should be given preference. On this topic the Sierra Club represents citizen science in action. Its biotechnology committee is all-volunteer. Some of its members are scientists but others are merely concerned citizens, worried about an unproven technology, who have researched the issue and feel compelled to act. Sierra Club committees make recommendations to the board of directors, which then formulates the club's *official* stand.

In the areas of energy conservation and renewables, the Sierra Club advocates for public transportation systems, energy efficient buildings and fuel efficient automobiles, and the use of renewable energy sources such as solar, wind, and geothermal power. The club has urged the U.S. Congress to provide for the expenditure of at least 2 billion dollars per year for at least five years for federal research and development—with emphasis on geothermal, solar, and fusion power; energy conservation and more efficient utilization of energy; and strip-mining reclamation. In 2001, when the U.S. government announced an energy plan that privileged oil, gas, and nuclear power interests, the Sierra Club sued to gain access to Vice President Dick Cheney's notes of meetings in which the energy policy was developed.

Following founder John Muir's statement that "Everybody needs beauty as well as bread, places to play in and pray in, where nature may heal and give strength to body and soul alike" (Muir 1912, p. 260), the Sierra Club has made an effort to broaden its preservation ethic to include what have come to be called *environmental justice* issues. Whether it is the threat to the Gwichin people's subsistence hunting from drilling in the Arctic National Wildlife Refuge or dioxin-spewing power plants in poor neighborhoods of Detroit or San Francisco, the Sierra Club attempts to reach out to communities not usually associated with the environmental movement and assist them in their struggles.

In the early 2000s the Sierra Club continues to promote outings, where hikers can explore and enjoy the wild places of the earth. But in a political and corporate environment that increasingly compromises the quality of water, air, and soil in pursuit of economic gain, organizations such as the Sierra Club have become essential advocates for the responsible use of the earth's ecosystems and resources. The Sierra Club's catalog of coffee table nature books and environmental literature can be accessed at http://www.sierraclub.org/books.

SIMON, HERBERT A.

Herbert Alexander Simon (1916–2001) was born in Milwaukee, Wisconsin, on June 15. He received his

Herbert Simon, 1916-2001. The study of decision-making behavior, especially in large organizations, led Simon to develop new theories in economics, psychology, business administration, and other fields. He was awarded the Nobel Prize in economics in 1978. He was also the first social scientist elected to the National Academy of Sciences. *(AP/Wide World Photos.)*

Ph.D. in political science from the University of Chicago in 1943, and taught at the Illinois Institute of Technology (1942–1949) before going to Carnegie Mellon University in 1949, where he remained until his death on February 9. Simon received major awards from many scientific communities, including the A.M. Turing Award (with Allen Newell; 1975), the Nobel Prize in Economics (1978), and the National Medal of Science (1986). During his career, Simon also served on the National Academy of Science's Committee on Science and Public Policy and as a member of the President's Science Advisory Committee. Simon made important contributions to economics, psychology, political science, sociology, administrative theory, public administration, organization theory, cognitive science, computer science, and philosophy. His best known books include *Administrative Behavior* (1947), *Organizations* (with James G. March 1958), *The Sciences of the Artificial* (1969), *Human Problem Solving* (with Newell 1972), and his autobiography, *Models of My Life* (1991). Having advanced the scientific analysis of decision-making, Simon's thought also has evident implications for bringing ethics to bear on science and technology.

A New Theory of Decision-Making

Decision-making was the core of Simon's work. It was the heart of his dissertation, later published as *Administrative Behavior,* and it became the basis of his other contributions to organization theory, economics, psychology, and computer science. Decision-making, as Simon saw it, is purposeful, yet not rational, because rational decision-making would involve a complete specification of all possible outcomes conditional on possible actions in order to choose the single best among alternative possible actions. In challenging neoclassical economics, Simon found that such complex calculation is not possible. As a result, Simon wanted to replace the economic assumption of global rationality with an assumption that was more in correspondence with how humans actually make decisions, their computational limitations, and how they access information in a current environment (Simon 1955), thereby introducing the concepts of *bounded rationality* and *satisficing.*

Satisficing is the idea that decision makers interpret outcomes as either satisfactory or unsatisfactory, with an aspiration level constituting the boundary between the two. In neoclassical rational choice theory decision makers would list all possible outcomes evaluated in terms of their expected utilities, and then chose the one that is rational and maximizes utility. According to Simon's model, decision makers face only two possible outcomes, and look for a satisfying solution, continuing to search only until they have found a solution that is good enough. The ideas of bounded rationality and satisficing became important for subsequent developments in economics.

Simon used this view of decision-making to create (together with March and Harold Guetzkow) a propositional inventory of organization theory, which led to the book *Organizations* (1958). The book was intended to provide the inventory of knowledge of the (then almost nonexistent) field of organization theory, and also a more proactive role in defining the field. Results and insights from studies of organizations in political science, sociology, economics, and social psychology were summarized and codified. The book expanded and elaborated ideas on behavioral decision-making, search and aspiration levels, and the significance of organizations as social institutions in society. "The basic features of organization structure and function," March and Simon wrote,

> derive from the characteristics of rational human choice. Because of the limits of human intellective capacities in comparison with the complexities of the problems that individuals and organizations face, rational behavior calls for simplified models that capture the main features of a problem without capturing all its complexities." (p. 151)

The book is now considered a classic and pioneering work in organization theory.

Interdisciplinary Contributions

Simon also incorporated these views into his contributions to psychology, computer science, and artificial intelligence. For example, in his work with Newell, Simon attempted to develop a general theory of human problem solving that conceptualized both humans and computers as symbolic information processing systems (Newell and Simon 1972). Their theory was built around the concept of an information processing system, defined by the existence of symbols, elements of which are connected by relations into structures of symbols. The book became as influential in cognitive science and artificial intelligence as Simon's earlier work had been in economics and organization theory.

During his amazingly productive intellectual life, Simon worked on many projects, yet essentially pursued one vision—understanding how human beings make decisions. He contributed significantly to many scientific disciplines, yet found scientific boundaries themselves to be less important, even unimportant, *vis-à-vis* solving the questions he was working on. Even as Simon sought to develop the idea that one could simulate the psychological process of thinking, he tied his interest in economics and decision-making closely to computer science and psychology. He used computer science to model human problem solving in a way that was consistent with his approach to rationality. He implemented his early ideas of bounded rationality and means–ends analysis into the heart of his work on artificial intelligence.

SIMON, JULIAN

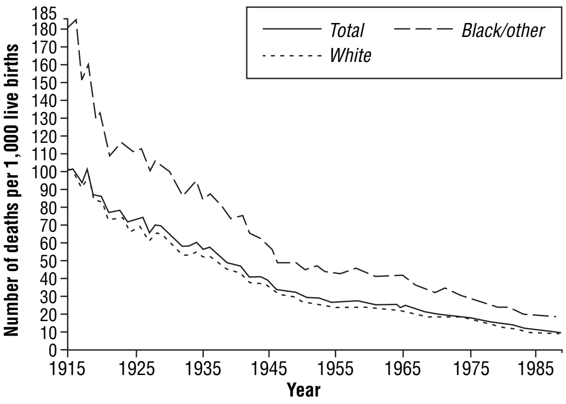
An economist who brought reams of evidence to bear against the conventional wisdom about the dangers of population growth and resource consumption, Julian Lincoln Simon (1932–1998) was born in Newark, New Jersey, on February 12; he attended Harvard University. After service in the Navy and work in advertising, Simon earned an MBA in 1959 and a Ph.D. in business economics in 1961, both from the University of Chicago. Although initially adopting the conventional Malthusian view that rapid population growth was a primary obstacle to economic prosperity in both the developed and developing worlds, his own research soon convinced him otherwise. Instead, science and technology, products of inexhaustible human ingenuity, have improved human welfare in nearly every measurable way and will continue to do so indefinitely into the future. He served as professor of business administration at the University of Maryland and distinguished senior fellow at the libertarian Cato Institute until his death from a heart attack in Maryland on February 8.

Against the Doomsayers

Simon had been fairly successful in the business and marketing fields during the mid-1960s. He operated a mail-order firm that was so lucrative he wrote the popular *How to Start and Operate a Mail-Order Business* (1965). But economic research led him to become critical of the grim Malthusian outlook on resource use and population growth popularized by Paul Ehrlich's *The Population Bomb* (1968) and *The End of Affluence* (1974), which argued that population growth was threatening human and environmental health. Simon replied that data from economists such as Simon Kuznets

FIGURE 1

Infant Mortality Rate, Total and by Race, United States, 1915–1989



SOURCE: *Historical Statistics of the US, Colonial Times to 1970,* Series B 136–147; *Statistical Abstract of the US, 1982–92*, table 111; *Statistical Abstract of the US, 1992*, table 109. In Simon (1995), p. 5.

(1901–1985) and Richard Easterlin (b. 1926) showed there was no general negative correlation between population growth and living standards (Regis 1997).

Simon began his much maligned public crusade against the conventional wisdom "doomsayers" with a 1980 article in *Science,* which declared that false bad news about resources, population, and the environment was being widely published in the face of contrary evidence. Tellingly, the article was written in the form of a statement followed by facts, because Simon believed that sound science revealed unequivocal facts about the state of the world. As he wrote in the preface to *The Ultimate Resource 2* (1996), "Indeed, the facts and my new conclusions about population economics altered my wider set of beliefs, rather than the converse" (p. xxxi). Here he implies that his adversaries are poor scientists because they allow preconceptions to trump empirical evidence. His major books and articles elaborating a positive view of the state of humanity are notoriously crammed with trend data in hopes that the weight of the facts will persuade readers of the doomsayers' errors.

Two trends that he saw as most convincing are declines in infant mortality and rises in life expectancy (see Figures 1 and 2). He also presented data on decreasing pollution, rising agricultural productivity, increasing standards of living, and the declining prices of natural resources and commodities. All of these figures detail the overarching story of human progress and affluence made possible by the ultimate resource, the human mind. Indeed, his central premise was that human ingenuity is boundless, creating unlimited resources to "free humanity from the bonds in which nature has kept us shackled" (Simon 1995, p. 23).

The Dialectic of Scarcity and Abundance

For Simon, the problems of scarcity and the achievements of abundance are not so much fundamental opposites as they are different moments in an ongoing process.

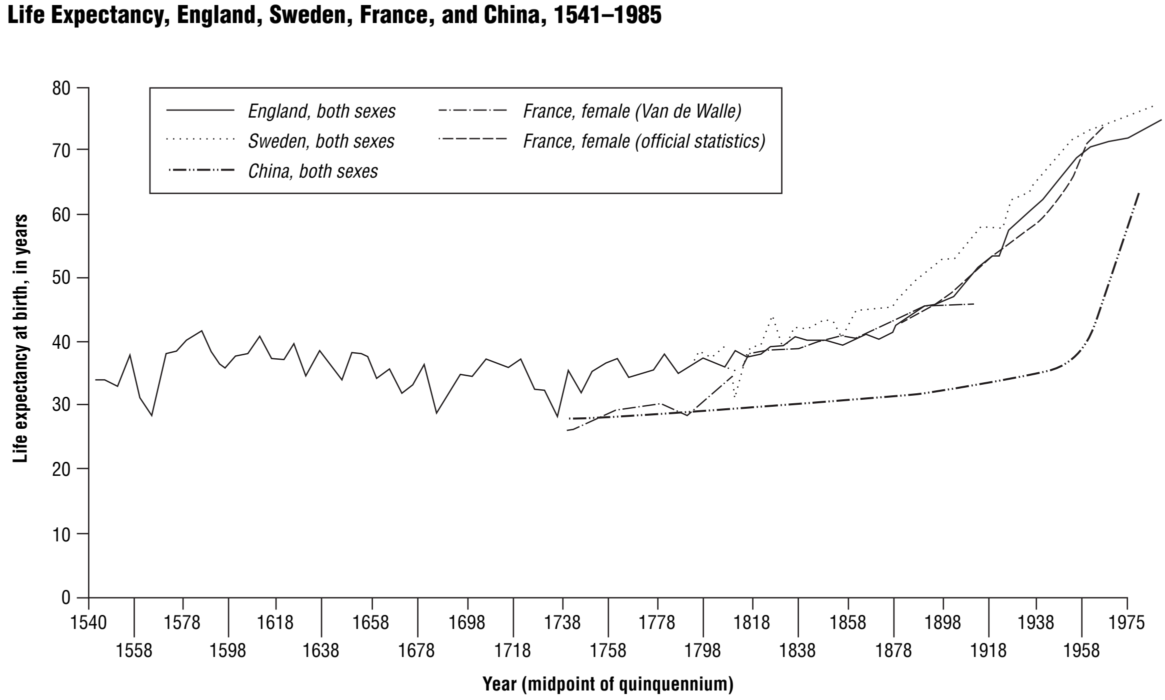
> The process goes like this: More people and increased income cause problems in the short run. These problems present opportunity, and prompt the search for solutions. In a free society, solutions are eventually found, though many people fail along the way at cost to themselves. In the long run the new developments leave us better off than if the problems had not arisen. [Indeed, human beings now have in their hands] the technology to feed, clothe, and supply energy to an ever-growing population for the next seven billion years. (Myers and Simon 1994, p. 65).

The evident hyperbole of this rhetoric should not be used to portray Simon as a Pollyanna. Problems do arise, people are harmed, and people often fail in trying to solve them. But the larger perspective reveals that the process produces ultimate benefits for human welfare, which Simon insists are best measured by long-run trends. There is a sense of theodicy in Simon's vision.

With regard to long-run measurements, absolute trends comparing present and past states of affairs are more important than relative trends comparing two contemporary variables. Simon also argues that broad aggregate measures should emphasize effects on people rather than phenomena themselves. For example, he measures life expectancy rather than occurrences of AIDS, or agricultural productivity rather than global warming.

Moreover, the dialectic between scarcity prediction and abundance production highlights Simon's core belief that liberty is the most important precondition for progress. Free markets, free institutions, and even the free flow of immigrants are necessary for long-term material progress. Most centrally, people ought to be free to have as many children as they desire, in part because children, through their own inventiveness, will add to human welfare. A better future does not happen automatically, but requires free and well-informed decisions.

FIGURE 2



SOURCE: Simon (1995), p. 9.

Finally, warnings about scarcities have a role to play in human welfare production. Unlike his opponents, who find his position detrimental, Simon actually grants critics an important if limited role in progressive developments. Simon's worldview partially depends on doomsayers to spark the impetus that steers humanity toward a better future.

Nonetheless, Simon believed that the "false bad news" of doomsayers is often overstated and can become counterproductive if not shamelessly self-promotional. With Herman Kahn (1922–1983) he co-edited *The Resourceful Earth* (1984) to discredit one such pessimistic volume, the *Global 2000 Report to the President* issued by the Global 2000 Study in 1980. More famously, Simon engaged in a highly publicized bet with Paul Ehrlich (b. 1932) in 1980. Ehrlich wagered that at least five of ten non-renewable resources (of his choosing) would be more expensive ten years later. Simon won the bet. In 1990, every one of the resources had declined in price by an average of forty percent. (When offered an opportunity to renew the wager for the next ten-year period, Ehrlich declined.)

As a result of his advocacy, Simon's ideas have won many converts to the idea that the status quo with some modest incremental adjustments will be sufficient for continued improvement in human well-being (e.g., Bailey 1993, Wildavsky 1995). His last major book, *The State of Humanity* (1995), was written with more than sixty collaborators. But despite the increased respectability accorded to Simon's views, they remain contentious and do not represent the mainstream in resource and population economics.

Science, Values, and the Hermeneutics of Data

From his very first article, Simon has been attacked by those who disagree with his views. Ehrlich called him an "imbecile," others considered his ideas simpleminded and dangerous, while most in the mainstream tried to refute the validity of his statistics (Regis 1997). But if the facts tell an unequivocal story, why is there so much disagreement? And if the facts corroborate Simon's analysis, why were his views so unpopular? Simon often felt that he was being ignored due to "a vast Malthusian population-environment-resources conspiracy of crisis" (1999, p. vii). In the posthumously published *Hoodwinking the Nation* (1999), he took up the question of why so much "false bad news" persists. He cited academic and media incentives and vested interests, psychological factors, strategies of change based on the assumption that crises mobilize action, racism, the non-intuitive nature of some of Simon's arguments, and widespread misunderstanding of resource creation and population economics. In all cases, he argued that what is at issue is the discrepancy between dominant, misguided beliefs and the facts of the matter.

On this level of psychological and sociological analysis, Simon undoubtedly presents some accurate findings. Yet a deeper level of analysis opens up beyond this limited argument that Simon has the true science and the absolutely correct data while others are just misled or willfully distorting the truth. For example, a graph may demonstrate that forest cover is increasing, but the reason for this may be the rise in forest plantations rather than recovery of more natural systems. Thus, the fact of increased forest cover leaves room for interpretation about its meaning and whether it is a good or a bad sign. Furthermore, some may find fault in Simon's anthropocentric view. They may regard global climate change as a problem even if humans are able to adapt to it, or they may object to his idea that genetic engineering and seed storage are reasonable responses to species extinction (1995, p. 15). Finally, some may argue that his categories miss the most important trends as he substitutes "what can be easily counted" for "what really counts." For example, in *The State of Humanity,* Simon admits that his trends describe only material and economic welfare but not emotional or spiritual welfare.

Unfortunately the underlying values differences between Simon and his adversaries are not often explicitly addressed. This held true of a similar controversy surrounding one of Simon's protégés, Bjørn Lomborg (b. 1965), author of *The Skeptical Environmentalist* (1998). Like Simon, Lomborg attacked the conventional wisdom and was in turn rebuked in a passionate series of exchanges with other scientists. Although disputants often claimed to be debating the facts, in reality the issues were much larger.

Despite his often zealous reliance on facts, Simon was perhaps aware of this dynamic to a greater extent than Lomborg. Whereas Lomborg concludes that we need to base decisions "not on fear but on facts" (p. 327), Simon concludes *The Ultimate Resource 2* with a section titled "Beyond the Data," including a subsection titled "Ultimately—What Are Your Values?" In this latter section he argued: "Whether population is now too large or too small, or is growing too fast or too slowly, cannot be decided on scientific grounds alone. Such judgments depend upon our values, a matter on which science does not bear" (p. 548). Measuring the real state of humanity or the world involves normative as well as scientific considerations.

SIMPLICITY AND SIMPLE LIVING

The term *simple living* is generally used to refer to a voluntarily chosen way of life that is significantly less frenetic, and significantly less focused on "getting and spending," than life in the mainstream. Simple living traditions exist in a wide array of cultures, and date back thousands of years. But they take on special salience in highly affluent societies dependent on science and technology for their patterns of production and consumption.

The term *simplicity* is sometimes used synonymously with *simple living,* but this can lead to confusion as one of the potential uses of high levels of income is to purchase solutions to the burdens of everyday life. Thus, the very wealthy can afford to have personal assistants to take care of their finances, assist in childrearing, and manage the household, vastly simplifying their existence.

Basic Arguments

A theme common to many diverse simple living traditions is that too great an involvement with money is deeply problematic. A classic presentation of this thesis is found in Aristotle's *Politics* (4th century B.C.E.), which opens with a critique of excessively commercialized civilization. Aristotle (384–322 B.C.E.) distinguishes between what he terms natural and unnatural ways of life. Among the natural ways are hunting, fishing, and farming. What is distinctly unnatural is commerce, whose hallmark is that the pursuit of money takes on a life of its own, knowing no bounds.

Aristotle offers two critiques. The first anticipates the economic theorists of the nineteenth century: Aristotle argues for the diminishing marginal utility of money, maintaining that beyond a limited sufficiency, additional money does not contribute to human happiness. His second thesis is yet more radical, arguing that the unbridled absorption in attaining money results in the misuse of human capabilities and the distortion of the personality. When elevated to the social level, this produces a society in which all social roles have been corrupted. Doctors no longer pursue the health of the patient; jurists no longer seek justice. All activities are ultimately undertaken in pursuit of financial gain.

The two issues Aristotle raises, distortion of the personality and corruption of social roles, are two of a number of concerns that have motivated proponents of simple living. An example of the first is Henry David Thoreau (1817–1862), who wrote in *Walden* (1854) that wealth is a curse because it enslaves us. "I see young men, my townsmen, whose misfortune it is to have inherited farms, houses, barns, cattle and farming tools; for these are more easily acquired than got rid of." And, "The finest qualities of our nature, like the bloom on fruits, can be preserved only by the most delicate handling. Yet we do not treat ourselves nor one another thus tenderly" (Thoreau 1965, p. 4 and p. 6).

An example of the second concern, the health of the society, can be found in what has been called *Republican Simplicity* by historian David Shi. In the mid 1700s prior to the American Revolution, many of the leaders of that Revolution looked to the history of ancient Rome and Greece for guidance in their democratic venture. The lesson that they drew was that public virtue was necessary for the success of a republic, and that it could be undermined by excessive commercialism. John Adams (1734–1826) and Thomas Jefferson (1743–1826) corresponded about how to build a non-materialist society, and Jefferson looked to state-supported schools and value education as a foundation.

In the writings of the Quaker theorist John Woolman (1720–1772), one finds two lines of thought, both of interest. First, in contrast to the Puritans, Woolman suggested that the simple life also involved limitations on the amount of work one would do. This would later be expanded on by Thoreau, who suggested that we should have one day of work and six days of Sabbath. Secondly, Woolman argued that most of the ills of the world—poverty, slavery, war—could be traced to luxurious desires. He urged that we examine our own lives and see whether, unwittingly, we are part of the problem. He said we should "look upon our treasures, and the furniture of our houses, and the garments in which we array ourselves, and try whether the seeds of war have nourishment in these our possessions or not." The contemporary application of this outlook is the suggestion that war in the Middle East, and perhaps terrorism as well, have their roots in our excessive consumption of oil.

Benjamin Franklin (1706–1790), another American advocate of simple living, came to it from a rather different direction. Franklin argued the importance of the individual's liberation from the demands of onerous labor. "Employ thy time well, if thou meanest to gain Leisure." But Franklin argued for sharply limiting our consumption, so that we may save. His message was that we could all become wealthy if we learned to discipline ourselves, limited our desires, and earned more than we consumed.

Assessment and Application

These various examples make clear that simple living can be advocated for a wide variety of reasons. It represents no single philosophy of life. And while there are some exceptions—perhaps Franklin is one—what they have in common is the view that the good life, both individually and socially, is to be found largely outside the economic realm. Human happiness is obtained not by consuming more and more of what the economy has to offer, but by satisfying core economic needs, and then turning away from the economic to other realms of importance, whether they be religion, science, literature, service to others, or friends and family.

While much of the simple living literature is directed at the individual, offering advice and suggestions for how to live, simple living at times emerges as a politics of simplicity. Here it looks to social policy to offer the framework within which it becomes feasible for the average person to opt for a simple life. Such a politics offers a different paradigm for understanding the relationship between a technological economy and the good life. Economic performance is assessed not in terms of growth, but in terms of success in meeting core needs of the entire population. Technological and economic progress is measured more in terms of the expansion of leisure than the growth of gross domestic product (GDP). And work, rather than being seen as one productive input within the production process, is seen, potentially, as a realm within which personal growth and meaning can be achieved.

SINGAPORE

Small states, like small businesses, often serve as the incubators of new forms of government. Perhaps no state has been so carefully and deliberately managed as Singapore, a multi-ethnic island city-state of 4 million inhabitants in an area of 250 square miles, or about the size of Guam. Because of the ways its management has sought to utilize science and technology to achieve certain social values, which has itself influenced some of these values, Singapore provides a useful case study in the possible relations between science, technology, and ethics.

Background

Located on the southern tip of the Malay Peninsula and separated from Indonesia, the largest Muslim country in the world, by the Straits of Malacca, Singapore was colonized by the British in the early 1820s due to its strategic location (for the British, it was the Gibraltar of the East). Important because it served as both a submarine port and had a major airfield, the Japanese captured Singapore during World War II. After the war it evolved toward independence in phases: It elected its first legislature in 1955 and was granted internal self-government in 1959. In 1963 Singapore joined the Federation of Malaysia, but separated in 1965 and has been fully independent since.

The People's Action Party (PAP), founded and dominated by Lee Kuan Yew (b. 1923), a British-educated lawyer, has led the country since the mid-1950s, creating a single-party state dedicated to the pursuit of economic growth through social order and efficiency under the guidance of a technocratic ideology. The result has been one of the most globalized entities in the world, measured in terms of foreign trade, investment, information inflows, and immigration. Between 1971 and 2003, Singapore's economy expanded at an average annual gross domestic product (GDP) growth rate of 7.2 percent. It enjoys one of the highest standards of living in Asia and was ranked sixth in the Growth Competitive Index conducted by the World Economic Forum in 2003.

From Stability to Creativity

Constant technological upgrading has been vital to the economic ascendancy of Singapore, and social policies have been reflexively monitored and implemented—whether in the streaming policies of the educational system, the level of civil liberties, or the value system of society—to ensure Singapore's global economic relevance. The political elite's Hobbesian view of national and international politics underpins Singapore's broad ethical approach to economic and technological development. The dominant image widely propagated in Singapore is that of a vulnerable city-state, lacking both natural resources and the cultural homogeneity of a Japan or a Korea (Singapore's ethnic composition is 76.8 percent Chinese, 14 percent Malay Muslim, and 8 percent Indian), and surrounded by potentially volatile Malay Muslim neighbors. The Singaporean leadership has used "survival" to justify the hierarchical management of society. The resulting political system has been dubbed by Chan Heng Chee (1989) as "the administrative state," a term that captures the depoliticization of the citizenry and the central place of a powerful bureaucracy in managing society. The political elite sees itself as practicing a pragmatic style of governance, understood as the ability to act rationally in the interest of the collective good without getting bogged down by moral and democratic excesses (Chua 1995).

The value framework has varied with the technological challenges facing Singapore. From the mid-1960s to the mid-1990s, technocratic planners invited multinationals from around the world to invest and manufacture consumer goods, and later highly sophisticated engineering components, for the global market. Founding leader Lee Kuan Yew, with strong eugenics views (Barr 2000), did not believe that Singapore's small population could produce a critical mass of creative individuals doing cutting-edge research. Instead, science and technology policies focused on producing highly competent citizens who could absorb and perhaps re-engineer products and processes from existing technology. Huge investments were made in tertiary education to supply technicians and engineers for the multinational sector at cheaper costs than in Western countries. Generous tax incentives, a highly controlled labor movement, and the sheer predictability of politics attracted some 7,000 well-known global companies to invest in the economy. These included such names as Philips, Honeywell, Hewlett-Packard, Seagate, Motorola, Exxon-Mobile, NEC, Siemens, and Sony.

In this phase, the ethical framework laid out by the government for technology development was a broad, society-wide one rather than a set of specific policies applied to particular industries or sectors. Singaporeans were expected to be socially disciplined, to comply with the technocratic goals of the government, and to refrain from excessive individualism and political expression (Quah 1983). They were asked to subscribe to a stereotypical notion of Asian values, which the leaders believed would help the population ward off pernicious Western practices, such as weak commitment to the family, a propensity for contention over consensus, and a disrespectful youth culture. Singapore became famous for harsh punishments for behaviors such as littering, failing to flush public toilets, and small-scale drug dealing. The government expected conformity and in turn promised order, prosperity, integrity, and dedication to the collective good.

In the 1990s, however, new competitive pressures led to a major shift in the government's approach to technological development, and in almost cybernetic fashion, adjustments in social regulation policies. Countries previously outside the global capitalist system, such as China, India, and Central Europe, were now entering the global market. The Asian crisis that began in 1997 saw multinationals changing locations in the region. Gripped by concerns of national survival, planners saw the need to go beyond using multinationals for economic development and technology transfer, and undertook to produce original knowledge and technology. The planners hoped to build on existing educational and scientific infrastructures, such as the Institute of Molecular and Cell Biology (IMCB), which had been set up in 1987, to embark on original research.

The sectors targeted to spearhead the knowledge-based economy were bioscience and biomedical research, with foci in tissue engineering, stem cell research, immunology, and cancer research. Through these efforts, Singapore hoped to become a major player in pharmaceuticals, medical equipment, and health services. More than a billion U.S. dollars was committed toward creating an integrated medical and biotechnological park, Biopolis, and huge funds were earmarked for strategic investments in local and foreign biotechnology companies.

Framework for Policy and Ethics

The key question was how Singapore, without a long history of broad-based original research, would make the transition from being a technology-recipient to technological innovator. This challenge was met with a two-pronged approach. The planners mapped out a research process in which innovation would be carried out and directed by global research stars drawn to Singapore by alluring financial terms, including generous research funding. The other tack, and an important further inducement for researchers, was the creation of a stable and predictable milieu for long-term research, particularly in the biomedical area, unencumbered by moral and religious obstacles. Some technologically sophisticated nations, especially the United States, were putting restrictions on research involving living embryos, so Singapore's ability to provide a liberal moral climate allowing for such research would place it in a comparative advantage. Singapore's technocrats now had to use skills that had provided the high degree of economic, social, and political predictability during the technology-receiving phase to lay the requisite financial and ethical predictability for these new research and technological goals.

The challenge in creating a liberal moral climate involved coming to terms with local religious groups, particularly those from the growing Christian population among the upper stratum of Singaporeans. In addition, to gain legitimacy from the international community of researchers and regulators, Singapore had to demonstrate that it was not a morally renegade society but was committed to socially responsible research. This led the government to set up the Bioethics Advisory Council (BAC) in late 2000 to make recommendations for bioscience and biomedical research in Singapore. The committee, which was chaired by the former Vice-Chancellor of the National University of Singapore, stated that it would consult civil society groups, professional associations, and religious organizations in carrying out its charge, and promised to proceed with caution "so our findings and recommendations will be acceptable to society" (*Straits Times*, February 7, 2001).

Civil society in Singapore was generally quiescent (Tamney 1996), but on this morally sensitive issue involving the use of human embryos for research, religious groups freely gave their opinion. (Singapore is 42.5 percent Buddhist, 15 percent Muslim, 14.5 percent Christian, 8.5 percent Daoist, 4 percent Hindu, and 15 percent claiming no religion.) Most professional groups went along with embryonic stem cell research, but there was consternation among the religious representatives. Muslim representatives, believing that ensoulment of the human being begins forty days after conception, were amenable to early stage embryonic research. The same was true of the Buddhist groups, which view genetic research as helping humankind. By contrast, Protestant and Catholic bodies, as well as Hindu and Daoist representatives, objected to any destruction of embryos to obtain stem cells. Daoists argue it was against nature's way, Christians define life as beginning at conception, and Hindus see the destruction of the embryo as short-circuiting the karmic cycle. The deontological ethical position of these groups was at variance with the BAC, whose desire was to see bioscience development in Singapore. As far as the BAC had an ethical position, it was a consequentialist one, proffering the benefit to humankind of finding cures to terrible diseases as a result of bioscience research. The Council subsequently ruled that its recommendations would not be dictated by religious positions, and argued, in typical pragmatic language, that research had to move ahead because "Singapore is a small place" (*Straits Times*, December 28, 2001).

Its recommendations, which were incorporated in the Biomedical Research Act of 2003, allowed for stem cells to be obtained from human embryos less than fourteen days old, the age just before the neurological system developed (Bioethics Advisory Committee 2002). Embryos less than fourteen days could be cloned but there would be no cloning of embryos for reproductive purposes. As if to underscore its ethical concerns, the Council stressed that all researchers and doctors required the consent of patients and embryo donors. In addition, the BAC was keen to point out that its recommendations were no more lax than legislation in other democracies such as the United Kingdom, Australia, Japan, and Sweden. In short, it was acting well within international norms. Despite some religious misgivings, resulting legislation is likely to preempt any future religious or moral objections, because both the government and the regulatory bodies can claim that society had been fully consulted in the decision-making process, and most groups went along with the final recommendations.

Singapore's liberal moral climate and weak civil society has earned the praise of many top scientists. A number of U.S. scientists, responding to the Bush administration's banning of embryonic research and its strict control over the use of existing stem cell lines, have found Singapore to be a more hospitable climate for their research. Dr. Philippe Taupin, a renowned biologist previously at the Salk Institute, gave the following reason for his move to Singapore in 2003: "I came here because I want to jumpstart my career. There are fewer ethical and political minefields than in the West, and Singapore has pledged a strong commitment to stem cell biology" (*Straits Times*, February 17, 2004).

Prospects

Singapore's strategy of bringing in experts from abroad has been impressive. Generous funding, which makes it unnecessary to apply constantly for research grants, and an uncritical climate, which extends to the plentiful supplies of laboratory mice undisturbed by animal rights activists, have been major draws. An influx of high-profile researchers would help both to leapfrog into cutting edge research and attract younger scientists the world over by establishing a prestigious and reputable climate. In 2003, 30 percent of the 3,600 Ph.D.s working in the biomedical sector were foreigners. Global stars such as Edison Liu, formerly at the National Cancer Institute in the United States, Alan Colman of "Dolly the sheep" fame, and Yoshiaki Ito from Kyoto University have given Singapore overnight attention as a global research center. Whole research teams from Japan and France have immigrated and been generously funded. The administrative coordination of education, immigration, and the health sector to support the advancement of bioscience has greatly impressed foreign researchers. Liu, who came to Singapore in 2001 to head the Genome Institute of Singapore (GIS), marveled at the integrative approach of the leaders and planners: "They are strategic thinkers, and are smart enough to view this as a whole. It is the most astounding social engineering I have seen in my life" (*Far Eastern Economic Review*, October 9, 2003).

The top-down control of society has not prevented the pragmatic relaxation of social controls from helping to realize the leaders' economic goals. Departing selectively from its previous preoccupation with social discipline and conformity, the government now asks Singaporeans to become creative individuals willing to take entrepreneurial risks. Activities such as bungee jumping, bar-top dancing, and street busking, once banned and frowned upon, are now being permitted to foster an adventurous spirit among the population. The most dramatic reversal has been to allow the lesbian and gay population to join the civil service. The tolerance of homosexuality, once derided as contrary to Asian values, is now seen as consistent with the pursuit of creativity—as argued by Richard Florida (2004).

Ethical Ambiguity

It would not be surprising if the urgency of meeting national economic goals in conjunction with the pragmatic design of the ethical framework for research should leave some ambiguity about the moral boundaries of research. A test case occurred in 2002, involving a world-famous British researcher, Dr. Simon Shorvon, a neurologist who had done pioneering work in epilepsy and Parkinson's disease. After being courted by Singapore authorities, he took up the position of Director of the National Neuroscience Institute. Shorvon's research into the role of genetic mutations in Parkinson's required patients to go off their medications while he studied the effects of administering various doses of L-Dopa and traditional Chinese herbs. The research design required 1,500 Parkinson patients, but only twelve volunteers were available as of July 2002.

To secure more subjects, Shorvon retrieved records from the databases of pharmacies, deliberately bypassing the patient's doctors, and then led patients to believe that they had their physicians' approval for their research participation. In his experiments, Shorvon and his co-workers sometimes administered drugs at dangerously high levels, causing a few serious complications. When Singapore neurologists learned of his research and complained, he dismissed their concerns by saying that his methods were sensible and efficient, and claimed he had the backing of the various hospital review boards. Many of the Singapore doctors, including established professors, were torn between their commitment to patient rights and research ethics and the presumed importance of Shorvon's research. None of his peers and fellow neurologists made an official complaint.

Consistent with the top-down system of control in Singapore, it took a member of the inner circle of the elite to highlight and publicize the wrongdoing. Dr. Lee Wei Ling, a neurologist and (then) Deputy Director of the National Neuroscience Institute, is also the daughter of Lee Kuan Yew and sister to the current prime minister. When she was hospitalized for a neurological problem, her fellow neurologists mentioned the activities of Dr. Shorvon (*Straits Times*, April 4, 2003). Dr. Lee then reported him to the relevant authorities, leading to his removal. The interesting point about this case is not the lack of ethical standards in Singapore's research setting, but the fact that individual doctors and researchers did not feel sufficiently empowered by the hierarchical ethical system to take it upon themselves to expose wrongdoing. It took a member of the elite, who fortuitously happened to personally object to the egregious activities, to give weight to the ethical framework already in place.

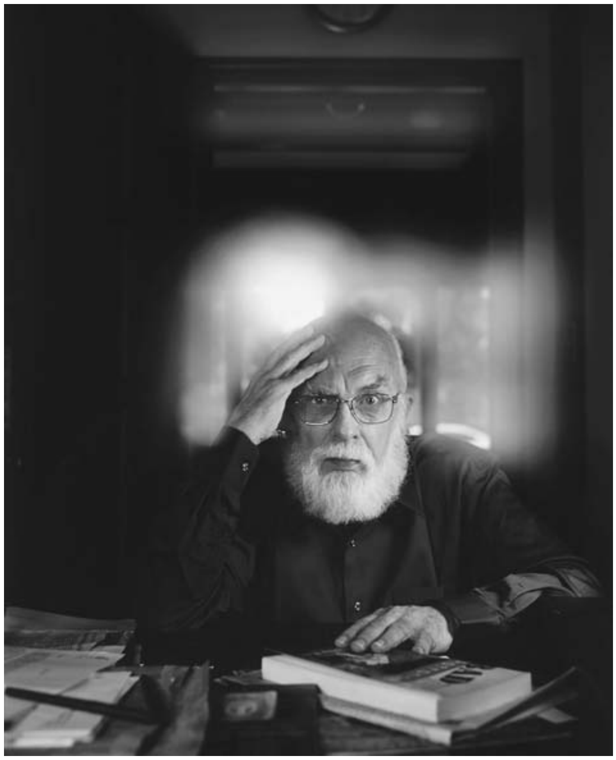
SKEPTICISM

Skepticism has a long history that includes multiple meanings and in the early twenty-first century has complex ethical implications for science and technology. It plays an important role *within* science and technology but also can be *applied to* the same areas. In the former case skepticism may serve as a means to reject mistaken or false claims, limit fraud and misconduct, and produce evaluations of engineering designs and the safety of technologies. In the latter case skepticism may help the public place the benefits of science and technology in a larger perspective, although it also may deprive the public of certain real benefits.

Antecedents

The roots of skepticism can be traced back at least 2,500 years to the ancient Greeks. The historian of skepticism Richard Popkin states: "Academic scepticism, so-called because it was formulated in the Platonic Academy in the third century, B.C.E., developed from the Socratic observation, 'All I know is that I know nothing'" (Popkin 1979, p. xiii). In fact, the philosopher Pyrrho and his followers doubted the possibility of real knowledge of any kind, a viewpoint that led to a form of nihilism. Skepticism in this sense is a positive assertion about knowledge and thus cannot be held seriously if it is turned on itself: If one is skeptical about everything, one also has to be skeptical about one's own skepticism. Like a decaying subatomic particle pure skepticism uncoils and spins off the viewing screen of the mind's intellectual cloud chamber.



Magician James "the Amazing" Randi. Randi's media presence has brought the skeptical movement into the public consciousness. *(© Jeffery Allan Salter/Corbis.)*

A more pragmatic meaning of the word *skeptic* can be found in the Greek word *skepsis,* which means "examination, inquiry, consideration." The *Oxford English Dictionary* gives this historical usage: "One who doubts the validity of what claims to be knowledge in some particular department of inquiry; one who maintains a doubting attitude with reference to some particular question or statement," along with "a seeker after truth; an inquirer who has not yet arrived at definite convictions." Skepticism is not "seek and ye shall find" but "seek and keep an open mind." In this context having an open mind means finding the essential balance between orthodoxy and heresy, between a total commitment to the status quo and the blind pursuit of new ideas, between being open-minded enough to accept radical new ideas and being so open-minded that one's brain cannot function.

Since the time of the ancient Greeks skepticism has evolved along with other epistemologies. On one level the Enlightenment was a century-long skeptical movement because there were few beliefs or institutions that did not come under the critical scrutiny of thinkers such as Voltaire (1694–1778), Denis Diderot (1713–1784), Jean-Jacques Rousseau (1712–1778), John Locke (1632–1704), and Thomas Jefferson (1743–1826). David Hume (1711–1776) in Scotland and Immanuel Kant (1724–1804) in Germany were skeptics' skeptics in an age of skepticism, and their influence continues to be felt in the early 2000s. In the twentieth century Bertrand Russell (1872–1970) and Harry Houdini (1874–1926) stood out as representatives of skeptical intellectuals and activists, respectively. Martin Gardner's *Fads and Fallacies in the Name of Science* (1952) launched the contemporary skeptical movement.

The Contemporary Skeptical Movement

Starting in the 1970s, the magician James "the Amazing" Randi's psychic challenges and media appearances pushed the skeptical movement to the forefront of public consciousness. In 1976 the philosopher Paul Kurtz (born 1925) founded an international skeptical organization called the Committee for the Scientific Investigation of Claims of the Paranormal (CSICOP), and in 1991 Michael Shermer cofounded the Skeptics Society and *Skeptic* magazine. This has led to the formation of a burgeoning group of people calling themselves skeptics who conduct investigations, hold monthly meetings and annual conferences, and provide the media and the general public with natural explanations for apparently supernatural phenomena.

Although intellectual skepticism flourishes in academia, skeptical activism has emerged as a powerful force in the application of science to all claims. In fact modern skepticism is embodied in the scientific method, which involves gathering data to formulate and test naturalistic explanations for natural phenomena. A claim becomes factual when it is confirmed to an extent where it would be reasonable to offer temporary agreement. However, all facts in science are provisional and subject to challenge, and skepticism thus is a method that leads to provisional conclusions.

Some claims, such as water dowsing, extrasensory perception (ESP), and creationism, have been tested and have failed the tests often enough that they may be rejected provisionally as false. Other claims, such as hypnosis, near-death experiences, and neurological correlates of consciousness, also have been tested, but the results have been inconclusive. Finally, there are claims, such as string theory, inflationary cosmology, and multiple or parallel universes, that are theoretically possible but have not been tested empirically. The key to skepticism is to apply the methods of science continuously and vigorously to make it possible to navigate the straits between "know nothing" skepticism and "anything goes" credulity. In this sense skepticism is the ethical component of science. It is the attitude that keeps the scientific method honest, the canary in the scientist's mine.

Ethical Issues

In regard to ethical concerns it is important to recognize the fallibility of science and skepticism. Although scientific skepticism is well suited for identifying certain kinds of mistakes and errors in thinking, such as what are called type I errors, or false positives, its standards are so high that it occasionally leads to the commission of a type II error, or false negative, failing to identify, for example, potential lifesaving medicines.

However, within this fallibility there are opportunities for self-correction. Whether mistakes are made honestly or dishonestly, whether a fraud is perpetrated unknowingly or knowingly, in time it will be recognized. The cold fusion fiasco in the late 1980s was a classic example of how organized skepticism can identify hype and error. Because of the importance of this self-correcting feature, there is in the profession what the Nobel laureate physicist Richard Feynman called "a principle of scientific thought that corresponds to a kind of utter honesty—a kind of leaning over backwards." As Feynman explained: "If you're doing an experiment, you should report everything that you think might make it invalid—not only what you think is right about it: other causes that could possibly explain your results" (1988, p. 247). Of course, not all scientists live up to this ideal.

What separates skepticism and science from other human activities is the tentative nature of all conclusions: There are no final absolutes, only varying degrees of probability. Skepticism is not the affirmation of a set of beliefs but a process of inquiry that leads to the building of a testable body of knowledge that is open to rejection or confirmation. In skepticism, knowledge is fluid and certainty is fleeting. That is the heart of its limitation and its greatest strength.

SKINNER, B. F.

The reinventor and foremost champion of behaviorist psychology, Burrhus Frederic Skinner (1904–1990) was born in Susquehanna, Pennsylvania on March 20, and died at age 86 in Cambridge, Massachusetts on August 18. Building on the work of Ivan Pavlov (1849–1936), Edward Thorndike (1874–1949), and J. B. Watson (1878–1958), B. F. Skinner made unique contributions to the science of human behavior and intended for his work to serve as the basis for technologies by which human beings could control themselves and others for the benefit of all.

Life and Achievements

Graduating from Hamilton College, New York, with a bachelor's degree in English, Skinner initially wanted to become a writer. This vocation eluded him, and after a period of time in Greenwich Village he enrolled for graduate studies at Harvard University, where he earned his doctorate in psychology in 1931. In 1936 he went to teach at the University of Minnesota, where he met and married Yvonne Blue. In 1945 he became chair of the psychology department at Indiana University, but three years later returned to Harvard as a professor, where he remained for the rest of his academic career.

B. F. Skinner, 1904–1990. The American experimental psychologist became the chief exponent of that form of behaviorism known as operationism, or operant behaviorism. *(The Library of Congress.)*

Skinner's work centered on the idea of *operant conditioning*. Unlike classical behaviorism, operant conditioning is the idea that as living organisms move about in their environments, behaviors that meet with reinforcing stimuli will be promoted, and other behaviors will not. Imagine saying "Hello" to associates at work, to which they give cheerful and friendly replies, leading to increased greetings; in the absence of any response, greetings will likely diminish or cease. Skinner elaborated this insight into diverse schedules of reinforcement (fixed and variable ratio and interval schedules) in order to investigate empirically their various degrees of effectiveness in behavior modification. Anthony Burgess's novel, *A Clockwork Orange* (1962) and the Stanley Kubrick film of the same title (1972) misrepresent behavior modification as using aversive reinforcement or stimuli (punishment) to discourage behavior, which Skinner regarded as ineffective.

Skinner was a fervent advocate of the application of operant conditioning. He even publicized that he applied his theories to his children, especially his younger daughter, who was in part raised in an air crib designed by Skinner. As a result of Skinner's work, operant conditioning became popular among therapists; some remained devotees into the twenty-first century.

But some problems with operant conditioning have led to skepticism. Among these are the underlying assumption of determinism and the dismissal of human consciousness. Skinner also proposed awkward ways for understanding emotions and thinking—the latter he dubbed "probability of verbal behavior"—so they would conform to the requirement of being observable (in Skinner's mind, a general requirement for all experimental sciences).

It is also unclear how some reinforcing stimuli become reinforcing in the first place. Suppose one hopes that saying "Hello" will encourage associates to leave one alone. Instead, they become intrusively friendly. The condition thus backfires. Ordinarily it is not difficult to tell a welcome response, but with complex actions this is no longer simple. Some critics argue that Skinner was openly ambivalent about whether human conscious life exists (Baars 2003), but others find in Skinner the most advanced way to apply modern science to human life and human society (Woodward and Smith 1996).

Controversies

Skinner thought that his insights into the technology of behavior ought to be used to cure sociopolitical problems. His presentation of this view in a utopian novel, *Walden II* (1948), and in such applications as *The Technology of Teaching* (1968), drew extensive criticism. Many charged him with proposing an anti-democratic technocracy that would extinguish human liberty and morality.

His response to this criticism was his most famous book, *Beyond Freedom and Dignity* (1971). Here he argued that "freedom" and "dignity" are pre-scientific concepts, and shifting to scientific terminology and applications would advance human life and society better than rhetoric. For Skinner, the scientific approach is the most dependable, reliable way to understand the world, and the implications of this approach are so significant as to render it imperative to follow it in all spheres of human concern. Religion, morality, free will, and even feelings are to be purged from an objective (that is to say, empirical) scientific conception of relationships to the world and each other. Indeed, Skinner thought that the more humans adopted his recommendations, the more likely they would be to achieve the goal of peace.

As to the overall success of Skinner's ideas, on some fronts his views have triumphed. His ideas that humans and other animals are pretty much the same have been well received in the burgeoning animal rights or liberation movement, for example. In applied psychology, however, Skinner has lost much appeal. Cognitive psychology, for example, has eclipsed his behaviorism. Skinner remains, however, one of the twentieth century's most prominent theorists about human behavior, next, perhaps, only to Sigmund Freud.

SLIPPERY SLOPE ARGUMENTS

"*Partial-birth abortion* bans are not themselves that bad. But you should oppose them because, if they are enacted, much broader bans on abortion will become more likely." "Letting dying people cut off their lifesaving treatment may seem proper on its own. But if we allow that, it may lead to dying people getting help in actively killing themselves, and then over time to involuntary killing of the comatose or even of the disabled." "Embryonic stem cell research might be OK in itself, but it may lead to people getting pregnant just to get abortions." Such arguments are commonplace in debates on many ethical topics: abortion, euthanasia, genetic engineering, gun control, free speech, privacy, and more.

All these arguments express concern about the *slippery slope:* the risk that implementing a seemingly modest and worthwhile decision A now will increase the likelihood of a much broader and more harmful decision B later. The arguments are sometimes made by political liberals and sometimes by political conservatives. They sometimes relate to judicial decisions and sometimes to legislative ones. But they are all prudential arguments about long-term consequences.

The slippery slope is not just a form of argument. It is also an asserted real-world phenomenon—the tendency of one decision to increase the likelihood of others. If this phenomenon is real, people may want to consider it when deciding where to stand on policy questions: After all, if a decision today does make likelier other decisions tomorrow, it is prudent to consider this risk when making the first decision.

Analyzing Slippery Slope Arguments

There is no well-established definition for what constitutes a slippery slope. Some limit it to situations where A and B are separated by a long series of incremental steps: first one restriction on gun ownership, then another, then a third, and eventually all guns are banned. Others limit slippery slopes to situations where A and B cannot be easily logically distinguished. Some philosophers define the slippery slope as a form of purely logical argument, that enacting A will logically require the enactment of B.

Still others look to the reason that people worry about slippery slopes. Voters, legislators, judges, and others often face the question, Should I support proposal A, or should I oppose it for fear that it might help bring about B? To answer this, one must consider all the possible ways that A can help lead to B—whether sudden or gradual, logical or political. This entry will therefore use this broad definition: A slippery slope happens whenever one narrow judicial or political decision now (for instance, banning Nazi or Communist speech) increases the likelihood that another, broader decision will be enacted later (for instance, censorship of more speech).

Not *We,* but *They*

Why would slippery slopes ever happen? Say that we think gun registration (A) is good but gun confiscation (B) is bad. Why would decision A make decision B more likely? If we dislike gun confiscation now, would we not dislike it as much even after gun registration is enacted?

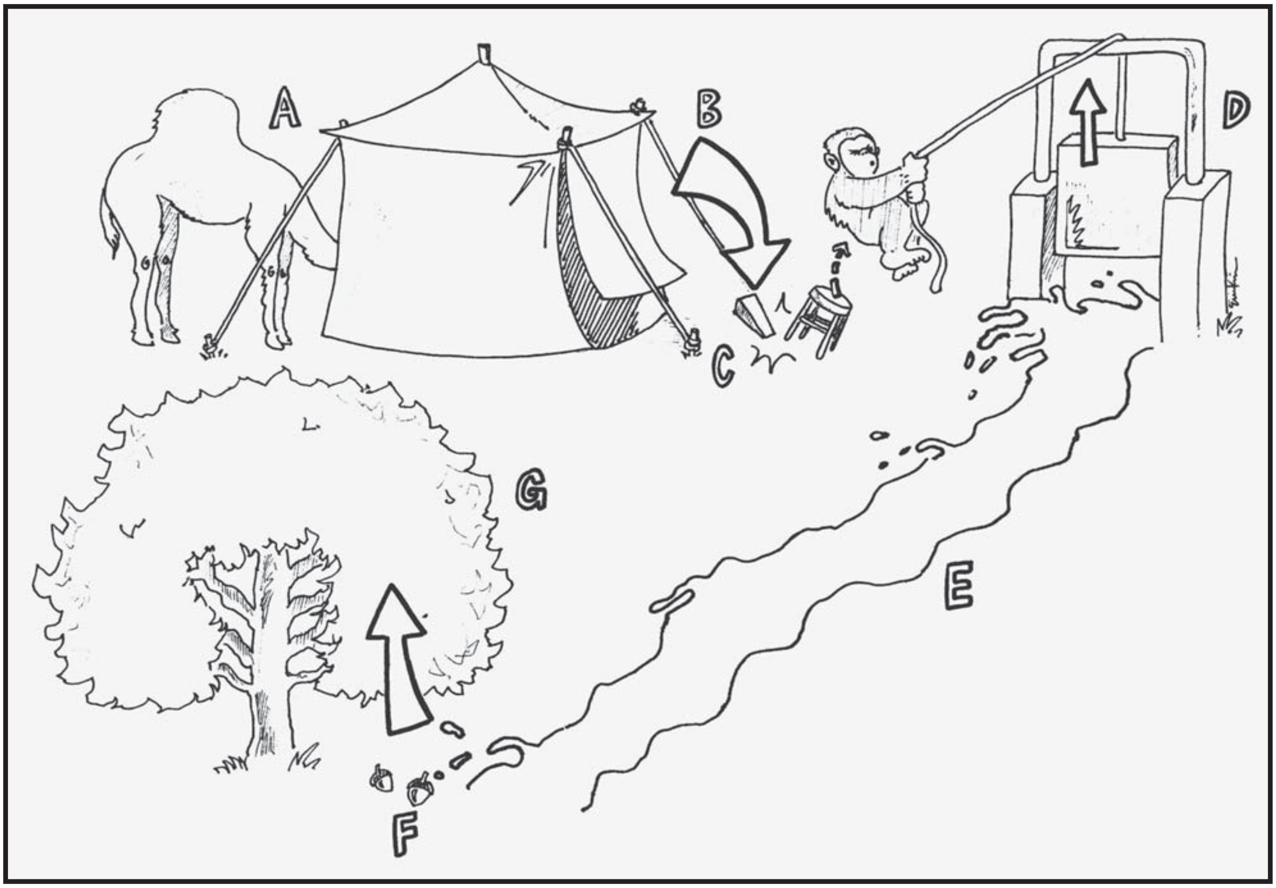
Social decisions are made by groups composed of individuals—voters, legislators, judges, and so on—who have different views. The slippery slope concern is that our support for decision A today will lead *other* people to support decision B tomorrow.

For instance, gun registration may make gun confiscation easier because the police will know where the guns are. It may also make confiscation more defensible legally because the police will be able to get warrants to search the homes of those people who have the guns. The cheaper a policy is, the more likely people are to support it. This year a swing group of voters may help enact gun registration because they like registration but not confiscation. But next year the same group might find itself outvoted by another group of voters who conclude that, because guns are now registered, confiscation is cheaper and thus more appealing.

The first group of voters will have fallen victim to the slippery slope: They voted for a modest step A, which they liked, but as a result got outcome B, which they loathe. They may then wish that they had considered the slippery slope dangers before making the first decision.

Different Slippery Slope Mechanisms

How can one evaluate the likelihood that supporting A will indeed lead others to support B? The metaphor of the slippery slope, unfortunately, will not help, precisely because it is just a metaphor. It is necessary to identify the mechanism behind it: How exactly will the first decision change the conditions under which others will evaluate the second proposal? There are several such mechanisms, all of which can be called slippery slopes,



Drawing illustrating the concept of a slippery slope argument. Camel (A) sticks his nose under the tent (B), which collapses, driving the thin end of the wedge (C) to cause monkey to open floodgates (D), letting water flow down the slippery slope (E) to irrigate acorn (F) which grows into oak (G). *(Drawing by Eric Kim. Courtesy of Eugene Volokh.)*

but which are analytically different. Here are just a few examples.

COST-LOWERING SLIPPERY SLOPES. The gun registration example is one scenario. If decision A makes decision B cheaper, then it makes B more likely.

EQUALITY SLIPPERY SLOPES. Decision A may lead some people to feel that decision B must be enacted as well for equality reasons. For instance, some people argue that it is unfair to allow the dying to commit assisted suicide while refusing to permit the same release to those who are in great psychological pain but are not dying. The first step A may push some voters, legislators, or judges to support B, not because they like B as such, but because they oppose discrimination between A and B.

ENFORCEMENT NEED SLIPPERY SLOPES. When a modest restriction A—for instance, a mildly enforced prohibition on some drug—is often violated, some people may come to support a much more severe restriction B (for instance, a war on drugs, with harsh punishments and intrusive searches) because they do not like to see the law being flouted. The intermediate position A thus becomes politically unstable, and slippage to B more likely.

ATTITUDE-ALTERING SLIPPERY SLOPES. Thus far this entry has discussed slippery slopes that operate without changing anyone's underlying attitudes. People might have the same attitudes about equality or cost as they did before A—but once A is enacted, those very attitudes lead them to support B, because of changed real-world circumstances.

Some slippery slopes, though, do operate by changing people's attitudes. Many voters, and even some legislators and judges, feel that they know little about certain issues. For instance, if they are asked whether they support some restriction on privacy, they might realize that privacy questions are very difficult, and that they have no good theory about which restrictions are good and which are not. Because they are thus *rationally ignorant*—they know the necessary limitations of their own knowledge—they may defer to the judgment of other authoritative institutions, such as courts and legislators. So if some kind of surveillance is legally permitted, many voters may therefore conclude that it is also morally proper.

This means that when proposal A is being considered, one must try to predict not only what A will do on its own terms, but also how it will change public attitudes. Will it, for instance, lead voters to alter their views to the point that they will also start supporting broader proposals like B? Will stem cell research on human embryos, for instance, change people's attitudes about the propriety of harvesting older fetuses or even babies for medical purposes? Would it lead people to think of abortions as a good rather than a necessary evil, and thus legitimize (for instance) people's getting pregnant just to harvest the resulting embryos? This sort of psychological prognostication is difficult, but it often has to be done if people are to decide whether the benefits of A indeed exceed its costs.

LEGISLATIVE-LEGISLATIVE, LEGISLATIVE-JUDICIAL, JUDICIAL-LEGISLATIVE, AND JUDICIAL-JUDICIAL SLIPPERY SLOPES. All these slippery slopes may in some measure operate whether decisions A and B are legislative decisions or judicial ones. Slippery slopes are often associated with judicial decision making, in which the doctrine of precedent helps accelerate the slide chiefly by strengthening the equality slippery slope and the attitude-altering slippery slope. But as some of these examples show, slippery slopes can operate even without any formal rule of precedent.

The Slippery Slope Inefficiency

None of these arguments, of course, always carry the day—nor should they. Sometimes we must make decisions even if there is a risk that the decisions will lead others to enact laws of which we disapprove. And yet some policy proposals that may be good on their own do end up being blocked because of eminently reasonable slippery slope concerns; one might call this the *slippery slope inefficiency*. Some people think this is true of gun registration, which has been blocked by concerns over a slippery slope to gun confiscation. Others think it is true of moderate assisted suicide proposals, which may be blocked by concerns that assisted suicide will become the norm for more and more patients.

Identifying this inefficiency suggests, perhaps surprisingly, that constitutional rights might sometimes *enable* modest regulation even while they *disable* broader prohibition. If gun right supporters feel that their right to own guns is constitutionally secure and, thus, that gun confiscation would be struck down by the courts, many of them might well drop their opposition to gun registration—an opposition that may be largely driven by slippery slope risks. If a trustworthy barrier against slippage is erected, then people may be more willing to take the first step out onto the slope.

SMITH, ADAM

Although Adam Smith (1723–1790) was not the originator of many of the ideas that became modern economics, his synthesizing treatise, *An Inquiry into the Nature and Causes of the Wealth of Nations* (1776), was so influential that he is generally considered the founder of the discipline. He effectively elaborated the concept of unplanned, spontaneous order, a feature of his economics that later played a part in other sciences such as evolutionary biology and cybernetics. Smith treated economic behavior as part of an entire ethical system, which he set out in his other major work, *The Theory of Moral Sentiments* (1759). Born in Kirkcaldy, Scotland, and baptized on June 5, he attended Glasgow and Oxford Universities and then returned to Glasgow as professor of moral philosophy. He died in Edinburgh on July 17.

Self Interest and Public Benefit

For Smith and contemporary practitioners, economics is in large measure the study of the outcome for society of

Adam Smith, 1723–1790. The Scottish economist and moral philosopher believed that in a laissez-faire economy the impulse of self-interest would work toward the public welfare. *(The Library of Congress.)*

individuals acting in their own interest without a view to public benefit. Smith thought the outcome was generally good. Unregulated, self-interested behavior could produce greater material wealth for society than could a system of policies designed by authorities to achieve wealth. Economists, historians, philosophers, and ethicists have debated his argument from his day to the present.

In support of his notion that beneficial order, not destructive chaos, can result from persons acting in their own interest, Smith repeatedly shows how desirable features of society are the unintended outcome of actions taken for other reasons. For example the division of labor, to which he attributed national wealth, was not the effect of human wisdom that intended the resulting material well being. Smith argues that humans, unlike animals that fawn to obtain favors, learn to divide tasks and specialize in producing goods and services that they can exchange for what they want. The division of labor, therefore, was the effect of the tendency of humans to barter in order to get what they want from others. It produces wealth because it saves time, develops specialized skills, and prompts workers to invent technologies to ease their tasks.

Being aware of the productive advantages of specialization, authorities may presume that they can plan the division of labor. Smith traces the steps involved in producing a simple item and makes it clear that a planner would be incapable of assessing people's desires, devising tasks to satisfy them, and assigning the tasks to various workers. Even if people made their desires known in any one place, no person or group could imagine the skills and resources required to provide for any one desire. The division of labor functions most effectively if individuals learn from market prices the best way to employ their own time and abilities to satisfy the desires of others, thereby offering productive resources of which a planner would be unaware. When entrepreneurs seek the most profitable employment of their capital and workers go where wages are highest, the result, which neither intended, is that they unintentionally supply the desires of others in the cheapest way. Individuals do not have to have benevolent motives to produce social benefits.

Smith, who did not romanticize business, thought that employers always try to conspire to keep wages down and that sellers in the same trade always conspire to raise prices. Accordingly he admonished governments never to take actions that would make it easier for members of the same trade to cooperate. Self-interest leads to public benefit, but only if competition prevails.

Unregulated markets, when competitive, harness self-interested behavior to produce public benefit. Smith understood, however, that the authorities did not deliberately institute a market system to achieve this end. On the contrary, history taught him that the system emerged when landlords used the produce of their agricultural estates to buy luxuries rather than to maintain hundreds of tenants, soldiers, and servants. When they were no longer bound to their landlords, these individuals became freer to exchange their services for market-determined wages.

Smith's understanding of how the pursuit of individual interest produces the wealth of all led him to advocate the system of *natural liberty* in which the government's role, while indispensable, is confined to providing national defense, law and order, and goods that are unprofitable for private persons to produce, even though their benefits exceed their costs. Attempts by government to fix prices, encourage particular technologies, or subsidize certain industries for the benefit of society would be useless if not pernicious.

The Moral Basis of Markets

Smith devotes much of *The Wealth of Nations* to working out the implications of individuals being able to pursue their own interests, but he was aware that his system of natural liberty had a moral foundation. Markets not only had to be free from improper government interference and monopoly; legal and moral rules also had to protect them from injustice—murder, theft, and broken promises. In *The Theory of Moral Sentiments* (1759), Smith contended that orderly society was possible because the Author of Nature endowed humans with resentment of injustice and a desire to see it punished. For Smith society is possible because people passionately desire to punish injustice, not because they reason that their group will suffer if crimes against its members go unpunished. In his treatment of the social support for justice, as in his explanation of the emergence and functioning of markets, Smith emphasizes unintended outcomes. Individuals do not seek a wealthy society; they pursue their own interest and national wealth results. Similarly individuals do not strongly desire orderly society; their resentment of malice provides the basis for order.

It is easy enough to see that humans would resent malice toward themselves, but what of hurtful actions toward others? Humans are self-interested, but, as Smith claims in the opening line of *The Theory of Moral Sentiments*, they also care about the fortunes of others. By imagining what they themselves would feel in a similar situation, humans sympathize with the resentment of sufferers of injustice.

Smith does not limit the role of sympathy to ensuring that members of society will punish perpetrators of injustice. He uses the term sympathy to mean the human capacity to experience, to some degree, all the passions of others. When people share the passions that prompt others to act in ways they themselves would act in similar circumstances, they consider the acts of others just and proper. Similarly people approve of their own conduct if they feel that an *impartial spectator* would sympathize with the passions that influenced it. The impartial spectator acts as a constraint on self-interest. It approves of such self-regarding virtues as prudence, industry, and temperance, but recoils at *malevolence or sordid selfishness*.

Thus although Smith recognized the power of self-interestedness, he understood and celebrated other motives as well. According to his figure of speech, if the pillar of justice prevails, a society of the merely self-interested can exist, but without the ornaments of friendship, generosity, gratitude, and charity, people live a less happy, agreeable, and comfortable life. In his words, "to restrain our selfish, and to indulge our benevolent, affections, constitutes the perfection of human nature" (Smith 1969, p. 71).

Relevance to Current Policy

Smith's system of natural liberty does not provide guides for policies for the contemporary problems of poverty, environmental degradation, or for the alleviation of the stultifying effects of specialization. In these areas, later developments in specialized fields of economics have surpassed Smith's approach. At the same time, his understanding of human behavior and the sources of national wealth is still pertinent. The human tendency to regard first self-interest and that of family and friends has a basis in nature and is not entirely the consequence of education or culture. Therefore persons who make laws and policies must acknowledge it. It is fruitless to hope that authorities can persuade humans to provide for each other's needs out of benevolence. Self-interested individuals, however, will serve each other as they pursue their own interests, if competition exists and there are rules that punish violators of personal and property rights. Moreover authorities, as compared with the public, are no less self-interested and no more able to judge which industries or technologies will provide the greatest future social benefits. One lesson from Smith, then, is that governments should forgo planning and concentrate on promoting wealth and happiness by having legal systems that protect property rights and by encouraging ethical standards that honor following the rules of justice.

Another lesson is that markets do not become free because of the vision of some well-meaning and enlightened group. In the case of England, Smith observed that the market system resulted when landlords lost power. This historical observation is in keeping with his understanding of the limited effect of beneficial intent.

The twentieth-century failure of planned economies relative to those with freer markets lends support to Smith's free-market policies for the growth of national wealth. Even so, international agencies and national governments should be careful about promoting free markets by financially supporting authorities that promise to create them. Smith's historical perspective suggests that markets become freer when power changes hands, not when powerful leaders purport to make them free.

SOCIAL CONSTRUCTION OF SCIENTIFIC KNOWLEDGE

The leading research orientation in contemporary science and technology studies—the social construction of scientific knowledge (SSK, or social constructivism)—has been controversial since its inception in the 1970s. It primarily consists of a set of methodological imperatives for the study of science and technology that focus on the means by which people, ideas, interests, and things are organized in specific places and times to produce knowledge that has authority throughout society, especially among those not originally involved in the process of knowledge production. Thus, social constructivists tend to stress the diversity of interpretations and applications of knowledge across social contexts. However, in areas where philosophers and scientists might interpret that diversity as different representations or instantiations of an already established form of knowledge, social constructivists treat that variety as part of the ongoing core process of knowledge production.

Social constructivists therefore do not recognize a sharp distinction between the production and the consumption of knowledge. Thus, social constructivism has a "democratizing" effect on epistemology by leveling traditional differences in the authority granted to differently placed knowers. To a social constructivist a technologist using a scientific formula is "constructing" that formula as knowledge in exactly the same sense as did the scientist who originated the formula. Each depends on the other to strengthen their common "cycle of credibility" or "actor-network," in the words of Bruno Latour, perhaps the leading social constructivist. In contrast, most philosophers and scientists would raise the epistemic status of the original scientist to that of a "discoverer" and lower the status of the technologist to that of an "applier."

Basic Attitudes and Origins

In philosophical terms social constructivism is a form of antirealism: Social constructivists do not presuppose the existence of a reality independent of the procedures available to the examined agents for deciding the truth value of their assertions. In this respect social constructivism has affinities with idealism, pragmatism, phenomenology, and even logical positivism. The proponents of all those movements agree that aspects of the world that traditionally have been cited as evidence for "external reality" are in significant respects the intended and unintended products of human practices. However, this common insight has led to rather different philosophical responses. For example, positivists and phenomenologists strive to design criteria that can command universal assent, whereas idealists and pragmatists regard the resolution of conflict in the application of such procedures as the basis of future epistemic developments.

Social constructivists differ from earlier antirealists by challenging their common fundamental assumption of a centralized decision-making environment, whether it is a unified self or society.

In contrast, social constructivists presuppose that the social world in which construction occurs is highly dispersed. This implies that different decisions are taken across many places and times. This often is considered a "postmodern" feature of social constructivism. However, despite the lip service paid to French poststructuralist thinkers such as Michel Foucault (1926–1984) and Gilles Deleuze (1925–1995), social constructivists originally derived this characterization from the social phenomenologist Peter Berger (Berger and Luckmann 1967), from his Viennese teacher Alfred Schutz (1899–1959), and ultimately from Schutz's mentor, the neoliberal political economist Friedrich Hayek (1899–1992).

Just as Hayek had argued in the 1930s, against the socialists, that no central planner can determine fair prices more efficiently than can the spontaneous self-organization of buyers and sellers, social constructivists deny that a single philosophical method can determine the course of science more efficiently than can the spontaneous self-organization of scientific practitioners. Hayek grounded his argument on the unique knowledge possessed by people differently placed in the market. Thus, the social construction of scientific knowledge can be seen historically as an extension of a market mentality into an aspect of social life—science—that for much of the twentieth century tied its legitimacy to the control mechanisms of the state.

Despite often being portrayed as antiscientific, social constructivism has precedents in the history of science, starting with Aristotle's view of matter as an indeterminate potential that is given form through human intervention. In the nineteenth and early twentieth centuries the constructivist position was represented most clearly by chemists who contested the idea of an ultimate form of physical reality as defined by, say, "atoms." Instead, chemists appealed to "energy" as an updated version of Aristotelian potential. Current versions of constructivism further "socialize" this perspective by invoking concepts such as work and practice as the media through which scientific objects are brought in and out of existence. According to its proponents, social constructivism is the spontaneous philosophy of the working scientist, who is concerned more with making things happen in the laboratory, as well as in society at large, than with completing a philosophically inspired picture of ultimate reality. Not surprisingly, Latour and other leading social constructivists have flourished in engineering schools rather than in pure science faculties.

The Trajectory of Social Constructivist Research

The social construction of scientific knowledge normally is described in terms of its opposition to two familiar, although extreme, views that might be called philosophical rationalism and sociological determinism. Philosophical rationalism implies that science ultimately is driven by a concern for the truth, perhaps even a desire to provide a comprehensive and unified picture of reality. From that standpoint the social dimension of science functions as either a facilitator or an inhibitor of this quest. Sociological determinism implies that the science of a particular time and place is an ideological reflection of the social conditions that sustain it. From that standpoint the development of science is dependent on its larger societal functions. Social constructivism differs from those two perspectives by denying a strong ontological distinction between the "cognitive" (or "natural") and "social" (or "cultural") dimensions of science. Both dimensions are coproduced in any episode of scientific activity. As a result social constructivists see science as much more subject to agency and contingency than either philosophical rationalism or sociological determinism allowed.

David Bloor's *Knowledge and Social Imagery* (1976) was the first book to put forward the social constructivist case against both philosophers and sociologists. Bloor, a mathematician and psychologist, was influenced by Ludwig Wittgenstein's (1889–1951) later writings on rule following. Wittgenstein implied that there is no correct way to continue a number series (for example, 2, 4, 6 . . .) except to abide by the judgement of the community engaged in the counting because any arithmetic series is open to an indefinite number of continuations (such as 8, 10, 12 . . . or 7, 8, 9 and then 10, 12, 14 . . .), depending on what is taken to be the rule underlying the number series. Bloor generalized that insight in the name of a thoroughly naturalistic approach to the study of knowledge that he called the "Strong Programme in the Sociology of Scientific Knowledge." That approach involved suspending all external normative judgements about the validity or rationality of knowledge claims. (In contrast, the "Weak Programme" would use sociology only to explain episodes of scientific dysfunction, because the canons of rationality were presumed to explain science's normal operation.) Bloor would look only to the standards of reasoning and evidence available to those who must live with the consequences of what they do. That approach encouraged what Bloor called a "symmetrical" attitude toward the various competing beliefs or courses of action in a particular situation. In other words the inquirer is to treat those beliefs or actions as seriously as the situated agents treat them, suspending any knowledge the inquirer might have about their likely or, in the case of historical cases, actual consequences. The import of this approach was to neutralize specifically philosophical appraisals of knowledge claims, which typically appeal to standards of rationality and validity that transcend the interests or even competence of the involved agents.

Whereas Bloor, along with his Edinburgh colleague Barry Barnes (1975), mapped out the conceptual terrain defined by social constructivism, the 1980s and 1990s brought a plethora of historical and sociological case studies inspired by that position. Constructivist historical studies characteristically reinterpret landmark scientific debates so that what traditionally was seen as an instance of truth clearly triumphing over falsehood came to appear as a more equally balanced contest in which victory was secured at considerable cost and by means that were specific to the contest. Attached to these reinterpretations is a view, traceable to Thomas Kuhn (1922–1996), in which every scientific success entails a rewriting of history to make it appear inevitable. In this respect social constructivist history of science aims to "deconstruct" the narratives of scientific progress typically found in science textbooks and works of science popularization.

Stephen Shapin and Simon Schaffer's *Leviathan and the Air-Pump* (1985) is perhaps the most influential work of this sort. It deals with Robert Boyle's (1627–1691) successful blocking of Thomas Hobbes's (1588–1679) candidacy for membership in the Royal Society. This episode normally is told in terms of Hobbes's persistent metaphysical objections to the existence of a vacuum long after it was found to be scientifically reasonable. However, it turns out that Hobbes was defending the general principle that experimental demonstrations are always open to philosophical criticism even if the philosopher could not have designed such an experiment. Hobbes's failure on this score set a precedent for the competence required for judging experiments that began to insulate science from public scrutiny.

Constructivist case studies typically draw on the sociological method of grounded theory, according to which the inquirer introduces a theoretical concept or perspective only if the agents under study also do so. Grounded theory originally was used to oppose structural functionalism, the leading school of U.S. sociology, which was associated with Talcott Parsons (1902–1979) and Robert Merton (1910–2003). Proponents of that school postulated that deviance is a well-defined role that performs specific functions in the social system. In contrast, for grounded theorists the deviant role, say, in the context of asylums and hospitals, had to be constructed from moment to moment because generally speaking there was no clear observable difference between the behavior of so-called normals and that of deviants.

Achievements and Weaknesses

The groundbreaking, albeit perverse, insight of Latour and Steve Woolgar (Latour and Woolgar 1986), Karin Knorr-Cetina (1981), and the other early constructivist sociologists was to imagine that "deviance" may apply to people on the positive extreme as well as the negative extreme of a normal distribution curve. Thus, in their daily laboratory tasks scientists do not sound or look especially different from people working in an industrial environment subject to an intensive division of labor. Nevertheless, scientists are socially constructed as exceptionally rational, producing knowledge that commands authority throughout society. How is this possible? For a constructivist sociologist the answer lies in the "made for export" language scientists use to describe their activities and the specific distribution channels in which that language, as expressed in journal articles, preprints, and press releases, circulates. This produces a forward momentum, involving many other people, laboratories, interests, and so forth, that eventually turns a unique set of events into a universally recognizable fact.

There is little doubt that social constructivism has provided an important challenge to standard historical, philosophical, and sociological accounts of science. The question is its implications for science itself. The steadfast adherence of constructivism to the symmetry principle has been both a strength and a weakness.

The strengths of constructivism extend beyond intellectual insight to the ease with which it can be used in science policy research, especially in a time when constrained budgets and skeptical publics demand that science be evaluated in terms of its actual consequences rather than its professed norms. In this respect social constructivism has been a success in the marketplace, proving especially attractive to the increasing proportion of academic researchers who depend on external contracts for their livelihood. However, beneath that success lies a weakness: Constructivism lacks a clear normative perspective of its own. This lack largely reflects its decentralized vision of social life. Although constructivists excel in revealing the multiple directions in which science policy may go, they refuse to pass judgment on any of them or even on the means by which their differences might be resolved. In this respect social constructivism is indifferent to the future of science and the role of science as the vanguard of rationality and progress in society at large.

The program of "social epistemology" has attempted to redress this imbalance in social constructivism. It argues that social constructivism can provide the basis for a science policy that is both genuinely democratic and experimental. Conventional science policy tends to be problem-centered without evaluating the relevant discipline-based knowledge. Indeed, science policy analysts rarely think of themselves as *constructing* problems the problems they address—they are simply treated as given. In contrast, social epistemology moves science policy toward constructivism by critically examining the maintenance of institutional inertia: Why don't research priorities change more often and more radically? Why do problems arise in certain contexts and not others? These questions are addressed on the basis of three presumptions that take seriously the normative implications of the social constructivism (from Fuller and Collier 2003):

- *The Dialectical Presumption:* The scientific study of science will probably serve to alter the conduct of science in the long run, insofar as science has reached its current state largely through an absence of such reflexive scrutiny.
- *The Conventionality Presumption:* Research methodologies and disciplinary differences continue to be maintained only because no concerted effort is made to change them—not because they are underwritten by the laws of reason or nature.
- *The Democratic Presumption:* The fact that science can be studied scientifically by people who are themselves not credentialed in the science under study suggests that science can be scrutinized and evaluated by an appropriately informed lay public.

SOCIAL CONSTRUCTION OF TECHNOLOGY

The phrase *the social construction of technology* is used in at least two different, though overlapping, ways. Broadly it refers to a theory about how a variety of social factors and forces shape technological development, technological change, and the meanings associated with technology. More narrowly, the phrase refers to a specific account of the social construction of technology; the acronym SCOT is used to refer to this version of the broader theory (Pinch and Bijker 1987). According to Ronald Kline and Trevor Pinch (1999), SCOT uses the notions of *relevant social groups*, *interpretive flexibility*, *closure* and *stabilization;* the concept of interpretive flexibility is its distinguishing feature. To claim that technology has interpretive flexibility is to claim that artifacts are open to radically different interpretations by various social groups; that is, artifacts are conceived and understood to be different *things* to different groups.

Contra Technological Determinism

The starting point for understanding both the broad theory of the social construction of technology and the

SCOT version of that theory is to compare them with another view of technology referred to as *technological determinism*. Technological determinism has two basic tenets: (1) that technology develops independently from society; and (2) that when a technology is taken up and used, it has powerful effects on the character of society. According to the first tenet, technological development either follows scientific discoveries—as inventors and engineers *apply* science—or it follows a logic of its own, with new inventions deriving directly from previous inventions. Either way, technological development is considered to be separate from social forces; engineers and inventors work in an isolated domain in which all that matters is discovering and manipulating nature.

According to the second tenet of technological determinism, when technologies are adopted by societies or particular social groups, the adoption brings about—determines—social change and patterns of social behavior. In one formulation, technological change is said to create a *cultural lag* until culture catches up. One specific determinist argument proposed by historian Lynn White (1962) is that feudal society evolved from the invention of the stirrup. Another example is Langdon Winner's (1986) claim that society cannot have nuclear power without hierarchical organization. Winner's broader claim is that technologies necessitate particular forms of political organization. This principle of technological determinism leads to the commonly held view that technology determines society; that is, when technologies are adopted and used, they change the character of society.

The broad theory on the social construction of technology denies the first tenet of technological determinism entirely but makes a more nuanced response to the second tenet. In denying the claim that technology develops independently from society and follows science or its own logic of development, social constructivists argue that technological development is shaped by a wide variety of social, cultural, economic, and political factors. Nature does not reveal itself in some necessary or logical order. Scientists and engineers look at nature through lenses of human interests, theories, and concepts; engineers invent and build things that fit into particular social and cultural contexts. Technologies are successful not by some objective measure of their goodness or efficiency; rather, technologies are taken up and used because they are perceived to achieve particular human purposes and to improve a particular social world or to further the interests of individuals and social groups.

Broad theory proponents respond similarly to the second tenet of technological determinism: They claim the theory misses the fact that technology is being shaped by social factors and forces. But here the social constructivist does not wholly deny the technological determinist claim that technology affects society; rather, constructivists argue that forces may move in both directions. Technology shapes society *and* society shapes technology. Social constructivists claim that the theory of technological determinism gives an inadequate and misleading picture of the technology-society relationship in leaving out the powerful social forces at work in shaping the development, adoption, use, and meanings associated with technology. Social constructivists have also gone further in claiming that shaping does not just work in both directions but that technology and society are mutually constitutive; they cocreate one another.

Specific Theories of Social Construction

The critique of technological determinism and the emergence of the theory of the social construction of technology began and gained momentum in the 1980s along with other activities contributing to the development of a new field of study sometimes labeled *science and technology studies* (STS) and other times *science, technology, and society* (also STS). Within this field of study, two theoretical approaches are often distinguished: the version of social constructivism referred to as SCOT and actor-network theory (ANT). Both theories seek to explain why and how particular technologies are adopted while others are rejected or never developed. Both SCOT and ANT are concerned with how technological designs are adopted and become embedded in social practices and social institutions.

Actor-network theory takes as its unit of analysis the systems of behavior and social practices that are intertwined with material objects. This is the *network* part of actor-network theory. The *actor* part of actor-network theory emphasizes the presence of many actors, human and nonhuman. For instance, nature plays an important role in determining which technologies come to be adopted, and nature can be described as one of the actors in shaping the technologies that succeed in becoming embedded in the social world. Technologies and artifacts can themselves also be actors. Humans, nature, and artifacts collectively are referred to in actor-network theory as actants.

Resistance to Social Constructivism

Two issues often get in the way of understanding social constructivism in the broad sense. The first is an issue about which social constructivists disagree, the extent to which nature is real or *merely* socially constructed. *Realists* claim that nature is real and has an inherent or fixed character that scientists and engineers must manipulate to succeed. The hard character of nature shapes what engineers can do and what technologies are developed. Nevertheless while constructivist-realists claim that there is something real or *hard* about nature, they generally acknowledge that the only way humans have access to nature is through human meaning, human constructs, and human theories, all of which are social. Thus nature can be represented in different ways, in different knowledge systems. At the same time, *anti-realists* claim that there is nothing hard or real about nature around which ideas and meanings can be constructed; at least, there is nothing real to which people have access. There are only ideas and meanings constructed by humans, and ideas and meanings are social.

While the chasm between realists and antirealists is wide, many social constructivists simply sidestep or bracket the issue without taking sides. For many social constructivists who seek to understand the cocreation of technology and society, it does not make a difference whether nature is real, because all concede that nature is viewed through the lenses of human beings, which are interested and social.

The second issue is the principle that new technologies build on older technologies. Technological determinists contend, for example, that computers could not have been developed if electricity and transistors and many other devices had not already been developed. Thus technology influences technology; later technology builds on prior technology. Social constructivists agree. What social constructivists reject, however, is that technological change and development follows a predetermined, linear path, a path necessitated by some nonhuman reality. Social constructivists argue that social factors influence the pace and direction of technological development and that development is often nonlinear.

How Social Construction Works

What does it mean to say that technology is socially constructed? As already mentioned, the theory referred to as SCOT makes use of the notions of relevant social groups, interpretative flexibility, stabilization, and closure.

THE BICYCLE STORY. Wiebe Bijker (1995) and Pinch and Bijker (1987) give an account of the development of the design of the bicycle—the design that has been used since the early-twentieth century. They argue that the path of development was complex, with various designs being tested and rejected by various groups in a nonlinear order. Relevant social groups—including sports enthusiasts, men and women who spent leisure time in public parks, bicycle makers, bicycle repair people, and more—responded to various models differently and found different advantages and disadvantages as well as meaning in them.

Development moved in many directions aimed at solving a variety of problems for riders, manufacturers, and those who repaired the bicycles; the problems included safety, ease of manufacture and repair, speed, ability to manage the roughness of roads, and so on. Designs had varying cultural meanings (was the bicycle macho or ladylike?), facilitated or constrained various social activities in public parks, and served the interests of various groups, including sports enthusiasts and manufacturers.

Design of the bicycle first took hold when the relevant social groups coalesced around one design because it solved problems for each group. This is the point Bijker refers to as stabilization. Once this happens small design changes may continue to be made, but tend to presume the overall design; designers tinker within that framework. In this way, Bijker shows that the design of the bicycle was socially constructed in the sense that the design that succeeded (that is, was adopted and pervasively used) was not the *best* in some objective sense, such as most efficient or elegant; rather, it was the one that the relevant social groups agreed upon because they were convinced it fit their needs.

The broader theory of the social construction of technology does not refute the SCOT theoretical apparatus; rather, the broader theory remains open to the use of alternative concepts, frameworks, and tools to study the cocreation of technology and society. Because social constructivism emphasizes the social shaping of technology, it may be useful to consider a few areas where social factors have a powerful influence on the technologies that are developed and what those technologies look like.

ECONOMICS. Perhaps the most obvious place to see the workings of society is in funding for the development of new technologies. Companies and government agencies invest large amounts of money, space, time, and effort in technological endeavors that seem promising. When enormous resources are put into an area of scientific or technological development, that area is much more likely to yield results. Thus, contrary to the inherent logic of development suggested by technological determinism, technology develops, at least in part, in an order that is determined by investment choices and other human decisions, and not by logic alone.

REGULATION. While governments often invest heavily in technological development, funding is not the only aspect of government that shapes technology. Governments often regulate technological domains and when they do so, the regulation affects future development. Consider, for example, the vast array of regulatory standards that automobiles must meet. Whether they are aimed at safety or clean air or decreasing dependence on fossil fuels, when governments set standards for automobiles, automobile manufacturers must design within the confines of those specifications. Hence regulation promotes development in a certain direction and forecloses development in other directions.

CULTURE. Yet another way that technological development is socially shaped is by the cultural meanings that influence the design of artifacts. Perhaps the best place to see this is in cross-cultural studies of technology. Such studies reveal how cultural meanings strongly influence technological development. Think, for example, of the lack of development in rail transportation in the United States where individualism and many other historical factors promote the use of automobiles, whereas in many European countries, this mode of public transportation has been successfully developed and enhanced for more than a century.

Ethics and Social Construction

Technological determinist theories such as that of Jacques Ellul (1964) seem to imply that technological development is autonomous and unstoppable; that is, individuals and even social movements can do nothing to change the pace or direction of development. Social constructivism can be seen as, at least in part, a response to the pessimism of technological determinism. Many social constructivist scholars see themselves as providing an account of technological development and change that opens up the possibility of intervention, the possibility for more deliberate social control of technology. Wiebe Bijker (1993), for example, describes the field as being rooted in critical studies. He claims that science and technology studies of the 1980s were "an academic detour to collect ammunition for struggles with political, scientific, and technological authorities" (Bijker 1993, p. 116). Thus, social constructivist theories might be seen as having an implicitly critical, and perhaps even a moral, perspective. However, social constructivist theories have been developed primarily by historians and social scientists, and scholars in these fields have traditionally understood the task of their scholarship to be that of description, not prescription. Hence, social constructivist theorists generally deny that their perspective is ethical.

Nevertheless, in bringing to light many of the otherwise invisible forces at work in shaping technology and society, social constructivist analysis often reveals the ways in which particular social groups wield power over others through technology. Knowledge of this aspect of technology opens up the possibility of deliberate action to counter the unfair use of power and the undesirable social patterns being created and reinforced through technology. A good example here is the work on gender and technology by such scholars as Judy Wajcman (1991) and Cynthia Cockburn and Susan Omrud (1993). By drawing attention to the ways in which technology reinforces gender stereotypes and more broadly, how gender and technology are co-created, these scholars make it possible for those involved with technological development to avoid reinforcing prevailing stereotypes or patterns of gender inequality. In this respect social constructivism has important ethical implications.

While social constructivism has significantly furthered the social analysis of science and technology, social constructivism is still relatively new. Perhaps the most serious criticism of social constructivism is that it consists only of a few theoretical concepts and a wide-ranging set of case studies. Hence, it still needs a more comprehensive theoretical foundation. Nevertheless, social constructivism has been influential and is likely to continue to be important in understanding the relationships among science, technology, and society.

Bijker, Wiebe E. (1993). "Do Not Despair: There is Life after Social-Constructivism." *Science, Technology, & Human Values* 18: 113–138. Bijker reviews four problems surrounding socio-historical technology studies: relativism, reflexivity, theory, and practice. He argues for scholars to break away from overly academic perspectives and to return to political issues.

Bijker, Wiebe E. (1995). *Of Bicycles, Bakelites, and Bulbs.* Cambridge, MA: MIT Press. Bijker provides three detailed case studies of the development of a technology. His sociological analysis of these cases makes use of and illustrates a theoretical, social constructivist framework.

Cockburn, Cynthia and Susan Omrud. (1993). *Gender and Technology in the Making.* London: Sage Publications.

Explains the evolution of "microwave technology" that became the "microwave oven." It is a story of a technology that begins as masculine and eventually becomes a feminine kitchen appliance.

Ellul, Jacques. (1964). *The Technological Society*, trans. John Wilkinson. New York: Knopf. This book is considered a classic. Ellul argues that the internal logic of technological development, that is, instrumental rationality and efficiency, transforms domains of human life and is not in control of humans.

Kline, Ronald, and Trevor J. Pinch. (1999). "The Social Construction of Technology." In *The Social Shaping of Technology*, 2nd edition, ed. Donald MacKenzie and Judy Wajcman. Buckingham, UK, and Philadelphia: Open University Press. This is an excerpt from a longer piece that appeared in 1996 in *Technology and Culture* 37: 763–795. Kline and Pinch concisely present the advantages and weaknesses of the specific version of the social construction of technology known as SCOT and developed by Bijker and Pinch.

Pinch, Trevor J., and Wiebe E. Bijker. (1987). "The Social Construction of Facts and Artifacts: Or How the Sociology of Science and the Sociology of Technology Might Benefit Each Other." In *The Social Construction of Technological Systems*, ed. Wiebe E. Bijker, Thomas P. Hughes, and Trevor J. Pinch. Cambridge, MA: The MIT Press. Using the conceptual apparatus of the SCOT model, this piece provides a historical account of the development of the bicycle.

Wajcman, Judy. (1991). *Feminism Confronts Technology*. University Park: Pennsylvania State University Press. Explores the relationship between technology and gender in western society. Wajcman uses the lens of feminism to examine the traditional association of technology with masculinity. She argues that this relationship is not natural but intertwined with socially and cultural processes. Notions of gender and technology social reinforce one another.

White, Lynn T. (1962). *Medieval Technology and Social Change*. New York: Oxford University Press. White examines the effects of technology on societies of medieval Europe. He attributes the collapse of feudalism to the development of machines and tools.

Winner, Langdon. (1986). *The Whale and the Reactor*. Chicago: University of Chicago Press. Consists of essays by Langdon Winner, which together constitute his unique perspective as a political scientist examining technology. As a whole the essays can be thought of as a critical philosophy of technology. Several of the essays had been published earlier and are seminal pieces in the field.

SOCIAL CONTRACT FOR SCIENCE

The social contract for science is an evocative ideological construct used to describe the relationship between the political and scientific communities. Participants in science policy debates often invoke the social contract for science uncritically and flexibly, ritually referring to Vannevar Bush as its author and *Science, The Endless Frontier* (1945) as its text. The term, however, has no explicit connection to Bush, but explaining its history and usage is enlightening.

Historical Origins and Decline

There are two helpful hypotheses for origin of the phrase. One focuses on what Don K. Price called the "master contract" that formed the "basic charter" of the postwar relationship between the U.S. government and the scientific community (Price 1954, p. 70). This relationship "gives support to scientific institutions that yet retain their basic independence" (Price 1954, p. 67–68). A second hypothesis holds that the social contract for science is related to a social contract for scientists, which describes how the profession of science is bound as a community to uphold behavioral norms and to "rely on the trustworthiness" of each other (Zuckerman 1977, p. 113).

Harvey Brooks polished the promise of the social contract for science as "widely diffused benefits to society and the economy in return for according an unusual degree of intellectual autonomy and internal self-governance to the recipients of federal support" (Brooks 1990, p. 12). Brooks's definition takes into account both hypotheses of origination by relying on the overall structure of Price's formulation and on the rationale of Zuckerman's formulation as why the *unusual degree* of autonomy and self-governance could be offered to science. That is, science could be granted autonomy because its members maintain their integrity by upholding group norms (Merton 1973).

In addition to evoking the contractual nature of the relationship between the public patron and the scientific community and the tacit trustworthiness of scientists to one another, the social contract for science has additional descriptive power. As with more formal social contracts from political philosophy, it offers an account of the provision of a public good, and it suggests the conditions of an original consensus against which change can be measured and evaluated (Guston 2000). Some scholars and policy makers, relying on a tacit understanding of the social contract for science, argue variously that science has been faithful to it but politics not particularly so (Press 1988); that the contract died in the late 1960s with a decline in research funding, only to be resuscitated in the 1980s (Smith 1994); and that the contract crumbled in the 1990s through various policy changes (Stokes 1997).

Using the Social Contract in Policy and Ethics

Guston (2000), however, argues that to serve as a baseline for historical change, the social contract for science must have its tenets elaborated in clear historical detail and have criteria for change derived from there. Thus although there is a consensus that any such agreement dates to the immediate post-World War II period, *Science, The Endless Frontier* is not the sole articulation of postwar science, and John Steelman's report, *Science and Public Policy* (Steelman 1947) must also be taken into account. Although these two analyses differed on how they imagined the organization and funding of postwar science, they both held—along with much theoretical writing of the period—that the political community would provide resources to the scientific community and allow the scientific community to retain its decision-making mechanisms and in return expects forthcoming but unspecified technological benefits. Such a contract was premised on the automatic provision of scientific integrity and productivity, which thus becomes the central criterion against which to measure change.

There were many potential challenges to the social contract for science, thus specified, over the postwar period in the United States, including inquiries into the loyalty of scientists in the 1950s, the changes in financial arrangements and funding in the 1960s, and greater emphasis on applied research and questions about the limits of scientific inquiry in the 1980s. But no challenges altered the presumption of the automatic provision of scientific integrity and productivity until the conflicts over scientific (or research) misconduct and over technology transfer in the late 1970s and early 1980s. Political perceptions in this period held that scientists might have broken the contract through the failure to control misconduct and to produce sufficient economic benefits. But scientific perceptions held that politicians might have broken the contract through meddling. Neither perspective is completely right (or wrong), but it was through their instigation of organizational innovation—the creation of the Office of Research Integrity and of offices of technology transfer—that these issues marked the end of the social contract for science and its assumption of the automatic provision of scientific integrity and productivity. The political and scientific communities collaborated over the creation of these institutions, and they ushered in a new era in which the political and scientific communities engage in a *collaborative assurance* of integrity and productivity instead. Scholars have traced similar transitions in science policies in European nations as well.

SOCIAL CONTRACT THEORY

The idea of a social contract can have broad and narrow meanings. In the broad sense a social contract can simply be short hand for expectations in relations between individuals or groups. In the narrow, more technical sense social contract theory has a long and venerable history that in the present has been rhetorically adapted to assess general expectations between science and society. A review of various theoretical perspectives nevertheless raises questions about the adequacy of such adaptations.

Social Contracts in General

Contracts in the strict sense are agreements between two parties that establish mutual obligations and are enforceable by law. The idea of a social contract is more fundamental, and argues that society comes into existence as a kind of contract. In the classical or premodern views that are sometimes identified as anticipations of social contract theory, the social contract is not so much an originating action as one that implicitly exists between a preestablished order and individuals within it. This is, for instance, the view argued by Socrates in Plato's *Crito*. The modern view, by contrast, is that individuals come first, and through their agreement establish a new phenomenon called the state.

For most modern theorists this contract is not a historical event, much less an actual legal document, but an ideal construct to aid in postulating how things should be. It depends on two key assumptions: (a) that human beings as individuals are in some sense prior to any established social order, so that their obedience to the state has to be justified; and (b) that the condition of human beings outside the socially constructed state, or in what is called the *state of nature*, is ultimately unsatisfactory, thus providing humans a reason to escape such a condition by social contract. From these assumptions Thomas Hobbes (1588–1679) and John Locke (1632–1704), without using the term, developed social contract theory to examine the status of a monarch. When Jean-Jacques Rousseau (1712–1778) subsequently coined the term *social contract*, he used the same kind of theory to defend a notion of democratic equality. Later John Rawls (1921–2004) adapted social contract theory to defend a system of distributive justice.

From Hobbes through Kant

Early modern versions of social contract theory were justifications for overthrowing tyrants who had overstepped the bounds allotted them, failing therefore to meet their obligations. Manegold of Lautenbach (c. 1030–c. 1112), Englebert of Volkersdorf (fl. c. 1310), Mario Salamonio (c. 1450–1532), and Junius Brutus (fl. 1572) all argued that a sovereign was bound by an implicit contract to act in the interest of his subjects. If he abused these obligations, the population had the right to take up arms.

Hobbes used contract theory for the exact opposite reason than most of his predecessors when he argued that a ruler should never be overthrown. Heavily influenced by the destruction of the English Civil War (1639–1651) and the resulting social upheaval, his version presented an appeal against such atrocities. In his *Leviathan* (1651), Hobbes pictured the original state of nature for prepolitical humans was one of constant war, which he argued any rational person would want to end. In their desire for peace, individuals would forfeit their natural liberty. Hobbes's contract between individuals rather than between subjects and sovereign establishes an obligation on all to obey the sovereign as a *rule of reason*, which he also calls a *law of nature*. Thus, for Hobbes, subjects never have the right to oppose their sovereign. Likewise Hobbes sees no contractual constraint on the sovereign, because only the sovereign can preserve a state of peace.

Unlike Hobbes, Locke in his *Two Treatises of Government* and *A Letter Concerning Toleration* (both 1689) argued that an absolute monarchy is inconsistent with civil society. For Locke, the prepolitical state of nature is a peaceful yet moral society where humans are bound by divinely commanded natural law. Social problems develop insofar as they lack a common judge with authority over all. In the absence of this common judge, individuals strive for power to exert wills and attempt to seize each other's property. This situation calls for someone with the authority to act as judge in order to protect life, liberty, and estate. The lack of a state prevents enforcement of the laws of nature, so citizens create one. As with Hobbes, the contract is between individuals rather than between governed and ruler. But citizens who institute a government to prevent people from occasionally violating natural law and showing partiality do not give up their liberty in the contract. They simply grant the state the right to judge and punish offenders of natural law. The state, therefore, has very limited authority based on its contractual powers. Its primary duty is to protect property. The contract is dissolved and resistance is justified if the government commits any breach of trust.

During the eighteenth century, a time of monarchial excess in much of Europe, social contract theory moved away from just overthrowing the king to arguing for a more equitable political system. The most notable theorist in this regard was Rousseau, whose treatise on *The Social Contract* (1762) foreshadowed both the American and French revolutions. These theories were no longer concerned with the status of a monarch, but with the idea that monarchy was itself a suspect political system. The social contract was no longer between the people and a sovereign; now the people have become sovereign.

Rousseau discussed the idea of social contract on two separate occasions. In neither case did he claim that the contract was an actual historical event. Instead he offered a theoretically ideal contract concerned with the origin of government. He did not write about how it actually happened but how it ought to have happened. He believed that the state of nature was one of individual liberty where each person was free and equal and none had by nature any legitimate authority over any other. The prepolitical state was also a presocial state. The result of the establishment of social relations was the rise of inequalities in social and economic forums. It is this that leads to conflict between individuals, because only social individuals could begin to acquire wealth and hence have reasons for war. The rich end up controlling the masses because they manipulate society in order to protect it from the ravages of war. Hence there is a need for an ideal contract that should be established to preserve equality. This contract between citizens establishes a government that is ruled by the general will or what is best for all. Rousseau's ideal contract creates not a sovereign person but a sovereign people. The government can only be an agent of the people's will. It is an exchange of natural liberty for civil liberty, where each member has an equal share in the expression of a general will.

More systematically than Rousseau, Immanuel Kant (1724–1804) extended social contract theory by presenting the contract as a regulatory ideal. Kant's contract was not so much what people would have agreed to as what they should have agreed to in such a hypothetical situation. For Kant, the social contract was that ideal to which individuals would agree if they were ideal moral beings. In his view all laws should be framed so that everyone would consent to them if given the choice.

The social contract theories of the eighteenth century provide a justification for a political system based on the equality of all citizens. The emergence of republican democracies at the same time is no coincidence. The idea that citizens were equal was not particularly novel, because earlier contract theory began with a prepolitical state of nature in which all were equal. But the idea that individuals in the political state should retain their equality creates a whole new conception of government.

It is important to note that social contract theory not only arose in historical association with the rise of modern democracy, but also in association with the rise of modern science and technology. Indeed the theories of the state of nature in both Hobbes and Locke provide justifications for the pursuit of technology. With Hobbes the justification is one of necessity, in order to escape the oppression of nature. With Locke the justification is more that of seizing opportunities for advancement. Moreover the social order within science is not unlike that elaborated by Rousseau and Kant: one of free and equal members in a well-ordered body politic. Indeed the scientists of the Enlightenment often referred to the *republic of letters* and the *republic of science*—and saw this democracy in science as a model for that to be established outside science. The term republic of science has continued to be used by such defenders of science as Michael Polanyi (1962) and Ian Jarvie (2001).

John Rawls and a Theory of Justice

Interest in social contract theory declined in the nineteenth century and was displaced by utilitarianism, the theory that actions are right when they produce more benefit than harm for society. But in the mid-twentieth century, social contract theory reemerged as a theory for justice, first in economics and then in philosophy.

Economist James Buchanan, for instance, has developed an argument derived out of rational choice theory dealing with the distribution of wealth in society. Like others, Buchanan is not talking about a historical event but rather suggests a contract theory that could be used to propose changes in political institutions. For him, the optimum decision making rule is to minimize the cost of collective action and promote what is advantageous to utility-maximizing citizens.

Philosopher Rawls, however, has altered the overall emphasis of the social contract by using it to promote a theory of justice. The social contract ensures that all people's interests are properly protected. The problem of justice arises because individuals make competing claims to the same goods produced through social cooperation. Unlike earlier versions of contract theory, Rawls sees social contract theory as a means for addressing this problem of conflicting interests. The distribution of social goods is just if and only if it would be acceptable to all parties prior to any party knowing which goods he or she might receive. In order to meet this requirement Rawls imagines a *veil of ignorance* behind which "no one knows his place in society, his class position or social status" (Rawls 1971, p. 12), a condition from which any social order could be constructed.

Michael Lessnoff's *Social Contract* (1986) argues that Rawls's theory of justice is the culmination of social contract theory. Although he believes that the problem of justice is the correct subject for contract theory, he nevertheless proposes a reformulation of Rawls. First, all must enjoy equal basic liberties unless an unequal distribution would improve the total basic liberty of those with less. Second, a fair and equitable opportunity must exist for all to achieve their desired social and economic positions, unless the inequality improves the lives of those with fewer opportunities. Third, inequalities of various social and economic goods must be to the benefit of those who have less of them.

Thus in the twentieth century social contract theory moved from a theory of governance to one of distributive justice. As such it has been used to question some of the situations brought about by science and technology. For instance, there are questions of justice regarding the practices of the United States that, with about 4 percent of the world's population, uses more than 20 percent of the world's resources. Distributive justice questions also come into play in assessing access to science and science education on the basis of economic class, gender, or ethnicity. Finally from the perspective of Rawls' veil of ignorance, one can ask whether the contemporary distribution of governmental funding for science is just. Instead of defending particular governmental funding policies for science from the perspective of particular scientific interest group politics, would it not be more just to ask how physicists, chemists, and biologists would distribute societal support for science, before knowing which kind of scientists they were going to become?

Science, Technology, and the Social Contract

The idea of a social contract has appeared in a number of different forms when discussing science and science policy. Classic sociology of science, such as that found in the work of Robert Merton (1973) and Joseph Ben-David (1984), although they do not use the term, might well be read as describing how a social contract among scientists leads to the creation of a distinctive scientific ethos. Studies of the history of engineering as a profession (Layton 1971) point in the same direction: that engineering as a profession was self-defined in part by means of a social contract among engineers. (It might also be interesting to note the special situation among social scientists, who both study and are constituted by such contracts.) In the broad sense, a social contract between science, technology, and society may also simply refer to common expectations in the relations between professional representatives in each of these three sectors: scientists, engineers and technologists, and politicians, respectively.

In this second sense of a social contract between scientists and the body politic, discussions have been at once more explicit and less well-grounded in social contract theory. As with social contract theory, a social contract for science need not refer to any specific historical agreement in a prepolitical period between the scientific community and the state or government. Instead it may be argued to be a logical extension of a desire on the part of individuals to better their condition, insofar as any such desire can itself be argued to benefit from scientific progress.

The whole concept of government spending on items such as science, technology, and medicine can thus be derived both from the original idea of individuals giving up their freedom to secure life, liberty, and property and from Rawls's idea of justice as directing resources to science and technology so as to increase benefits for all. Because the government is obligated by the social contract to improve its citizens' welfare, and insofar as science and technology are seen as having the potential to improve citizens' lives, the government invests in science, technology, and medicine.

Most explicitly science policy analysts in the United States have argued that Vannevar Bush's *Science—The Endless Frontier* (1945) established a social contract between the scientific community and government. In this case the public was left out of the agreement or at best represented by the government. In this contract, scientists promised to eliminate disease, feed the world, increase national security, and increase jobs in return for government funding and the right to maintain their autonomy. One description of this contract as a military-industrial complex became a focus for liberal political criticism during the 1960s. Antitechnology criticism of science as the cause of environmental pollution was a further spur to such criticism. In the 1980s and early 1990s with the downturn in the U.S. economy and the end of the Cold War, policy analysts began to question this social contract as well. They argued that the scientific community had failed to live up to its end of the bargain or was no longer as crucial to national welfare as it had been previously, and that public funding of science should be reexamined. With the reemergence of the U.S. economy in the mid-1990s and the rise of global terrorism in the 2000s such concerns tended to disappear.

The previous analysis assumes a kind of symbiosis between science and technology in what is often called technoscience. But in fact it can be argued that the situation with technology, especially that form of technology known as engineering, needs to be distinguished. For engineers, at least in the United States, any presumed social contract is mostly manifested in the marketplace. Industrial or market success substitutes for the social contract. When it comes to engineering, the problem is that there is no social contract—and yet the technologies that are developed and commercialized often have a social impact that consumers are not able intelligently to anticipate and governmental regulation is not sufficient to control.

The idea of a social agreement or contract continues to be invoked by politicians. For instance, in 1974 the British Labor Party proposed to save the United Kingdom by means of a social contract with the trade union movement. In 1994 the Republican Party in the United States ran its political campaign based on a *Contract with America*. The usefulness of social contract theory is its ability to ask what rational individuals would do if given a choice, and then to critique a system based on an argument about what is best for everyone. Even in Hobbes's defense of the monarchy, he begins with the assumption of what is best for all and not just a minority. Rawls extends this idea to justice and the distribution of resources to criticize any historical situation. Both approaches have been indirectly appealed to in discussions of a social contract for science, but it remains to be shown that such rhetoric has drawn at all deeply on the social contract theory tradition.

SOCIAL DARWINISM

Social Darwinism was a prominent ideology in the late-nineteenth and early-twentieth centuries that emerged when biologists and social thinkers tried to apply the biological theories of Charles Darwin (1809–1882) to human society. Social Darwinists believed that humans were subject to scientific laws, including Darwinian natural selection and the struggle for existence. They viewed human competition as a beneficent force bringing progress. However serious differences emerged among those who tried to formulate social theories based on Darwinism. One of the most controversial disputes among social Darwinists was whether humans should model their societies on nature or use scientific knowledge to vanquish nature. Specifically the question was whether humans should sharpen or soften the struggle for existence. Though most social Darwinists never admitted it, this fundamental question was not tractable scientifically, but depended on one's ethical perspective, because Darwinian processes could not predict future outcomes nor provide moral guidance. Not all Darwinists embraced social Darwinism, of course, and some promoted eugenics as a way to evade the human struggle for existence.

From Malthus to Darwin

Tracing the origins of social Darwinism is complicated, because many ideas associated with social Darwinism—such as laissez-faire economics, militarism, and racism—predated Darwin and influenced the formulation of his biological theory. Probably the most important of the forerunners of social Darwinism was Thomas Robert Malthus (1766—1834), whose population principle claimed that human populations tend to expand faster than the food supply. This population imbalance, according to Malthus, inevitably produces human misery, famine, and death. Darwin forthrightly incorporated Malthus's ideas, along with other concepts from nineteenth-century economics, into his biological theory. However he also gave a new twist to Malthus that would be important in the rise of social Darwinism. While Malthus considered the human misery caused by overpopulation entirely harmful and lamentable (though inevitable), Darwin construed it as beneficial and progressive, because it drove the evolutionary process, producing new species. The rise of Darwinian theory in the late-nineteenth century gave greater currency to Malthus's ideas, which became prominent in social Darwinist circles.

Darwin was clearly a social Darwinist, because he believed that the Malthusian population principle demonstrated the necessity of a struggle for existence among humans, leading to competition both within and between human societies. However these two levels of competition could work at cross-purposes, presenting Darwin (and other social Darwinists) with a dilemma. Which was more important: individual or group competition? Most social Darwinists—including Darwin—insisted that both operated simultaneously, though they did not always agree on which was more important. Darwin believed that individual competition among humans manifested itself primarily as peaceful economic competition, while group competition often brought warfare and racial conflict.

Another important plank of social Darwinism that Darwin propagated was human inequality. Natural selection could only function if there were significant differences between organisms. Also, in order to make their theory of human evolution more plausible, Darwinists had to emphasize the tremendous diversity within the human species, while showing the proximity of humans to other species. This led them to stress the differences between races, and the proximity of "primitive" races to primates. Darwin specifically claimed that "savage" races were biologically inferior to Europeans. He believed their intellectual prowess was far below that of Europeans, and because he considered moral character a hereditary trait, he also accused them of being biologically inferior in their moral character.

In most of his writings Darwin confined himself to *describing* the process of human evolution. However at times he became *prescriptive,* proposing public policy based on his theory. He generally supported laissez-faire economics, because it would promote competition among individuals, allowing the "fittest" to succeed. In a private letter he expressed concern that labor unions were deleterious, because they opposed individual competition. He also used his theory to justify national and racial competition, which was reflected in British and other European attempts to dominate the globe through imperialism. In *The Descent of Man* Darwin stated, "At some future period, not very distant as measured by centuries, the civilised races of man will almost certainly exterminate and replace throughout the world the savage races" (Darwin 1981, vol. 1, p. 201). Darwin, however, did make it clear that despite his view that wars have played a crucial role in human evolution, he hoped they would cease in the future.

Classic Social Darwinism

While justifying and supporting human competition as biologically beneficial, Darwin did not believe that the human struggle for existence was completely ruthless. He thought that human morality—which he explained as a product of the struggle for existence—tempered the struggle, at least within societies. Herbert Spencer (1820–1903), whom Darwin and many of his contemporaries considered a great philosopher, but whose star has waned since, likewise argued that ethics was the pinnacle of human evolution. However, like Darwin, he thought that too much altruism would be detrimental to humanity, because it would diminish human competition.

Spencer's role in the development of social Darwinism has been hotly debated, because before Darwin published his theory, Spencer already believed in biological evolution and embraced a competitive ethos and laissez-faire economics. However Spencer's pre-Darwinian ideas about evolution were shaped by Lamarckism, which taught that organisms passed acquired traits on to their offspring. Spencer's pre-Darwinian view of competition was not really social Darwinism. After 1859 Spencer integrated natural selection and the struggle for existence into his social views, thus espousing a form of social Darwinism. Like Darwin, he did not think the human struggle for existence had to be violent. On the contrary, he thought the struggle was becoming more and more peaceful as society progressed.

Not all social Darwinists thought warfare was becoming obsolete, as Spencer did. William Graham Sumner (1840–1910), a prominent American sociologist who pioneered social applications of Darwinism, claimed that Darwinism proved the inevitability of war. He even stated that "nothing but might has ever made right" (Hawkins 1997, p. 117), a position that Darwin rejected, but that several social Darwinists embraced. Even so, Sumner advised avoiding war if possible, so he was far from being a rabid militarist. However some social Darwinists, including the German general Friedrich von Bernhardi (1849–1930), author of the best-selling book, *Germany and the Coming War* (1912), used social Darwinism to promote militarism.

Racial competition was an even more prominent and widespread theme in social Darwinist thought than was national competition. Ernst Haeckel (1834–1919), the leading Darwinian biologist in Germany in the late-nineteenth century, was even more racist than Darwin. He argued that the distinctions between the human races were so great that humans should be divided into twelve separate species, which he placed in four separate genera. These races, he claimed, were in a competitive conflict that would only end with the extermination of the least fit races. Ludwig Gumplowicz (1838–1909), a law professor at the University of Graz in Austria, published one of the most extensive treatments of this theory in *The Racial Struggle* (1883), a term that became popular among social Darwinists in the 1890s and first decades of the twentieth century. Gumplowicz did not consider races a biological entity at all, however, as did most later racial thinkers, but rather he stressed their cultural construction. Nonetheless he argued that races are locked in an ineluctable Darwinian struggle for existence, and he believed that the ethnic conflicts within the Austro-Hungarian Empire were part of this universal struggle.

Another influential social Darwinist in the late-nineteenth and early-twentieth centuries who emphasized the racial struggle for existence was Georges Vacher de Lapouge (1854–1936), who exerted greater influence in Germany than in his native France. Lapouge was worried that certain "inferior" European races were displacing the "superior" forms. He wanted to supplement the racial struggle with eugenics. He hoped to replace the slogan of the French Revolution—liberty, equality, fraternity—with a more "scientific" triad—determinism, inequality, and selection. He warned in 1887, "In the next century people will be slaughtered by the millions for the sake of one or two degrees on the cephalic index [i.e., cranial measurements]. . . . the superior races will substitute themselves by force for the human groups retarded in evolution, and the last sentimentalists will witness the copious extermination of entire peoples" (Hecht 2000, p. 287).

Social Darwinist racism also found much support in Britain and the United States. Walter Bagehot (1826–1877), one of the first writers in Britain to apply Darwinism to politics, thought racial competition was a blessing to the human race, stimulating progress. He asserted that even though some races may not accept the superiority of the European race, "we need not take account of the mistaken ideas of unfit men and beaten races" (Hawkins 1997, p. 70). Karl Pearson (1857–1936), a leading British biologist, wanted to mitigate individual competition to increase national and racial vitality. He promoted eugenics as a way to give the British a competitive advantage in the racial struggle, and he supported the extermination of other races to make room for British settlement. In 1916 Madison Grant (1865–1937), a well-connected lawyer who served as president of the New York Zoological Society, published *The Passing of the Great White Race*. The preface to his book was written by one of the leading scientists of his time, Henry Fairfield Osborn (1857–1935), who was both a professor at Columbia University and president of the American Museum of Natural History. In his book Grant proposed using immigration restrictions and eugenics to restore the vitality of the "Great White Race," which was threatened with biological decline. Pearson and Grant were by no means idiosyncratic in supporting eugenics within their countries to strengthen their nation or race to compete successfully in the wider national or racial struggle for existence.

Conflicting Perspectives

One of the striking things about nineteenth-century social Darwinism was the variety of political positions that could use social Darwinist arguments to buttress their positions. British liberals—like Darwin—could use the theory to support laissez-faire economics and imperialism. But some non-Marxian socialists thought social Darwinism was on their side. For example, the physician Ludwig Büchner (1824–1899), one of the earliest and most famous Darwinian popularizers in Germany, argued that individual competition was essential for human advancement. However, he denied that the capitalist system was best in promoting competition. Capitalism, he thought, skewed the struggle for existence, because those who inherited capital would have an unfair advantage over those from poor families. Büchner suggested eliminating the inheritance of capital to level the playing field, so one's biological traits and abilities would be the only factors determining success or failure. Similar arguments were advanced by prominent Fabian socialists in Britain, such as Sidney Webb (1859–1947), and by the Labour Party leader, Ramsey MacDonald (1866–1937), who both promoted their socialist ideas as the logical outcome of Darwinian theory.

Though appropriated by scholars and politicians embracing a wide variety of political positions, social Darwinism would have its greatest impact on the world stage through the political power exerted by a fanatical social Darwinist whose racist brand of social Darwinism would drive him to unleash World War II in Europe. In *Mein Kampf* (1925–1927) Adolf Hitler argued that racial competition was a part of the universal struggle for existence, which destroys the weak and unfit. Hitler believed that morality consisted in cooperating with nature in destroying the weak, so the healthy, "superior" individuals could triumph.

Social Darwinism declined in popularity in the mid-twentieth century, and not only because of its association with the Nazis. Biological explanations for human behavior gave way in the mid-twentieth century to environmental explanations. Behaviorism dominated psychology in the 1950s, cultural relativism dominated anthropology, and Marxism and other non-Marxist forms of economic and environmental determinism displaced biological determinism in the social sciences. By the 1960s biological determinism had almost completely disappeared from serious scholarly work. After Richard Hofstadter wrote the first major historical work titled *Social Darwinism in American Thought* (1944), the term social Darwinism was generally used disparagingly.

In the 1970s a new movement within the scientific community emerged that reinvigorated biological determinism. Edward O. Wilson provoked intense controversy with the publication of his book, *Sociobiology* (1975). Many accused Wilson of resurrecting social Darwinism, but he and supporting colleagues denied the charge. Indeed Wilson did embrace some of the positions of earlier social Darwinists (for example, his stress on biological determinism, the importance of Darwinian selection on human behavior, and so on), but he did not embrace the crude nationalism and racialism that Hofstadter identified as leading characteristics of social Darwinism.

Weindling, Paul. (1989). *Health, Race and German Politics between National Unification and Nazism, 1870–1945*. Cambridge, UK: Cambridge University Press. A long chapter on social Darwinism in Germany shows the predominance of political liberalism in social Darwinist discourse. Much of the rest of the book examines eugenics.

Young, Robert. (1985). "Darwinism *Is* Social." In *The Darwinian Heritage*, ed. David Kohn. Princeton, NJ: Princeton University Press. Young cogently explains how social thought impacted Darwin and influenced the formulation and expression of his theory.

SOCIAL ENGINEERING

Social engineering occurs in two forms: large scale and small scale. The debate surrounding these two approaches to the design of social institutions constitutes a fundamental issue in the ethics of science and technology. To what extent is it possible and legitimate for scientific expertise to serve as the basis for social policy and action? Can humans use science to rationally design and successfully implement an enduring society? Different concepts of scientific knowledge and technological action supply different answers to these questions and variously support large scale versus small scale engineering efforts.

Large Scale Social Engineering

Large scale efforts to improve the human condition are a modern phenomenon. Such endeavors require technical knowledge, political muscle, and economic resources. In supporting these claims, James Scott (1998) characterizes the rise of high modernism in social-political, agricultural, industrial, and architectural contexts during the last two centuries. High modernism encompasses a quest for authoritarian control of both human and nonhuman nature, a belief that carefully crafted social order surpasses happenstance, and a confidence in science as a means to social progress. Once the improvement of humanity becomes a plausible state goal, the convergence of rising social science, state bureaucracy, and mass media undergirds five-year collectivist plans, colonial development schemes, revolutionary agricultural programs, and the like, often under the control of a single planning entity.

In urban planning, for example, Scott details the designs of the Swiss architect, Charles-Edouard Jeanneret, (1887–1965), known professionally as Le Corbusier. For Le Corbusier, urban design expresses universal scientific truths. His geometric symmetries often structured human activity, as inhabitants conformed to the design rather than vice versa. This approach applied to entire cities as well as individual homes ("machines for living"). Le Corbusier's formulaic concatenation of single function components produced simplicity via widely separated spaces for living, working, shopping, and recreating. Defining the good of the people, often the working poor, in terms of detached, scientific principles and their authoritarian imposition is, according to Scott, emblematic of high modernist, large scale attempts at social engineering.

Small Scale Social Engineering

In conceiving the perfect, nondecaying state, Plato envisions a radical departure from existing society. Marxists, too, as self-described social engineers, use historical interpretation in aiming for revolutionary, holistic change. The Anglo-Austrian Philosopher, Karl Popper (1902–1994) contrasts these utopian endeavors with "piecemeal social engineering." When society needs reforming, the piecemeal engineer

> does not believe in the method of re-designing it as a whole. Whatever his ends, he tries to achieve them by small adjustments and re-adjustments which can be continually improved upon. . . . The piecemeal engineer knows, like Socrates, how little he knows. He knows that we can learn only from our mistakes. Accordingly, he will make his way, step by step, carefully comparing the results expected with the results achieved, and always on the look-out for the unavoidable unwanted consequences of any reform; and he will avoid undertaking reforms of a complexity and scope which make it impossible for him to disentangle causes and effects, and to know what he is really doing. (Popper 1957, pp. 66–67)

These claims resonate with Camus's (1956) distrust of ideologically calculated revolution and his preference for limited but inspired rebellion. In Popper's view, mistakes are inevitable, and more radical innovations produce more mistakes. Because foolproof social forms are unattainable, some mechanism for identifying needed improvements must be an integral part of a necessarily gradual implementation process. This view contrasts with that of large scale social engineering on several dimensions and highlights multiple points of contention.

Spontaneous versus Consciously Controlled Change

Popper's (1972) concept of evolutionary epistemology supports not only the idea that advances are slow and piecemeal but also that they are guided by no overarching plan. This view resembles that of the twentieth-century British economist Friedrich Hayek (Nishiyama and Leube 1984). Hayek (1967) emphasizes the view that significant social phenomena emerge spontaneously via the unintended effects of individual actions, and he finds support for the benefits of this process in the ideas of the British political economist, Josiah Tucker (1711–1799), and especially the Austrian economist Karl Menger (1840–1921), that social institutions compete with one another in a kind of survival of the fittest. Because knowledge required for large-scale planning is widely distributed among many minds and cannot be narrowly concentrated, Hayek rejects centralized planning. Popper (1963a) advocates "negative utilitarianism," the view that proposals for reform should be judged by how little suffering is caused. Government should thereby ameliorate enduring social ills (such as poverty and unemployment) and leave efforts to increase happiness to individual enterprise. These views shape the method (monitored, incremental change) and the goals (amelioration) of social engineering.

The nature of social reform is also examined by the American philosopher and educator John Dewey (1859–1952). But when Dewey speaks about the need for liberalism to advance beyond its early gains in securing individual freedom, his vision is incongruent with that of Hayek and Popper. For Dewey, liberalism should advance a social order that "cannot be established by an unplanned and external convergence of the actions of separate individuals, each of whom is bent on personal private advantage" (Dewey 1963 [1935], p. 54). This social reform must be thoroughgoing in its quest for institutional change.

> For the gulf between what the actual situation makes possible and the actual state itself is so great that it *cannot be bridged by piecemeal policies undertaken ad hoc*. The process of producing the changes will be, in any case, a gradual one. But "reforms" that deal now with this abuse and now with that without having a *social goal based upon an inclusive plan*, differ entirely from efforts at re-forming, in its literal sense, the institutional scheme of things. (p. 62)

Dewey sees the necessity of early planning in his thinking about social reform (Geiger 1971 [1939]), and while it is clear that Popper restricts not planning per se but only its scope and method, Dewey projects a wider, more vibrant use of planning in achieving social renovation. Education, science (the method of intelligence), and well-designed government policy are keys to social improvement.

The Nature of Scientific Knowledge

Any call for social engineering requires some clarification of the relationship between science and engineering. Popper differentiates natural and social science in ways that Dewey does not. In natural science, Popper's realist perspective dictates that theories make claims about unobservable realities responsible for observed regularities. These claims are tested by means of controlled experiments. In contrast, Popper construes social science as producing low-level empirical laws of a negative sort ("you cannot have full employment without inflation"), which are tested through practice in social engineering. This amounts to a narrow view of social science and contributes to the contrast between his scientific radicalism, which focuses on natural science, and his engineering conservatism, which is linked to social science. The contrast between Dewey the pragmatist and Popper the realist is instructive here. From Dewey's pragmatic perspective, "the ultimate objects of science are guided processes of change" (Dewey 1958 [1929], p. 160). Both natural science and social science provide an illustration of this concept (Dewey 1947). Popper's general aversion to abstract theories in social science may be linked to his desire to reject certain theories, such as that of the Austrian psychiatrist Sigmund Freud, on the basis of unfalsifiabilty. Dewey's acceptance of a wider range of theory plus empirical law in social science allows for testing to occur in a greater range of circumstances, not only in practice (which is often problematic: even piecemeal change simultaneously introduces multiple causal factors) but also in controlled, even laboratory, settings. Contemporary studies in social science embrace such methods, including those of simulation (Liebrand, Nowak, and Hegselmann 1998; Ilgen and Hulin 2000). Moreover, when guided by theory and experimental tests, changes introduced into practice need not be small scale. Large-scale changes may be introduced for larger scale problems (such the Great Depression or disease epidemics). Linking Science to Practice Popper and Dewey differ when relating science to social engineering. In disputes with the American philosopher Thomas Kuhn (1922–1996), Popper emphasizes the value of critical and revolutionary action (bold conjectures and severe tests) over and above the uncritical plodding of normal science (Popper 1970). This contrasts with his recommendations for social engineering where action should be piecemeal. This contrast, acknowledged by Popper (1976) himself, may arise from the use of the scientific community as a model for society at large. Nevertheless, the degree of openness and fruitfulness of criticism differs significantly within these two realms (Burke 1983). Robert Ackermann proposes that an explanation "of the relative isolation of theoretical scientific knowledge from practical concerns is required to explain how a form of social conservatism can be held consistently with a form of theoretical radicalism" (Ackermann 1976, p. 174).

Such concerns are related to Scott's analysis of why large scale schemes have often failed to improve the human condition. Scott sees knowledge of how to attain worthwhile, sustainable solutions as being derived not from scientific theory, nor from the low level empirical laws cited by Popper, but by a form of know how (*metis*, from the ancient Greek) rooted in localized, cultivated practice. Like Dewey's conception, which builds an inherent normative element ("*guided* processes") into knowledge itself, there is no need to search for means of effective "application." The implication is that useful knowledge springs from contextualized activities, not from using local conditions to fill in the variables of general principles. This view raises serious doubts about the practical relevance of scientific expertise, in the modern sense, and its ability to produce sustainable solutions to social problems. Indeed, some have suggested that such limitations exist not only in large scale enterprises but also in small scale efforts involving more narrowly focused problems (Hamlett 1992, Winner 1992). A narrow focus can undermine the need to address larger issues and long run concerns and can mire the political process in gridlock. From these considerations, it should be clear that small scale engineering offers no panacea and that different concepts of small scale enterprise point the way in somewhat different directions.

Impact of the Social Engineering Issues

Questions concerning appropriate scale and the interaction of social science and social engineering have wide impact. An entire school of social scientists use Popper as a guide in trying to design effective social policy. The works of the incrementalist Charles Lindblom (*The Intelligence of Democracy*; *Usable Knowledge: Social Science and Social Problem Solving*; *Inquiry and Change: The Troubled Attempt to Understand and Shape Society*; etc.) provide, by title alone, some measure of the impact of Popper and Dewey and of social scientists' pursuit of social engineering. Moreover, differences between planned, rule-governed (top-down) versus unplanned, evolutionary (bottom-up) approaches inform methodologically diverse explorations within social science itself (Banathy 1996, Read and Miller 1998). Whether or not humans can effectively design social systems is essentially a question concerning human intelligence, and efforts to build automated intelligent systems confront the same methodological controversy concerning rule-governed versus connectionist, evolutionary designs ("Sackler Colloquium" 2002). Finally, controversies over the promises of planned societies continue to echo the dispute between Popper and Marxists over the true nature of social engineering (Cornforth 1968, Marquand 2000, Notturno 2000, Postrel 2001).

SOCIAL INDICATORS

The historical tradition of social indicators may be traced back to Jeremy Bentham's (1789) ideas about a *felicific calculus* that would allow decision makers to calculate the net pleasure or pain connected to everyone affected by an action, with evidence-based public policy choices made to get the greatest net pleasure or least net pain for the greatest number of people. From a consequentialist moral point of view, the aim of government should be to increase the pleasure or happiness, broadly construed, of the maximum number of persons.

This approach is similar to the naturalist tradition in American pragmatism as argued in work by William James (1909), Ralph Barton Perry (1926, 1954), John Dewey (1939), and C. I. Lewis (1946), but more complicated. It is similar in the sense that pragmatism, like Bentham, naturalizes ethics by basing it in subjective preferences. It is more complicated in that most early-twenty-first century social indicators researchers believe the relatively objective circumstances of people's lives merit at least as much attention as how people assess those lives. The argument is that a morally complete assessment of people's lives, or a full assessment of people's lives from a moral point of view, requires a thorough examination of the nature or being as well as the value or good of those lives. In philosophical jargon, social indicators rest on an ontological answer to the question, What is its nature?, and an axiological answer to the question, What is its value?

Basic Concepts

The term *social indicator* denotes a statistic that has significance for measuring the quality of life. The term *social report* designates an organized collection of social indicators, and *social accounts* names a balance sheet in which costs and benefits are assigned to the indicators in a social report. Briefly the main difference between social reports and accounts is that the former answers the question, How are we doing?, and the latter answers the question, At what price?—where price may be measured in dollars, energy, personal satisfaction or dissatisfaction, or some other applicable metric.

From a linguistic perspective, social indicators usually consist of a term denoting a subject class and a term denoting some *indicator property*. For example, the second term of the phrase *infant mortality* denotes the indicator property mortality and the first term denotes a particular class of things, namely infants that may possess that property. By replacing the subject term infant by *one-year-old, two-year-old,* or more, one can routinely generate (social) mortality indicators for as many age groups as desired. Similarly by replacing the subject term by *male, Indian,*or others, one can routinely generate mortality indicators for as many kinds of groups as one likes.

Social indicator phrases are like variable names in logic and mathematics, and social indicators are like the variables themselves. Furthermore just as one speaks of the values of variables in logic and math, one may speak of the indicator-values of social indicators. For example, the annual percent of undergraduate degrees awarded to females in engineering in the United States in the 1990s was about 16 percent. So one may say that this variable (annual percent of undergraduate degrees awarded to females in engineering in the United States in the 1990s) had an indicator-value of 16 percent.

Social indicators that refer to personal feelings, attitudes, preferences, opinions, judgments, or beliefs of some sort are called *subjective indicators*, for example, satisfaction with one's health, attitudes toward science or scientists, and beliefs about the dangers of some new technology. Social indicators that refer to things that are observable and measurable are called *objective indicators,* for instance, the height and weight of people, numbers of automobiles manufactured or sold each year, and numbers of people employed in research and development.

Positive indicators are those for which most people equate an indicator-values increase with quality of life improvement, such as elderly citizens incomes and minority-group educational attainment. The female engineering degrees indicator mentioned above would be regarded as positive by those who think that the quality of women's lives tends to improve as their access to the full range of professional occupations improves. *Negative indicators* are those for which most people equate an indicator-values increase with quality of life deterioration, namely, infant mortality rates and murder rates. (Notice that an indicator is regarded as positive or negative not in virtue of whether or not its values in fact increase or decrease, but only in virtue of whether or not most people would like its values to increase or decrease. What is relevant is not the *fact* but the *desirability* of an increase or decrease in its values.)

Unclear indicators are such that either (a) most people will not be willing or able to say whether higher indicator-values indicate a better or worse state of affairs, for instance, welfare payments, or (b) there is serious disagreement about whether higher indicator-values indicate a better or worse state of affairs, namely, divorce rates. In the case of welfare payments, it is difficult to say, because as the values increase there may be an increase of people in need of such assistance, which is bad; while, at the same time, there is an increase in the amount of assistance given, which is good. In the case of divorce rates, many people know exactly what they want to say, and they happen to disagree with what some other people want to say.

Input indicators indicate some sort of inputs into a process or product, such as numbers of people engaged in research and development. *Output indicators* indicate some sort of output of a process or product, such as numbers of articles published or patents awarded per 1,000 people employed in research and development. Unlike the previous indicator classifications, what counts as an input or output indicator depends on the purposes of the classification. For example, from the point of view of a teacher, the amount of time a student spends studying could be regarded as an output indicator measuring the effects of a student's own need for achievement as well as from advice, admonitions, and threats given to the student. However from the point of view of a student, time spent studying could be regarded as an input indicator measuring the necessary investment made in the interest of obtaining such important measurable outputs as university degrees, good jobs, and higher income. In some contexts it is useful to talk about *intermediate output indicators* (for example, that count the machines that make consumer products), *throughput indicators* (for instance, that assess choices people make for certain consumer goods) and *outcome indicators* (such as those that measure longer-term net results of inputs).

When people use the phrase *quality of life,* they sometimes intend to contrast it with quantities or numbers of something. There are, then, two different things that one might reference when using the phrase *quality of life*. First, one might want to refer to sorts, types, or kinds of things, rather than to mere numbers of things. For example, one might want to know not merely how many people received bachelors degrees majoring in mathematics, but also something about who they were, male or female, in public or private institutions, with or without scholarship aid, and so on. When the term *qual-*

ity in the phrase *quality of life* is used in this sense, one may say that it and the phrase in which it occurs is are intended to be primarily *descriptive*.

Second, one might want to refer to the value or worth of things when using the term quality in the phrase *quality of life*. For example, one frequently hears of people making a trade-off between a high salary and better working or living conditions. Presumably the exchange here involves monetary and some other value. That is, one exchanges the value of a certain amount of money for the value of a certain set of working or living conditions. When the term *quality* in the phrase *quality of life* is used in this sense, one may say that it and the phrase in which it occurs is intended to be primarily *evaluative*.

Both senses of the phrase *quality of life* are important. It is important to be able to describe human existence in a fairly reliable and valid fashion, and it is important to be able to evaluate human existence in the same way. In the early years (1960s) of social indicators research, people asked, Should researchers measure the nature and value of life with objective or subjective indicators, or both? In the early twenty-first century, nearly everyone agrees that both kinds of measures should be used.

Uses and Abuses

It cannot be emphasized too strongly that social reporting is an essentially political exercise and that its ultimate success or failure depends on the negotiations involved in creating and disseminating the reports. Every opportunity to use social indicators is equally an opportunity to abuse their use. For examples, indicators:

(1) provide convenient numerical summaries of important features of society, but also encourage commission of The Number-Crunchers' Fallacy, which is this: Anything that cannot be counted is unimportant and anything that can be counted is important.

(2) can be used to predict and alter future behavior, for better or worse depending on the nature of the behavior and the alterations.

(3) can give visibility to problems, and also create them by focusing attention on them, or by hiding some in the interest of emphasizing others.

(4) can help obtain balanced assessments of conditions against mere economic assessments, and can distort appropriate assessments by assuming that everything valuable can be given a price in monetary terms.

(5) can help in the evaluation of current public policy and programs, and also contribute to perverse evaluations because the statistics routinely collected may not allow decision makers to control for important contaminating variables when they are trying to decide what has caused what.

(6) can help determine alternatives and priorities, but also allow an elite corps of statisticians and other experts to unduly influence the public agenda by providing the *official version* of the state of the world.

(7) can facilitate comparisons among nations, regions, and cities, and service providers, but also encourage invidious comparisons, raising aspirations and hopes too high or not high enough.

(8) can suggest areas for research to produce new scientific theories and more knowledge about the structures and functions of systems, but also retard action because people may be unwilling to act in the absence of a perfect theory or model.

(9) can provide an orderly and common framework for thinking about social systems and social change, perhaps so orderly and common that alternatives from different points of view might be perceived as unrealistic, unthinkable, totally radical, and incredible merely because they are different.

(10) can stimulate thinking about new polices and programs, or stifle such thought as a result of massive *group-thinking*.

Critical Issues

Anyone constructing social indicators with the aim of integrating them into a social reporting or accounting system to monitor changes in the quality of people's lives will have to address the following thirteen issues, which collectively yield more than 200,000 possible combinations representing at least that many different kinds of systems.

1. *Settlement/aggregation area sizes:* For example, best size to understand air pollution may be different from best size to understand crime.
2. *Time frames:* For example, optimal duration to understand resource depletion may be different from optimal duration to understand impact of sanitation changes.

3. *Population composition:* For example, analyses by language, gender, age, education, ethnic background, and income, among others, may reveal or conceal different things.
4. *Domains of life composition:* For example, different domains such as health, job, family life, and housing give different views and suggest different agendas for action.
5. *Objective versus subjective indicators:* For example, relatively subjective appraisals of housing and neighborhoods by actual dwellers may be very different from relatively objective appraisals by experts.
6. *Input versus output indicators:* For example, expenditures on teachers and school facilities may give a very different view of the quality of an education system from that based on student performance on standardized tests.
7. *Measurement scales:* For example, different measures of perceived subjective well-being provide different views of people's well-being and relate differently to other measures.
8. *Report writers:* For example, different stakeholders often have very different views about what is important to monitor and how to evaluate whatever is monitored.
9. *Report readers:* For example, different target audiences need different reporting media and/or formats.
10. *Quality-of-life model:* For example, once indicators are selected, they must be combined or aggregated somehow in order to get a coherent story or view.
11. *Distributions:* For example, because average figures can conceal extraordinary and perhaps unacceptable variation, choices must be made about appropriate representations of distributions.
12. *Distance impacts:* For example, people living in one place may access facilities (hospitals, schools, theatres, museums, and libraries) in many other places at varying distances from their place of residence.
13. *Causal relations:* Prior to intervention, one must know what causes what, which requires relatively mainstream scientific research, which may not be available yet.

In the presence of the potential abuses and the great variety of reports that might be produced as people make different choices regarding the thirteen critical issues, the general rule to be used is to try to have a development process that is maximally inclusive and transparent. William James came close to capturing the appropriate aim in 1891.

> That act must be the best act . . . which makes for the *best whole,* in the sense of awakening the least sum of dissatisfactions. In the casuistic scale, therefore, those ideals must be written highest which prevail at the least cost, or by whose realization the least possible number of other ideals are destroyed. . . . The course of history is nothing but the story of men's struggles from generation to generation to find the more and more inclusive order. (James 1977, p. 623)

SOCIAL INSTITUTIONS: OVERVIEW

Ethics is involved not only with personal decisions and the assessments of individual behavior but also with social institutions, especially, in the contemporary world, with those institutions constituted by scientific and technical professions as well. Classic sociology—as developed by social scientists considered in entries on "Durkheim, Émile," "Marx, Karl," and "Weber, Max," among others—identified a number of basic social institutions such as the family, religion, state, economy, and education. Social institutions in this sense are defined by persons acting in concert to address distinctive human interests; as such they are characterized by social roles that people accept when acting, for instance, in relation with those to whom they have biological links (the family), in relation to that which is seen as sacred (religion), in relation to the exercise of group power (state), and so on. Each social institution is thus defined by and defines a sphere of human behavior, and the roles woven into these institutions traditionally constitute both descriptive or empirical (and in this sense scientific) and prescriptive or normative (and thus ethical) phenomena. Roles both describe and prescribe human behavior within the contexts of social institutions.

Science and technology, while acquiring the status of social institutions, have likewise influenced and altered other social institutions and social roles in at least three overlapping ways. First, technological change over the long sweep of human history has shifted the relative weights or balances between different roles. For thousands of years, during the preliterate period of human history, when humans were primarily hunters and gatherers, the institution of the family occupied the dominant position with only the most modest autonomy granted to religion and even less to those activities now associated with the state, economy, and education. With the domestication of plants and animals, however, divisions of labor arose that in turn gave rise and increasing prominence to religion, state, economy, and education, while also transforming the institution of family (as is considered, for example, in the entry on "Family").

Second, over the course of written history science or the systematic pursuit of knowledge in its various permutations altered fundamental ideas about these basic social institutions and their justifications. Mythical narratives of the gods and relations between gods and humans as the original behavior patterns to be differentially imitated by different social institutions were supplemented by accounts that appealed to patterns in nature. The science of nature slowly introduced alternative understandings of social institutions and social roles, as can be seen, for instance, in Plato's *Republic*, with its rational account of the need for myths or likely stories about the differences between the social roles of the three basic classes (or social institutions) of artisans, soldiers, and rulers.

Finally, in the modern period, new unifications of science and technology in both the "Scientific Revolution" (sixteenth century) and the "Industrial Revolution" (eighteenth century) intensified the proliferation of social institutions and social roles through the development of scientific disciplines and industrial divisions of labor. These historical changes altered anew the balances between institutions (giving both science and economy, for instance, a weight previously unknown in human history), granted each institution more autonomy or independence, and ultimately relativized the power of particular social roles through their very proliferation. Beginning in the second half of the twentieth century, the growing multiplicity and complexity of roles began to be linked and networked in synchronic hybrids of interdisciplinarity and diachronic career changes. (Entries on "Education" and "Interdisciplinarity" are especially relevant in regard to such changes.)

Beyond entries already mentioned, others in the *Encyclopedia of Science, Technology, and Ethics* break out social institution–related issues in different ways. The perspective of the basic institution of religion finds expression in a series of entries on "Buddhist Perspectives," "Christian Perspectives," "Hindu Perspectives," and more. The basic institution of the state is engaged with entries on "International Affairs," "Military Ethics," "Police," "Science Policy," and "Science, Technology, and Law." Entries on such basic social institutions are complemented by ones on more fine-grained social organizations and agencies (professional societies such as the "American Association for the

Advancement of Science"), on related processes (such the emergence of "Professions and Professionalization"), and on ethical questions that repeatedly challenge and are challenged by social institutions (such as "Justice").

SOCIALISM

Socialism has been one of the most popular political ideas in history, rivaling in some ways even the great religions. By the late 1970s, a mere 150 years from the time the term *socialism* was coined, roughly 60 percent of the world population was living under governments that called themselves "socialist," although these varied widely in their institutions and were often violently at odds with one another.

Socialism drew impetus from the rise of industry in Europe in the nineteenth century. The new wealth generated by new methods of production encouraged the belief that now it would be possible to assure a comfortable standard of living for every member of society. The uneven distribution of this new wealth was seen to pose ethical questions that were less often asked about long-entrenched class disparities prevalent in the countryside. Socialism was seen by many of its advocates as not only an ethical but also a scientific response to these new circumstances. Drawing on the Enlightenment critique of religion, socialism offered an image of the ideal life as something to be achieved in the here and now rather than in the great beyond.

Five Types of Socialism

The myriad forms of socialism that were actually put into practice might be grouped into five broad categories: communism, social democracy, Third World socialism, fascism, and communal socialism. (There were others, such as anarcho-syndicalism, that remained forever in the realm of speculative thought.) Each of these five requires a note of explication.

In the early decades of socialist thought the terms *socialism* and *communism* were often used interchangeably, and while some writers attempted to define the distinction between the two, no such distinction ever achieved widespread acceptance. When Vladimir Ilich Lenin (1870–1924) led his group of Bolsheviks to power in Russia in 1917, he announced that they would henceforth call themselves communists. Until then, they had been merely the *bolshevik* (meaning majority) segment of Russia's Social-Democratic movement. (This had been a single party, at least formally, until 1912, when Lenin's faction announced it was a party in itself. Still they were all social democrats.)

In the years following 1917, as parties modeled after Lenin's appeared in dozens of countries, a clear distinction emerged between social democracy and communism. There were countless points of dispute and differences, but probably the most profound was that social democrats sought parliamentary means to power and adhered to the principle that political systems should have multiple parties, whereas communists envisioned a revolutionary path to power and believed that communist parties, as the only true representatives of the working class, were the only legitimate ones. This made for such a wide gulf that thereafter social democrats never called themselves communists, and communists never called themselves social democrats. The distinction, however, continued to be clouded by the fact that both sides claimed the term *socialism* for themselves. Thus the country Lenin created was called the Union of Soviet Socialist Republics, and at the same time the international federation that brought together the world's social democratic parties (the British Labour Party, the German Social Democrats, etc.) called itself the Socialist International.

Third World socialism is a loose category comprising "African socialism," "Arab socialism," and various cognate forms that appeared elsewhere in poorer countries after World War II. These were usually dictatorial in their political practice (although not in all cases: India offers a dramatic counterexample), but rarely was the state as all controlling as in communist systems. Some of these states (for example, Tanzania under Julius Nyerere [1922–1999]) elaborated complex blueprints of economic development, whereas in others "socialism" probably served as little more than a popular label for a hodgepodge of policies of a military dictator or a rationalization for strengthening the power of the central government (for example, Somalia under Mohammed Siad Barre [c. 1919–1995]).

To include fascism as a subset of socialism invites controversy because fascist movements often made their appeal on the promise to protect society from socialists or communists, because they were almost always part of the Right (whatever that may mean) rather than the Left, and because their inclusion may be taken as a polemical device to tar socialism with the odium attached to fascism. Yet the historical basis for their inclusion is strong. Adolf Hitler's party called itself National Socialist (as did some similar groupings in other countries, such as Hungary, some of which thought up the name independently of, and even prior to, Hitler). In Italy, Benito Mussolini formed his fascist movement as a leftist pro-war breakaway from the Socialist Party, of which he was a top leader. Each of these movements attempted to retain some of the elements of socialism while substituting the nation (or in Hitler's case the German *volk*) for the working class that had been seen as the main engine and beneficiary of socialism in traditional theory. Once in power, both Mussolini's party and Hitler's continued to preserve some of the accouterments of their socialist heritage. Mussolini himself probably captured best the relationship between these isms when he declared that fascism was a "heresy" of socialism, suggesting something that had sprung from the same premise but turned to challenge some of socialism's integral tenets.

Communal socialists differ from all the others in that they do not focus on trying to gain power (whether by vote or violence) in order to establish a socialist system over an entire country. Rather they are groups of individuals whose primary goal is to live a socialist life themselves by organizing communities operating on socialist principles. (No doubt many commune members also hope that their example might inspire emulation.) Usually such communities have numbered a few hundred members, although some have measured only in the tens and others in the low thousands. In the United States, a few hundred such societies were founded over the course of the nineteenth century, some by people whose driving belief was socialism, per se, others by devotees of religious sects, such as Shakers, for whom sharing property was but a facet of their sense of spirituality. Israeli kibbutzim are another important example of this form.

Historical Origins

Except for the communal, all of these forms grew from the same acorn: the French Revolution of 1789, with its ethos of "liberty, equality, fraternity." Although the Revolution itself did not aim for socialism, and although the term socialism was not coined until decades later, it was in pursuit of this inspiring triad of goals that socialism came to be conceived and then popularized. How can there be equality, it was asked, with vast disparities between rich and poor? How can there be brotherhood in a context of heartless economic competition? How can there be liberty if most people are enslaved to material necessity?

These questions presented themselves with greater urgency as the Industrial Revolution took hold. Although the poor of the factories were not poorer than the poor of the farms, their poverty, concentrated in urban slums, was more visible. Moreover, the Industrial Revolution entailed new ills such as industrial accidents and work environments devastating to human health. The labor of young children in factories offered a spectacle more heartbreaking than work of children on farms, which seemed a natural part of rural life from time immemorial.

The solution, it was argued, was to be found in collective ownership of property and the egalitarian distribution of the goods of society. These twin principles were to remain at the heart of socialism, although each of them, as well as many lesser points of doctrine, were to be disputed, refined, and amended repeatedly. Collective ownership in an individual commune was easy to envision. Collective ownership of the economic assets of an entire society was more difficult to conceptualize. It might mean ownership by the central government, but in other versions it might mean something less centralized—for example, that individual enterprises would be owned by the people who worked in them or by local communities. Egalitarian distribution did not necessarily mean exactly equal shares. The most fetching socialist slogan was "from each according to his abilities; to each according to his needs," which implied a measure of inequality but raised the question of how such needs would be determined. In Israeli kibbutzim, one place where an earnest effort was made to implement this principle, special committees existed to which kibbutz members could bring their special needs or abilities (a medical condition, an artistic calling, a family emergency abroad that required travel, and the like), and these committees were empowered to distribute resources accordingly.

Relation to Science and Technology

The connection between socialism and science originates in the claim of Karl Marx (1818–1883) and Friedrich Engels (1820–1895), the most influential of all socialist thinkers, to have discovered "scientific socialism." By this they meant to distinguish themselves from such early-nineteenth- (or in a few cases, late-eighteenth-) century visionaries as Henri de Saint-Simon

(1760–1825), Robert Owen (1771–1858), Charles Fourier (1772–1837), and Étienne Cabet (1788–1856), who had inspired the founding of various communes. Marx and Engels ridiculed the idea that a group of individuals could move the world toward socialism by creating model communities to demonstrate socialism's benefits. They saw this as naive because they doubted that political forms or even political ideas emerged simply from the free play of the human mind. To believe this, they said, is to be "utopian."

This term *utopian* itself is misleading because Marx and Engels were not objecting to the fancifulness of some of the early socialist visions. (Fourier's socialism, for example, envisioned that lions and whales would be tamed so as to free humans from physical labor and that each citizen would be entitled not only to a "social minimum" of economic rewards but also a "sexual minimum" of carnal satisfaction.) The fleeting glimpses Marx and Engels offered of life under socialism were pretty idyllic in themselves: People would do only those activities that they find intrinsically gratifying, say, hunting in the morning, fishing in the afternoon, writing poetry in the evening. Rather, what Marx and Engels found unrealistic, hence "utopian," about the earlier thinkers were their ideas about how socialism could be brought about. "Life is not determined by consciousness but consciousness by life," they wrote (*The German Ideology* part 1A,1845).

What they meant by this was that socialism could not come about until the objective conditions—which meant a certain level of wealth and technology—were right. Nor would it be brought about by individuals who happened upon the idea of socialism through reading or contemplation; rather its engineers would be people impelled to fight for socialism by the very conditions of their daily lives. Specifically, they held that socialism had not been possible in rural society but that the advent of industrialization laid open a new era. For one thing, the new technologies generated unprecedented abundance, making it possible for every member of society to enjoy a high standard of living. (Of course, what seemed a high standard in 1850 would be considered quite low by twenty-first-century standards, a wry comment perhaps on the elasticity of human need.) Moreover, the character of industrial production, depending on highly collective human effort, was conducive to collective ownership, making socialism a natural choice.

For the first time, because of this change, socialism had become a realistic possibility. Indeed its appearance had become likely, perhaps even inevitable. This was because industrialization brought the flowering of capitalism. Capitalist competition forced manufacturers to cut costs, including labor costs, thus driving down rates of pay. As a result, the very individuals whose sweat was providing the new abundance were left with too little income to share in it themselves. Eventually, driven in part by a sense of injustice but even more by the whip of destitution, they would rise up to abolish the system of private capitalism and replace it with socialism. This would not be because anyone had persuaded or taught them to do so but because bitter circumstances would impel them to do it.

In sum, Marx and Engels believed that they had discovered the processes that drive social and political change, and that these were rooted in the march of technology rather than in anything as arbitrary as individual will or cognition. They believed that this revelation of the laws of social evolution was analogous to the recent sensational revelation of the principle of the evolution of species. As Engels put it in his graveside eulogy to Marx in 1883: "Just as Darwin discovered the law of development of organic nature, so Marx discovered the law of development of human history."

Relation to Science and Ethics

Science, itself, as it is now understood, was not as clearly demarcated in their time, and from the perspective of the early twenty-first century it is easy to see the flaws in Marx and Engels's claims to science. To start with, they did an injustice to those they invidiously compared to themselves as "utopian." Owen among others also considered himself a man of science. Like Marx and Engels, Owen sought to draw generalizations about human behavior from his observations. His most cherished belief was that persons' characters are formed by the circumstances of their lives rather than by inner moral convictions or any other factors that they can control themselves. This notion, that one's thoughts and actions are shaped by forces larger than oneself, is very akin to Marx and Engels's central scientific claim and anticipated them by a full generation.

Moreover, in their approach to socialism, a good case can be made that the "utopians" were more scientific than Marx and Engels. Having hit on the idea that socialism would furnish a cure for society's ills, they set out to demonstrate its efficacy by attempting socialist experiments. Insofar as experimentation lies at the heart of the scientific method, the "utopians" were more genuinely "scientific socialists" than Marx and Engels, who discounted any such attempt. The latter duo claimed they could see where history was heading, but it is hard to imagine how this counts as more scientific than any other exercise in prophecy.

Beyond the absence of experimental method, Marx and Engels never stated any testable proposition nor did they betray any doubts inspired by the failure of specific details of their prophesies. Tellingly, they never treated their own forecasts as if they did amount to "science," at least as the term has come to be understood. As the decades passed they poured forth an endless stream of commentary, much of it arresting, on unfolding political events. But they rarely displayed any sense of needing to examine whether and in what way these new events comported with their larger theories. That is, they conducted themselves as what today are sometimes called "public intellectuals" or as activists, not as people who thought of themselves as scientists.

Still, it is difficult to dismiss Marx and Engels's claim to "science" without conceding that their method of attempting to distill systematic generalizations from the study of contemporary history constitutes a main building block of contemporary social science. There may be room to debate about how "scientific" social science is, falling as short as it does from the methodological rigor of "hard science," but insofar as its scientific legitimacy is accepted, then Marx and Engels must be given credit as pioneers, however imperfect their methodology.

In terms of its relationship to ethics, socialism presents an ambiguous picture. By claiming that they were doing no more than divining historical laws that showed that socialism was due to triumph, Marx and Engels shifted the argument in favor of socialism from the realm of "ought" to "is" (or, more precisely, to "will be"). And they specifically denied the possibility of absolute or universal moral principles, as opposed to principles that merely served the interests of a particular class. "Law, morality, religion are to [the proletarian] so many bourgeois prejudices, behind which lurk in ambush just as many bourgeois interests," wrote Marx and Engels in *The Communist Manifesto* (1848).

At the same time, it would be hard to deny that the force of Marx and Engels's indictment of capitalism is the sense of moral indignation that flows through it. Despite their own militant atheism, they decried capitalism as a system under which "all that is holy is profaned." A similar ambiguity can be found in various non-Marxist socialists. To take Owen, his fervent assertions that people's characters were molded for them seemed to negate any sense of moral responsibility. Yet he was very interested in discovering methods to mold characters to some kind of proper moral standard. He was for this reason a pioneer in early childhood education, and the organization of his followers in the 1830s called itself the Society for the New Moral World.

Owen, like Marx and Engels, was a vituperative opponent of revealed religion. (They called it an "opiate"; he called it one of the "three great evils" afflicting humanity.) In contrast, however, there have always been some religious socialists. As already mentioned, various socialist communes rested on religious bases, and a broader movement of Christian socialism made a strong appearance during the twentieth century. These adherents saw socialism as an expression of the biblical precept to love thy neighbor as thyself and of the Christian emphasis on spiritual rather than material values.

This points toward another aspect of the ambiguity of the relationship between socialism and ethics. On the one hand, socialist ideas aim to create a society that will fulfill certain moral goals, such as liberty, equality, and brotherhood. On the other hand, the emphasis on politics and policy has meant that many socialists have made little use of traditional notions of individual moral agency. The socialists who have most fully avoided this dilemma are the communal socialists who aim to carry out socialism in their own lives rather than to engineer larger political changes.

Their great emphasis on improving the world through political and economic changes rather than uplifting individual behavior has also brought socialists into a fraught confrontation with the question of whether, or to what extent, ends justify means. In the main, communists (as well, of course, as fascists, if one counts them under the socialist umbrella) have been ruthless in their means and ruthless in justifying this. As Leon Trotsky (1879–1940) once put it: "Only that which prepares the complete and final overthrow of imperialist bestiality is moral, and nothing else. The welfare of the revolution—that is the supreme law!" ("The Moralists and Sycophants Against Marxism," essay in his *Their Morals and Ours* [1936])

Social democrats and other noncommunist socialists have ordinarily rejected such claims, and they have often chastised the communists on moral grounds for their deceptive or violent tactics. Yet the force of such condemnations in intrasocialist debates was often vitiated by the emphasis on social change as the preeminent path to improving the world. If social change bulks so much larger than individual behavior, then might not unsavory tactics be justified in pursuit of the necessary policies?

The Legacy of Socialism

By the twenty-first century, much of the body of socialism has wasted away. Fascism, if it ever deserved to be counted here, is little more than a grim memory—although the term continues to be applied to various violent authoritarian movements. Communism has disappeared from the large majority of once-communist states. The remaining communist states all seem either to be following China in gradually shedding their distinctly communist features or to be living on borrowed time, awaiting the demise of a powerful dictator. Communal socialist societies are few and far between. Even their most triumphant exemplars, the kibbutzim, have mostly transformed themselves into miniature market economies.

What remains strong, however, is the legacy of social democracy. Social democratic parties justly claim most of the credit for various forms of worker protection and a wide variety of services and benefits that every developed democratic society provides. And these parties continue as powerful forces throughout the democratic world. None of them aim any longer to displace capitalism; rather their program is to continue to tame or modify it. Although markets have, to most minds, proven their superiority over the socialist dream of "economic planning," there still are social values—protection of the weak or of the environment or the provision of certain public services, for example—that unfettered markets do not serve. Social democracy has found an enduring niche as the advocate of these values—which have been put into practice through such programs as social security and socialized medicine.

If this is a dilute residue of socialism, so, too, do the scientific and ethical issues that have long surrounded socialism endure in dilute form. Contemporary protests against "globalization" echo earlier ones against capitalism itself. While there are few remaining believers in "scientific socialism" or in Marx and Engels's economic determinism, the question of the degree to which individual behavior should be attributed to free will as opposed to external or biological influences continues to be hotly debated in such policy areas as criminal justice and the rights of homosexuals. And the deep discourse over whether it is more efficacious to improve society by uplifting individuals or to improve individuals by reforming the society seems certain to endure.

SOCIAL THEORY OF SCIENCE AND TECHNOLOGY

The idea of social theories of science and technology initially seems counterintuitive, because commonsense notions of science and technology separate them from the social world, and place them instead into the world of nature and fact. But closer scrutiny reveals a number of relevant aspects of social theory that can assist in understanding the development of science and technology, and the ethical and political aspects of such changes.

Social Theory: Scale, Structure, Agency, and Critique

Social theory is a body of scholarly work that describes and explains the social world. While ordinary people use workable models of social interaction and causality to get through the day, these folk sociologies, psychologies, and economic theories are not carefully articulated as testable models, and are often limited in scale and scope.

The idea of scale—or the size, duration, and level of complexity at which phenomena occur—is one of the first dimensions of variation in all social theory. One expects, and finds, different mechanisms and patterns to explain the behavior of small groups in comparison with large, complex societies. The disciplines themselves mirror this issue of scale, in which psychology, for example, is mostly concerned with individuals and small-group processes while sociology, anthropology, or economics examine the behaviors of whole populations or cultures. Moreover within each discipline of the social sciences and humanities are specialties that focus on different scales or levels of analysis. In sociology, this is the distinction between micro- and macro-sociologies, between models of small-group interactions and explanations of whole social systems.

With distinctions based on issues of scale, questions arise concerning scope—to articulate models appropriate at one scale with those of a larger or smaller level of analysis, or of a longer or shorter duration in time. What are the relationships among small groups and larger social institutions? How do social forces, historical trends, and cultural formations impact individuals? This remains a challenge for interdisciplinary social theory, and points to a related set of questions regarding the relationship between individual agency and social structure as well as relations between ethics and politics. How, and in what ways, are individual thoughts and actions, including ethical assessments, influenced by preexisting cultural, social, and economic conditions? If individual actions are strongly determined by social structure, where does social, scientific, or technological innovation come from—not to mention ethical criticism? If individuals freely innovate and criticize, why do social structures and belief systems persist over time? Issues of scale, structure, and agency link very closely to long-standing issues in the study of science and technology, particularly concerning questions about the balance between society determining technology (social constructivism) and technology determining society (technological determination)

The issue of social criticism is particularly important to science, technology, and ethics. Much social theory includes some assessment (positive or negative) of the social world. For example, Karl Marx (1818–1883) articulated his theory of the means of production determining the social structure and belief system of a society, while witnessing the devastating poverty of rapid industrialization and urbanization in Manchester, England in the mid-nineteenth century. Twenty-first-century authors are concerned with an array of issues, such as explaining new technologies and their effects on indigenous cultures, often with an implied concern that these societies are threatened by technological change. Others focus on the way common work and language practices of science shape how experiments are conceived and interpreted, or how social power influences what research is prioritized for funding. Focusing on how technology affects work and employment often leads to concern with systems of wealth and social stratification, with the unequal distribution of goods and harms. Social theory, then, always intersects with the political and ethical sides of science and technology because it is concerned ultimately with the human dimensions, both causes and consequences, of change.

Approaches to Science and Technology Studies

Science and technology studies, like economic theory, can be read as an argument with the ghost of Marx. In his voluminous writings, Marx articulated a model of the constitution of society literally from the ground up. In this model, the productive relationships of a society, meaning economy and agriculture, determined the basic social organization, in terms of classes and the structure of the state. Society then determined the cultural formations and basic ideologies, including science as an explanatory system. This model implies a degree of technological determinism in which social relations are determined by technology. The first generations of scholars concerned with science and technology wrestled with this issue, with Lewis Mumford (1895–1990), Jaques Ellul (1912–1994), and Ivan Illich (1926–2002) leading the way in developing critical theories of contemporary society adopting and criticizing Marx's insights. In the early-twenty-first century, Langdon Winner (1986, 1977) continued this tradition.

Focused on science, Robert Merton was also influenced by another founding social scientist, Max Weber (1864–1920), to formulate a theory of science as a modern institution based on the Protestant work ethic and the development of capitalist economic systems. Merton's *normative structure of science* articulated formally what had been a set of assumptions and values governing science as it emerged in sixteenth-century Europe. The values of *communalism*, in which knowledge is to be shared; *disinterestedness*, against personal or economic gain from knowledge acquisition; *universalism*, in which the identity of the author of scientific statements is not to be taken into account; and *organized skepticism* to provide the mechanisms for self-correction in science continue to be upheld and are presented to science and technology students as the primal values governing good science. Writing in the mid-twentieth century, Merton was concerned with demonstrating that democracy needed science, and science needed democracy, to avoid the distortions of Stalinist and Nazi influence he saw occurring early in his career.

Scholarship on science and technology struggled, however, with whether or not the social structure affected merely the social organization of these activities or the content and details of scientific and technological change as well. Within historical scholarship on technology this led to two major streams of thought: the internalist, which focused on the internal logic of development, seeing it as resistant to all social influences, and the externalist, which focused on the pervasiveness of social influences and impacts on scientific and technological change. This parallels questions of whether internal professional ethics or external political pressures should be granted priority in the governing of science and engineering.

Toward the latter third of the twentieth century the opposition between social and technological determinism was partially resolved with the development of the social construction conjecture. Social construction is based, in part, on insights derived from Thomas Kuhn's (1962) work in the history and philosophy of science, especially his notion of paradigm and paradigm shift, which spread quickly through the scholarly world, influencing studies of both science and technology. Focus on moments of change and controversy allowed scholars to see how both the social and natural are always present in shaping science and technology. The first generation of scholarship (Mulkay and Knorr-Cetina 1983) articulated what would come to be called the empirical program of relativism that generated the *symmetry principle,* which proposes that both true and false beliefs should be amenable to the same kind of social analysis. (In the past, true propositions were explained as reflecting the way nature is, false ones as reflecting the distorting interests of scientists or society.) Symmetry models have been further refined over time, for example by scholars such as Bruno Latour, who with colleague Steve Woolgar articulated the term *technoscience* to represent the confluence of technology and science as organized ways of interacting with the material world.

Technology studies applied these insights in its own way, and the editors of *The Social Construction of Technological Systems* (1989) presented a collection of works for what would become the *SCOT* model. This model describes how the *working* of a technology is primarily dependent on the social processes leading to its manufacture and the decisions of various end user groups as to whether or not it meets their needs as they decide how to employ the new technology. A technology whose material parts are in functioning order may still, and is often, deemed to be *not working* or a failure because it does not meet people's needs. In effect this appeared to constitute an ethical and political assessment of the adequacy of the status quo, a position criticized by Winner (1993) and generating further scholarly discussion.

What the initial constructivist studies of science and technology focused on was the microsocial processes of laboratory and workbench activities, such as the socially-grounded work of the interpretation of experiments. Negotiations among different groups in the design processes followed quickly, eventually moving up in scale to study organizational and bureaucratic contexts for generating models of change. Studies of cultural ideas, language, and values can generate explanations for the general trends of development in science and technology, but not the strong causal explanations aspired to by prior generations of scholars. Despite the advantages of having concrete artifacts and well-defined scientific ideas to trace, the shift from context to context and across different scales of social action remains challenging for social theorists of science and technology.

Similarly the question of determinism and the relationship between individual agency and social structure still challenge explanatory models. Rather than strong causal laws, heuristics outlining the applicability of models and propositions guide social studies of science and technology. For example, while a strongly deterministic model of the origins of new science and technology cannot be true, because that would be to ignore all evidence of the work, politics, and economic choice leading up to the new technoscience, it often *feels* true to consumers of science and technology to whom all of those prior social relations are invisible. Wiebe Bijker (1997) has developed a theory that helps to explain this by noting that people with low inclusion in the construction process often face a *take-it-or-leave-it* choice with new science and technology. Technoscience seems determined, to them, while those with high inclusion in the process see much of the construction. This interpretation of the construction of technoscience raises important ethical and political issues related to levels of participation in scientific and technological processes.

Indeed the roles of end users and stakeholders in science and technology have gained increased attention, in research on the public understanding of science, vernacular design, and consumer analyses. In the first instance, it has been pointed out that users are strongly dependent on technological *scripts*—that is, cultural and behavioral frameworks for understanding and interacting with technologies (Bijker and Law 1992). But users also create opportunities to rewrite scripts, and to modify not only the meaning, but the materiality and affordances of new technologies. End users can be creative appropriators of technology: "Low-riders" are transformations of automobile suspension systems by Hispanic urban culture for cultural self-expression; artisans use old tools in new ways to produce new effects; cell phones can be used to organize "smart mobs" and synchronize political action.

Contemporary Issues and Elaborations of the State of the Art

John Staudenmaier (1989) has cataloged the major historical themes in the history of technology since the inception of the Society for the History of Technology (1958), such as work and labor, military, aerospace, and gender. Recent scholarship on science and technology continues and expands these topics. For example, technology, labor, and work receive attention from sociologists such as Steven Vallas (2001), particularly in the roles that information technology and computerization have in different kinds of industries and organizations. Older models of technology, as always deskilling workers and centralizing power in organizational leadership, have given way to more nuanced models of context- and work-dependent implementations of new technology.

Computerization has become a major topic in social theories of technology. Much work is focused on the emergence of information and telecommunication technologies, their contexts of production, and the impacts of their use and adoption. A second, also revolutionary area of inquiry is the transformation of the life sciences, producing the emerging biotechnology industry, in which distinctions between pure and applied research or fundamental understanding of life processes and product development are increasingly blurred. These two areas come together in interesting ways in *cyborg theory*. Developed by Donna Haraway (1991), this is the treatment of human beings and the material world as interconnected and interdependent, with humans seen as biological, social, and information-based beings that obscure traditional boundaries between nature and culture, human and machine.

Some level of constructivism in both science and technology is well-argued consensus within the field, although its counter-intuitive elements often provoke commentary and criticism from those outside the social studies of science and technology. Finer distinctions among models and theories have been generated, for example between SCOT and its sibling, actor-network-theory (Law and Hassard 1999). Actor-network theory analyzes the networks of humans and material objects to generate specific explanations for the success or failure of ideas or artifacts. It is perhaps a methodology rather than a theory, per se, but nonetheless has value in generating detailed analysis of the various components of technoscientific projects. Such a method may also offer resources for analyzing the influence or failure of various ethical or political responses to technoscience.

Various social movements have picked up insights from social theories of science and technology. A first heuristic derived from constructivism is that things might have been otherwise. Designs could have turned out differently; the pursuit of scientific knowledge prioritized on different values would lead in new directions.

A second heuristic is that scientific and technological change generally follows the lines of power and resources already prevalent within a society. This does not mean that technoscience cannot have revolutionary effects on social relations, but that it is more likely that people will use technoscience to attempt to preserve power and privilege that already exists.

From these insights, environmentalists, social justice organizations such as feminist and anti-racist groups, and critics of development and globalization can make better informed interventions in the formulation, conduct, and effects of scientific and technological change. Feminists and racial or ethnic minorities, for example, point to the potential benefits of increasing the diversity of formal scientific and technological involvement because diverse backgrounds can be resources for new ideas, and for different values to motivate practice. They also point to the inventive and problem-solving activities of ordinary people, and take into account the moral and cultural values that might have bearing on the products of technoscience and their consequences for diverse communities.

Environmentalists point to the unequal distribution of the harms of technoscience, for example that poor communities and nations often face far greater harm from industrial pollution, and conduct research to help ameliorate those problems. There is also an evident tension between improving the economic and health circumstances of people in non-industrialized countries and preserving important ecological and cultural configurations. Social theories of science and technology may help anticipate the related consequences of technological change, and design interventions to minimize their negative outcomes.

Formal policy-making has taken up social theories of science and technology unevenly. One of the most concise models of science and society from a policy perspective is indirectly informed by social theories of technoscience. Backing away from a traditional linear model that privileges basic research leading directly to development and application, Donald Stokes (1997) proposes a more complex model in which different kinds of technoscientific problem formulation and research processes are supported and managed in different ways.

Whether broadly or narrowly defined, social theories of science and technology are as dynamic as technoscientific change itself. The connection is both strength and weakness. There is always a lot to do; new questions emerge daily. But there are too few resources or people to do all the work. Cutting edge analysis of technoscience easily becomes a quaint historical account of a forgotten technology or discredited science. More seriously, with rapid change and diverse topics, it is often difficult to see commonalities across fields of inquiry, and to develop generalizations about scientific and technological processes that are independent of specific contexts and thus subject to general ethical assessment. Integrating research across different scales of interaction, from individuals and identity formation processes to macroeconomic changes in global economic activity, remains a daunting task for all forms of social theory.

The final challenge for social theories of science and technology is one faced by all disciplines: to remain relevant to a diverse public audience and policy professionals. All disciplines face the possibility of becoming too focused on internal, scholastic issues, rather than seeking to develop broad heuristics that can be of benefit to those seeking to understand the important questions all social theories engage: How do I know? Why did this happen? Is it a good thing? What can be done about it?

SOCIOBIOLOGY

Sociobiology denotes the attempt to provide a biological explanation for the social behavior of animals, including humans, although the focus is more often on social insects such as ants and honey bees. Because ethics is also concerned with social behavior among human beings, achievements in sociobiology may also have implications for a possible science of ethics.

The Darwinian Background

As a term the word sociobiology first appears in *Principles of Animal Ecology* (1949) by Warder C. Allee, Alfred E. Emerson, et al., but the subject matter is much older. In *On the Origin of Species* (1859), Charles Darwin argued that there is constant population pressure brought on by the fact that numbers of organisms always outstrip food and other resources. There is therefore a constant struggle for existence. Some organisms have features enabling them to better succeed in the struggle, and thus there is a natural selection of the winners over the losers. This leads to evolution, but evolution of a special kind. Selection produces and perfects features useful in the struggle—organisms have adaptations such as the hand and the eye that aid them in survival (and, even more importantly, to reproduce).

Darwin realized that behavior is as much part of an animal's repertoire in the struggle for existence as are any physical adaptations. He was particularly interested in social behavior such as that of the hymenoptera (the ants, bees, and wasps). His interest was spurred not only by the phenomenon itself but because (in Darwin's opinion) such behavior seems to go against the workings of selection. Darwin believed that the struggle for existence pits every organism against every other organism, and hence selection can only promote adaptations that are valuable to the individual. (In contemporary language, Darwin was an individual selectionist rather than a group selectionist.) How then do organisms develop social features that seem to help the nest, perhaps even at the cost of total sacrifice of the interests of the individual? Sterile workers apparently spend their whole lives looking to the needs of their mothers and siblings. Eventually Darwin came to believe that the nests of social insects should be regarded as one large superorganism, rather than a group of individuals working together. In that way, the individuals in a nest are more parts of the whole (like the heart and liver are parts of the human body) rather than organisms existing in their own right with their own interests.

For a number of reasons, in the century after *On the Origin of Species* was published, the study of behavior by biologists lagged behind other areas of evolution. First behavior is much more difficult to record and measure than are physical characteristics. Experimentation is particularly difficult, for it is notoriously true that animals change their behaviors in artificial conditions. Secondly practitioners of the new social sciences thought that they exclusively should examine behavior, and that biology had no place in their endeavors. Unfortunately there existed a strong ideology that experience and training are the cause of most, if not all, behavior, and hence evolutionary factors tended to be discounted before any research was done. Continental students of behavior known as ethologists were a notable exception to this indifference to evolutionary theory, although their work was (as judged by twenty-first century standards) hampered by unjustified assumptions about the significance of group selection.

Breakthroughs in the 1960s

Major breakthroughs occurred in the 1960s, due, in large part, to the work of William Hamilton (1936–2000) in England. Promoting the theory now known as *kin selection,* Hamilton, then a graduate student, pointed out that in modern terms, selection is equivalent to passing on a particular individual's genes (or rather copies of those genes) more effectively than competitors. However when a person's close relatives reproduce, because they share copies of that person's genes, they also pass on those same copies: reproduction by proxy as it were. Normally it is biologically most efficient to reproduce oneself because (except for identical twins) an individual cannot be genetically more closely related to any other being. Hamilton argued there are some exceptions to this general rule. The hymenoptera particularly have an unusual reproductive system, with females having both mothers and fathers and males having only mothers. Queens get all the sperm they will ever use on the nuptial flight. To produce a female, the queen releases a sperm; in contrast, in producing male offspring, no sperm is released. Thus sisters (50% ♂ + 50% ♀ x ½ = 75%) are more closely related than mothers and daughters (50% ♀ x ½ + 50% ♂ x ½ = 50%), and so, from an evolutionary perspective, a nest member is better off raising fertile sisters than fertile daughters. From an individual selection perspective, sociality is advantageous.

After Hamilton others proposed theories using an individualistic perspective. One important contribution was Robert Trivers's notion of *reciprocal altruism,* based on the *you scratch my back and I'll scratch yours* principle, which holds that some forms of sociality succeed because organisms gain more through cooperation than through conflict. Also significant were insights based on the use of game theory, particularly the idea of an Evolutionarily Stable Strategy (ESS). A whole group is sometimes less well adapted than it could be because self-interest is paramount. Sex ratios are a case in point. Females do not need a large number of males for fertilization. But because 50:50 seems to be a more stable balance in the population, the group maintains a surplus of males, instead of a more efficient 10:90 male to female ratio. Building on ideas like this, the study of evolution started to change dramatically, and by the 1970s the study of social behavior, in theory and in practice, became one of the most advanced and exciting areas of evolutionary inquiry. The ideas were presented in popular form by British biologist Richard Dawkins in his *The Selfish Gene* (1976), and in what became the bible of the movement and gave the field its name, *Sociobiology: The New Synthesis* (1975), by the American scholar of the study of social insects, Edward O Wilson.

Controversies

These works, Wilson's in particular, were highly controversial, mainly (although not exclusively) because they extended to humans. Much like Darwin himself, having surveyed social behavior in the animal world from the most primitive forms to the primates, Wilson argued that Homo Sapiens is part of the evolutionary world in its behavior and culture. Although he did allow that experience and training can have some effects, Wilson believed that genes are the real key to understanding human thought and behavior. In male-female relationships, in parent-child interactions, in morality, in religious yearnings (a very important phenomenon for Wilson, a Southerner), in warfare, in language, and in much else, biology matters crucially.

Social scientists and left-leaning biologists (especially Richard Lewontin and Stephen Jay Gould), and philosophers (especially Philip Kitcher in a witty attack, *Vaulting Ambition*), accused sociobiologists—particularly human sociobiologists—of a multitude of sins. Epistemologically these detractors judged the work of sociobiologists to be false, and then (not entirely consistently) charged them with producing ideas and theories that are not falsifiable. One particularly effective rhetorical charge was that sociobiologists's claims are akin to the *Just So* stories by Rudyard Kipling, in which a fantastical tale is created (i.e., that of how the elephant's nose is long because it was pulled by a crocodile) and then is alleged to be fact. Sociobiologists were also found to be wanting ethically. Their work was attacked as sexist, racist, homophobic, capitalist, and in short, guilty of every possible transgression that exists in a patriarchal, unjust society. They were accused of supporting the status quo in Western societies, and of pretending to give genuine scientific answers to bolster what were really ideological convictions.

There was undoubtedly some truth to all of these claims. Yet some change can be progress, and there is little doubt—at the animal level particularly—that evolutionists have taken full note of critics' complaints and worked hard to address them. Modern techniques, particularly those that employ the insights of molecular biology, have been of great help here. For instance many sociobiological claims concern parenthood. If males are competing for females, for instance, and (as in birds) males are also contributing to childcare, one expects efforts to be tied to reproductive access and success. But while it is difficult if not impossible to determine paternity with traditional methods, that Gordian Knot is cut as soon as one starts using genetic fingerprints. Not only are the scientific claims testable but in many cases they have been found to be correct. Animal sociobiology is no more tentative than other scientific fields. It can be persuasively argued that in science bold conjectures are needed in abundance. However when those conjectures are accepted as fact without being tested, there is a problem. Science requires continual, rigorous challenge.

Human sociobiologists argue that they too have theories that can be, and are, put to the test, such as theories about infanticide, showing that this occurs when and generally only when it is in the biological interests of parents not to have all of the children to which they (or sometimes, rivals) have produced. One well-known theorem (with much support in the animal realm) asserts that females who are more fit will tend to skew birth rates toward males, and less fit females toward females. The reason for this is that even unfit females generally get impregnated, whereas if there is competition among males—and there usually is—the fitter male tends to get the prize. Hence because fit mothers are more likely than unfit mothers to have fit offspring, for fit mothers having males is a good strategy, whereas for unfit mothers having females is a good strategy. There is incidentally no necessary presumption that this always requires conscious intention—fluctuating hormones, for instance, might be the proximate causes. Human sociobiologists argue that this also occurs in human societies, with the members of upper classes tending to dispose of daughters, either physically by allowing them to die or giving them away shortly after birth, or through other methods that effectively prevent reproduction even without killing (for instance, by forcing daughters into religious orders that require celibacy thereby effectively preventing them from reproducing). In recent years, human sociobiology has changed into what is now called *evolutionary psychology*. The emphasis is less on behavior and more on the mental traits that lead to behavior. This view is still philosophically controversial, with much debate about how and whether one can talk of psychological characteristics as being *innate* (and how one would test the theory).

Sociobiologists have countered vigorously against the social and ethical charges levied against them. Almost without exception, human sociobiologists have not had significant social agendas and are greatly concerned by the misuse that can (and sometimes is) made of their work. They repudiate strongly the charge that they are crypto-nazis or subscribers to other vile doctrines, and deplore the fact that sometimes people favorable to these ideas invoke the authority of sociobiology in support. They stress that differences between races, for instance, are far less than similarities, and in any case differences in themselves do not necessarily spell superiority or inferiority. Although their work has been much criticized by feminists, human sociobiologists respond that pointing out differences between males and females is not in itself sexist. Indeed one might argue that not to recognize differences can be morally wrong. If boys and girls mature at different rates, insisting that they all be taught in the same ways could be detrimental to both sexes. In more specific issues also sociobiology is not necessarily erroneous or promoting an immoral agenda. To hypothesize that something such as sexual orientation is dictated by an individual's genes (and that there is a pertinent underlying evolutionary history to explain it) could be a move toward recognizing that all people are equally worthy of moral tolerance and respect.

There is ongoing philosophical debate over all of these issues. In the early twenty-first century there is renewed interest in the possible evolutionary underpinnings of religion. It is clear that sociobiology—animal and human, and by whatever name the field is known—is not about to disappear, and is in fact a thriving area of inquiry.

SOCIOLOGICAL ETHICS

Sociology, or the scientific study of society, social institutions, and social relationships, is one of the most important social sciences and may include in its concerns anthropology, economics, history, political science, and psychology. As a field of study it is inherently intertwined with ethics. Because any society is dependent on common assumptions about what is acceptable and unacceptable behavior among its members, sociological analysis has to include descriptions of those ethical beliefs and practices. Indeed, the society constituted by sociologists may be defined by its internal ethical commitments. At the same time, insofar as sociologists do research in and on society, they produce knowledge about moral values and their social functions, and questions arise about the proper guidelines for their work, especially when that work may conflict in various ways with accepted social norms.

The Sociology of Ethics

Early in the formation of sociology morals and values entered into the picture and influenced sociological thought and practice. A specific concentration such as a "sociology of moral values" may not exist (Durkheim 1993, p. 14), but morality has played a central role in the prevailing concepts that have shaped and molded sociology. This ideology can be seen in the works of individuals such as Karl Marx (1818–1883), Max Weber (1864–1920), and Emile Durkheim (1858–1917). These classical sociologists agreed on issues surrounding industrial capitalism and how values and morals worked to keep a society together; however, they nonetheless differed in their views of the function these elements have and how they change over time.

Although Marx is credited for playing a key role in establishing the field, Weber is the one considered to be the father of sociology. Marx's challenging social criticism was replaced by Weber's value-neutral sociology, which nevertheless stressed, as in *The Protestant Ethic and the Spirit of Capitalism* (1904), the ethical foundations of social orders. Marx was intrigued by the interaction between science and society, whereas Weber examined social structure and focused more on the notion of value-free science. Weber believed people acted on their own accord and emphasized the importance of the individual rather than the role of society as a collective whole. He also emphasized the notion that people should not expect science to tell them how to live their lives.

Durkheim's theories are considered by some sociologists to be even more applicable today than they were at the time he formulated them (Turner 1993). His primary contribution to sociology was his stance on social solidarity, social roles, and the division of labor. Morality and the connection between science and society also influenced Durkeim's work on professional ethics. Durkheim touted the importance of moral education on everyday life and emphasized its inclusion in the study of sociology. Marx, Weber, and Durkheim may have developed their theories in a different academic era, but they continue to influence and impact the field of sociology today.

Works by Weber and Durkheim were the precursors to those by Robert Merton, the first sociologist to win the National Medal of Science and the founder of the sociology of science. Merton's focus was on the functional analysis of social structures, and he discounted subjective dispositions, such a motives and aims. Things Merton is best known for are coining the terms "self-fulfilling prophecy," "deviant behavior," and implementing the focus group concept in a research setting.

The Ethics of Sociology

The first attempt to promote international cooperation and professionalize the field of sociology can be seen in the formation of the International de Sociologie by Rene Worm in 1893. In 1905 a number of well-known sociologists across the United States met to create an entity to promote the professionalization of the field of sociology. This organization was called the American Sociological Society and later evolved into what is known today as the American Sociological Association. Today, the ASA is the largest organization of sociologists and its membership is not only made up of students and faculty, but 20% of its membership is comprised of individuals who represent government, business, and non-profit groups. In the spring of 1997, the ASA membership approved its current version of the Code of Ethics. It includes an introduction, a preamble, five general principles, and specific ethical standards. Rules and procedures for handling and investigating complaints are also noted.

As time went on, more organizations such as the International Sociological Association were formed to support sociologists and advance knowledge about this field of study. Like ASA, these entities have also developed and established codes of ethics for their membership to follow. ISA, an organization founded in 1949, drafted its own code of ethics and the current version was approved by their Executive Committee in the fall of 2001. Other groups, such as the North Central Sociological Association, have preferred to base their codes on those outlined by ASA.

New and exciting research opportunities often bring unforeseen scenarios, many of which revolve around the sociologist's relationship with subjects. Dilemmas involving the applicability of informed consent, the use of deception, and the protection of privacy and confidentiality are common in social science research. A conflict between the desire to protect human subjects and the goal of obtaining data may not be easy to rectify even if guidelines are followed.

Research misconduct and authorship violations are also concerns that face social scientists. Abuses vary in severity and may encompass plagiarism, data fabrication, and falsification of data and results. The ethical dilemmas encountered in sociology are not unique. As science and technology become intertwined further with society, these ethical questions will become even more complex.

Sociological Issues Related to Science and Technology

Problems that occurred during the 1960s and 1970s, such as the thalidomide drug tests (1962) and the Tuskegee syphilis study (1932–1972) emphasized the fallibility and injustices of scientific research and added momentum to appeals for more regulations and guidelines. Scientific investigations, especially those in biomedicine, often are considered high-risk and life-threatening, but the social sciences also have encountered less obvious but not necessarily less dangerous situations. One case that is discussed frequently in social science circles is Stanley Milgram's work on obedience to authority in 1963. Milgram found that a majority of the individuals participating in this series of studies were willing to administer what they believed to be harmful electrical shocks to their victims. Laud Humphreys's tearoom trade in 1970 also sparked controversy. Humphreys studied homosexual encounters in a St. Louis park restroom without revealing the true nature and intention of his research. Philip Zimbardo's Stanford prison experiment in 1973 is another example of an infraction that sent up red flags to those involved in protecting human subjects (Sieber 1982). Zimbardo's study, which ended early due to concerns about its effects on the subjects, used role playing to determine what happens when good people are put in an environment that fosters evil.

Informed consent is a key component of human subjects research, but it can be controversial in disciplines such as sociology. Regulations require that in most cases informed consent be obtained before research can commence, but consent often is seen as an unrealistic obstacle in the social sciences. Research conducted by social scientists often involve the use of ethnographic methods, the collection of oral histories, and survey procedures, which do not readily lend themselves to the written informed consent process. Obtaining written consent may be problematic for researchers working in situations where language and cultural differences pose as a barrier. This may occur in situations where the individuals are illiterate or merely speak a different language. Some cultures consider the signing of a document taboo or an act reserved for certain situations such as the signing of legal documents. Evidence also indicates that subjects who sign consent forms, like those who participated in Milgram's study, do not always comprehend the full extent of the project (Mitchell 1993). Many social science initiatives include individuals involved in illegal activities where anonymity is essential. In these situations the informed consent document may compromise confidentiality by being the only link to the subject.

Steps taken to protect the privacy of the subject and ensure the confidentiality of the data may instill a false sense of security in the researcher and the subjects. A researcher may code identifiers, destroy data after project completion, use pseudonyms to mask identity, and avoid gathering personal information altogether in an attempt to provide protection. These measures are not infallible, and violations are evident in numerous cases. The use of thinly disguised pseudonyms that provoked the "Springdale" controversy can be seen in Arthur Vidich's *Small Town in Mass Society* (Vidich and Bensman 2000). Sociologist Arthur Vidich and anthropologist Joseph Bensman conducted a study of small town life and assigned the pseudonym "Springdale" to the upstate New York community. It didn't take long for the community's true identity to be revealed, which caused Vidich's and Bensman's research practices to be called into question. Other infractions have involved the subpoena of data, as in the case of Rik Scarce, who underwent 159 days of incarceration for refusing to release his field notes (Scarce 1995). Even with protections in place the subject's privacy and confidentiality may be at risk.

All researchers wrestle with similar issues of research misconduct. A survey published in *American Scientist* (November–December 1993) that measured perceived rather than actual misconduct examined some of those concerns. Doctoral candidates and faculty members representing the fields of chemistry, civil engineering, microbiology, and sociology were asked questions about scientific misconduct, questionable research practices, and other types of wrongdoing. Several conclusions were extracted from the data results, including reports that scientific transgressions occurred "less frequently than other types of ethically wrong or questionable behavior by faculty and graduate students in the four disciplines" surveyed (Swazey, Anderson, and Lewis 1993, p. 552). Other entities, such as the media, chose to concentrate on practices that painted a dire picture of academic integrity.

Funding and sponsor involvement constitute other factors that can create serious ethical dilemmas for researchers. Certain departments, such as sociology, often struggle for financial support and rely heavily on government and corporate sponsorship. Project Camelot, which has been regarded by some as "intellectual prostitution," was used to "predict and influence politically significant aspects of social change in developing nations of the world, especially Latin America" (Homan 1991, p. 27). Warnings by critics like Derek Bok, the former president of Harvard and author of the book "Universities in the Marketplace: The Commercialization of Higher Education" (Princeton University Press) indicate that pressure by academia to attract industry involvement is a precarious undertaking that can lead to the "commercialization of higher education" (Lee 2003, p. A13). These relationships also may result in pressure on researchers to skew results to favor the sponsor. In the end stiff competition for research funding and pressure to attract industry involvement may compromise ethical and professional standards (Homan 1991).

Changes in Science and Technology That Affect Sociology

Regulations and guidelines based on a biomedical model have had a dramatic impact on sociology. After the atrocities that occurred during World War II a series of codes were implemented to focus on the protection of human subjects in research. Some of the more noted ones include the Nuremberg Code, the Declaration of Helsinki, and the 1971 guidelines published by the U.S. Department of Health, Education, and Welfare (DHEW).

The Nuremberg Code, a set of ten principles designed to protect human subjects in research, was a ruling announced in 1947 by the war crimes court against Nazi doctors who conducted experiments on their prisoners. The Declaration of Helsinki was approved by the Eighteenth World Medical Assembly in 1964 and was designed to assist physicians in biomedical research involving human subjects. The continuation of ethical infractions invoked calls for additional regulations. Guidelines published in 1971 by the DHEW were one response to those demands and would prove to be the inspiration for the development of institutional review boards (IRBs) for federally funded research initiatives.

Another instrumental document resulted from the formation of the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research. The Belmont Report elaborated on the ten points outlined in the Nuremberg Code and placed the emphasis on respect for persons, beneficence, and justice. Those regulations were revised in 1981, and Title 45, Code of Federal Regulations, Part 46, became known as the Common Rule.

Professional codes of ethics are a relatively recent phenomenon. The codes that existed before World War II were found primarily in the major professions of that time, such as medicine and law. Most modern organizations have developed codes based on those in the sciences, but the codes used in the social sciences often lack the power to impose sanctions for noncompliance. Unlike the case in some professional associations, participation in an organization such as the American Sociological Association (ASA) is not necessary for a person to be a sociologist or to conduct social science research. The lack of an enforcement mechanism for ethical violations also weakens the power of codes such as that of the ASA. The notion that professional codes of ethics are merely symbolic has been attributed to the government's decision to implement regulations (Dalglish 1976).

Contributions to Science, Technology, and Ethics Discussions by Sociology

A debate has been brewing among scientists and social scientists who submit research protocols for approval. The DHEW declared on July 12, 1974, that to obtain federal funding for a research project an IRB had to be in place to review projects that involved human subjects in biomedical and behavioral research. Today IRBs apply one set of rules, based on a biomedical format, to review all project submissions. Those requirements have proved to be inapplicable to numerous social science proposals and are next to impossible to carry out in all research settings. Sociologists and other social scientists have joined forces to form alliances, such as the Social and Behavioral Sciences working group, to improve the IRB process for social science researchers. In some cases, however, IRBs continue to interpret "the requirements of the Common Rule in a manner more appropriate to high risk biomedical research, ignoring the flexibility available to them in the Common Rule" (Sieber, Plattner, and Rubin 2002, p. 2).

Sociologists also have collaborated with researchers in science and technology on a number of ethics initiatives. Joint facilities and centers have helped facilitate those efforts by encouraging cross-curriculum dialogue and research. The Hastings Center was founded in 1969 to "examine the different array of moral problems engendered by advances in the biomedical, behavioral, and social sciences" (Abbott 1983, p. 877). The Center for Applied Ethics at the University of Virginia, also founded in 1969, has worked on integrity issues that span various fields and subject matters. Another interdisciplinary effort is the Ethical, Legal and Social Implications Research Program (ELSI). Founded in 1990, ELSI has focused on a number of issues, including informed consent, public and professional education, and discrimination, by bringing together experts from multiple, diverse disciplines and conducting workshops and orchestrating policy conferences to discuss these pertinent issues.

Education is imperative to promote academic integrity, and students in all disciplines should be instructed on matters that may have an adverse effect on their research. Acceptable academic behavior can be conveyed through formal methods such as workshops and symposia or through the use of informal techniques such as discussions with advisers, mentors, and classmates. Conversations that introduce possible solutions to the ethical predicaments encountered in research also can be beneficial. Teaching new researchers how to act in an ethical manner will help reduce the number of violations and will create research professionals dedicated to upholding the morals that are valued in society.

The Future

Ethical dilemmas will continue to plague researchers whether they are in the sciences or the social sciences. A state of risk-free research is not foreseeable, and steps will continue to be taken to minimize the severity and frequency of these problems. Changes in the regulations will be felt most heavily in the biomedical and science fields, but the social sciences will not be spared from increased scrutiny. Some efforts may prove to be worthy and circumvent or minimize ethical quandaries, whereas others may violate personal rights and academic freedom in the process. Cooperation among disciplines is essential to communicate the importance of ethics and create researchers who conduct their work with integrity. In the words of Johann Wolfgang von Goethe, "Knowing is not enough; we must apply; willing is not enough, we must do."

SOFT SYSTEMS METHODOLOGY

Soft systems methodology provides a framework for structuring, analyzing, and solving problems in systems that involve people. It integrates logical, cultural, and political analyses of a problem situation in order to imagine, discuss, and then implement actions to improve the situation, with the consensus of the participants. Soft systems methodology is used primarily by managers and consultants working on technical or organizational problems; it has proved particularly useful in the Information Technology/Information Systems sector.

Peter Checkland developed soft systems methodology because classic systems engineering and systems analysis (*hard* systems methodologies), which work excellently in many engineering situations, often disappoint in management situations. Hard systems methodologies are well-suited for designed systems where the task of the analyst is to find the most efficient means of reaching a well-defined goal, but they cannot deal with the cultural and social dimensions in what Checkland terms human activity systems, which are systems that include human self-consciousness and freedom of choice. One of the characteristics of human activity systems is the wide range and importance of world-views, or *Weltanschauungen*, held by the participants in the system, and the consequent lack of clearly defined or agreed goals within such a system. Soft systems methodology is designed to deal with human activity systems where "in the complexity of human affairs the unequivocal pursuit of objectives which can be taken as given is very much the occasional special case" (Checkland 1999, p. A6).

There are four main activities in Checkland's methodology:

1. Finding out about a problem situation, including its cultural and political dimensions;
2. Formulating relevant purposeful activity models (devising scenarios of possible future actions and outcomes);
3. Debating the situation with participants, using the models, seeking from that debate both

a) changes that would improve the situation and are regarded as both desirable and (culturally) feasible, and

b) the accommodations between conflicting interests that will enable action-to-improve to be taken;

4. Taking action in the situation to bring about improvement. (Checkland 1999, p. A15).

Soft systems methodology provides practitioners with almost the same analytical techniques and many of the same conceptual approaches as Harold D. Lasswell's policy sciences, but laced with more pragmatism and less idealism. Soft systems methodology focuses on business and industry applications, it seeks agreed solutions, and is based in management science and engineering. The policy sciences are concerned with representative democracy and public policy, they are rooted in the social sciences, and they emphasize a moral rather than consensual basis for decision making. Both approaches agree that the analyst becomes involved in the system under examination; that the viewpoint of the analyst must be made explicit; that there are non-rational elements in human behavior; and that history, perception, relationships, and culture are important factors in human activity systems.

Peter Checkland, the founder of soft system methodology, was born in Birmingham, England in 1930. He studied chemistry at Oxford University in the 1950s, then worked at ICI Ltd. as a technologist and manager. He moved to the Department of Systems at the University of Lancaster in 1969, and in the early twenty-first century is Professor of Systems, Management Science, in the Lancaster University Management School.

SOKAL AFFAIR

The Sokal Affair was the central and most highly publicized episode of the "Science Wars," a fracas that roiled the academic atmosphere throughout the 1990s. The main point at issue in these conflicts was the accuracy and indeed the legitimacy of critiques of science and technology propounded by scholars committed to or influenced by postmodern thought and identity politics. The hoax itself, as well as the volume of *Social Text* (no. 46/47, Spring/Summer 1996) in which it appeared, arose chiefly in response to an earlier science wars salvo, the book *Higher Superstition: The Academic Left and Its Quarrels with Science* by Paul R. Gross and Norman Levitt (1994), which aggressively criticized the "science studies" movement that had emerged from poststructuralist and social-constructivist doctrines.

The squabbles ignited by *Higher Superstition* alerted Alan Sokal, a mathematical physicist at New York University, to the controversy. Further research nullified his initial suspicions that the book might merely be yet another "culture wars" diatribe from the right. He concluded, despite his own leftist sympathies, that postmodern and relativistic views of science epitomized the weaknesses he had already discerned in some versions of contemporary left-wing thought. It struck him that a parody article satirizing the pretensions of science studies might provoke useful debate around this issue. The resulting essay, *Transgressing the Boundaries: Toward a Transformative Hermeneutics of Quantum Gravity*, mischievously combined references to arcane physics and mathematics with laudatory citations of major postmodern theorists, ostensibly to support the thesis that postmodern dogma accords with advanced ideas in foundational physics.

The essay was submitted to *Social Text* just as that journal was planning its own rejoinder to *Higher Superstition*. Editor Andrew Ross, himself a prominent target of Gross and Levitt, had recruited a number of well-known proponents of science studies as contributors. When Sokal's Trojan-horse manuscript arrived, its Swiftian character escaped detection and the piece was promptly accepted because of the author's physicist credentials, as well as his authentic leftist pedigree and his feigned detestation of the enemy camp.

The "Science Wars" number of *Social Text* appeared in May 1996. Within days, Sokal unmasked his own hoax in the magazine *Lingua Franca,* and the episode quickly made its way into the mass media. Subsequent denunciations of Sokal by *Social Text*'s editors and supporters did little to staunch the widespread glee that erupted from some quarters.

The greatest significance of the affair lies, indeed, in the very fact that it became so widely known and evoked such intense responses. In itself, Sokal's piece was intentionally sophomoric, a transparently silly joke. It "proved" little more than that a handful of academics had been overeager to recruit a "real" scientist to their side of an acrimonious dispute. Why, then, the enormous uproar?

The answer lies in the hostility that had been building for a decade or more in response to the pretensions and what many saw as the monopolistic ambitions of the postmodern left. Such resentment was hardly limited to scholars of conservative bent: It was widely shared by liberals and leftists who had come to view postmodern academic culture as bizarre and overbearing. Consequently, the Sokal Hoax became the symbolic center of an intellectual firestorm whose stakes extended well beyond anything directly connected to the prank itself. It brought into the open long-brewing anxieties over scholarly priorities and their effect on the academic pecking order. The myopia of *Social Text* came to stand, rightly or wrongly, for the pretensions of postmodern scholarship per se. Sokal's success emboldened many long-suffering professors to decry at last the impostures of a subculture that had long cowed them with its self-ascribed sophistication. Most scientists were understandably amused by the spectacle, but in regard to what was really at issue, they were bystanders. This was, at heart, a battle fought by non-scientists.

In the early twenty-first century, the postmodern left seems to have declined, at least as the hegemonic trendsetter of the academy. For good or ill, many of its social precepts remain central to university culture, but with diminished stridency. "Theory," as postmodernists were wont to use the term, has lost much of its power to intimidate. At the same time, many humanist scholars who once employed the vaunted insights of science studies to disparage science now affect to admire it deeply. Postmodernism and the political style linked to it certainly endure, but in a more subdued mode. The Sokal Affair was by no means the sole or even the most important catalyst for these changes, but it was timely and amazingly effective.

SPACE

To the question, "Where are you in this moment?" a pilot would answer, "At longitude *x*, latitude *y*, altitude *z*." But if one asks, "Where do you live?", the answer may instead evoke neighborly relations weaved through the years, a climate, old stones, the freshness of water. Depending on who is asked about what, the *where* question can be answered by *space* determinations or by the memories of a concrete *place.* Space and place are two different ways of conceiving the "where" or, using the Latin word for "where" as a *terminus technicus,* two answers to the *ubi* question.

Place and Space

Place is an order of beings vis-à-vis the body. This order (*kosmos* in Greek) always mirrors the great cosmos. This vis-à-vis or mirroring is the essence of what has been called *proportionality* (Illich and Rieger 1996). According to Albert Einstein, the concept of space disembedded itself from the "simpler concept of place" and "achieve[d] a meaning which is freed from any connection with a particular material object" (Einstein 1993, p. xv). Yet Einstein insisted that space is a free creation of imagination, a "means devised for easier comprehension of our sense experience" (Einstein 1993, p. xv). In pure space, however, the body would be out of place and in a state of perceptual deprivation.

The focus here is on the radical monopoly that space determinations exert on the *ubi* question. Wheels and motors seem to belong to space as feet do to places. And just as the radical monopoly of motorized transportation on human mobility leaves some freedom to walk, space determinations leave remnants of placeness to linger in perception and memory. Ethics, then, can only be rebuilt by a recovery of placeness.

Origins of Space

A general conception of space is conspicuously absent from ancient mathematics, physics, and astronomy. The Greek language, so rich in locational terms, had no word for space (Bochner 1998). *Topos* meant place, and when Plato in the *Timaeus* (360 B.C.E.) located the demiurge in an uncreated *ubi* in which one can have no perception because it does not *exist,* he called it *chôra,* fallow land, the temporary void between the fullness of the wild and cultivation. According to Plato, the demiurge's chôra could only be conceived "by a kind of spurious reason," "as in a dream," in a state in which "we are unable to cast off sleep and determine the truth about it" (passage Timaeus 52). In hindsight, one may say that this was a first intuition of the antinomy between place and what is has come to be called "space." In the fourteenth century, Nicolas d'Oresme imagined an incorporeal void beyond the last heavenly sphere, but still insisted that, in contrast, all real places are full and material. Space, still only a pure logical possibility, became a *possibile realis* between the times of d'Oresme and Galileo (Funkenstein 1986, p. 62).

Following the canons of Antiquity and medieval cartography, a chart summarized bodily scouting and measuring gestures. Pilgrims followed *itineraria;* sailors, charts of ports; and surveyors consigned ritually performed acts of mensuration on marmor or brass plates. These were not maps in the modern sense, because they did not postulate a disembodied eye contemplating a land or a sea from above. The first maps in the modern sense were contemporary with early experimentations in central perspective and, like these, construed an abstract *eye* contemplating a distant grid in which particulars could be relatively situated. In 1574, Peter Ramus wrote a *lytle booke* in which he exposed a *calculus of reality* where all topics were divided in mental spaces that immobilized objects in their definitions precluding the understanding of knowledge as an act (Pickstock 1998). Cartesian coordinates and projective geometry gave the first mathematical justification to the idea of an immaterial vessel, unlimited in extent, in which all material objects are contained.

Non-Euclidean Space

Had space been invented, as Einstein contended, or discovered? In the eighteenth century, Immanuel Kant announced that space was an *a priori* of perception. For him, Euclidean geometry and its axioms were the mathematical expression of an entity—space—that cannot be perceived, but, like time, underlies all perceptions. The first attempt to contradict Euclidean geometry was published in Russian in 1829 by Nicolay Lobachevsky (1792–1856), whose ideas were rooted in an opposition to Kant. For him, space was an *a posteriori* concept. He sought to prove this by demonstrating that axioms different from Euclid's can generate different spaces. In light of Lobachevsky's—and then Georg Riemann's (1826–1866)—non-Euclidean geometries, Euclidean geometry appears ex post facto as just another axiomatic construct. There is no a priori space experience, no *natural,* or *universal* space. Space is not an empirical fact but a construct, an arbitrary frame that *carpenters* the modern imagination (Heelan 1983).

Einstein occupies an axial and simultaneously ambiguous position in the history of this understanding. In order to express alterations of classical physics that seemed offensive to common sense, he adopted a mathematically constructed *manifold* (coordinate space) in which the space coordinates of one coordinate system depend on *both* the time and space coordinates of another relatively moving system. On the one hand, like Lobachevsky and Riemann (1854), Einstein insisted on the constructed character of space: Different axioms generate different spaces. On the other, he not only came to consider his construct as ruling the unreachable realms of the universe, but reduced earthly human experience to a particular case of it. In Einstein's space, time can become extension; mass, energy; gravity, a geometric curvature; and reality, a distant shore, indifferent to ethics. This view of space has reigned over the modern imagination for a century. Yet the idea that the realm of everyday experience is a particular case of this general construct has not raised fundamental ethical questions.

Ethics in Space

The subsumption of the neighborhood where one lives into the same category as distant galaxies transforms neighbors into disembodied particularities. This loss of the sense of immediate reality invites a moral suicide. Hence, ethics in the early-twenty-first century requires an epistemological distinction that evokes that of d'Oresme in the fourteenth: Contrary to outer space, the perceptual milieu is a place of fullness. According to its oldest etymology, *ethos* means a place's gait. Space recognizes no gait, no body, no concreteness, and, accordingly, no ethics. The *ubi* question must thus be ethically restated.

Body historians and phenomenologists provide tracks toward an ethical recovery of placeness in the space age. Barbara Duden (1996) argues that one can only raise fundamental ethical questions related to pregnancy by relocating the body in its historical places. For their part, phenomenologists, those philosophers who cling to the *primacy of perception* in spite of tantalizing science-borne and technogenic *certainties*, restore some proportionality between body and place. For Gaston Bachelard (1884–1962), for instance, there is no individual body immersed in the apathetic void of space, but an experience of *mutual seizure* of the body and its natural *ubi*. Maurice Merleau-Ponty (1908–1964) further articulates the complementarity of these two sides of reality. These can be steps toward a recovery of the sense of the vis-à-vis without which there is no immediate reality, and hence no ethics.

SPACE EXPLORATION

Space exploration is the investigation of the cosmos beyond the upper regions of the Earth's atmosphere using telescopes, satellites, space probes, spacecraft, and associated launch vehicles.

Background

The desire to explore space is nearly primal for Homo sapiens. Early humans quickly spread out of Africa to every region on the planet, then came to speculate that the stars and planets were yet other material places worthy of exploration. The idea to travel to these other worlds was inevitable.

However for thousands of years, humans commonly drew fundamental distinctions between the Earth and non-Earth environments. In the formulation of Aristotle taught that the laws of nature that applied on Earth did not necessarily apply beyond the Earth, thus severely restricting the very possibilities for human space exploration.

During the great age of European exploration of the Earth, astronomers such as Galileo Galilei (1564–1642) and his contemporary, Johannes Kepler (1571–1630), began the modern observational exploration of the heavens, in fact of space, using new techniques and instruments of science. A result of this exploration of space was the scientific revolution itself. Science was now seen as applicable to understanding the entire world, to both heaven and Earth. Civilization was transformed.

It now seems natural that Kepler's "Somnium," about a journey to the Moon, includes a realistic description of the lunar surface and how a traveler might physically survive such a trip. But this pioneering story began a long tradition of science fiction literature examining ethical and political issues of space exploration and scientific enterprise.

Twentieth-Century Developments

Planning and experiments to develop the science and technology of physical space exploration began with Konstantin E. Tsiolkovsky (1857–1935) in Russia and Robert Goddard (1882–1945) in the United States. Both of these inventors considered the long-term implications of their work for humanity. Application of their technology to weapons of war soon became evident. Although Goddard helped the U.S. military with rocket-assisted take off of conventional aircraft, it was the Germans who made extensive use of Goddard's published rocket development during World War II.

As the war ended, the *space race* began in earnest between the Soviet Union and the United States. Efforts were made by both countries to enlist German scientists, who had worked on the Nazi rocket program. Many Americans were shocked when, on October 4, 1957, the Soviet Union launched the first artificial earth satellite, Sputnik I. Some Americans viewed the Soviet triumph as an indication of U.S. weakness in science and technology, and considered it a political imperative to match and surpass Soviet accomplishments. Many voiced concern about the threat presented by the combination of nuclear weapons with ballistic missiles.

At the same time, some saw a great potential for peaceful exploration and development of the space environment. Ethical issues were debated about both the commercial and military aspects of this new human enterprise. The National Aeronautics and Space Administration (NASA) was created by Congress in 1958, at the height of the Cold War. It is remarkable that the NASA charter specifically states that the agency is restricted from military activity. (Nonetheless NASA would not always adhere to the charter. For instance, design of the space shuttle was driven significantly by military requirements at a time when Congressional support for NASA was waning.)

Space Law

Despite international competition, there was early agreement that space and celestial bodies were open to peaceful use by all nations, and that principles of international law would be followed in this new realm. Parallels with, and precedents set by, maritime law guided the formulation of space law and regulation. On December 13, 1963, the U.N. General Assembly adopted the Declaration of Legal Principles Governing Activities of States in the Exploration and Use of Outer Space. Further work by the United Nations resulted in the Outer Space Treaty, first signed by sixty-three nations in 1967, and adopted by most countries in the early twenty-first century.

Although much progress has been made in space law, there are challenging near-term issues. For example, the orbital location and radio frequency allocation of communication satellites is a type of territorial issue. At bottom, these resources are limited. Humans have the ancient challenge, in new guise, of how to share these resources peacefully and wisely. The information content of direct-broadcast satellite transmissions is also a complex issue involving national sovereignty on the one hand, and freedom of expression on the other. Observation or spy satellites bring issues of privacy versus freedom of inquiry and information. The United States, Russia, and others have entered into more than 100 treaties and agreements regarding issues of orbit and frequency allocation, as well as launching, tracking, monitoring, and recovery of satellites and space vehicles.

Human Exploration

The first human to orbit the earth, Soviet cosmonaut Yuri Gagarin, returned safely from space in April of 1961. The U.S. astronaut John Glenn followed with a similar mission the next year. These flights, and the many that followed, helped to transform human perspective of the earth and its place in the universe, just as the unmanned missions were doing. Only eight years after Gagarin's flight Neil Armstrong stepped onto the lunar surface on July 20, 1969.

Following the first earth orbit missions, both nations continued without a reported loss of human life until 1967 when three astronauts were lost during a ground test of Apollo 1 and a cosmonaut was lost during return from a Soyuz space mission. Nonetheless, manned space exploration has had a remarkably good safety record. Any space mission must balance goal, schedule, and budget, as well as recognizing risk and the unknown. In achieving this balance in space missions, it is important to keep in mind Richard Feynman's remarks about the loss of the space shuttle *Challenger*: "For a successful technology, reality must take precedence over public relations, for nature cannot be fooled" (Feynman 1986, F5).

Over the last several decades launch failures have been on the order of 1 percent. The space shuttle record, with a total of 112 successful flights and the loss of shuttle *Challenger*, reflects this value. *Columbia*, on the other hand, was the first loss of an American crew on reentry. In both cases the loss appears to be due to schedule and mission demands taking priority over safety.

The loss of human life in space flight development has been relatively low compared to the pioneering days of aviation. This may in part be due to risk-benefit and budget considerations. Experimental airplanes were relatively inexpensive to create and pilots were willing to take considerable risks. It was cost effective to risk pilot and plane to develop the new technology. This is not the case with spaceflight development and exploration. The loss of one mission costs billions of dollars and results in untold costs in schedule slippage and decreased political support. It is remarkable though that during the Mercury, Gemini, and Apollo spaceflights, there was no loss of human life. The Russian space effort has also been relatively free from loss of human life. The most well known soviet accident, Soyuz 11 in 1971, resulted in the death of three crew members as they returned to earth. Overall the loss of life in the U.S. and Russian programs has been similar, if one includes the unannounced Soviet losses of perhaps twelve.

The live coverage loss of *Challenger* and *Columbia* reminded the world that spaceflight is not yet routine. Exploration at the frontier must always remain riskier than day-to-day experience. There is, however, reasonable expectation that near-earth spaceflight will become safer in the foreseeable future. It remains to be seen how the advent of commercial spaceflight will change the equation, but the long term effect should be for improved safety.

Ethical Issues

Although certainly chartered upon a wider canvas, the challenges in space development are, in the first instance, those related to the ongoing challenges faced by the nation states. These issues are mostly of increased degree, rather than entirely new for humans. The ethics of space exploration from this perspective are addressed in such documents as the ESA-UNESCO report, *The Ethics of Space Policy* (Pompidou 2000).

Beyond these issues are those prompted by questions about the impact on human civilization of asteroid and comet orbit modification, space elevators-to-orbit development, or planetary, space, and asteroid colonization. Such endeavors could have impact on civilization beyond that of *normal* human activity.

Also of importance are issues such as interplanetary contamination, the terraforming of planets, and contact with extraterrestrial intelligence. These issues center on questions about the effect of the universe on human beings, and their effect on it.

An elementary case of this sort is the detection of primitive extraterrestrial life in the form of microbes or microfossils. Because the nature of such life is not known, one can only make informed speculation about what the effects might be on civilization and on life on Earth. Or, indeed, what effect humankind might have on such life.

Space exploration may result in the detection of extraterrestrial life or even other civilizations. A scientific Copernican-Darwinian worldview suggests the likelihood of finding evidence of this sort. In any case, it appears likely that people will continue to look for such evidence.

Several outcomes of the detection of life elsewhere in the universe have been suggested: a mostly harmless event, with gain in the knowledge that other life exists in the universe; a major change in life itself or civilization; the loss of civilization; the change or loss of dominant species; loss or change of all *higher order* species; loss of the planetary biosystem; or some unpredicted transformation of life and civilization. These changes are not necessarily in only one direction.

Several decades prior to the physical exploration of space the British ethicist and philosopher Olaf Stapledon (1886–1950) and the crystallographer J. D. Bernal (1901–1971), wrote about some of these wider issues of space exploration. Their pioneering efforts influenced later thinkers from the futurist and novelist Arthur C. Clarke (b. 1917) to the British-American physicist Freeman Dyson (b. 1923).

Responding to Ethical Issues

Humans have attempted to develop some approaches for dealing with the new ethical issues presented by space exploration. Prevention of potential contamination to the Earth's biosphere was practiced during the first lunar expeditions. Astronauts, spacecraft, lunar samples, and equipment were isolated upon their return to Earth from the Moon. The Lunar Receiving Laboratory is in operation to this day, protecting lunar rocks and soil, even though there is now no risk to life on this planet. Space probes are decontaminated prior to leaving the Earth in most cases. Considerable care of this sort was taken with spacecraft, such as Viking (1975) and Sojourner (1996) that would land on the Martian surface. The trajectory of Galileo (1989) was purposely changed, at the end of its mission, in order to send the spacecraft to fiery destruction in the upper atmosphere of Jupiter to insure no contamination of the Jovian moons with terrestrial microorganisms.

In 1991 the Declaration of Principles Concerning Activities Following the Detection of Extraterrestrial Intelligence was drafted by the International Academy of Astronautics (Billingham 1994). The Board of Directors of the International Institute of Space Law approved the declaration. This document is an effort to outline a responsible and orderly set of activities for scientists and others to follow after the detection of extraterrestrial intelligence. An obvious objective of this protocol is to protect life and civilization on Earth.

One can optimistically view the development of portions of the agreements regarding space exploration as the emergence of a principle of non-interference with extraterrestrial life. In a sense humankind seems to be developing a sort of *prime directive* rule of space exploration, which was once only addressed in science fiction. The prime directive restricts human beings from interfering with any extraterrestrial life that is *less developed* than they are.

Carl Sagan (1934–1996) and others have argued that the sort of extraterrestrial life that is likely to be detected will either be of an elementary sort, or a civilization well beyond our imagination. If this turns out to be the case, then the proper conduct, in either of these situations, will not be the sort fancied in the popular space operas of interstellar diplomacy and conflict. Humans would be either the fortunate caretakers of a wholly new primitive life system or the subjects of scientific interest, perhaps protected or transformed beyond recognition.

The American biologist and essayist Stephen Jay Gould (1941–2002), pointed out that the revolution of Copernicus and Galileo was about *real-estate*, but that the Darwinian revolution was about *essence* and thus had much the greater impact. This situation is reflected in questions about the present and future exploration of space. Presently human explorers are experiencing the Galilean, or real estate, phase of the space enterprise. But soon the essence, or Darwinian, phase may commence. Beginning in the mid-1990s, many planets, orbiting other stars, were found by astronomers. Spaceborn experiments directed at trying to detect some telltale signs of life on planets of other solar systems are planned for the first half of the twenty-first century. Even in the Earth's home-system there is hope for detecting life: The oceans that may exist below the ice surface of the Jovian satellite Europa are currently of prime interest to astrobiologists.

The nation states of Earth have created many agreements for the peaceful exploration of space. Space law is now an active field. Humankind has made a start in constructive and peaceful conduct during the early stages of space exploration.

Space exploration is not a one-way enterprise. The "pale blue dot" vision of earth in space, the close-up images of the many worlds of this solar system, returned samples from space, and the countless Hubble space telescope vistas, are transforming the human mind. This transformation is playing a key part in the evolution of the ethics of space exploration—an evolution that may now be at a stage where there is a need to develop a preliminary "prime directive," in order to define conduct with other life in the galaxy. The need may be closer than imagined.

SPACE SHUTTLES *CHALLENGER* AND *COLUMBIA* ACCIDENTS

The losses of the space shuttles *Challenger* in 1986 and *Columbia* in 2003 dramatically illustrated the risks involved in the human exploration of space, and provide starkly instructive case studies in the ethics of science and technology.

A central mission of the National Aeronautics and Space Administration (NASA) is human exploration of space. Given this legitimate political commitment to human space exploration, the space shuttle program is ethically and politically acceptable insofar as the agency in charge, NASA, promotes careful and honest examination of the human risks and, in reaching the compromises unavoidable in balancing safety against performance, involves those most subject to the risks and those making the political commitment.

The careful, honest examination of risk cannot be done once; it must continue as flight experience accumulates. In balancing safety and performance the shuttle's design both represents NASA's understanding of the system and predicts that the shuttle's flight will safely meet performance requirements. To count as a success, a shuttle flight must perform as the design predicts, not merely return "safely" to Earth. As long as flight does not conform to design, that is, has "anomalies," the design remains provisional; it is not fully understood; and the system is "developmental" not "operational." Both disasters revealed that NASA truncated the examination of risk by deeming the shuttle "operational"; by treating as "successful" flights that did

FIGURE 1

Space Shuttle System

The figure shows the launch configuration of the main elements of the Space Shuttle System, in "top" and starboard views: The winged Orbiter, which sits atop the large External Tank. On each side of the external tank are the two Solid Rocket Boosters.

not perform as predicted; and by "accepting" risks inherent in anomalous performance. Continuing instances of anomalies signaled the existence of inexplicable risks, which, accepted, culminated in the disasters.

Shuttle History and Design

After Apollo NASA needed a large program to justify its size and budget. It ambitiously planned a shuttle, a space station, and planetary exploration, but budgetary constraints limited the post-Apollo program to the space shuttle. To secure approval of the shuttle, NASA promised to launch all U.S. payloads. Also the reusable orbiter was presented as a means of long-run cost savings: With regularly scheduled, once-per-week operational launches promised by the mid- to late 1980s, the shuttle was to pay for itself. To develop fifty shuttle payloads every year, however, would have required a space budget ten times as large as NASA's actual budget. There was clearly an unrealistic presentation of feasibility on the part of NASA and uncritical thinking on the part of the U.S. Congress. The promises remain a root cause of pressure to launch the shuttle on schedule.

As Figure 1 shows, the shuttle consists of two solid rocket boosters (SRBs) to provide major thrust at launch, an external tank that carries fuel for the orbiter's main engines, and the orbiter, which carries the crew, payload, and main engines. The burnt-out SRB casings drop into the ocean where they are retrieved and later reused. The orbiter returns to Earth for servicing and reuse. The external tank is taken nearly to orbit before separation from the orbiter, and burns up on reentry. The official investigative reports, cited below, describe the shuttle, normal operations, and each disaster.

Shuttle development presented many design problems. One of the most challenging was a "thermal protection system" to protect the orbiter from the heat of reentry, when temperatures may exceed 5,000 degrees Fahrenheit. Another was providing a reliable seal between SRB segments.

Disasters Compared

The two disasters were very different superficially. The *Challenger* disaster occurred in the first moments of launch on an unusually cold January 28, 1986. Because of the cold weather, an O-ring seal between SRB segments leaked hot combustion gas, which quickly triggered the explosion that destroyed the vehicle. The dynamics of launch cause the joints between SRB segments to flex, and to prevent leaks the O-rings must be resilient enough to "follow" this flexure and maintain their seal. The cold O-rings were too stiff to follow the joint flexure.

The *Columbia* disaster culminated during reentry on February 1, 2003, after completion of the mission's on-orbit tasks. During launch the external tank had shed a large piece of foam insulation, which struck the orbiter's left wing, damaging its thermal protection system. Because of this unknown damage to the wing during launch, the heat of reentry destroyed the wing, leading to the breakup of the orbiter.

Similarities between the cases in three areas—no-return decisions, misunderstood anomalies, and overridden concerns from engineers—reveal the common ethical issues.

NO-RETURN DECISIONS. In both cases an explicit no-return decision left no chance to avoid disaster: For *Challenger* this occurred at launch—specifically, the ignition of the SRBs. For *Columbia* this came at initiation of reentry—the firing of the retro-rockets. Between the identification of an anomaly and this no-return decision there was time to have averted the disaster.

Regarding *Challenger*, the danger of a cold launch was suspected from heat damage to SRB seals—anomalies—in previous flights over several years. But the analysis of trends of seal damage as related to temperature omitted flights suffering no seal damage, all of which occurred at warm temperatures. This omission obscured the relationship of damage to temperature. If the many no-damage, warm launches had been considered, the significance of the few high-damage, cold launches would have emerged and convinced engineers that cold launches were unsafe (Vaughan 1996).

With respect to *Columbia*, occurrences of shedding of foam—anomalies—were known even before the *Challenger* accident. Foam strikes were "accepted" because efforts to prevent foam shedding were unsuccessful but flights were "successful." If NASA can fix the shedding problem in the halt in shuttle flights that followed the *Columbia* accident, so it could have during the similar halt after *Challenger*. This would have caused minimal (if any) delay and would have prevented the second disaster.

MISUNDERSTOOD ANOMALIES. The root cause of both disasters was misunderstanding anomalies. The 2003 *Columbia* disaster report quotes the 1986 *Challenger* report to show that the causes were identical. In effect, anomalies in performance—if followed by a successful landing—were considered evidence of safety instead of what they really were, evidence that the shuttle did not perform as designed. Thus safely landing after foam shedding or seal erosion reinforced the conviction of safety. This "normalization of deviance" violates the trust given NASA to accomplish human spaceflight safely (Vaughan 1996).

OVERRIDEN CONCERNS FROM ENGINEERS. In both cases working-level engineers most familiar with the relevant systems expressed timely concerns that could have averted the disaster, and their concerns were overridden. Regarding *Challenger*, engineers at the SRB contractor wanted to postpone the launch for a few hours or for a day for warmer weather, and were heard by company management in last-minute "readiness-to-launch" reviews, but management overrode them after NASA officials expressed frustration and desire to launch. They were overridden in part because of the inadequate trend analysis mentioned above. Warmer conditions could have averted the disaster. Desire to launch prevailed. With respect to *Columbia*, because the impact seemed more significant than the many previous instances of foam striking the orbiter, NASA engineers reviewing launch videos were alarmed. They requested a damage assessment but were overridden by management without a hearing. Had management honored the request, the disaster might have been prevented—the crew rescued but the orbiter lost (CAIB 2003).

The engineers did not push their arguments because of fear for their careers. Deciding to launch a shuttle had changed from a process requiring agreement that the system is safe to launch, per the design, to a process assuming launch and requiring anyone asking for delay to prove it unsafe. As "accepted" risks, damage to seals and strikes by foam were no longer an issue. This acceptance meant that a major foam strike on a launch shortly before *Columbia* (on October 7, 2002) was not declared an anomaly (CAIB 2003). Consistent with NASA's 1982 declaration of the shuttle as "operational," insulation strikes and seal damage became normal, while raising questions about these issues became deviant. William Langewiesche (2003) shows the depth of NASA managers' belief that insulation striking the orbiter was not a risk; he shows that only seeing an experimental demonstration of damage to a mock wing could destroy their belief, and that the demonstration left them in shock. Raising questions about foam shedding to such managers would damage one's career.

A healthy organization provides an environment and information conducive to decisions that advance the organization's goals within ethical constraints. Clearly, pressure to launch biased decisions by overemphasizing the partial, short-term goal of launching on schedule, reified in a lack of substantive, ethical discussion preceding the fatal no-return decisions. Astronauts, those most at risk, were not represented in the discussions. As the official reports reveal, typical predecision discussions were formal and procedural and laden with acronyms, emphasized the need to launch, and lacked ethical substance.

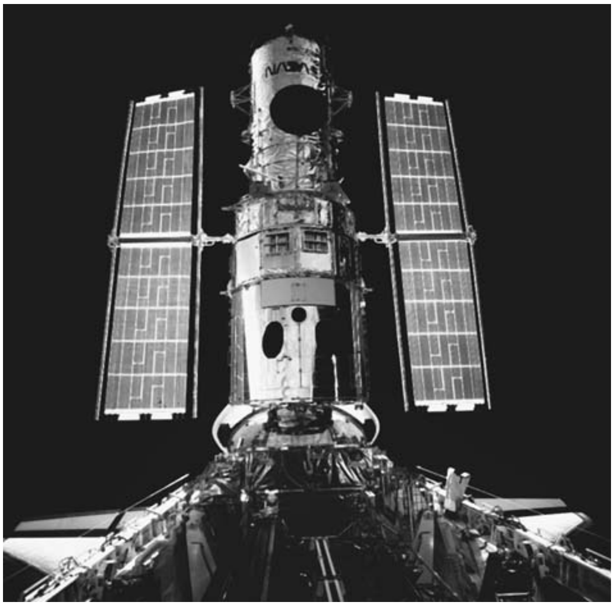
SPACE TELESCOPES

The idea of a space-based telescope dates back to a proposal by R. S. Richardson in a 1940 issue of *Astounding Science Fiction*, but Richardson thought the moon would be a suitable venue. The U.S. proposal to put a telescope in orbit around the earth was made by Lyman Spitzer in "Astronomical Advantages of an Extra-Terrestrial Observatory," a paper written for a project for the Rand Corporation in 1946. In 1958, after a call for proposals by the Space Science Board of the National Academy of Sciences, the National Aeronautics and Space Administration (NASA) Space Sciences Working Group began developing proposals for orbiting astronomical observatories. The idea of an orbiting observatory received support at the highest government levels on the basis of arguments for national prestige, which was in need of shoring up after the launch of *Sputnik I* in 1956 by the Soviet Union.

Project Development

In 1960 and 1961 NASA initiated the process that eventually led to the Hubble Space Telescope (HST). It issued several calls for proposals for launch vehicles and astronomical hardware. By separating the two issues NASA created the grounds for serious planning problems because the limitations of the launch vehicle would have serious implications for the size and design of the observatory. By not insisting on coordinating the two from the start, NASA was, perhaps unknowingly, preparing the ground for later arguments about the constitution of the observatory.

In 1969 after debates among a variety of interest groups, the National Academy of Sciences clearly backed the proposal for a space-based telescope. NASA soon bought into the idea. However, NASA always has been and continues to be a management enterprise of considerable complexity with a myriad of problems that lead to difficulties in making decisions. Much decision



The Hubble Space Telescope, attached to a space shuttle. Named after Edwin Hubble, the telescope was launched into orbit in 1990 as a joint project of NASA and the European Space Agency. Initial optical errors were corrected in 1993, and high-quality imaging began in 1994. HST is projected to continue operating until 2009. (© 1996 *Corbis*.)

making at NASA is influenced strongly by politics. The many and often competing interests NASA managers felt they had to satisfy ranged from internally competing science groups to contractors, politicians, public interest groups, regional NASA facilities, and national priorities, along with international considerations. In addition, there was always competition from other NASA projects. Funds were limited, and the demands were many. The space telescope, as was the case with many other projects, stalled.

Among other activities under way at NASA at the time when the space telescope was being debated was the planning of a space shuttle program, which was approved in 1972. To restart the stalled planning for the space-based telescope, NASA proposed that the launch vehicle for the telescope be the shuttle. That proposal had serious design implications for the telescope, which would have to fit into the baggage bay of the shuttle.

The Large Orbiting Observatory project was beset by arguments that delayed its completion. There were arguments over where the central control would be: The Goddard Space Flight Center at Beltsville, Maryland, or The Marshall Space Flight Center at Hunbtsville, Alabama.. There were arguments over who would have authority over what; what kinds of instruments should be built; how much money was available; which contractor would build the instruments; how much existing technology, such as military spy satellite technology, could be appropriated; and eventually, who would be blamed for the big mistake of the spherical aberration of the primary mirror and how it would be fixed.

The Large Orbiting Observatory, by now called the HST, was completed in 1986, shortly before the *Challenger* disaster. The grounding of the shuttle program forced a four-year delay in launching the HST. When the HST finally orbited in 1990, it was discovered immediately that its primary mirror had a spherical aberration: The images it sent to earth were blurry. After a number of investigations, including congressional hearings, it was concluded that the mistake was due to a failure of both the engineering team at the contractor for the mirror, Perkin-Elmer, and its management. Perkin-Elmer agreed to repay the government $25 million.

The problems with the Hubble eventually were fixed, and the HST has been instrumental in revolutionizing scientists' conception of the universe. It allowed astronomers to look deeper into space than ever before, revealing features of the universe that confirmed some theories and made others doubtful.

Reflections

When one reflects on the history of the HST, the variety of factors that played a role in its development, and its impact on astronomical understanding, several themes emerge. First, the building of a large and expensive scientific instrument is not a simple process. Furthermore, instruments with the size and complexity of the HST require such vast resources that only a national government or another entity capable of putting together a conglomerate of considerable size can undertake a project of such magnitude. Second, in a world of limited resources the commitment to undertake one project of that size means that other projects will suffer. Thus, not only was there considerable tension between advocates of earth-based telescopes and advocates of space-based ones, directing funds toward the HST meant that less money was available for new and larger earth-based telescopes. Third, most of the conflicts involving the HST were clashes of values that often were multidimensional.

The initial battle over launching a large space telescope as opposed to several smaller, more specialized telescopes was not just an argument about whether the project was feasible. In a 1983 symposium sponsored by the Smithsonian Institution the physicist Freeman Dyson (b. 1923) argued against the idea of doing science with instruments with the size and scale of the HST and for a smaller, diversified kind of science employing specialized, smaller, and much cheaper instruments. Dyson was arguing against big science, which had become a distinctive characteristic of the U.S. physics community.

Dyson may have had a point. The U.S. physics community had continued to rely on large instrument projects to a risky extent. The lesson was learned the hard way when the Super-Conducting Super Collider (SSC) project was canceled fifteen years after it had been proposed and billions of dollars had been spent. The physics community reacted as if it had received an amputation: It had no visible capacity to do microphysics at the cutting edge.

This episode shows the flaw inherent in insisting on a hegemony in a science. The lesson to be learned from the Hubble, however, actually goes in the other direction. The turn to big science/technology need not limit the scientists to one large project; it also can generate small science projects in its wake. Smaller and less expensive types of telescopes, such as an infrared telescope, are being placed in orbit to discover what the Hubble could not reveal. What was missing from the thinking about the SSC were ideas about what would follow from it by way of subsidiary projects such as smaller more specialized experimental devices.

The HST illustrates other value clashes as well. Many people argue against this kind of project while people are suffering from hunger, disease, and lack of education. Big science/technology, it is claimed, is a luxury at a time when many millions are living in misery. This is a hard argument to refute, and it is not clear that one should try. It is important to be reminded of the human cost of science and technology. At the same time it is possible also to consider another human dimension to big science/technology that although it does not refute the argument from human physical need speaks to a different form of human need.

In the Middle Ages there was much misery. In Europe most of the population lived in squalor, disease was rampant, and ignorance was the norm. However, despite those circumstances, people in that era gave of their time, labor, and meager belongings to build some of humankind's most magnificent edifices: Gothic cathedrals. The cathedrals of Europe present a statement of humanity's commitment to seek more than it can find on earth. Projects such as the HST may be considered a continuation of that quest.

SPECIAL EFFECTS

Special effects (which typically refers to visual effects in live-action moving-image media but also includes audio effects and other possibilities) are the methods used to produce on-screen (or on-air) events and objects that are physically impossible or imaginary, or too expensive, too difficult, too time-consuming, or too dangerous to produce without artifice. The ethics of the related technologies are seldom discussed but are nevertheless significant.

Origins

Cinematic special effects grew out of trick photography and began with the trick film tradition popularized by early filmmakers such as Georges Méliès (1861–1938), a special effects pioneer who was the first to develop many in-camera techniques. Silent films used a variety of special effects techniques, particularly in the genres of science fiction and horror. Many new special effects technologies became possible after the invention of the optical printer in 1944, resulting in a new generation of science-fiction films in the 1950s that used the new techniques, as well as more realistic-looking effects in other films. Finally, the late 1980s and 1990s saw another advance in effects technology: the rise of digital special effects created in computers, which allowed live-action footage to be combined with anything that could be rendered in computer graphics.

Special effects are a large part of the film industry in the early twenty-first century, with a number of companies such as Industrial Light & Magic and Digital Domain specializing in the production of special effects.

Jim Carrey as Stanley Ipkiss in a scene from the 1994 film *The Mask*.

Special effects can be found in almost every genre of filmmaking, in both big-budget and low-budget films, as well as on television, most notably in advertising, where high budgets and short formats allow filmmakers to experiment with expensive new techniques.

Types of Special Effects

Special effects can be divided into four types: practical effects, in-camera effects, optical effects, and digital effects. Practical effects, also known as physical effects, are those that occur in front of the camera, such as rigged explosions, pyrotechnics, animatronics figures or puppetry, makeup effects, and so forth. Practical effects have the advantage of occurring on the set where they appear directly in the scene and the action of the shot, and require no postproduction processes.

In-camera effects are achieved through forms of trick photography and are made in the camera at the time of shooting. Such effects include shots taken at different camera speeds, shots using lens filters, and day-for-night shooting, all of which change the kind of image being recorded. Superimpositions and multiple-exposure matte shots require the film to be exposed, rewound, and exposed again, adding two or more images together onto the same piece of film before it is developed (this combining of imagery is also called *compositing*). Foreground miniatures, glass shots, and matte paintings make use of the monocular nature of the camera by falsifying perspective and making small objects close to the camera look as if they are part of larger objects farther away from the camera. Buildings can be extended and other large set pieces can thus be made inexpensively through the use of detailed models and paintings done with the correct perspective. Front projection and rear projection processes combine foreground sets and actors with backgrounds made from projected imagery (most typically as moving background imagery placed behind an actor driving a car).

Optical effects involve the use of an optical printer, a device invented by Linwood Dunn in 1944 that allows images on developed pieces of film to be rephotographed and composited together onto a single piece of film. An optical printer is basically a camera and a projector (or multiple projectors, in some cases) set up with a camera in such a way that film frames can be rephotographed directly from another strip of film. Optical processes allow frame-by-frame control and greater preci-

A special-effects artist signs autographs near a model of the character Gollum from the *Lord of the Rings* film trilogy. The groundbreaking CGI character was built around an actor's voice, movements, and expressions by using a motion capture suit which recorded his movements and applied them to the digital character. *(© Reuters NewMedia Inc./Corbis.)*

sion in spatially positioning elements than is possible with in-camera compositing. Perhaps the most common form of optical compositing is the matte shot, wherein a foreground element is combined with a background, without the background visible through the foreground element (as would be the case with superimposition). To achieve this, keying processes are used for the production of foreground elements, and the most typical of these, blue screening and green screening, place the actor in a solid-color background, which is later optically removed from the shot. A holdout matte is made from the foreground element, which leaves a part of the rephotographed background plate unexposed, and the foreground element is later exposed onto the same plate, fitting into the unexposed area. Traveling mattes also make this technique possible for moving objects and moving camera shots.

Digital effects are all done in a computer. Images are either shot with digital cameras or scanned from film into a computer, where they are edited and composited digitally. Digital effects avoid the generational loss (the loss that occurs when film images are rephotographed onto another piece of film) that happens during optical rephotography, and the computer makes matteing much easier and faster and gives the effects technician greater control over the image. Digital effects technology also allows computer-generated imagery to be combined with live-action footage, and allow images to be controlled down to individual pixels. Light, shadow, and color can all be adjusted, and digital grading can replace color correction and matching that was previously done during the color timing (the matching of colors from shot to shot during postproduction) of prints in postproduction. Digital effects were experimented with during the 1980s and came into common use during the mid-1990s as techniques were developed and computer systems became powerful enough to make digital effects work affordable.

Some special effects (such as dinosaurs, space battles, monsters, and so forth) are obviously special effects no matter how well they are done, because the objects or events they portray clearly do not or no longer exist. Other effects, known as "invisible effects," are less noticeable because they portray objects and events (for example, background buildings, smoke, and building extensions) that do not call attention to themselves and that usually could have been done conventionally had the budget allowed it. Another type of invisible effects are effects in which something is erased or removed from the image. One example is wire removal, in which the wires used to fly an actor or object are digitally erased during postproduction.

Ethics

The alteration and faking of photographs has existed as long as photography itself. Whether or not the use of special effects is ethical depends on the intentions and truth claims of the work in which they appear. By altering, combining, or fabricating images, special effects work reduces or removes the correspondence, or indexical linkage, that an image may have to its real-world referent. Thus, while special effects may be acceptable in films that are fictional or are clearly re-creations of events, one would not expect to find them in news or documentary footage that claims to be a record of actual events. Even when they are used in an entirely fictional film, how special effects are used can still greatly determine how a film is received by an audience. For example, Jackie Chan's earlier films, in which he actually does all his own stunts, are more impressive than his later films in which some of his stunts are the result of wire work and special effects. Likewise, while the digital crowd scenes in *The Lord of the Rings: The Two Towers* (2002) and *Star Wars, Episode II: Attack of the Clones* (2002) are impressive, one is still aware that they are special effects, unlike the massive crowd scenes in older movies such as *Gandhi* (1982) and the Russian version of *War and Peace* (1966–1967), which were all done using actual crowds. At the same time, not only are special effects used to create spectacle, but their creation itself has become a spectacle, as witnessed by "making of" featurettes often found among the DVD extras. For many, knowing how an effect was made can enhance the viewing experience rather than spoil the effect.

Advances in special effects have made fantastic ideas possible and allowed filmmakers to give them concrete expression. The fact that many effects in the early twenty-first century are photo-realistic and seamlessly integrated into live-action footage also means that a discerning viewer will need a certain degree of sophistication. Combined with unlikely storylines, the use of special effects, which makes unlikely or impossible events appear possible and plausible, may help to erode the ability of younger or unsophisticated viewers to distinguish between what is plausible and what is not. Despite the fact that the films in which special effects appear are often clearly fictional, seeing photo-realistic representations of what look like actual events can make an impression on some viewers, particularly in a culture in which so much of what people see of the world is mediated through film and television imagery. At the same time, because of magazines, books, and DVD extras detailing special effects techniques and technology, contemporary viewers often are more aware of how special effects are done and how they are incorporated into a film.

SPEED

The word *speed* is derived from the Middle English *spede* (good luck), which in turn originated from older roots meaning to prosper or succeed. In its contemporary usage, speed refers to a rate of change. It commonly denotes the time it takes to travel a certain distance (e.g., a rate of 60 miles per hour), but it is also used to describe the time needed to perform certain tasks or operations, especially in information processing (e.g., a computer with a 500-megahertz processing speed). Individual artifacts such as cars, airplanes, and computers are achieving ever-greater speeds, which has effectively decreased and in some cases nearly eliminated distance. The speed of modern travel and communication has shrunk the world and radically altered the experience of time and place for individuals, corporations, and nations. Increased speed at this level of analysis presents several important safety and ethical issues.

The Technological Singularity and Other Analyses

But even more profound implications derive from the speed at which the very processes of technological innovation and knowledge creation occur. Moore's law (holding that growth in the number of transistors per integrated circuit will be exponential) was generalized to all technologies by Raymond Kurzweil in his "law of accelerating returns." Some futurologists claim that this acceleration will lead to a "technological singularity." This denotes the point in the development of a civilization at which technological change accelerates beyond the ability of present-day humans to fully comprehend, guide, predict, or control it. It derives mostly from the use of the term *singularity* in physics to indicate the failure of conventional models to predict change as one approaches a gravitational singularity—an event or location of infinite power such as a black hole, where matter is so dense that its gravity is infinite. When a black hole absorbs nearby matter and energy, an event horizon separates this region from the rest of the universe, constituting a rupture in the structure of space and time. Vernor Vinge (1993) developed the concept of technological singularity and applied it more specifically to the advent of greater-than-human intelligence. Beyond the technological singularity lies a fundamentally transformed world, perhaps one dominated by machines that have goals inconsistent with those of humanity. Vinge concluded that if the singularity can happen it will, because the competitive advantage afforded by advances in technology assures their implementation.

Many other analyses of modernity have noted this acceleration and described its personal and social consequences. Theodore Kaczynski, the Unabomber, warned of its actual and impending dehumanizing effects. Alvin Toffler (1970) summed up this wider rendition of speed with his coinage "future shock," as the overwhelming rate of change transforms institutions, shifts values, and undermines cultural and personal foundations. Toffler argued that the rate of change can be even more important than the direction of change in terms of psychological and social impacts. With his concept of "cultural lag," William F. Ogburn (1922, revised 1950) focused more on differential rates of change between interdependent parts of society. For example, science and technology usually operate at a much faster—though in his 1950 revised version, Ogburn admitted it might not be an ever increasing—rate than cultural beliefs and social institutions. Deborah G. Johnson (2001) argued that this differential speed creates "policy vacuums" as social decisions lag behind technological innovation. The French essayist and urbanologist Paul Virilio (1995) similarly claimed that immediacy and instantaneity present the most pressing challenges and ethical concerns at the personal, economic, political, and military levels.

Perception and Experience

In a psychological and even existential sense the perception of relative speeds is rooted in the workings of human consciousness. Oliver Sacks (2004) noted how early psychologists used developments in cinematography to elucidate the perception of time. Late-nineteenth-century innovations in cinecameras allowed photographers to register larger or smaller numbers of events over a given period by adjusting the frames exposed per second. This allowed them to capture the frenzied flapping of bees' wings or the slow unfurling of fern crosiers and re-present them at the rate of normal human perception.

In his *Principles of Psychology* (1890), William James (1842–1910) used the metaphor of altering the frames per second exposed to light to explain the human perception of time. If we were able to process 10,000 events per second instead of the usual ten, then time (measured, as it must be, by our experiences or sense impressions of the world) would slow down. So too, if we were able to process only one-thousandth of the sensations per second than normal, then time would speed up. In the former case, the sun would stand still. In the latter case, mushrooms would spring up and shrubs would rise and fall like restlessly boiling water. Human consciousness is a roll of film spinning at such a rate as to expose a certain number of frames per second, thus giving rise to normal perceptions of time and the speed, as it were, of human awareness or being.

Later sensory psychologists have examined cases of aberrant time perception. For example, several subjects have reported a tremendous slowing of time when suddenly threatened with mortal danger. The metaphorical explanation often proposed for these phenomena is that the human brain, in moments of extreme stress, is able to reduce the duration of individual frames and expose more of them per second. This accelerates thought and increases the speed of decision-making capabilities. From a physiological perspective, such instances may result from a flood of excitatory or a relaxation of inhibitory neurotransmitters.

Certain drugs also provide departures from normal time. Hashish makes events appear to slow down, whereas mescaline and amphetamines accelerate them. Indeed the latter drug is commonly referred to as "speed," indicating the subjective, phenomenological quality of time as a function of brain chemistry and consciousness. Sacks notes there are persistent disorders of neural speed, some of which can be caused by encephalitis lethargica and Parkinson's disease. Some patients can experience radical slowing of thought and movement, which can sometimes be reversed by reducing dopamine deficiencies with the drug L-dopa.

On another experiential level, Virilio states that the primary consequences of the increasing speed of modern life are personal, amounting to disorientation concerning reality. He argues that the globalized, instantaneous flows of information in cyberspace undermine the deep-seated spatial and temporal anchors of the human experience. His views find support, for example, in the way that some virtual relationships have led to tragic decisions by teenagers who become victims of sexual predators on the web. The lightning speed of cyberspace communications has undoubtedly altered fundamental human experiences such as love and intimacy. In many urban areas the Internet is reshaping dating and courtship. Love at hyperspeed brings conveniences by matching supply and demand in a more systematic fashion than haphazard meetings, but it also shifts the meaning of relationships in ways that require personal and social adjustment.

The speed of Internet and satellite communication provides the benefit of instantaneously connecting loved ones separated by great distances. Cyberspace, however, may give only a false sense of closeness. For example, the members of a suburban family in the United States usually have hectic schedules that scatter them significantly in physical space and, when by means of a cell-phone family plan, computer messaging, or both, they succeed in communicating mostly on-the-go, this form of communication eclipses more traditional ones occurring in such shared places as the dinner table or the living room.

It is nevertheless important not to romanticize the past. At least since the 1950s in industrialized countries, family time and communication between fathers and their children were infrequent in many households. The increase of dual-income families and the rise of television viewing have further undermined family intimacy. Nonetheless, the experience of cyberspace communications is qualitatively different in that the interlocutors' bodily presences and languages are absent from voice or text messages.

Despite variances in the range of speeds at which human thought can operate, there are basic neurological determinants that limit human cognitive capacities (e.g., serial computations, recognition, and associations). These limits are frequently tested by the accelerated flows of information and technical change in modern life, but drugs, supplements, and perhaps even neural human–computer interfaces may be able to expand cognitive processing speeds. Cognitive prostheses can improve human cognition, much as eyeglasses improve vision. For example, an airplane cockpit display has been developed that shows crucial information so that a pilot can understand what the aircraft is doing in a fraction of a second instead of the usual few seconds (Bower 2003). Such technologies are based in human cognitive studies research on information processing and visual tracking.

There is, however, controversy about whether such mind-expanding devices are a blessing or a curse, because they bring about even greater pressures by increasing the speed of information processing. This raises the stakes in case of human or machine error. Beyond concerns of safety, however, these actions raise profound issues about how humans synchronize with nature and society. Toffler (1970) echoed the sentiments of many critics of modernity by suggesting that there is something dangerous and even alienating about the rapid tempo of change. Individuals and society are maladapted to such breakneck speeds, and we require social and personal mechanisms to regulate change and decelerate it to a more human pace.

Economic Consequences

At least since Karl Marx's critique of industrial capitalism in the mid-nineteenth century, many theorists and workers alike have disparaged some of the effects of greater speed introduced into manufacturing processes by automated production equipment. They argue that these devices should conform to the humans operating the equipment, not the other way around; otherwise, increased speed jeopardizes the physical and mental health of workers. Critics also point out that these changes often involve exploitation by decreasing bargaining power, pay, status, and/or self-esteem. The increased speed and efficiency of machines has also caused unemployment as human workers become less profitable. Tracking the economic consequences of technological innovation is difficult, however, because it often creates new employment opportunities elsewhere.

The increased speed of financial and economic activity raises more concerns than just competitiveness versus risks to physical and mental health. Indeed, on a larger scale, it could be argued that the competitive profit motive driving capitalism is a major cause of the accelerating pace of modern life. Internet transactions have globalized financial markets as investments can be made at the speed of light and funds shuffled between countries at the press of a button. Transnational businesses are able to create information networks that bypass the traditional power of the nation-state. Toffler (1980) noted the rise of "third wave" societies based on information, communication, and technologies operating at rapid speeds. Not only does this shift power in the sense that nonstate actors make more and more major decisions, but it also increases the interconnectivity of third wave countries because communication linkages and knowledge have largely replaced industrial processes as their economic lifelines.

Interconnectivity brought about by increased reliance on swift, automated information technologies allows for a more fluid and responsive economy and greater specialization of production. It also, however, increases volatility and vulnerability to shocks anywhere in the system. This had led some (e.g., Siegele 2002) to propose the need for economic "circuit breakers" to protect global markets from cascading failures. Such precautionary measures and restrictions, however, need to be balanced against the benefits of free flows of global capital. Furthermore, even if the speed and integration of information flows may lead to more sudden downturns, they can increase the rate of economic recovery as well. Nonetheless, economic laws, regulations, and institutions are forced to globalize at the same speed as the technology in order to secure and harmonize economic activities.

The instantaneity of communication has generated the real-time economy, which has large macroeconomic effects and impacts at the level of individual companies. Real-time enterprises, ideally, will be able to monitor internal and external conditions in order to react to changes instantaneously. Through increased communication with customers, they will also be able to rapidly offer new products and services, thus more tightly coupling demand and supply. The flood of information threatens to overload companies, which have responded by developing software to optimize supply chains and automate certain responses to real-time cues.

Rapidly changing markets and technologies increase competitive pressures for firms to increase integration and flexibility, which can lead to organizational problems. The emergence of the real-time economy more directly pins economic vitality on the smooth functioning of integrated technologies. A software virus, for example, could cause massive economic collapse. Ludwig Siegele (2002) offers the conclusion that such drawbacks are not inherent in the technologies, but arise from the way they are used. But he adds, "it is worth asking to what extent we want computers to run our lives" (p. S20).

Cultural benefits are also generated by the speed of new communication technologies. For example, the time gap between the release of a Hollywood movie in the United States and its debut elsewhere in the world has been drastically cut, symbolizing the free flow of art and culture made possible by these new speeds. In some cases this may foster greater cross-cultural understanding and tolerance. Some, however, perceive this as a threat to local economies and cultures, which now must accelerate to keep up with foreign competition. Cultural homogenization may result.

Social and Political Consequences

Economic consequences of increased technological speed spill over into social changes. Harriet B. Presser (1999) noted that the use of rapid communication technologies is one factor in the widespread prevalence of nonstandard work schedules. The globalization of markets and the ability to be "on call" all the time require expanded hours of operation. This affects the family lives of workers and requires social institutions such as daycare to adapt to changing needs. The increased reliance on rapid communication technologies by the military also carries social and political consequences. Such advances in the U.S. military have tested the limits of telecommunication capacity, or bandwidth, which is expensive to expand. Although the real-time information gained can help protect both troops and civilians, politicians face trade-off dilemmas concerning the best investment of public funds.

Real-time politics has brought both beneficial and detrimental effects to democratic processes. The immediacy of citizen participation in government may contribute to political accountability and strengthen civic commitments. For example, the Internet has sparked a new wave of social responsibility by organizing protestors around the world (McPherson and Schapiro 2001). It allows like-minded activists to communicate, build consensus, coordinate activities and information, and provide mutual moral support. Campaigns against "sweatshop" labor have been primarily organized via the Internet. Such forms of communication may even help foster democracies in nations controlled by tyrants. One drawback, however, is that passions unleashed at the speed of the Internet often outstrip facts and evidence, which can delegitimize well-meaning social reformers.

Other negative effects can result from real-time politics. Virilio argues that representative democracy is undermined by the virtualization of government and the rise of opinion democracy patterned on viewer counts and opinion polls. Political leaders may pander to public opinion rather than make unpopular, but perhaps better, decisions. Public opinion polls often reflect short-term interests, whereas leaders must balance these with long-term common-interest goals. The greater speed of communication often undermines careful deliberation and reasoned judgment, but it can also better inform such deliberation. But referendum reforms were altering the balance of participatory and representative democracy before the real-time computerization of politics. So, cyber-speeds may aggravate more than cause this dilemma.

Increasing speed of information flows can exacerbate the complexity and multiplicity of policy issues, leading to issue overload. This is a situation in which the multitude and complexity of issues exceeds what individuals can understand and societies can handle through the courts (leading to court-case overload), legislation (producing tunnel-vision laws), or executive or other institutional channels (Breyer 1993).

On a larger scale, Stewart Brand (1999) argued that the accelerating pace of technological change, the short-term perspective of consumerist lifestyles, and the short-term focus of political election cycles have all eroded the concept of long-term responsibility. The acceleration of experiential time effectively reduces the timescale of interest, thus shrinking the horizon of felt obligation. Brand writes, "Our ever hastier decisions and actions do not respond to our long-term understanding, or to the gravity of responsibility we bear" (p. 8). In order not to be doomed by speed, we must slow down enough to allow time to apply the brakes in case of emergencies.

He proposed a balancing corrective to this shortsightedness to help us accept our long-term responsibilities to nature and future generations. In cooperation with others, Brand founded the Long Now Foundation in 1996 and began to design the Clock of the Long Now, a giant mechanical clock to be set somewhere in the U.S. desert to record time for 10,000 years. The goal is to embody deep time in a way that counterbalances the shrinking timescales experienced by those caught up in the speed of modern life.

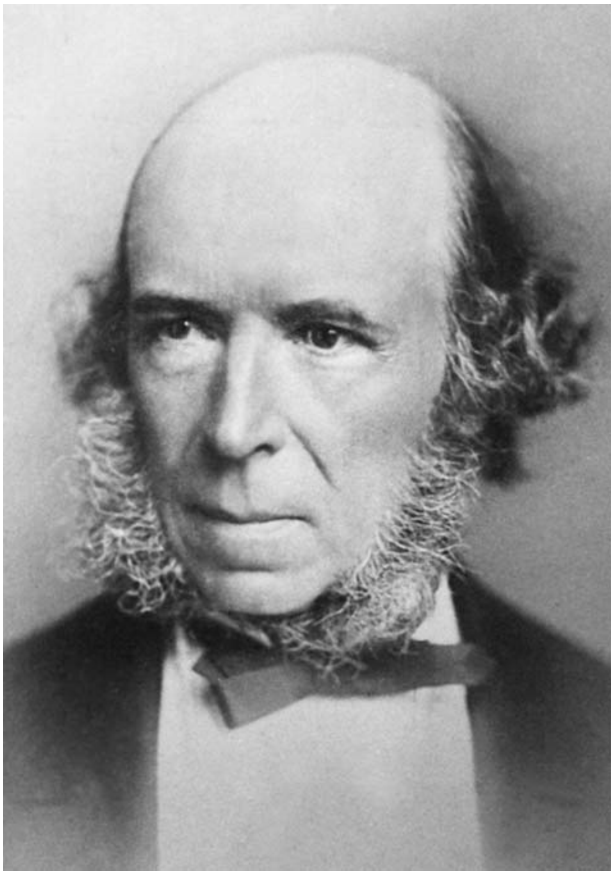
SPENCER, HERBERT

British philosopher and sociologist, Herbert Spencer (1820–1903) was born in Derby, England, on April 27, and became well known for developing and applying evolutionary theory to sociology, philosophy, and psychology. Following an informal education in the anti-establishment views of his father, he briefly trained as a civil engineer before becoming a journalist and political writer. Spencer began writing books in the early 1850s, and presented a systematic and comprehensive account of his views on ethics, sociology (government, politics, and education), and biology in the nine-volume *A System of Synthetic Philosophy* (1862–1893). Although his ideas were influential during the last few decades of the nineteenth century, his reputation subsequently waned. Spencer died in Brighton, England, on December 8.



Herbert Spencer, 1820–1903. Spencer was an English philosopher, scientist, engineer, and political economist. In his day his works were important in popularizing the concept of evolution and played an important part in the development of economics, political science, biology, and philosophy. *(The Library of Congress.)*

Basic Ideas

Spencer's scientific and empirical method exhibits affinities with Auguste Comte's positivism. Central to his approach was the synthetic practice of deriving fundamental principles from disparate phenomena in many sciences and then demonstrating how the principles of one science interact with and affect the other fields of inquiry. Using Charles Darwin's evolutionary theory, Spencer thus constructed a general account of human progress that came to be known as "Social Darwinism."

For Spencer, natural progress was the necessary process of evolution from simple to more complex and heterogeneous forms, but this was not, he insisted, teleological or purpose-driven. Spencer coined the phrase "survival of the fittest," which Darwin employed in later editions of *On the Origin of Species* (first published in 1859), but neither thinker addressed the ambiguity (that is, are individuals, groups, or species the relevant unit of selection?) and near tautology of this phrase ("fitness" is often defined in terms of survival, so that survival of the fittest is akin to saying survival of that which survives the best). Although Darwin admired Spencer, the two disagreed on several aspects of evolutionary theory including the possible inheritance of acquired characteristics.

Human life is on a continuum with the evolutionary unfolding of the natural world, and, because progress toward complexity and individuation are necessary, human nature cannot be thought of as stable and unchanging. Rather, humans are collections of instincts and sentiments that must continually adapt to the changing societal context. Society is likewise an extension of the organic human body and nature. Finally Spencer argued that society too expresses evolutionary laws or principles that can serve as the foundation of morality and law. Evolutionary science, then, serves as the base of his comprehensive natural law philosophy of morality and politics and explains how *The Principles of Biology* (1864, 1867) flows naturally into the conclusions reached later in *The Principles of Sociology* (1882, 1898) and *The Principles of Ethics* (1892).

Spencer believed that modern evolutionary science had weakened traditional beliefs in ethics as a supernatural code of divine commandments. Science could fill this ethical vacuum left by religion, by providing the principles from which to deduce a naturalistic ethics of rational egoism. Science ought, therefore, to command the dominant position in education, displacing art and the humanities (1861). Spencer reconciled the apparent contradiction between his naturalized, a-teleological laws of society and morality, on one hand, and human freedom and purpose, on the other, by arguing that it is precisely individual freedom that alone can guarantee continued evolutionary progress. Indeed for Spencer, individual liberty is primary and relations with others are largely contractual, made from the realization that social life is necessary to reach certain individual goals.

Furthermore, in a move that is similar to John Stuart Mill and the logical commitment implied in Alan Gewirth's "principle of generic consistency," Spencer claimed that morality contains a "law of equal freedom." This law states that individuals must recognize the individuality of others and curtail their freedom so as not to infringe on the freedom of others. This sort of minimalist, contractual view of society underpins his *laissez faire* political philosophy from *Social Statics* (1851) to *Man versus the State* (1884). The state's function is condensed to dispensing justice, which amounts to protecting individual rights. These rights follow naturally from the law of equal freedom, because the recognition of others' individuality immediately implies the duty to recognize their rights.

Decline and Continuing Influence

Spencer's decline can be attributed to several inconsistencies in his work, growing social unease with founding society on evolution, social rejection of his strongly libertarian principles, and the demise of any residual scientific belief in the inheritance of acquired characteristics. Yet some of Spencer's voluminous thoughts continue to be of influence. His work on intellectual and physical education has left deep imprints on modern curricula. His political thought, especially his defense of natural rights, has been invoked by libertarian philosophers such as Robert Nozick. And Spencer's idea that nature shows a progressive trend toward increased complexity of organization has been revived by some biologists and social theorists. Robert Wright (2000) argues that evolution tends to produce ever more complex forms of life, because cooperation through expanded forms of organization produces selective advantages. In human social evolution, this explains the move from primitive hunting-gathering tribes to large states and finally to global systems. New technologies—such as the agricultural production of food or the transmission of information through computer networks—make possible wider forms of social cooperation.

The evolutionary theorist Stephen Jay Gould (1989) nevertheless rejected Spencer's idea of progressive evolution and argued instead that the history of life is a random process that could have turned out differently. By contrast paleobiologist Simon Conway Morris (2003) sees evidence for evolutionary patterns inclined to produce intelligent life. If Gould is right, then the human sense of purpose has no ontological support. If Conway Morris is right, human purposefulness might fulfil an end inherent in the universe from the beginning. The fundamental issue—with deep moral and religious implications—is whether the universe is pointless or purposeful. This was also the central tension underlying Spencer's lifelong attempts to bridge the natural and the human worlds.

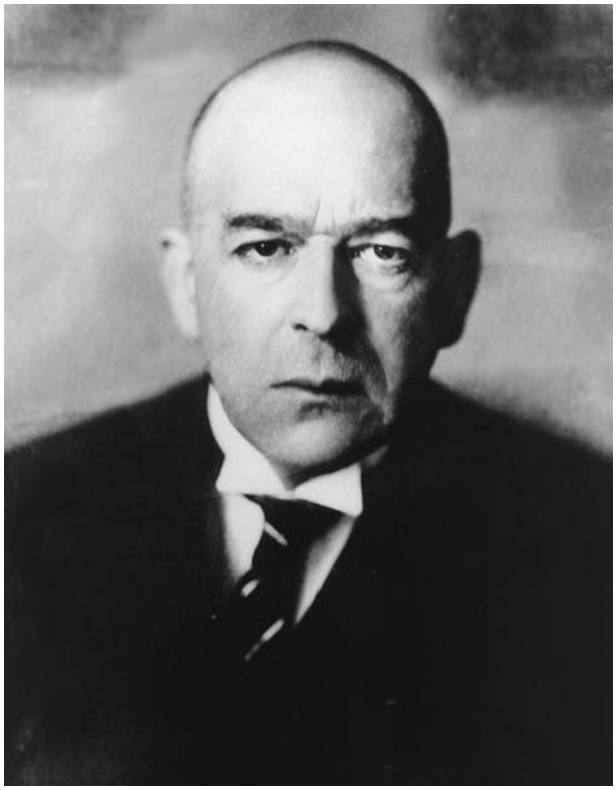
SPENGLER, OSWALD

Oswald Spengler (1880–1936) was born in Blankenburg, Germany, on May 29, and attended the universities of Munich, Berlin, and Halle, where he studied mathematics and the natural sciences, which led to his becoming a secondary school teacher of mathematics in Hamburg. He abandoned teaching in 1911 to work on his magnum opus—*The Decline of the West* (1918–1922)—which he did steadily during the World War I. He intentionally published the first volume to coincide with the German military defeat and industrial collapse of 1918, and the second four years later. From this time until his death in Munich on May 8, he wrote other, shorter books and pamphlets on social and political subjects, including *Man and Technics* (1931).

Despite his marginal status in the German academic world and the controversy with which his ideas were greeted, Spengler's influence on social science was far greater than that of those who tried furiously to refute him. His impact derives from the fact that in examining the nature of Western Europe and North America he makes predictions about its future, drawing inferences based on a metaphysical reading of history during a period of serious crisis.

The key to Spengler's philosophical anthropology and accompanying philosophy of history is his use of the Faustian legend in popular German literature to interpret modern technology. According to him, humans are the only predators able to select and design weapons for attacking nature and each other. At some point around the tenth century this ability developed to such an extent in Western European culture that humans seized for themselves the prerogatives of domination over nature. This inexorable destiny is a radical break with earlier periods of thought, in which humans saw themselves as subject to nature; yet it was a destiny made possible by nature, when nature gave human beings both mental superiority and hands. The hands are fundamentally weapons. More than a *tool of tool,* as described by Aristotle, the hand perfects itself in conflict more than manufacture. Indeed just as Spengler interprets the plough as a weapon against plant life, so he sees instruments of worship as arms against the devil. But Spengler does not confuse technology with tools or technological objects. Technology is a set of procedures or practical means for producing a particular end in view. In Spengler's words, technology *is the tactics of living,* a conception that goes beyond human life. Following Friedrich Nietzsche, he identifies life with struggle, a fierce and merciless struggle that springs from the will to power, with the machine being the *subtlest of all possible weapons*.



Oswald Spengler, 1880–1936. The German philosopher is famous for his *Decline of the West*. He held that civilizations, like biological organisms, pass through a determinable life cycle and that the modern West was approaching the end of such a cycle. (© *Corbis-Bettmann.)*

Having placed the origin of Faustian culture in the Nordic countries, Spengler interprets the Enlightenment as the moment when the machine replaced the Creator. The machine became a god, with factories for temples and engineers for priests, whose mysteries were the esoteric features of mechanization. Nineteenth-century machine age industrialization imposed itself on nature with standardized, inert forms that are hostile to the natural world and the precursors of decline. But in order to feed the *technological-machinist army* Western Europe and North America furthered the destruction of nature across the globe, creating an untameable monster that threatens to conquer humans themselves and lead culture to a grandiose suicide. The tragedy of humanity lies in humans raising their hands against their own mother—nature. All the great cultures defeats. The struggle against nature is a struggle without hope, even though people pursue it to the end.

Contrary to the views of Enlightenment theorists such as Henri de Saint-Simon or Auguste Comte, the domination of nature by Faustian technology does not seek human emancipation, but is the manifestation of a blind will to power over the infinite. As Hermínio Martins (1998) argues, Spengler rejects the rationality of technological history. The history of Western European and North American technology is simply human tragedy because the infinite is always greater than efforts to tame it. Inspired also by Nietzsche's cyclic vision of history, Spengler sees culture, rooted in the soil, being replaced by civilization, in which the intellect prevails, decaying again eventually into culture.

The significance that Spengler attributes to technology, his defense of science-as-technology, his cultural pessimism, and his hostility to liberal, democratic values and institutions were commented on by Max Weber, and influenced thinking during the Nazi regime, despite the fact that he rejected national socialism completely in 1934. Many of his insights and expressions regarding the essentially non-transferable character of Western European and North American technological culture as a destiny, the will to power as the foundation of technology, and the conceptual and ontological dependency of science on technology are further echoed in Martin Heidegger and Ernst Jünger, as well as in some members of the first generation of the Frankfurt school.

SPORTS

Ethical issues related to science and technology in sports only began to attract critical attention during the second half of the twentieth century. This paralleled the increasing scientific study of sports and the creation of sports science, as well as the discovery and development of performance enhancing drugs and technological transformations in sports equipment. The latter two influences have been especially problematic, and have played a central role in the emergence of critical studies in the field.

Modern Sports Development

This scientizaton reflects a shift in values concerned with sports. Allen Guttmann describes, in *From Ritual to Record* (1978), how the development of timing technology introduced the possibility of records, now a dominant feature of modern sports. The late-nineteenth century British public school games, which championed *muscular Christianity,* repositioned physical exertion as central to the development of a productive and civil society. It also led to the politicization of sports and, along with the revived modern Olympic movement, which began in 1896, steadily became a focus of international political propaganda. With a philosophy that champions humanistic virtues of peace, culture, and education, the modern Olympic movement is less about sports contests than about ideology. It occupies an ambiguous social position as an organization that has devalued amateurism and embraced commercialization, while maintaining that there is something philosophically and socially meaningful about the games.

Ethical discussions concerning technology in sports generally focus on establishing what constitutes just or fair competition. The limited accessibility of a technology is often used as a reason for prohibiting its use in competition. In addition if the use of a particular innovation contravenes the agreed upon rules, that use may also be unethical. However because disputes exist as to what rules have been agreed to, the ethical issues are often blurred.

Drugs and Sports

During the 1980s, concerns about technology in sports focused largely on technologies of doping and drug use. This was prompted by a series of doping incidents in international sports, some of which resulted in death or serious injury for a number of athletes (Brown 1980, Houlihan 2002). The situation was accentuated by high-profile cases, for example that of the Canadian runner Ben Johnson who was stripped of the gold medal he won at the 1988 Olympics in Seoul after testing positive for anabolic steroids. Discussions about doping continue, accentuated by the emergence of new technologies, such as genetic modification, that challenge the ability of anti-doping authorities to detect *cheaters* (Miah 2004). Gene doping could challenge ethical theories in sports: Are genetically enhanced athletes cheats if they are altered before birth (embryogenesis)? Also if the genetic technologies at issue are not harmful to athletes, there is no persuasive health argument to support a ban on their use.

Sports Artifacts

Beyond doping, the increased use of technology and technologically advanced artifacts in sports raises a number of ethical questions (Miah and Eassom 2002, Gelberg 1998). Innovative techniques have radically changed some sports or events, such as the Fosbury flop in high jumping or the O'Brien shuffle in shot put. These have been seen as ethically contentious, though legitimate, because they increased the demands placed on athletes in competition.

Since the late-twentieth century, events in the sporting world have clearly illustrated the ethical implications that arise from the use of technology in sports. A few examples are the development of running shoe technology; lighter and stronger implements, such as golf clubs, cricket bats, and tennis rackets; and innovations such as the Fast-Skin swimming suit, which was used for the first time at the 2000 Olympics in Sydney. Many new sports technologies have been accepted. Technologically advanced running shoes, tennis rackets, bicycles, golf clubs, and others have been identified as beneficial improvements to sports because they enhance the safety of an activity or allow athletes to perform without interference from inadequate, cumbersome technology.

Technology has even democratized participation in sports to some extent, with the mass production of equipment permitting more people to play sports with the same kind of equipment used by elite athletes. However, this has also carried a burden of making elite sports subservient to the public or more specifically, sport spectators. Television audiences often dictate scheduling for competitions, which raises problems for sports federations, because so-called prime-time television schedules can conflict with the time of day when it is most desirable for athletes to compete.

One of the central components of these ethical discussions is the degree to which technologies are replacing the athlete in performance or are dehumanizing sports (Hoberman 1992). For example, double-stringed (so-called spaghetti strung) tennis racquets were banned in the 1980s because they offered too much performance enhancement by enabling athletes to exert an unusually high amount of spin on the ball. There is an ethical concern about the *means* that allow athletes to achieve high levels of performance: An *undeserved enhancement* is considered unethical. Yet it can be argued that sports performances are necessarily technological and athletes must embrace their cyborgian identities by recognizing technology as a valued aspect of their performance.

When technology appears to make a sport easier for athletes, thus seemingly undermining or *devaluing* the performance, there are also ethical issues raised. Of key importance is what is meant by devaluing sports, because it is possible that technology could also be described as removing performance inhibitors, which is desirable when such inhibition is athletically irrelevant. For example, highly sophisticated running shoes might appear to enhance performance, or alternatively can be said to reduce inhibitions caused by the natural weakness the human foot.

This argument requires determining the factors that are *athletically relevant* to specific sports, an often contentious issue that can appeal to definitions of the goals of sports (Suits 1973). Do piezoelectric circuits in skis remove a performance inhibitor or make the activity unacceptably easier? The technology is designed to reduce the vibrations felt by skiers, thus giving them better control. It can certainly be argued that the new technology has made the activity easier because athletes no longer have to deal with the same degree of vibration as before. However it can also be argued that vibration is an irrelevant aspect of skiing—skiing does not test the ability of athletes to cope with vibration—and thus that the technology is not ethically suspect. Breaking records in the wake of technological advances in a particular sport suggests that an activity has become easier as a result of the innovation or that the advances have contributed to enhanced performance. It is, however, sometimes more accurate to conclude that the new technology has enabled a more representative measure of athletic performance.

Other ethical discussions involve whether technology changes the nature of the sport. For example, despite having sanctioned many changes to the construction of competitive bicycles, the International Cycling Union (ICU) banned Graeme Obree's *superman* design, in which one rides with arms stretched out in front of the body (like Superman), crouched over the handlebars. The ICU justified the ban by arguing that the new design would be generally unavailable, and thus the competitive sport would actually be different than the *normal* cycling experienced by the average rider. The ban seems to have been imposed because the innovation created a new concept of what constituted cycling, which conflicted with some kind of traditional, ideal form.

However some technological changes are beneficial to sports and disallowing them because they change traditional concepts is wrong. Changes to the construction of the javelin in the 1980s paved the way for a new type of successful participant, as opposed to the athletes who had been traditional winners in the event. However without such changes the natural progress of the sport would have resulted in athletes throwing the javelin into the audience, possibly requiring elimination of the activity from track and field competitions.

Conclusion

Alasdair MacIntyre's (1985) articulation of practice communities, which discusses the intrinsic good of sports and the distinction between novice and expert, is a useful retheorization of sports values (Morgan 1994). William Morgan's thesis is an explanation of the political economy of sports and the problematic hierarchical structures that have marginalized specific voices within specific practice communities. According to Morgan, there are two possibilities when sports are altered through technological developments. Society must either redescribe the activity—such as in the case of the javelin throw when the sport changed to sustain its character. Or society must accept the emergence of cyborg-athletes, which entails a redefinition of what it means to be a human being. By offering a subtle shift in the perception of humanness, sports provide an arena in which what it means to be human, as a living being and as an athlete, is ambiguous, liberated, and technologized.

STAKEHOLDERS

The stakeholder concept derives from a simple premise: Organizations and technologies exist in constellations of relationships. Organizations operate in a network of market and nonmarket relationships with other organizations, groups, and individuals. Likewise technologies emerge and exist in a network of suppliers, end users, and others who bear the impact of the technology. Generally with reference to both organizations and technologies, these related parties are termed *stakeholders*, meaning that they hold a stake in the outcomes of the organization or technology.

Stakeholder research has important implications for science, technology, and ethics, as stakeholder thinking concerns itself both with the distribution of benefits among stakeholders and the procedures by which stakeholders work together toward desirable ends. After a brief history of the concept, this entry summarizes the distributive and procedural aspects of stakeholder thinking, particularly as they apply to three areas: corporate decision making, technology assessment, and environmental regulation.

History of the Concept

The stakeholder concept has its origins in the study of corporations and how they make decisions. R. Edward Freeman's *Strategic Management: A Stakeholder Approach* (1984), is regarded as seminal in the study of stakeholders, though Freeman attributes the term to scholars at the Stanford Research Institute in the 1960s. Farther back still, the premise that organizations must concern themselves with the demands of multiple constituencies traces back to classic management studies by Chester Barnard and Mary Parker Follett.

Contemporary discussions of stakeholders address three main questions. Social scientists have examined two. First, what are the consequences of different approaches to managing stakeholder groups? For example, Thomas Jones (1995) argues that a corporation's ethical treatment of its stakeholders has demonstrable financial implications. Second, why do stakeholder groups behave the way they do? For example, Tim Rowley and Mihnea Moldoveanu (2003) trace collective action by stakeholder groups to both the interests and the collective identity of group members. Put simply, the first question concerns the *instrumental* value of managing stakeholders effectively; the latter is a *descriptive* question aimed at helping decision makers to understand the environment in which they operate (Donaldson and Preston 1995).

Philosophers have concentrated on a third and equally important question: How should corporations behave toward stakeholders? This inquiry reflects the essentially normative nature of the concept—the term *stakeholder* itself serves as a counterpoint to the claim that corporations are responsible only to their stockholders—and has given rise to the search for a so-called *normative core* for stakeholder theory, a fundamental set of principles governing the ethical treatment of stakeholders (Donaldson and Preston 1995). Drawing on a host of ethical theories, ethicists have developed Kantian, feminist, rights-based, and Rawlsian arguments, among others.

The Distributive Dimension

In practical terms, much stakeholder research (especially in the third, normative, stream) addresses the issue of distribution: how corporations, public policy makers, and technology managers allocate rights and values across multiple stakeholders. Normative stakeholder arguments offer ways to assess the moral quality of these distributive patterns, and these arguments have important implications for ethical issues in the realm of science and technology.

For example, the question of who should benefit from emergent technologies—nanotechnology, pharmaceutical advances, and the human genome, among others—is, at its core, a question of distribution (Singer and Daar 2001) that stakeholder theory helps to resolve. Specifically the principle of stakeholder fairness developed by Robert Phillips (2003) derives from a widely accepted notion of reciprocity and holds that obligations accrue to participants in a cooperative scheme in proportion to contributions by stakeholder groups.

This logic also applies to the less tangible benefits and costs of technology. An emerging issue concerns the steps technology managers take to prevent employees from inappropriately using information technology resources such as e-mail and the Internet. The conflict is not over material resources but rather the tension between the privacy rights of employees, who seek to use these resources for personal reasons without the threat of invasive monitoring, and the property rights of stockholders, who would bear the cost of lawsuits if inappropriate technology use results in hostile work environment lawsuits. An exclusive emphasis on stockholder interests might advocate a total ban on the use of these technologies for nonbusiness purposes, whereas stakeholder theory would suggest a moderate position, allocating rights proportionally and allowing, for example, some personal use of information technology resources along with unobtrusive forms of monitoring to protect stockholder interests.

The Procedural Dimension

Stakeholder research also addresses procedural concerns that are central to the application of stakeholder theory to science and technology. Evan and Freeman (1993) draw on a Kantian perspective to spell out principles specifying how corporations should engage with stakeholders. They suggest, in part, that stakeholders have a right to participate in decisions that affect them. This concern for procedural justice extends to decisions in the realm of science and technology, where technologies, development paths, and potential science-related policies must be evaluated in light of stakeholder interests. Consequently one finds frequent reference to the procedural aspects of stakeholder theory in the areas of technology assessment and environmental regulation. Here stakeholder theory maintains that those groups with a vested interest in a technology, action, or organization should have an opportunity to express those interests and, in some cases, to participate in decision making. As some have argued, this participation should take the form of comprehensive dialogue among various stakeholder groups .

As diverse development agencies, corporations, and government regulators (from the United Nations to the World Bank to Motorola Corporation) apply these procedural principles by initiating dialogue with stakeholders concerning new technologies and environmental policies, they discover that the procedural aspect of stakeholder management is not only ethically desirable but highly practical. As stakeholder thinkers have long maintained, sharing information, ongoing dialogue, and meaningful participation in decision making enables better collaboration, reduces conflict, and ensures smoother implementation of policies and technologies (Freeman 1984, Johnson-Cramer, Berman, et al. 2003).

In sum, the value of stakeholder theory in resolving ethical issues in science and technology lies, to date, in offering prescriptions (a) that answer the distributive questions arising from development, utilization, and marketing of new technologies by businesses, and (b) that guide the procedural treatment of stakeholders in diverse areas such as technology assessment and environmental regulation. Ultimately amidst efforts to develop general principles and insights, stakeholder researchers have done little to apply their insights to specific questions about science and technology. The potential is clear, but much work remains to be done to demonstrate the usefulness of stakeholder theory in this domain.

STATISTICS

• • •

Basic Concepts of Classical Inference
History, Interpretation, and Application

BASIC CONCEPTS OF CLASSICAL INFERENCE

Statistics may be defined as the study and informed application of methods for drawing conclusions about the world from fallible observations. It has three distinct components: (1) It is based on the mathematical theory of probability, (2) as inductive inference it belongs to the philosophy of science, and (3) its subject matter is any of a wide range of empirical disciplines.

Humanity has been counting, measuring, and recording from antiquity, but the formal history of statistics dates to the first systematic analyses of official registries in the seventeenth century. The origin of the name is from the eighteenth century, the German *Statistik*, meaning "study of the state" or political science (generally qualitative). It was appropriated in the 1780s for use in English as *statistics*, an unusual new name for the quantitative analysis of conditions in a country (replacing *political arithmetic*), in order to attract public attention (Pearson 1978). Applied subsequently to measurement error in astronomy, the statistical approach using probability spread in the nineteenth century to social phenomena, to physics, and then to biology. Formal statistical inference came into being around the turn of the twentieth century, motivated in large measure by the study of heredity and evolution.

Intensive developments of theory and methodology, with the enormous impact of the electronic computer, have made statistics the most widely used mathematical discipline, applied to virtually every area of human endeavor. Analysis and interpretation of empirical results is basic to much of modern technology and the controversies surrounding its use. Statistical methodology, readily available in computer software packages, is easy to apply but not so easy to understand. Lack of professional competence, conflicts of interest, and oversimplified reporting by the media pose real dangers of abuse. Yet intelligent participation in the shaping of public policy requires the insights of a thoughtful, well-informed electorate.

There is a vast and constantly growing body of statistical methods, but the most commonly reported results employ the classical, or Neyman-Pearson, theory of statistical inference. Presented herein are the basic concepts of the classical theory in concise form. Further details, with many examples, can be found in textbooks on various levels of mathematical sophistication.

Descriptive versus Inferential Statistics

Statistics can be understood as descriptive or inferential. *Descriptive statistics* are methods for organizing, summarizing, and communicating data, or the data themselves. The resulting tables and graphs may represent complete information on a subject or only a selected sample. *Inferential statistics*, the subject here, refers to methods for reaching conclusions extending beyond the observations actually made, to statements about large classes of potential observations. It is inference from a sample, beyond its description.

From Sample to Probability

Statistics begins with data to explore a question about some large *target population* (of people or objects) that can be expressed in quantitative form. It is often impossible to observe the entire population of interest, and therefore a sample is selected from the best available, sometimes called the *sampled population*, to distinguish it from the target population.

RANDOM SAMPLE. The sample, on which the inference will be based, should be representative of the population, and thus be selected at random. This means that each member of the population should have an equal chance of being selected—an aim that in real-life situations can at best be approximately met. For example, to determine what proportion of patients with a certain type of cancer would benefit from a new treatment, the outcome of interest could be the proportion surviving for one year after diagnosis, with the study sample drawn from patients being seen in a particular hospital. The representativeness of the sample is always a key question in statistics.

STABLE RELATIVE FREQUENCY. It is known from experience that the observed proportion of a characteristic of a population becomes stable with increasing sample size. For example, the relative frequency of boys among the newborn fluctuates widely when studied in samples of size 10, and less so with samples of size 50. When based on samples of size 250, it is seen to settle just above .5, around the well-established value of .51. It is the observed stability of frequency ratios with increasing sample size that connects statistics with the mathematical concept of probability.

FREQUENTIST DEFINITION OF PROBABILITY. Classical statistical inference uses the *frequentist* definition of probability: The probability of an event denotes the relative frequency of occurrence of that event in the long run. This definition is reflected in a fundamental principle of probability, the *law of large numbers:* In the long run, the relative frequency of occurrence of an event approaches its probability. The probability may be known from the model, such as obtaining a six with a balanced die, namely 1/6. This is an example of the classical definition of probability, pertaining to a finite number of equally likely outcomes. Otherwise by definition the probability is whatever is obtained as long-run relative frequency. The size of the sample is of central importance in all applications.

The frequentist definition is embedded in the axiomatic approach to probability, which integrates statistics into the framework of modern mathematics. There are three basic axioms, using concepts of the theories of sets and measure. Expressed simply, the axioms state that: (1) the probability of any event (set) in the sample space of events is a number between 0 and 1, (2) the probability of the entire sample space is 1, and (3) if two events are mutually exclusive (only one of them can occur), then the probability that one or the other occurs is the sum of their probabilities.

RANDOM VARIABLES AND THEIR DISTRIBUTIONS. The numerical or coded value of the outcome of interest in a statistical study is called a *random variable*. The yes/no survival status of a cancer patient one year after diagnosis is a *binary* random variable. In a sample of size n, the number of patients surviving is some number S_n between 0 and n, called a *binomial* random variable. S_n/n is the relative frequency of surviving, and $1 - S_n/n$ the relative frequency of not surviving one year. The distribution of S_n, to be discussed below, is the binomial distribution showing the probabilities of all possible outcomes between 0 and n. An example of a *continuous* random variable X is the diastolic blood pressure (in millimeters of mercury) of patients treated for hypertension, at a given point of treatment. The relative frequency of different values assumed by X is the observed distribution of the random variable.

The concrete examples of a random variable and its distribution have direct counterparts in the mathematical theory of probability, and these are used in the development of methods of inference. A random sample of size n in statistics is considered a sample of n independent, identically distributed random variables, with independence a well-defined mathematical concept. These are abstract notions, often omitted in elementary presentations that give only the computational formulas. But they are the essential link for going from an observed set of numbers (the starting point of statistics) to mathematical entities that are the building blocks of the theory on which the methods of statistics are based.

PARAMETERS OF A DISTRIBUTION. The *probability distribution* of a random variable X describes how the probabilities are distributed over the values assumed by X along the real line; the sum of all probabilities is 1. The distribution is defined by *parameters*, constants that specify the location (central value) and shape of the distribution, often denoted by Greek letters. The most commonly used *location* parameter is the *mean* or *expected value* of X, $E(X)$, denoted by μ ("mu"). $E(X)$ is the weighted average of all possible outcomes of a random variable, weighted by the probabilities of the respective outcomes. A parameter that specifies the *spread* of the distribution is the variance of the random variable X, Var(X), defined as $E(X - \mu)^2$ and denoted by σ^2 ("sigma square"). It is the expected value of the squared deviations of the observed values from the mean of the distribution. The square root of the variance, or σ, is called the *standard deviation* of X.

THE BINOMIAL DISTRIBUTION. An important distribution deals with counting outcomes and computing proportions or percentages, often encountered in practice. Independent repetition of an experiment with a binary outcome and the same probability p of success n times yields the *binomial distribution* specified by the parameters n and p. The random variable X, defined as the number of successes in n trials, can have any value r between 0 and n, with probability function

$$P(X = r) = C(n, r)p^r(1 - p)^{n-r},$$

where $C(n, r)$ is the combination of n things taken r at a time and has the form

$$C(n, r) = \binom{n}{r} = \frac{n!}{r!(n - r)!}.$$

($n!$, called "n factorial," is the product of integers from 1 to n, with $0! = 1$. For example, $4! = 1 \times 2 \times 3 \times 4 = 24$.) It can be shown that for a binomial random variable, $E(X) = np$, and $\mathrm{Var}(X) = np(1 - p)$. As the sum of n outcomes coded 0 or 1, X is also denoted by S_n.

THE NORMAL DISTRIBUTION. The most basic distribution in statistics is the *normal* or *Gaussian distribution* of a random variable X, defined by the probability density function

$$f(x) = \frac{1}{\sqrt{2\pi}\sigma} e^{-\frac{(x-\mu)^2}{2\sigma^2}},$$

where μ is the mean and σ is the standard deviation. The formula includes the constants $\pi = 3.142$ and $e = 2.718$, the base of the natural logarithm.

One reason for the importance of this equation is that many variables observed in nature follow an approximate normal distribution. Figure 1 shows frequency histograms of two samples, of height and diastolic blood pressure, with the corresponding normal distribution. The smoother fit in Figure 1a is the result of the

FIGURE 1

far larger sample size as compared with the number of observations used in Figure 1b.

THE STANDARD NORMAL DISTRIBUTION. An important special case of the normal distribution is the *standard normal*, with mean 0 and standard deviation 1, obtained by the transformation

$$Z = \frac{X - \mu}{\sigma}.$$

Any normal variable can be transformed to the extensively tabled standard form, and the related probabilities remain the same. Figure 2 shows areas under the normal curve in regions defined by the mean and standard deviation, for both the X-scale and Z-scale. It is useful to remember that for a normally distributed random variable, about 95 percent of the observations lie within two standard deviations of the mean.

THE SAMPLE MEAN. Statistical inference aims to characterize a population from a sample, and interest is often in the *sample mean* as an estimate of the population mean. Given a sample of n random variables $X_1, X_2, \ldots, X_n$, the sample mean is defined as

$$M = \bar{X} = \frac{X_1 + X_2 + \cdots + X_n}{n}.$$

If the variables are independently distributed, each with mean μ and variance σ^2, then the *standard error of the mean* is

$$SE = SE(\bar{X}) = \frac{\sigma}{\sqrt{n}}.$$

For simplicity of notation, the symbols M and *SE* are used below.

THE CENTRAL LIMIT THEOREM. The normal distribution plays a special role in statistics also because of the basic principle of probability known as the *central limit theorem:* In general, for very large values of n, the sample mean has an approximate normal distribution. More specifically, if $X_1, X_2, \ldots, X_n$ are n independent, identically distributed random variables with mean μ and variance σ^2, then the distribution of their standardized mean

$$\frac{M - E(M)}{SE} = \frac{\bar{X} - \mu}{\sigma/\sqrt{n}}$$

tends to the standard normal distribution as $n \to \infty$. Nothing is said here about the shape of the underlying distribution. This principle, observed empirically and proved with increasingly greater precision and generality, is important to much of statistical theory and methodology.

APPLICATION TO THE BINOMIAL DISTRIBUTION. In the case of the binomial distribution, where $X = S_n$ is the sum of n independent random variables with outcomes 0 or 1,

$$M = \frac{S_n}{n} \text{ and } E(M) = p,$$

$$\mathrm{Var}(M) = \frac{p(1-p)}{n} \text{ and } SE = \sqrt{\frac{p(1-p)}{n}}.$$

a. Two-sided test (both tails of distribution)
b. One-sided test (either upper or lower tail)

SOURCE: Courtesy of Valerie Miké.

By the central limit theorem, the distribution of the standardized mean

$$\frac{M - E(M)}{SE} = \frac{S_n/n - p}{\sqrt{p(1-p)/n}}$$

tends to the standard normal distribution as $n \to \infty$. (The approximation can be used if both $np > 30$ and $n(1 - p) > 30$. A so-called continuity correction of $-1/2n$ in the numerator improves the approximation, but is negligible for large n.)

Inference: Testing Statistical Hypotheses

Performing tests of statistical hypotheses is part of the scientific process, as indicated in Table 1, ideally with the professional statistician as member of the research team. The conceptual framework of subject matter specialists is an essential component, as is their close participation in the study, from its design to the interpretation of results.

FORMAL STRUCTURE. The formal steps of testing, summarized in Table 2, involve defining the null hypothesis, denoted H_0, to be tested against the alternative hypothesis H_1. The aim is to reject, or "nullify," the null hypothesis, in favor of the alternative, which is typically the hypothesis of real interest. The test may be two-sided or one-sided. For example, if the mean of a distribution is μ_0 under the null hypothesis, one may use the *two-sided test*, usually displayed as follows:

$$H_0 : \mu = \mu_0 \ \text{ vs. } \ H_1 : \mu \neq \mu_0.$$

$$\text{Reject } H_0 \text{ if } |z| > z_{\alpha/2} = c,$$

that is, if the absolute value of the *test statistic* z, calculated from the observations, is outside the *critical value* c, determined by the significance level α ("alpha"). The corresponding *one-sided test* would be one of the following:

$$H_0 : \mu \leq \mu_0 \ \text{ vs. } \ H_1 : \mu > \mu_0.$$

$$\text{Reject } H_0 \ \text{ if } z > z_\alpha = c.$$

$$H_0 : \mu \geq \mu_0 \ \text{ vs. } \ H_1 : \mu < \mu_0.$$

$$\text{Reject } H_0 \ \text{ if } z < z_\alpha = c.$$

An outcome in the *rejection region*, the tail(s) of the distribution outside c, is considered unlikely if the null hypothesis is true, leading to its rejection at significance level α. The form of the test used, one- or two-sided, depends on the context of the problem, but the actual test used should always be reported.

AN EXAMPLE IN TWO PARTS. A senator, running for reelection against a strong opponent, wants to know his standing in popular support. An eager volunteer conducts a survey of 100 likely voters (Case #1) and reports

Table 2: Testing a Statistical Hypothesis: the Procedure

1. Set up *null hypothesis* vs. *alternative hypothesis.*
2. Collect data in accordance with research design.
3. Analyze data for overall patterns, outliers, consistency with theoretical assumptions, etc.
4. Compute the *test statistic,* to be compared with the *critical value,* which divides the distribution of the test statistic under the null hypothesis into "likely" and "unlikely" regions, determined by the *significance level* α. The conventional division is 95% and 5%, for $\alpha = .05$.
   a. If the test statistic is in the 95% region, considered a "likely" outcome, do not reject the null hypothesis.
   b. If the test statistic is in the 5% region, considered an "unlikely" outcome, reject the null *hypothesis.* The result is said to be *statistically significant* at P= .05.
5. Review analysis with subject matter specialist, for possible implications and further studies.

SOURCE: Courtesy of Valerie Miké.

back that 55 plan to vote for the senator. Meanwhile, a professional pollster retained by the campaign manager takes a sample of 1,100 likely voters (Case #2), and also obtains a positive response from 55 percent. What can they conclude?

Each may choose a two-sided test of the null hypothesis that the true proportion p of supporters is .5, at significance level $\alpha = .05$:

$$H_0 : p = .5 \quad \text{vs.} \quad H_1 : p \neq .5.$$

By the central limit theorem for the binomial distribution each can use the test statistic z, assuming the standard normal distribution,

$$z = \frac{M - .50}{SE},$$

and carry out a z-test for Case #1 ($n = 100$) and Case #2 ($n = 1{,}100$). The sample mean M is .55 for each, but SE involves the sample size:

Case #1:
$$SE = \sqrt{p(1-p)/n} = \sqrt{.5 \times .5/100} = .05$$
$$\text{so that} \quad z = \frac{.55 - .50}{.05} = 1.0.$$

(To distinguish between a random variable and its observed value, the latter is often denoted in lower case, such as Z versus z.) As seen in Figure 3a, this test statistic is just one standard deviation from the mean under the null hypothesis, well within the likely region. Figure 3b shows that even a one-sided test would require a test statistic of at least $z = 1.645$ to reject H_0. The senator cannot be said to be ahead of his opponent.

Case #2:
$$SE = \sqrt{p(1-p)/n} = \sqrt{.5 \times .5/1{,}100} = .015$$
$$\text{so that} \quad z = \frac{.55 - .50}{.015} = 3.33.$$

Figure 3a shows that this test statistic is greater than the critical value 1.96, leading to rejection of the null hypothesis. The pollster can report that the senator is statistically in the lead, whereas the volunteer's result is inconclusive.

ERRORS ASSOCIATED WITH TESTING. Two types of error that may occur in testing a statistical hypothesis are shown in Table 3: Type I, rejecting H_0 when it is true, and Type II, not rejecting it when it is false. (The expression "accept" instead of "do not reject" H_0 is sometimes used, but strictly speaking the most that can be asserted is that the observed result is consistent with, or is a "likely" outcome under, the null hypothesis; it is always a tentative conclusion.) The Type I error means that when H_0 is rejected at $P = .05$ (or $\alpha = .05$, the significance level of the test), an outcome in the rejection region would occur by chance 5 percent of the time if H_0 were true. The Type II error, its probability denoted by β ("beta"), is not as well known; many users of statistical methods even seem unaware that it is an integral part of the theory. The complement of β, or $(1 - \beta)$, the probability of rejecting H_0 when it is false, is called the *power* of the test.

THE P-VALUE. In reporting the results of a study, statistical significance is usually indicated in terms of what has become known as the P-value, written as $P < .05$ or $P < .01$, referring to the significance level α. In analyses carried out by computer, the software typically also provides the actual value of P corresponding to the observed test statistic (properly doubled for two-sided

TABLES 3–4

Table 3: Errors Associated with Testing a Statistical Hypothesis

Conclusion of test	Null hypothesis true	Null hypothesis false
Do not reject H_0 "Not statistically significant"	No error	Type II error (β)
Reject H_0 "Statistically significant"	Type I error (α or P) Significance level	No error (1-β) Power

tests). In Case #1 above, the value corresponding to $z = 1.0$ can be read off Figure 2 as $P = .32$. For Case #2, the value for $z = 3.33$ is seen as $P < .003$; it can be looked up in a table of the normal distribution as $P = .0024$. In results reported in the applied literature, at times only the observed *P*-value may be given, with no discussion of formal testing.

THE POWER OF THE TEST. Tests of the null hypothesis can be carried out without reference to the Type II error, but along with α and the sample size *n*, consideration of β is crucial in the research design of studies. The level of β, or equivalently, the power of the test, is always defined in terms of a specific value of the alternative hypothesis. The relationship between α and β for fixed *n* is shown in Figure 4 for a one-sided test of μ_0 versus μ_1. Changing the critical value *c* shows that as α increases, β decreases, and vice versa. A shift of μ_1 in relation to μ_0 indicates that the distance between them affects the power of the test.

Power as a function of sample size and alternative hypothesis is illustrated in Table 4. Assuming that a certain type of cancer has a one-year survival rate of 50 percent with the standard treatment, a randomized clinical trial is planned to evaluate a promising new therapy. The table shows the power of a two-sided test at $\alpha = .05$ for a range of possible survival rates, with the new treatment and different numbers of patients included in each arm of the study.

For example, if there are 100 patients in each group, a new treatment yielding a one-year survival rate of 75 percent would be detected with probability (power) .96. "Detect" here refers to the probability that the observed difference in survival rates will be statistically significant. But if the improvement is only to 60 percent, the corresponding power is a mere .30. To detect this improvement with high power (.99) would require a sample size of 1,000. In any particular case, investigators have a general idea of what improvement can reasonably be expected. If the survival rate in the study arm is unlikely to be higher than 60 percent, then a clinical trial with just a few hundred patients is not a good research design and may be a waste of precious human and financial resources.

Inference: Estimating Confidence Intervals

An intuitive everyday procedure is point estimation, obtaining a summary figure, such as the sample mean, for some quantity of interest. But it is generally desirable to give an indication of how good—how precise—this estimate is, and this is done with the confidence interval.

THE FORMAL STRUCTURE. It is assumed here that the normal distribution is applicable, so that the terms already introduced can be used, with estimation of the population mean μ by the sample mean M. By definition, the following holds for the standard normal z-statistic

$$P\left(-z_{\alpha/2} < \frac{M-\mu}{SE} < z_{\alpha/2}\right) = 1-\alpha.$$

As can be seen from Figure 3a, for $\alpha = .05$ this becomes

$$P\left(-1.96 < \frac{M-\mu}{SE} < 1.96\right) = .95.$$

Rewriting the expression inside the parentheses yields

$$P(M-1.96SE < \mu < M+1.96SE) = .95,$$

which is called a 95 percent confidence interval for the unknown population mean μ. It means that in a long sequence of identical repeated studies, 95 percent of the confidence intervals calculated from the sample would include the unknown parameter. There is always a 5 percent chance of error, but a larger sample size yields a smaller *SE* and narrower limits.

TWO-PART EXAMPLE CONTINUED. In the senator's reelection campaign, the point estimate M = .55 was obtained with different samples by both the volunteer and the pollster, and here the unknown parameter estimated by M is the true proportion *p*. Using the expression above yields

Case #1: $P(.45 < p < .65) = .95,$

for $n = 100,\ SE = .05.$

Case #2: $P(.52 < p < .58) = .95,$

for $n = 1{,}100,\ SE = .015.$

The critical value $c = 1.96$ for the standard normal (two-sided, $\alpha = .05$) is close to 2.0, and results are often presented in the form M ± 2*SE*.

Case #1: $.55 \pm .10$

Case #2: $.55 \pm .03$

The latter expression may be reported by the media as "55 percent with a 3 percent margin of error," putting the senator clearly in the lead. What is omitted is that this is a 95 percent confidence interval, with a 5 percent chance of error on the interval itself.

RELATIONSHIP BETWEEN TESTING AND ESTIMATION. Any value included in a $(1-\alpha)$ confidence interval would in general be accepted (not rejected) as the null hypothesis in the corresponding test of significance level α, and values outside the interval would be rejected. In this example the null hypothesis of $p = .50$ was rejected in Case #2, but not in Case #1. The confidence interval is a useful, informative way to report results.

Overview

A statistical study may be *observational* or *experimental* and may involve one or more samples. The polls and the clinical trial were examples of a *one-sample* survey and a *two-sample* experiment, respectively. The methods of inference described a simple prototype of the Neyman-Pearson theory, using the binomial and standard normal distributions, but they are valid in a wide range of contexts. Other important probability distributions include two generated by a stable random process: the *Poisson*, for the number of events occurring at random in a fixed interval, and the *exponential*, for the length of the interval between the occurrence of random events. Radioactive decay, traffic accidents in a large city, and calls arriving at a telephone exchange are random processes that illustrate both distributions.

If the variance of a normal distribution is unknown and estimated from the sample (using a computational formula involving the observations), the *z-test* used above is replaced by the *t-test* for small samples ($n < 30$), with its own distribution. For larger samples the normal distribution is a close approximation. The *chi-square test*, perhaps the most widely used method in applied statistics, assesses the relationship between two categorical variables (each taking on a finite number of values, displayed in a two-way table), or the "goodness-of-fit" of observed data to a particular distribution. *Multivariate techniques* deal with inferences about two or more random variables, including their interaction; basic among these are *correlation* and *regression*. Important and central to the design of experiments is the *analysis of variance*, a method for partitioning the variation in a set of data into components associated with specific causes, in order to assess the effect of any hypothetical causes on the experimental result.

There are specialized techniques for *time series* and *forecasting*, for *sample surveys* and *industrial quality control*. *Sequential analysis* refers to procedures for repeated testing of hypotheses along the way, to minimize the sample size needed for a study. The class of *nonparametric methods* uses tests that do not assume a specific parametric form for the probability distributions, all within the classical theory. *Decision theory* formulates statistical problems as a choice between possible decisions based on the concept of utility or loss.

The same data can often be analyzed by different techniques, using different assumptions, and these may yield conflicting results. Statistical theory aims to provide the best methods for a given situation, tests that are most powerful across the range of alternatives, and estimates that are unbiased and have the smallest variance. Given an adequate model, statistics can control the uncertainty attributable to *sampling error*. But it cannot control *systematic error*, when the data are not even closely representative of the assumed population. Inference is based on an abstract logical structure, and its application to messy reality always requires the mature judgment of experienced investigators.

HISTORY, INTERPRETATION, AND APPLICATION

Numerous jokes are associated with statistics and reflected in such caustic definitions as "Statistics is the use of methods to express in precise terms that which one does not know" and "Statistics is the art of going from an unwarranted assumption to a foregone conclusion." Then there is the time-worn remark attributed to the English statesman Benjamin Disraeli (1804–1881): "There are three kinds of lies: lies, damned lies, and statistics."

Statistics may refer to individual data, to complete sets of numbers, or to inferences made about a large population (of people or objects) from a representative sample of the population. The concern here is with inferential statistics. Its methodology is complex and subtle, and the risk of its abuse very real. There is no end in sight for the public being inundated with numbers, by the market and all kinds of interest groups. It has been estimated that children growing up in a pervasive television culture are exposed to more statistics than sex and violence combined. It was another Englishman, the novelist and historian H. G. Wells (1866–1946), who said: "Statistical thinking will one day be as necessary for efficient citizenship as the ability to read and write."

For those who understand, statistics is an exciting venture, a bold reaching out by the human mind to explore the unknown, to seek order in chaos, to harness natural forces for the benefit of all. Its development was integral to the rise of modern science and technology, its critical role recognized by the brilliant founders of new disciplines.

After a brief sketch of the history of statistical inference, this article offers a commentary on interpretations of statistics and concludes with a discussion of its applications that includes a case study of statistics in a scientific context.

Highlights of History

This quick survey of the history of statistics is presented in two sections, beginning with the emergence of statistical inference and then turning to the use of statistical concepts in philosophical speculation.

FROM STATISTICAL THINKING TO MATHEMATICAL STATISTICS. The normal distribution, which plays such a central role in statistics, was anticipated by Galileo Galilei (1564–1642) in his *Dialogue concerning the Two Chief World Systems—Ptolemaic and Copernican* (1632). He spoke of the errors in measuring the distance of a star as being symmetric (the observed distances equally likely to be too high as too low), the errors more likely to be small than large, and the actual distance as the one in which the greatest number of measurements concurred—a description of the bell-shaped curve. Discovered by Abraham de Moivre (1667–1754), the normal distribution was fully developed as the law of error in astronomy by Pierre-Simon de Laplace (1749–1827) and Carl Friedrich Gauss (1777–1855).

The statistical approach was applied to social phenomena by the Belgian astronomer Adolphe Quetelet (1796–1874), in what he called *social physics*, by analogy with *celestial physics*. He introduced the concept of the *average man* to show that observed regularities in the traits and behavior of groups followed the laws of probability. He strongly influenced Florence Nightingale (1820–1910), the British nursing pioneer and hospital reformer, who urged governments to keep good records and be guided by statistical evidence.

The fundamental contributions of the Scottish physicist James Clark Maxwell (1831–1879) to electromagnetic theory and the kinetic theory of gases would lead to communications technology and ultimately to Albert Einstein's special theory of relativity and Max Planck's quantum hypothesis. Having learned of Quetelet's application of the statistical error law to social aggregates, Maxwell theorized that the same law governed the velocity of gas molecules. His work in statistical mechanics and statistical thermodynamics foreshadowed a new conception of reality in physics.

The Austrian monk Gregor Johann Mendel (1822–1884) carried out plant crossbreeding experiments, in the course of which he discovered the laws of heredity. Traits exist as paired basic units of heredity, now called genes. The pairs segregate in the reproductive cell, and the offspring receive one from each parent. Units corresponding to different traits recombine during reproduction independently of each other. Mendel presented his results at a scientific meeting in 1865 and published them in 1866, but they were ignored by the scientific community and he died unknown.

Statistical inference as a distinct discipline began with Francis Galton (1822–1911), a cousin of Charles Darwin, whose *On the Origin of Species* (1859) became the inspiration of Galton's life. The theory of evolution by natural selection offered Galton a new vision for humanity. He coined the term *eugenics* to express his belief that the conditions of humankind could best be improved by scientifically controlled breeding. He devoted himself to the exploration of human inheritance in extensive studies of variability in physical and mental traits, constructing what would become basic techniques of modern statistics, notably regression and correlation. In 1904 he established the Eugenics Record Office at University College, London, which in 1911 became the Galton Laboratory of National Eugenics, with Karl Pearson (1857–1936) appointed its director.

A man of classical learning and deep interest in social issues, Pearson was attracted to Galton's work in eugenics. Becoming absorbed in the study of heredity and evolution by the measurement and analysis of biologic variation, he developed a body of statistical techniques that includes the widely used chi-square test. In 1901 he founded the journal *Biometrika*. But he never accepted Mendel's newly rediscovered laws of inheritance involving hereditary units as yet unobserved, and engaged in a feud with Mendelian geneticists. Pearson was appointed the first professor of eugenics in 1911, with his Biometric Laboratory incorporated into the Galton Laboratory of National Eugenics, and the department became a world center for the study of statistics. When he retired in 1933, the department was split in two; his son Egon Pearson (1895–1980) obtained the chair in statistics, and Ronald A. Fisher (1890–1962) became professor of eugenics.

Trained in mathematics and physics, Fisher emerged as the greatest single contributor to the new disciplines of statistics and genetics and the mathematical theory of evolution. He did fundamental work in statistical inference, and developed the theory and methodology of experimental design, including the analysis of variance. Through his books *Statistical Methods for Research Workers* (1925), *The Design of Experiments* (1935), and *Statistical Methods and Scientific Inference*

(1956), he created the path for modern inquiry in agronomy, anthropology, astronomy, bacteriology, botany, economics, forestry, genetics, meteorology, psychology, and public health. His breeding experiments with plants and animals and his mathematical research in genetics led to the publication of his classic work, *The Genetical Theory of Natural Selection* (1930), in which he showed Mendel's laws of inheritance to be the essential mechanism for Darwin's theory of evolution.

Egon Pearson collaborated with the Russian-born mathematician Jerzy Neyman (1894–1981) to formulate what is now the classical (Neyman-Pearson) theory of hypothesis testing, published in 1928. This is the theory used across a wide range of disciplines, providing what some call the null hypothesis method. Neyman left London in 1937 to become a strong force in establishing the field in the United States. Another major contributor to American statistics was the Hungarian-born mathematician Abraham Wald (1902–1950), founder of statistical decision theory and sequential analysis.

STATISTICS AND PHILOSOPHY. Statistical developments in the eighteenth century were intertwined with natural theology, because for many the observed stable patterns of long-run frequencies implied intelligent design in the universe. For Florence Nightingale in the nineteenth century, the study of statistics was the way to gain insight into the divine plan.

Francis Galton had a different view. For him the theory of evolution offered freedom of thought, liberating him from the weight of the design argument for the existence of a first cause that he had found meaningless. Karl Pearson, author of *The Grammar of Science* (1892), was an advocate of logical positivism, holding that scientific laws are but descriptions of sense experience and that nothing could be known beyond phenomena. He did not believe in atoms and genes. For him the unity of science consisted alone in its method, not in its material. Galton and Pearson gave the world statistics, and left as philosophical legacy their vision of eugenics.

James Clark Maxwell was a thoughtful and devout Christian. He argued that freedom of the will, then under vigorous attack, was not inconsistent with the laws of nature being discovered by contemporary science. The statistical method, the only means to knowledge of a molecular universe, yielded information only about masses of aggregates, not about individuals. He urged recognition of the limits of science: "I have endeavored to show that it is the peculiar function of physical science to lead us to the confines of the incomprehensible, and to bid us behold and receive it in faith, till such time as the mystery shall open" (quoted in Porter 1986, p. 195).

In 1955 Fisher, by then Sir Ronald Fisher, said in a London radio address on the BBC: "It is one of the evils into which a nation can sometimes drift that, for about three generations in this country, the people have been taught to assume that scientists are the enemies of religion, and, naturally enough, that the faithful should be enemies of science" (Fisher 1974, p. 351). Scientists, he insisted, needed to be clear about the extent of their ignorance and not claim knowledge for which there was no real evidence. Fisher's advice remains sound at the start of the twenty-first century.

Interpretation: A Commentary

The following are comments on various aspects of statistics, painted of necessity in broad strokes, and concluding with some thoughts concerning the future.

STATISTICS AND THE PHILOSOPHY OF SCIENCE. Two distinct types of probability—objective and subjective—have been recognized since the emergence of the field in the seventeenth century. The classical (Neyman-Pearson) theory of hypothesis testing is based on the objective, frequentist interpretation. The subjective, degree-of-belief interpretation yields variations of so-called Bayesian inference. The latter involves combining observations with an assumed prior probability of a hypothesis to obtain an updated posterior probability, a procedure of enduring controversy. But the frequentist theory, as pointed out by its critics, does not provide any measure of the evidence contained in the data, only a choice between hypotheses. The American mathematical statistician Allan Birnbaum (1923–1976) did pioneering work to establish principles of statistical evidence in the frequentist framework, his two major related studies being "On the Foundations of Statistical Inference" (1962) and "Concepts of Statistical Evidence" (1969). Exploring the *likelihood principle*, Birnbaum reached the conclusion that some sort of confidence intervals were needed for the evaluation of evidence. A leading advocate of the subjective approach, of what he called personal probability, was another American statistician, Leonard J. Savage (1917–1971), author of the classic work *The Foundations of Statistics* (1954).

Statistics as commonly taught and used is that based on the frequentist theory. But there is lively interest in Bayesian inference, also the focus of serious study by philosophers (Howson and Urbach 1993). The entire subject has been engaging philosophers of science, giving rise to a new specialty called the philosophy of probability. An example is the edited volume *Probability Is the Very Guide of Life: The Philosophical Uses of Chance* (Kyburg and Thalos 2003), a collection of essays by philosophers of probability that explores aspects of probability as applied to practical issues of evidence, choice, and explanation—although without consensus on conceptual foundations. The title refers to a famous remark of Bishop Joseph Butler, one of the eighteenth-century natural theologians who saw statistical stability as a reflection of design and purpose in the universe (Butler 1736). Another edited volume, *The Nature of Scientific Evidence: Statistical, Philosophical, and Empirical Considerations* (Taper and Lele 2004), has contributions by statisticians, philosophers, and ecologists, with ecology used as the illustrative science. What remains clear is the persistent conflict between the frequentist and Bayesian approaches to inference. There is no unified theory of statistics.

STATISTICS IN THE FIELD. At the other end of the statistical spectrum is the approach expressed by the term *exploratory data analysis* (EDA), introduced by John W. Tukey (1915–2000), the most influential American statistician of the latter half of the twentieth century. Exploratory data analysis refers to probing the data by a variety of graphic and numeric techniques, with focus on the scientific issue at hand, rather than a rigid application of formulas. Tukey's textbook on EDA (1977) contains techniques that can be carried out with pencil and paper, but the approach is well suited to computer-based exploration of large data sets—the customary procedure. EDA is an iterative process, as tentative findings must be confirmed in precisely targeted studies, also called *confirmatory data analysis*. The aim is flexibility in the search for insight, with caution not to oversimplify the science, to be wary of pat solutions.

Practicing statisticians need to understand established theory, know the methods pertaining to their area of application, and be familiar with the relevant software. They must know enough about the subject matter to be able to ask intelligent questions and have a quick grasp of the problems presented to them. For effective communication they must be sensitive to the level of mathematical skills of the researchers seeking their assistance. It is easy to confuse and alienate with technical jargon, when the intention is to be of service. What is asked of them may range from short-term consultation—analysis of a small set of data, or help with answering a statistical reviewer's questions on a manuscript submitted for publication—to joining the research team of a long-range study that is being planned. Unless otherwise agreed, it is understood that frequentist theory will be used, with routine preliminary exploration of the data. A statistician who strongly prefers the Bayesian approach may recruit investigators interested in collaborating on Bayesian analysis of suitable scientific problems.

Some points to remember: Statistics is a tool—more precisely, a collection of tools. Creative researchers know a lot of facts and have hunches and ideas; they may seek interaction with a compatible statistician to help sort things out, and that is where the tools come in. Which ones are actually used may not matter so much in the end. On occasion, the statistician's real contribution may not even involve formal analysis. A mind trained in mathematics views problems from a special perspective, which in itself may trigger insight for the scientist immersed in the material. Other situations require structured research designs with specification of proposed methods of analysis. These include cooperative studies, such as large multinational clinical trials involving hundreds of investigators. But in any case and even in the most masterful hands, statistics can be no better than the quality of the underlying science.

THE FUTURE OF STATISTICS. The explosive growth of information technology, with its capacity to generate data globally at a fast pace and in great volume, presents the statistical profession with unprecedented opportunity and challenge. The question is not that of either/or, of theory versus practice, but of perspective and balance: Continue exploration on every front, but make what is established widely available. Apply what is known, and do it well. Make sure that wherever statistics is potentially useful, it is at hand.

A promising development here is the Cochrane Collaboration, founded in 1993, an independent international organization dedicated to making accurate, up-to-date information about health care interventions readily available around the globe (Cochrane Collaboration). The organization promotes the search for evidence in the form of randomized clinical trials and provides ongoing summary analyses. By late 2004 there were twelve Cochrane centers worldwide, functioning in six languages, serving as reference centers for 192 nations, and coordinating the work of thousands of investigators. Such a vast undertaking must use objective criteria and uniform statistical methods that can be precisely communicated. That is the strength of the standard frequency approach.

In the realm of theoretical advances, some economic constraints may be cause for concern. Young graduates in academic positions, often struggling in isolation while carrying heavy teaching loads, are under great pressure to produce publications, any publications, to attain job security and professional advancement. This may not be the wisest use of their intellectual potential. A man of wit, Tukey would say that one should do theory only if it is going to be immortal. By contrast, those in a practical setting, such as a large biostatistics department, have to cope with the endless flow of data to be analyzed, under the constant pressure of immutable deadlines. The loss of major research grants may put many jobs in jeopardy, including their own. There should be other, readily available and steady sources of support that provide time for reflection, to find and explore areas of interest that seem to offer promise down the road. Such a path should include attention to what is happening in philosophy and close involvement with a field of cutting-edge empirical research. The great founders of statistics were widely read, hands-on scientists.

Application of Statistics

In the last decades of the twentieth century statistics continued its vigorous growth into a strong presence not only in the sciences but also in political and social affairs. Its enormous range of applications, with specialized methodology for diverse disciplines, is reflected in the thirteen-volume *Encyclopedia of Statistical Sciences*, published between 1982 and 1999 (Kotz, Johnson, and Read). The term *statistical science* refers to statistical theory and its applications to the natural and social sciences and to science-based technology. The best general advice in the application of statistics is to proceed with care and suspend hasty judgment. This is illustrated by a case study of the diffusion of neonatal technology.

STATISTICS IN CONTEXT: A CASE STUDY. The role of statistics in the interplay of forces affecting technological innovation was explored in a case study in neonatal medicine, a specialty created by technology (Miké, Krauss, and Ross 1993, 1996, 1998). It is the story of transcutaneous oxygen monitoring (TCM) in neonatal intensive care, introduced as a scientific breakthrough in the late 1970s and rapidly adopted for routine use, but abandoned within a decade. The research project included interviews with executives and design engineers of ten companies marketing the device, with investigators who had pioneered the technology, and with directors of neonatal intensive care units (NICUs).

Supplemental oxygen, essential for the survival of premature infants, had been administered since the 1930s, first via incubators and then by mechanically assisted ventilation. But in the 1940s an eye disease often leading to blindness, initially called retrolental fibroplasia (RLF) and later renamed retinopathy of prematurity (ROP), became the major clinical problem of surviving prematurely born infants. Over fifty causes were suggested, and about half of these were formally evaluated, a few in prospective clinical trials. When in the mid-1950s supplemental oxygen was identified as the cause of ROP in two large randomized clinical trials, the recommended policy became to administer oxygen only as needed and in concentrations below 40 percent. By this time more than 10,000 children had been blinded by ROP worldwide.

But subsequent studies noted higher rates of mortality and brain damage in surviving infants, as the incidence of ROP persisted and then rose, with many malpractice suits brought on behalf of children believed to have been harmed by improper use of oxygen. There was an urgent need for better monitoring of oxygen in the NICU.

Measurement of oxygen tension in arterial blood by means of the polarographic Clark electrode had been possible since the 1960s. The procedure was only intermittent, however, and the related loss of blood harmful to tiny, critically ill newborns. The new technology of TCM involved a miniaturized version of the Clark electrode that could monitor oxygen continuously across the skin, bypassing the need for invasive blood sampling. But the device was difficult to use, babies were burned by the electrode, and ROP was not eliminated. Within years TCM was being replaced by pulse oximetry, a still more recent technology with problems of its own.

A number of issues emerged. Subsequent review found serious flaws in the two randomized clinical trials that had implicated oxygen, and a series of methodological errors was noted in the early studies of other possible causes. The effectiveness of TCM in the prevention of ROP had not been shown before the adoption of the technology, and results of a randomized trial finally published in 1987 were inconclusive. It became clear that the oxygen hypothesis was an oversimplified view. ROP had a complex etiology related to premature physiology, even as the patient population itself was changing, with the survival of smaller and smaller infants.

A mistaken view of disease physiology, coupled with preventive technology advocated by its pioneers, heralded by the media, and demanded by the public—with industry only too eager to comply—led to the adoption of an untested technology that was itself poorly understood by those charged with its use. There was no special concern with statistical assessment, reliance on regulations of the Food and Drug Administration (FDA) being the norm. And there is no clear-cut way to assign ultimate responsibility. The study concluded with the overarching theme of complexity and uncertainty.

SUMMING UP Statistics is a powerful tool when in competent hands, one of the great intellectual achievements of the twentieth century. Ethical issues pertain to its misuse or lack of adequate use.

Elementary texts of applied statistics have traditionally been called "cookbooks," teaching mainly the "how" and not the "why." But in the present-day fast food culture hardly anyone cooks any more, and this applies equally to statistics. Computer software provides instant analysis of the data by a variety of techniques, allowing the user to pick and choose from the inevitable sprinkling of "significant" results (by definition of the meaning of *P*-value) to create a veneer of scientific respectability. Such meaningless and misleading activity, whatever the reason, can have harmful consequences. Another danger of abuse can come in the phrasing of questions in public opinion polls, known to affect the response, in a way that biases the results in favor of the sponsor's intended conclusion.

The ideal role of statistics is to be an integral part of the investigative process, to advise, assess, and warn of remaining uncertainties. The public needs to be informed and offer its support, so that the voice of statistics may be clearly heard in national life, over the cacophony of confusion and conflicting interests. This theme has been developed further in the framework of a proposed *Ethics of Evidence*, an approach for dealing with uncertainty in the context of contemporary culture (Miké 2003). The call for education and responsibility is its predominant message.

STEINMETZ, CHARLES

Electrical engineer and socialist Charles Proteus Steinmetz (1865–1923), born in Breslau, Germany, on April 9, was a public figure of the Progressive Era who tried to *engineer* a better society by creating an early code of engineering ethics, running for political office, and advocating a technocratic form of socialism. He died on October 26 in Schenectady, New York.

Trained in mathematics and physics, Steinmetz emigrated to the United States in 1889 to avoid being arrested for his socialist activities as a student in Germany. He became a leading researcher in the areas of magnetic hysteresis (a property of the metal cores used in transformers and electrical machines) and theories of alternating currents, electrical machinery, and high-voltage transmission lines. As chief consulting engineer of the newly formed General Electric Company (GE), which he joined in 1893, Steinmetz trained a generation of engineers in the use of advanced mathematics to design electrical equipment, established an engineering research laboratory, and published several books while teaching part-time at Union College in Schenectady, New York, the headquarters of GE. A dwarfed hunchback with a flair for publicity, he gained a national reputation as an electrical wizard for creating lightning in the laboratory and engaging in politics within and outside the engineering profession.

Steinmetz developed a distinct philosophy regarding the social responsibility of engineering. He argued that engineers should compromise with business interests in regard to ethical concerns within professional societies and address political issues on their own. In this way, engineers could maintain control over the profession against commercial interests and be able to promote political solutions in a wider arena.

Steinmetz carried out that philosophy in 1912 when he helped write the first code of ethics for the American Institute of Electrical Engineers (AIEE), the forerunner to the Institute of Electrical and Electronics Engineers (IEEE). Steinmetz was a president of the AIEE (1901–1902) and an active member of its first two ethics committees. The AIEE code, established in 1912, favored the interests of the employer over that of the engineer—up to a point. Rather than making engineers responsible for defective equipment, as the first draft of the code had done, for example, the revised code required engineers simply to report the problem, a common element in twenty-first century engineering codes of ethics. Inside GE, Steinmetz advised engineers in his group to keep silent rather than defend a company position with which they disagreed.

Steinmetz was active in politics at all levels. He served as president of the board of education under George Lunn, the socialist mayor of Schenectady in 1912, and was president of the city council in 1915. An evolutionary socialist who belonged to the conservative wing of the Socialist Party of America, Steinmetz drew on his corporatist experiences at GE, his work in local politics, his presidency of the AIEE, and as president of the National Association of Corporate Schools (NACS) to develop a theory of corporate socialism, which he expressed in some detail in *America and the New Epoch* (1916). In this form of technocracy, an enlightened industrial corporation, one that attended to the welfare of its workers, was the model for society. He proposed that the U.S. government be reorganized like an efficient corporation with democratic safeguards. The government would own and operate transportation and communication systems. An Industrial Senate, composed of leaders of large corporations, would coordinate and supervise industry. A democratically elected Tribunicate would set national and foreign policy, but could only veto the Senate.

Near the end of his life, Steinmetz acted on his belief that widespread electrification, by requiring cooperation to build networks and regulate consumption, would lead to socialism. He ran for New York state engineer in 1922 on a platform of harnessing the full power of Niagara Falls. The same year, he offered to help Vladimir Ilyich Lenin electrify Russia, in accord with Lenin's proposal text "Soviets + Electricity = Socialism."

To resolve the tensions he faced as a corporate engineer and a socialist, Steinmetz developed a patchwork of compromises that allowed agencies, such as the AIEE and NACS, and engineering colleges to retain autonomy by cooperating with industrial corporations. This would prepare corporations to become the model for the state and thus would be a step on the road to socialism. His ideas influenced President Woodrow Wilson's *war collectivism* and later proposals for the New Deal.

Steinmetz was able to promote his peculiar combination of conservative and radical views because of his public status as an electrical wizard, a new breed of scientific researcher that replaced cut-and-try inventors such as Thomas Edison. Steinmetz used his public position to demonstrate one way in which corporate engiees could address ethical and social issues in engineering.

STRAUSS, LEO

Leo Strauss (1899–1973) was the most influential political philosopher of the twentieth century as well as its most extraordinary teacher. He was born into an Orthodox Jewish family in Kirchain, Hessen, Germany, on September 20. Strauss completed a doctorate at Hamburg in 1921 and immigrated to the United States in 1938. He taught at several American universities and attracted many gifted students. Their respect for his thought has led to those students being called disciples or *Straussians.* He died on October 18 in Annapolis, Maryland.

Philosophy and History

Like many scholars who left Germany in the 1930s, Strauss believed that a philosopher's work must be understood in the light of a political situation. Perhaps uniquely, he thought that all philosophers are in the *same* situation. Every regime, every society that sustains a government, is founded on certain shared opinions about what is noble and sacred, what is just, and what is in the common interest. Philosophers want to replace those cherished opinions with knowledge. This means that philosophy is by definition potentially subversive and is always likely to arouse the hostility of the regime. The story of Socrates' trial and execution is the best expression of this problem.

Strauss's view of philosophy is closely connected to his doctrine of esoteric writing, which is elaborated in

Persecution and the Art of Writing (1952). When philosophers write books, they must take pains both to protect philosophy from the hostility of citizens and to protect political life from subversion by philosophy. Their complete teachings can be communicated only by hints and clues. For example, a philosopher may write in one place that nothing should be taken seriously unless it is founded on experience and write in another place that religion is not founded on experience; only an attentive reader will be able to tell how seriously the author takes religion.

Because he read philosophy in this way, Strauss rejected the historicism that was prevalent in his time. According to historicists, person-to-person communication is not possible across historical boundaries; it is necessary to study past thinkers as objects in their historical context rather than as persons trying to talk to their later readers. Strauss taught that it is possible to understand Aristotle as he understood himself, for at least in the respect discussed above his situation is not fundamentally different from that of his modern readers. Strauss's most important book, *Natural Right and History* (1953), presents a sustained challenge to historicism. It is likely that the title implies a challenge to the philosopher Martin Heidegger's (1889–1976) *Being and Time* (1927). For Strauss, it is possible to arrive at a grasp of being that is not radically dependent on the flow of history.

Quarrels in Philosophy

Philosophy is the desire for wisdom, not the possession of wisdom. It may never amount to more than a clear grasp of the most fundamental questions. Strauss organized those questions into a number of historical quarrels. One of the most important is that between Athens and Jerusalem. Jerusalem stands for the concept of biblical revelation: Everything human beings must know is revealed to them in God's law. Athens stands for reason: Human beings can find out what they want to know by means of relentless questioning. Strauss taught that this quarrel was the most important source of intellectual vitality in Western civilization. However, although Strauss wrote extensively about Jewish philosophy and theology, his students disagree about how seriously he took biblical revelation.

With the power of revelation fading in modern civilization, Strauss sought to revive another quarrel: the one between the ancients and the moderns. The ancient thinkers, classical and medieval, looked to an authority higher than the human (nature or God) as the standard of truth and justice and based their political teachings on duties and virtues. The moderns began with a more or less explicit rejection of ancient thought. They viewed humankind as independent of any higher authority and based their teachings on rights rather than duties and on frank appraisals of human nature. Strauss argued, against the scholarly orthodoxy, that classical political philosophy had to be taken seriously as an alternative to the modern version. It is not clear whether he believed that ancient thought is superior on the whole.

Political Philosophy and Science

Strauss did consider classical social science to be manifestly superior to its modern counterpart. Social science in Strauss's time aspired to be "value-free." It sought to explain social facts the way a physicist explains the momentum of particles, without contaminating the explanation with historically conditioned expectation or judgment. However, the clarity the scientific method secures for physics induces a dangerous blindness when it is applied to human things: "A social science that cannot speak of tyranny with the same confidence with which medicine speaks of cancer cannot understand social phenomena for what they are" (Strauss 1991, p. 177). Classical social science recognized that human communities may flourish or fall victim to decay, and so it had something useful to say.

However, classical social science seems to rest on the strength of Strauss's analogy between the science of medicine and the sciences of politics and ethics. The physician not only can describe human biology but can prescribe remedies because medicine distinguishes what is naturally healthy from what is not. Can a knowledge of human nature similarly allow a philosopher to identify what is just and what is unjust, what saves and what destroys families and cities? The Platonists argued that it could, and Strauss refers to their teaching as classical natural right.

Classical natural right is concerned with articulating a hierarchy of natural ends. Thus, the perfection of human capacities, which the ancients called virtue, is primary and provision for survival, comfort, and freedom is secondary. Early modern political philosophy rejected the former and concentrated on the latter. That was largely a consequence of the rejection of Aristotelian teleology by modern science. Aristotle ascribed goals and purpose, or *teloi,* to nature. Modern thought recognizes only mechanical forces as natural; goals are products only of human will.

According to Aristotle, the issue between the mechanical and biological accounts of nature turns on how one interprets the motion of heavenly bodies. On this count the victory of modern science seems complete: There is no teleology on a cosmological scale. Because a value-free social science is useless, it becomes necessary to accept a dualism consisting of nonteleological physical sciences and social sciences that allow teleology. In a letter Strauss ascribes to Plato the view that this dualism cannot be reconciled. Strauss seems to have accepted this limitation for the most part, confining himself to political questions and largely ignoring not only modern natural science but classical biology and physics as well.

However, Strauss was choosing not the ancients over the moderns but Plato over Aristotle. Aristotle believed that biology could bridge the gap between "knowledge of inanimate [nature] and knowledge of man" (Strauss 1991, p. 279). His biology gives full weight to matter and momentum but recognizes a role for formal and teleological explanations. If Strauss had lived a bit longer, he would have witnessed some rehabilitation of Aristotle as a philosopher of biology, and that might have led him to reconsider the question.

Philosophy and Moderation

Although Strauss ignored contemporary science, he was attentive to its roots in modern thought. The early moderns proposed the unlimited conquest of nature for the purpose of the eventual satisfaction of all human desires. That project would include the conquest of human nature by some state, and that state would have to become universal and homogeneous if it were to eliminate all contradictions between states or between citizens. Such a state would need technologies of manipulation and coercion beyond any previously available to a government. Once the state accomplished its goal, perhaps it would whither away. Why would it be necessary to govern those whose every desire is satisfied?

However, if, as Strauss suspected, the complete satisfaction of human desires is impossible, the last state would in fact become a pervasive and immortal tyranny. This would mean the end of freedom and hence of philosophy. Strauss preferred Socratic philosophy to its modern counterpart at least insofar as it combined the pursuit of wisdom with moderation. It would be far better to settle for a decent form of government than to risk everything for one that is perfect. Of course, the philosopher will, because of the nature of this choice, be especially aware of its imperfections.

Accordingly, Strauss was both a supporter and a critic of modern liberal democracy. Although democracy is almost certainly the best viable form of government, Strauss had witnessed the weakness of the Weimar Republic in Germany and was concerned that a similar failure of nerve would affect Western democracies in their confrontation with communism. Moreover, democracy seemed problematic for philosophical reasons. Philosophers must stand apart from their fellow citizens and put more confidence in what reason tells them than in what the majority says. Philosophy is therefore elitist by necessity. Finally, because it is difficult to combine wisdom and political power, Strauss distrusted radical politics in any form. Anticommunism, elitism, and an insistence on political moderation have not endeared Strauss or the Straussians to their more orthodox colleagues in the universities.

STRESS

Stress is an engineering concept that is applied metaphorically in the life sciences and social sciences. The ethical implications of stress in the social sciences lie in its perceived significance for work and health in technologically advanced societies. Stress provides an exemplary case for the interactions of science, technology, and ethics.

Origins

Although the word *stress* existed long before it became a technical term—it originally meant hardships and afflictions, as in "the stress of weather"—the earliest modern meanings of the term belong to engineering. In the nineteenth century considerations of stress in a modern sense took shape in several fields: strength of materials, thermodynamics, and medicine. William Rankine (1820–1872), who did pioneering work in civil engineering and thermodynamics, defined stress as the forces a material exerts in response to external forces applied to it. Those engineering developments applied not only in theory but also in practice as the steam engine, railroads, and heavy industry transformed the everyday world. If the resultant stresses are not taken into consideration, buildings and bridges collapse.

At that time physicians turned their attention to engineering aspects of the human body. In the eyes of nineteenth-century physicians, "overstrain" and "overpressure" of the nervous system and the heart produced serious and even fatal diseases. In part, "overstrain of the heart" and "neurasthenia" expressed people's anxiety over the "strange disease of modern life" (Arnold 1853 [1965]) with its harried pace and engineered infrastructure.

Twentieth-Century Developments

In the twentieth century the experimental psychologist Walter B. Cannon (1871–1945) developed the concept of homeostasis to call attention to an organism's response to emergency situations: the fight or flight syndrome. In "The Stresses and Strains of Homeostasis" (1935) Cannon reviewed the forces that lessen the efficiency of homeostatic processes in an organism. The physiologist Hans Selye (1907–1982) studied other endocrine responses to external threats, leading to his concept of stress as "a specific syndrome which consists of all the nonspecifically-induced changes within a biologic system" (Selye 1976, p. 64). Laboratory studies represented the intersection of clinical work in psychosomatic medicine and psychiatry, especially the work of the migraine identifier Harold G. Wolff (1898–1962) and others. Two military psychiatrists, Roy Grinker (1900–1993) and John Spiegel (1911–1991), who treated U.S. Army Air Corps crews published their findings in *Men under Stress* (1945). Through such investigations stress emerged as a central category to describe the effects of modern warfare and then was extended to include all of modern life. The meaning of stress was complicated by the fact that Selye's definition referred to the response, whereas in the other cases it referred to the stimulating cause of psychosomatic distress.

In the 1970s the related notion of trauma, or excessive stress, became a key to legitimating posttraumatic stress disorder as a diagnosis for American veterans of the Vietnam War. Stress as a cause of war neuroses later was extended backward to include puzzling illnesses that appeared during the American Civil War (irritable heart and nostalgia), World War I (shell shock, traumatic neurosis, neurasthenia), and World War II (combat fatigue). Trauma and stress became emblematic of the violence, productive and destructive, of technologically advanced societies.

After the 1950s stress became a key term in cybernetics and the social sciences. In cybernetics and systems theory the concept of stress was applied to all levels of organization, from the cellular to the global, organism and machine. One result has been vagueness in the meaning of the term, especially in the social sciences: Stress can refer to objective features of life events measured by psychological instruments such as the Social Readjustment Rating Scale of Thomas H. Holmes (1918–1988) and Richard H. Rahe (b. 1936), subjective features as in Richard S. Lazarus's (1922–2002) notion of the cognitive appraisal of threat as vital in the stress-coping process, and an interaction between situational and dispositional factors.

Stress as a category has had the most significant impact in the areas of health and work. A stress-diathesis model of illness causation proposes that excessive demands (stress) on adaptive capacities interact with psychosocial and biological predispositions (the diathesis), resulting in the breakdown of the weakest link in an individual's biopsychosocial systems. Thus, one person develops asthma, another depression, and a third cardiovascular disease. Although oversimplified, this suggests the thrust of contemporary thinking about possible causal links between stress and disease. Insofar as considerations of stress affect health, they affect work, and stress management has become important in the regulation of behavior in technologically advanced societies.

Ethics

The ethical implications of stress are twofold. First are the implications that arise from the experience of what is called stress. Stress plays a role in defining the limits of human performance: If demands are excessive, psychological or physical illness can result. Individual, corporate, and social responsibilities for minimizing stress and its effects have become significant. Excessive stress has become the basis for legal action. Although social inequalities are sources of stress, the emphasis in some societies, such as the United States, has been on individuals assuming increased personal responsibility for lifestyle choices that can result from and/or lead to stress and its deleterious effects.

Second are the implications that arise from the way that stress frames the trials and troubles of living. The construct of stress reframes the tribulations of living in rationalized or engineered terms: Stress is what individuals and organizations seek to manage. Ethical considerations thus appear in terms of efficiency and control. Management as the norm for dealing with stress reduces the ethical act to devising means to adjust to ends that may not be questioned.

SUSTAINABILITY AND SUSTAINABLE DEVELOPMENT

The concept of sustainable development (SD) has been a part of the global ecological dialogue among scientists and governmental leaders for more than two decades. One outcome of the 1992 United Nations Conference on Environment and Development (UNCED, or the Earth Summit) was The Earth Charter, a policy statement about the ethics of international SD. The Charter opens, "We must join together to bring forth a sustainable global society founded on respect for nature, universal human rights, economic justice, and a culture of peace" (Earth Charter International Secretariat 2000).

This statement captures the ethical context in which policy-makers developed the SD concept.

The most commonly used definition of SD comes from the 1987 report prepared for the Earth Summit, *Our Common Future* (1987). SD is "Development that meets the needs of the present without compromising the ability of future generations to meet their own needs" (WCED 1987). The 178 heads of state that gathered at the Earth Summit sought to address both the *environmental problem* and the *socioeconomic development problem*. The SD concept presented a paradigm in which officials viewed environment and development as partners rather than adversaries. The WCED view of SD presumed that socioeconomic growth and environmental protection could be reconciled in an equitable manner.

The SD idea contrasts with development that focuses on socioeconomic gain often at the expense of the environment. Some natural resource extractive industries, such as mining and fishing, deplete resources in the name of promoting socioeconomic growth. Unsustainable development, however, can be devastating for the environment and society. In 1992, for instance, the northern cod fishery collapsed in Newfoundland due to overfishing. The government, in light of this natural resource drawdown, called for a two-year moratorium on cod fishing so that the stocks could recover. This action affected thousands of workers (Haedrich and Hamilton 2000). The tension between biological/ecological concerns and human socioeconomic concerns, in this case and others like it, highlights the importance of finding a balance between society and the environment.

While the WCED definition has the greatest international recognition, a range of definitions are associated with SD. David Pearce and colleagues, for example, present a thirteen-page annex of definitions of the term. What the WCED brief definition has in common with others is that it identifies three main, but not equal, SD goals: (a) socioeconomic growth; (b) environmental protection; and (c) social equity. Interest groups highlight different aspects of this three-part definition. The economic concerns of national and transnational industrialists are incorporated into the definition, as are the concerns of environmentalists, and the socioeconomic concerns of nongovernmental organizations and governments wishing to alleviate poverty and injustice.

While the WCED popularized the concept, the phrase *sustainable development* had already been around for at least ten years. The International Union for the Conservation of Nature used the term in *World Conservation Strategy (1980)*. *World Conservation Strategy*, however, emphasizes ecological sustainability, not the integration of ecological, economic, and social sustainability. SD draws upon *limits to growth*, *appropriate and intermediate technologies*, *soft energy paths*, and *ecodevelopment* discourses of the 1970s and 1980s (Humphrey, Lewis, and Buttel 2002, Mitcham 1995).

For example, the limits to growth debate centers around the much-publicized *The Limits to Growth* (1972), a study produced by Donella Meadows and others for the Club of Rome (Humphrey and Buttel 1982, Mitcham 1995). The book presents evidence that severe biophysical constraints would impinge upon the growth and development of societies. *The Limits to Growth* predicts ecological collapse if current growth trends continued in population, industry, and resource use. The study provoked tremendous international debate, attention, and critique (Sandbach 1978). The limits to growth idea became politically unpopular in the less developed countries (the Global South) "on the grounds that it was unjust and unrealistic to expect countries of the [Global] South to abandon their aspirations for economic growth to stabilize the world environment for the benefit of the industrial world" (Buttel 1998, p. 263).

While the limits to growth debate asks whether environmental protection and continued economic growth are compatible, the mainstream SD discourse assumes that the two are complimentary and instead focuses on *how* SD can be achieved (Baker, et al. 1997). The SD discourse does not assume there are fixed limits to socioeconomic development; it is pro-technology, pro-growth, and compromise oriented. The WCED report clearly states, "The concept of sustainable development does imply limits—not absolute limits but limitations imposed by the present state of technology and social organization on environmental resources and by the ability of the biosphere to absorb the effects of human activities. But technology and social organization can be both managed and improved to make way for a new era of economic growth" (Ekins 1993, p. 91).

The discourse on SD presents a shift in thinking about human development. SD is presented as a solution to the problems of economic development and environmental degradation. International aid agencies, such as the U.S. Agency for International Development (USAID) and the World Bank, adopted the SD framework for the design of their development programs. The emergence of the concept came at the same time that environmental policymakers began framing environmental problems such as biodiversity loss, the greenhouse effect, and the thinning of the ozone layer, as *global problems*. No longer was it enough to *think globally, act locally*. In an era of globalization, the new interpretation of environmental problems suggested that people must *think globally, act globally*. SD ethically frames many of these actions.

The Definitional Problems of SD

While critics of SD come from many policy positions, they all agree on its lack of clarity. What should be *sustained* in SD: the economy, the environment, human welfare? Whose *needs* and whose *development* should be promoted? What should be *developed?* Is *development* the same as growth? Does development refer to production growth, as is typically indicated by growth of gross national product; does it refer to environmental growth, such as an improvement of environmental resources; or does development refer to growth in human welfare, including health, working conditions, and income distribution? (Ekins 1993). To deal with some of these problems, analysts and communities have begun constructing indicators for SD, such as those being created by "sustainable cities," such as Seattle (Portney 2003).

Some critics of the concept argue that it is old wine in new bottles in that it only requires slight modifications to existing modes of production, existing political structures, and existing values. New laws, international treaties, and better education, among others, will produce SD. Marxist interpretations, such as that put forward by Sharachandra Lélé, note that the concept "Does not contradict the deep-rooted normative notion of development as economic growth. In other words, SD is an attempt to have one's cake and eat it too" (Lélé 1991, p. 618). Fred Buttel, nonetheless, points out some of the advantages of the concept:

> SD still does focus our attention on the two great contradictions of the world today: The long-term compromising of the integrity of ecosystems (local as well as global ones) and the tendency toward reinforcement of the socioeconomic processes of social exclusion of billions of the world's people. Because of its relevance to spotlighting attention on these two great institutional failures of our epoch, SD allows a range of groups to contest structures and policies and to develop alternative visions of the future. (Buttel 1998, p. 265)

The treatment here assumes that there are three realms involved in SD that must be harmonized: ecological, economic, and social. Edward Barbier asserts that the objective of SD is "to maximize the goals across all these systems through an adaptive process of trade-offs (1987, p. 104). In sum, for development to be sustainable, the environment should be protected; people's economic situation should be improved; and social equity should be achieved.

Alternative Theoretical Perspectives on SD

According to some social theorists and science policy analysts, the impending scarcity of oil, the carbon buildup in the atmosphere, and the potential for global climate change are among the leading ecological problems now facing the world. These problems do not speak well for the sustainability of western cultural traditions, such as the national and international expansion of free market capitalism. Yet modern social theorists and science policy analysts are not of one mind as to how science, technology, and society may deal with these ecologically critical, global sustainability issues in the twenty-first century. Three different models to approach a sustainable future are outlined: the conservative, ecological modernization model; the state-oriented, managerial model; and the radical, neo-Marxian model.

THE CONSERVATIVE, ECOLOGICAL MODERNIZATION PERSPECTIVE. Some theorists and science policy analysts foresee the twenty-first century as the period of ecological modernization. As the impending global ecological crisis gathers force, capitalists—the leaders of national and multinational business and industry—will reflect upon their vital predicament and, through the power of the market and innovative technologies, create sustainable societies throughout the world.

In 1997 Amory and Hunter Lovins of the Rocky Mountain Institute together with Ernst von Weizsacher, Director of the Wuppertal Institute (Germany), published *Factor Four: Doubling Wealth, Halving Resource Use*. Their work, in the spirit of ecological modernization, focuses on waging a worldwide *efficiency revolution—increasing energy savings by a factor of four*. They note that, historically, production efficiency improved through technological changes in labor practices: industrialization, automation, and robotics. For them, the new focus of the production efficiency revolution will be gains in the use of natural resources, notably energy. To wage this revolution, they propose harnessing the power of markets through price adjustments to create incentives for technological innovation.

The authors of *Factor Four* cast a wide net, focusing on how the efficiency revolution applies to transportation, design and building methods, natural resource conservation, agriculture, and energy. Common to these ways of using energy and natural resources more efficiently is the argument that "in many cases saving resources could cost less than buying and using them" (von Weizsacher, Lovins, and Lovins 1997, p. 146). Their examples include the Morro Bay, California, homebuilding program. In that program, builders were required to demonstrate that they reduced water consumption by twice what their next new home owners would consume by free installation of water efficient plumbing in already existing homes. Other examples include the use of more costly fluorescent lamps that last ten times longer than incandescent lamps; laptop computers that use one percent of the electricity consumed by desktop units; and more efficient air conditioning, in part through *superwindows* made to emit light, not heat.

Von Weitzsacher, Lovins, and Lovins identify former President Clinton's Partnership for a New Generation of Vehicles as a voice of the efficiency revolution. The hypercar is the centerpiece of this partnership between government and the Big Three U.S. auto makers—DaimlerChrysler, Ford, and General Motors. Capable of making a coast-to-coast trip on a single tank of fuel, the hypercar achieves fuel efficiency through the dual strategy of a streamlined, *slippery* body that is ultralight and a hybrid-electric/gasoline power unit. The hypercar also circumvents the problem of managing the waste build-up of engine batteries that could leak acid into the ground, water, or both.

The ecological modernization approach may contribute to economic growth and environmental protection, however, it is not clear whether it promotes or enlarges social equity. The model has been especially prevalent in Europe (Mol and Spaargaren 2002).

THE STATE-ORIENTED, MANAGERIAL PERSPECTIVE. A managerial approach seeks to reform, but not revolutionize, the existing political and legal structure of societies to achieve SD. Some recent programs undertaken by national governments and government-funded international development agencies exemplify managerial approaches. One such managerial effort is biodiversity conservation. Biodiversity protection addresses the goals of SD by preserving biological diversity and providing the potential for long-term social and economic benefits through sustained resource use and tourism. This effort at SD is exemplified by work on Ecuador done by environmental sociologist Thomas Rudel in 2003.

Esmeraldas, located in northwestern Ecuador, consists of tropical rain forests that contain an array of rarely seen biodiversity. It also has one of the highest deforestation rates in Latin America (between 2–4% annually). The rapid deforestation of this ecologically significant environment drives international efforts to make forestry sustainable in Ecuador. At least three social forces impel the rapid deforestation of Esmeraldas's lush tropical forests: It contains commercially valued hardwood; it is accessible to urban markets; and there is economic and population pressure to attain work logging the rain forest.

Over the last half of the twentieth century, the Ecuadorian government established an extensive set of national parks and forest reserves. Two reserves are located in Esmeraldas, the Cayapas-Mataje Reserve and the Cotacachi-Cayapas Reserve. A state-appointed forest service manages all of Ecuador's forest reserves. The forest service issues logging permits to the urban-based lumber companies and receives a stumpage tax for harvested trees in the reserves. The Ecuadorian government uses the tax receipts to pay forest service officers and to pay off government debt to international economic development agencies. Thus a fourth cause to deforestation in this area is that this state managerial arrangement encourages the exploitation of Ecuador's rain forests.

In spite of this state-induced system of tropical deforestation, increasingly influential national and international environmental groups and development organizations working in Ecuador have managed to promote sustainable forestry practices in the reserves. One such arrangement involves an economic development contract between the Ecuadorian government and USAID. The goal of this program is to form and develop Sustainable Use of Biological Reserves (SUBIR) in Ecuador. Using USAID funds, Ecuadorian officials fund ecologists to set the annual volume of rain forest harvesting equal to the annual rate of rain forest growth in the reserves and buffer zones adjacent to the reserves. In the rural community of Playa de Oro outside of the Cotacachi-Cayapas Reserve, village leaders are trying to take advantage of SUBIR by developing ecotourism. Thus the USAID program is leading to both sustainable forestry and economic growth for a rural village.

In another example, Deutche Gesellschaf fur Technische Zusammenarbeit (GTZ), the German equivalent of USAID, has organized a council of more than fifty Afro-Ecuadorian village leaders to practice sustainable forestry, to bargain collectively with the lumber companies, and to replant whatever trees are harvested. By practicing sustainable forestry, and by gaining a fairer return on the trees harvested in the reserves, Esmeraldas villages are an important, new experiment in sustainability in a highly diverse ecosystem.

These Ecuadorian SD efforts represent two of thirty-two working contracts involving international economic development agencies, national and provincial officials, village leaders, lumber companies, and environmental organizations. These efforts simultaneously attempt to alleviate problems of poverty, inequality, and biodiversity loss through land conservation. They are not without problems; however, they are a concrete attempt at reconciling the tensions between ecological, economic, and social systems.

THE RADICAL, NEO-MARXIAN PERSPECTIVE. Marxists or, in this designation, radicals, conceptualize environmental problems as inherent irrationalities in the capitalist mode of production (Humphrey, Lewis, and Buttel 2002). Radicals insist that economic expansion is the basic causal force by which capitalism resolves economic and social crises. The capitalist class and their allies, such as state officials, deflect discontent with social inequality by perpetuating economic growth necessary for the increased wages and rising material standards of living for the working class. Through this material, wage-based enfranchisement of workers, the capital class avoids the overt repression of workers, protects their own privileged relationship to private property, and garners monetary profit, at a substantial cost to the environment.

Anthropologist Ramachandra Guha's *The Unquiet Woods* (2000) illustrates the radical framework in the context of Badyargah. Located in the foothills of northern India's Himalayas, Badyargah is a cluster of homogeneous, egalitarian rural villages in the state of Tehri Garhwal. For centuries, the villagers of Badyargah, practiced a form of sustainable subsistence agriculture. Badyargah villagers lived well on fresh fish, rice, wheat, millet, and the meat of their lambs and sheep. The sustainability of Badyargah's agriculture began to decline following the first state-subsidized road building in the mid-1960s. At the time India's national government began boosting private capital expansion by awarding private logging contracts to outside lumber companies. Once a national forest surrounding a Badyargah village was harvested, Indian state foresters strictly excluded villagers from reentry to protect the regeneration of commercially valued trees.

Anticipating a particularly large commercial logging contract in 1979, Badyargah village leaders began planning rural, grassroots resistance. They contacted Sunderlal Bahuguna, a leading environmental activist in the Indian hill region. Bahuguna and his followers persuaded residents of forest-dependent villages to practice Chipko. To resist logging, the villagers hug trees. The Chipko movement forces loggers to choose between sparing the trees or taking human lives. As part of this episode, Bahuguna went on a well-publicized hunger strike, and, day and night, 3,000 villagers guarded the site of the anticipated commercial logging. The government and contractor abandoned the logging plans.

This radical, grassroots resistance movement to protect local forests for use by the villagers was by no means an isolated episode in this part of rural India. Local, radical resistance to commercial logging in Tehri Garhwal became so prevalent that the government forestry department declared a fifteen-year, statewide moratorium on commercial logging beginning in 1982. Yet scholarly observers such as Guha do not anticipate the end of the Chipko movement in northern India. The modernization process, driven by capitalism, is bringing large dams, increased mining, and mountaineer tourism into the region. "The intensification of resource exploitation," Guha writes, "has been matched almost step by step with a sustained opposition, in which Chipko has played a crucial role, in catalyzing and broadening the social consciousness of the Himalyan peasantry" (Guha 2000, p. 179). Whether this radical environmentalism will bring back the sustainable rural economy of rural northern India remains to be seen.

Assessment

Beginning with the international debates over the implications of *The Limits to Growth* in the 1970s, scientists, environmentalists, and state officials have extensively engaged in global efforts to seek international consensus about the meaning and practice of SD. SD policies, ultimately, involve ethical decision-making about how science and technology can be applied in economic development efforts worldwide. The examples used to illustrate contemporary SD efforts highlight an important point. There is no one-size-fits-all model of SD.

Ecological modernization appears to be central to SD efforts in the Global North (the more developed, industrialized nations) in the early twenty-first century. Led by profit-oriented entrepreneurs trained in science and technology, ecological modernization aims to ecologize the economies of advanced industrial countries. Ecological modernization as an SD effort, exemplified by the hypercar, has a strong appeal to capitalists and mainline environmental groups. This form of modernization emphasizes ecological rationality in the use of natural resources for profit. Using the ethical criteria for SD, however, indicates that ecological modernization trades off social equity concerns for the sake of environmental and economic gains.

The grassroots, rural resistance movements against modernization in parts of the Global South—exemplified by the Chipko movement in northern India—is an oppositional struggle for SD. Reflecting the Gandhian tradition of nonviolent resistance that brought India to national independence in the mid-twentieth century, the Chipko movement brings sustainable rural subsistence traditions to SD efforts in India. The Chipko movement trades off economic growth for the sake of social equity and environmental integrity.

Rural development in the province of Esmeraldas, Ecuador, underscores the not-one-size-fits-all nature of SD. According to Rudel, forest-dependent organizations in Esmeraldas have initiated lobbying efforts to lift the national ban on timber exports. Because of the sustainable harvesting practiced by these Ecuadorian organizations, and because of the relatively high wages earned by the new logging cooperatives, Esmeraldas's export lumber could be ecologically approved by an international, third party certification agency. This potential certification could mean a higher demand for Ecuadorian tropical woods in the international lumber market. That potential development, in turn, could bring more wealth, sustainable forestry, and, possibly, more income equality among Esmeraldas workers—the three criteria needed for fully meeting the ethical standards for SD. Esmeraldas, thus, could become an exemplary SD model in the early-twenty-first century.

SYSTEMS AND SYSTEMS THINKING

A system is defined by a set of distinctive relationships among a group of components that interact with one another and their environment through the exchange of energy, matter, and/or information. These relationships produce a new entity, the whole, that requires its own level of analysis. The technical use of the concept of a system in science and technology dates back to the 1950s. Systems thinking subsequently become a catchall term for different postwar developments in a variety of fields, such as cybernetics, information theory, network theory, game theory, automaton theory, systems science and engineering, and operations research. An underlying theme in these developments is a shift from reductionistic thinking and compartmentalized organization to holistic thinking aimed at understanding linkages among parts and increasing organizational communication. The rise of systems thinking has broad ethical and societal implications that range from practical changes in public decision making to the emergence of a worldview critical of some instances of scientific and technological hubris.

A Taxonomic History

During the second half of the twentieth century amalgams of the terms *system* and *systems* became ubiquitous. Computer and operating systems were joined by biological, business, and political systems. Systems science and systems engineering were complemented by systems management, systems medicine, and the practice of looking at the earth as a system. However, the systems thinking in all these cases can be divided into three basic types: systems theory, systems methodology, and systems philosophy. In the history of systems thinking each realm has followed its own path, with many overlaps and interactions.

SYSTEMS THEORY. The birth of systems theory took place in the technical sciences during World War II when the scientist Norbert Wiener (1894–1964) studied control problems with antiaircraft fire. Those studies concerning communication and control in particular technical systems inspired Wiener to more general reflections on what he came to call the science of cybernetics (Wiener 1948). Although Wiener did not stress the system concept, system, he argued in effect that any type of system can be understood with the help of general laws or principles. In Wiener's cybernetics two main ideas figure: feedback, with its regulating and stabilizing properties, and transmission of information, which helps transform the many parts of a complex system into a whole. A mathematical elaboration of the concept of information was developed by Claude E. Shannon (1916–2001).

The success of cybernetics and information theory created a fertile climate for a theoretical movement based on new principles and oriented toward concepts such as system, organization, and regulation. A leading figure in the rise and development of systems theory was the biologist-philosopher Ludwig von Bertalanffy (1901–1972), who attempted to overcome mechanistic reductionism, in biology in particular but also in scientific thought in general, and persistently opposed a machine view of the world. Although he agreed with Wiener that cybernetics can provide insights into the teleological behavior of systems, he argued that the principle of feedback adopts essentially a machine view.

For von Bertalanffy (1968) a machine is composed of durable components and therefore is primarily static in character. A characteristic of the cybernetic model is that fixed structures must be present to make regulation by feedback possible. An organism, however, is characterized primarily by a dynamic ordering and maintains its structures in a continuous process of building up and breaking down (e.g., human red blood cells are replaced at a rate of 2 million to 3 million per second). The organism is thus not a closed system with a static mechanical structure but an open system in flowing or dynamic equilibrium. Such systems also are characterized by emergent properties: characteristics that are not evident when one studies system components in isolation from one another. Systems theory often is seen as a way to retain holism and organicism without positing teleological or vitalist philosophies.

Opposing Wiener's claim that the cybernetic model is the basis for a universal science, von Bertalanffy argued that the open-system model has universal validity and provides the proper foundation for a "general system theory." In 1954 he and others, among them Kenneth Boulding, Anatol Rapoport, and Ralph Gerard, founded the Society for General Systems Research, which later was renamed the International Society for the Systems Sciences (ISSS). The ISSS brought together areas of research with dissimilar contents but similar structures or philosophical bases to enable researchers in various fields to develop a common language. Systems theory in this sense aspired to become a transdisciplinary science.

Systems theory and the quest for a general systems theory received a new impetus in the 1960s when Heinz von Foerster (1911–2002) introduced the concept of self-organization and later, in the 1970s, when Humberto R. Maturana and Francisco J. Varela (1980) proposed the concept of autopoiesis and developed the model of the organism as an autopoietic system. The term *autopoiesis* means "self-creation" and refers to the propensity of living and certain other nonequilibrium systems to remain stable for long periods despite the fact that matter and energy flow through them. Ilya Prigogine (1917–2003) further refined systems theory with the notion of dissipative systems: open systems that exchange energy, matter, and information with their environment; operate far from thermodynamic equilibrium; and display the spontaneous appearance of complex organization.

According to the social theorist Niklas Luhmann (1995), the concepts of self-organization and autopoiesis allow a further step, moving from a general systems theory based on the open-system model to a general theory of self-referential systems of social meaning and communication. Luhmann's application of systems theory to modern societies rejected the normative orientation of sociologists such as Émile Durkheim (1858–1917) and Talcott Parsons (1902–1979). He argued instead that systems theory has to drop all references to actors and their self-interpretations and focus on the ways in which complex social systems arise, much as living organisms do, through autopoiesis.

SYSTEMS METHODOLOGY. Systems methodology is concerned with the scientific method for approaching practical problems in technology and society. It may be defined as the theoretical study of practice-oriented methods in science and engineering, in which the notion of the system indicates an approach that is intended to be integrating and holistic. As with systems theory, systems methodology arose out of postwar developments in technology, in this case systems engineering and operations research. Although operations research usually is concerned with the operation of an existing system, systems engineering investigates the planning and design of new systems.

The dominance of reductionistic and mechanistic thinking that was criticized by von Bertalanffy (1968) in his quest for a general system theory also became an important issue in systems methodology. As a leading representative, Russell L. Ackoff (1974) defended a systems approach to counter what he called "Machine Age" thinking. Together with C. West Churchman he founded one of the first systems groups in the United States at the philosophy department at the University of Pennsylvania shortly after World War II. Comparable developments took place in England at the University of Lancaster with the pioneering work of Geoffrey Vickers and Peter Checkland. Checkland observed that variants of systems thinking transferred from technology to the social domain were not especially successful. Following from that observation Checkland started to seek an alternative for the engineer's approach and tried to shift from what he called "hard systems thinking" (technical, quantitative models) to "soft systems thinking" (the incorporation of human values and perspectives).

A new impetus to the development of systems methodology came from the work of the social theorist and philosopher Jürgen Habermas (b. 1929). Habermas critiqued the dominance of technical categories in Luhmann's theory and the absence of human actors with conscious intentions in the development of modern society. In the 1980s this inspired a younger generation to work out a program termed critical systems thinking. Michael Jackson, Robert Flood, and Werner Ulrich became influential in this area.

In the late 1990s, inspired by the legacy of the Dutch philosopher and legal theorist Herman Dooyeweerd (1894–1977) an attempt was made in systems thinking to break with the Western idea of human autonomy and autonomous rationality. Fundamental to that research program was the notion of intrinsic meaning and the normativity of reality. Merging Dooyeweerd's theory of modalities and Stafford Beer's cybernetic theory of management, J. D. R. de Raadt launched "multi-modal systems thinking." Sytse Strijbos followed another more radical strategy by focusing on the underlying ontology and philosophical underpinnings of systems methodology. Borrowing from Dooyeweerd's notion of disclosure, Strijbos laid the foundations of "disclosive systems thinking." Industrial ecology and product life-cycle analyses are other versions of systems methodology that are used to make large-scale decisions with the goal of achieving sustainable energy and material flows (Graedel and Allenby 2003).

SYSTEMS PHILOSOPHY. Although systems philosophy was mentioned earlier in conjunction with systems theory (Wiener, von Bertalanffy, and others all attempted to develop the philosophical implications of their work) and systems methodology (for a while Ackoff and Churchman were based in an academic philosophy department), this approach merits independent recognition. In the 1970s, for instance, the Hungarian philosopher Ervin Laszlo tried to build on von Bertalanffy's ideas for a new scientific worldview, including a philosophy of nature, to develop a systems philosophy that would bring the latest developments in science to bear in conceptualizing the social problems of the emerging global society (Laszlo 1972). However, for clarity it is useful to distinguish at least four senses in which the terms *system* and *philosophy* have been connected.

First, there is the traditional sense in which philosophy aspires to be systematic, that is, to cover all the basic issues in a manner that properly subordinates and relates them. It is in this sense that one speaks of a philosophical system such as those of the philosophers Immanuel Kant (1724–1804) and Georg Friedrich Wilhelm Hegel (1770–1831). This is the oldest but in the current instance least significant connection.

Second, in the 1970s Laszlo aspired to formulate a systems philosophy keyed to the latest developments in science and to the urgent problems of contemporary global society. This type of systems thinking plays heavily into larger changes both in cultural norms and in social laws and institutions. Laszlo has been a prolific author whose books range from promotional work on systems philosophy to analyses of world modeling, sustainability, globalization, consciousness, and future studies. He is the founding editor of *World Futures: The Journal of General Evolution*, which began publication in 1980. Systems philosophers of this type often draw inspiration from process philosophy, especially the ideas of Alfred North Whitehead (1861–1947).

A more hard-nosed version of systems philosophy is found in the work of the Argentine-Canadian philosopher Mario Bunge (1979). For Bunge systems science is a research program for the construction of a "scientific metaphysics" built on well-defined, scientifically based concepts but having broad generality.

Third, systems philosophy deals with the philosophical issues of systems theory. Systems philosophy in this sense may be related to philosophical analyses of chaos and complexity and efforts to draw from those studies general implications for understanding nature and acting in the world. Chaos theory and complexity theory especially emphasize emergent properties and the self-organization of complex systems.

Fourth, systems philosophy concerns the philosophical foundations of systems methodology and thus deals with issues about human intervention in the world. It is a distinguishing feature of E. G. Churchman's work in management science that it closely connected with a philosophy of the systems approach. Management to Churchman has to deal with the ethical challenge to design improvement. But what constitutes an improvement and how can we design improvement without understanding the whole system?

Implications and Assessment

Systems thinking denotes the effort to define a nonreductive method for conceptualizing and explaining phenomena in both nature and society. As such it has a number of ethical and political implications that may be indicated roughly as follows.

First, systems thinking often claims to give a better account of the genealogy of ethics than did previous analyses. Ethics is described as an emergent property of complex living systems. Second, the opposition of systems thinking to nonsystems thinking almost always has a moral dimension. Systems thinking is said to be superior to nonsystems thinking in both theory and practice because it understands the world more accurately and provides better guidance for human action. Just as systems science yields better knowledge of the complexities of nature and artifice, systems engineering and systems management ground more effective interventions in nature, the construction of large-scale artificial systems, and the maintenance and management of their complex interactions.

These morally flavored claims can, however, cut two ways: to promote science and technology or to delimit them. On the one hand, systems thinking has played a large role in advancing scientific knowledge and technological development in the post–World War II era. It has done this both in the form of specific methodologies and theories and in the inculcation of a general receptivity to and awareness of interconnectivity in scientific and engineering communities. Some of its most significant impacts have occurred in biology, especially in the rise of ecology and in refinements of genomics. Institutional changes in the social structure of knowledge, especially increased interdisciplinarity, also have resulted from systems thinking.

On the other hand, systems thinking at times has criticized the modern scientific and technological project. In this critique of technological hubris, connections can be developed easily, for instance, between systems thinking and environmental thinking. Although he did not use the term, Aldo Leopold (1887–1948) essentially argued that the concept of the system forms the foundation of ethics: "All ethics so far evolved rest upon a single premise: that the individual is a member of a community of interdependent parts" (Leopold 1949, p. 203).

In a like manner Fritjof Capra (1997) has argued that new research on the organization of living systems promotes a reexamination of social policies. Systems thinking is both a scientific shift and a cultural paradigm shift away from mechanism and reductionism, but the relationship between those two shifts is complex and ethically charged. Capra, for instance, argues that systems research supports social egalitarianism, but that argument raises ethical questions about deriving political and moral conclusions from observations about nature. This is the same dilemma often raised by political conclusions drawn from the more reductionistic theories of sociobiology. The focus on wholeness, interconnectedness, and complexity thus has had an ambiguous impact on the larger realm of cultural and philosophical thought.

Thus, although it doubtlessly has been associated with some criticisms of technological and scientific hubris, systems thinking also has generated new versions of that hubris. For example, Luhmann's brand of systems thinking seeks to abstract a "grand theory" or a universal framework that is not concerned with individual humans, only the abstractions of information exchange. That led Habermas to label it as a version of "antihumanistic" sociology that denies the ability of individuals and institutions to guide social change consciously. Indeed, worldviews that stress holism always create a risk of losing lose sight of individual values such as dignity, freedom, and intentionality. In this case modern societies are seen as polycentric, and democratic participation and control as illusory, in the face of overwhelming complexity. However, it is difficult to conceive of justice and many other social values being realized by an autopoietic process devoid of intentional agency.

Similar two-sided features can be identified in proposals by Brad Allenby and others for the development of earth systems engineering and management. The bottom line is that systems and systems thinking remain ambivalent in their ethical import with regard to science and technology, but that ambivalence also may be their basic strength. Surely there is a sense in which science and technology need to be promoted and criticized at the same time.

T

TAYLOR, FREDERICK W.

Frederick Winslow Taylor (1856–1915), who believed that his system of scientific management provided the foundations for a scientific ethics, was born in Germantown, Pennsylvania, on March 20. His early education took place in private schools in Pennsylvania, Europe, and New Hampshire, and he was accepted for admission into Harvard University. But fascinated by the relationship among science, technology, and ethics, he decided on an apprenticeship at a steel company in Philadelphia, where, from 1878 to 1884, he advanced from common laborer to a supervisory mechanical engineer. In the process he became familiar with *soldiering,* when workers, to protect jobs and keep piece-rates high, increased output while bosses were watching and decreased it otherwise. An ardent believer in the Puritan work ethic, Taylor was troubled by this inefficient and unethical behavior, and came to believe that he had a solution not only for the Midvale Steel Company but for institutions throughout the world. He pursued this vision until his death in Philadelphia, Pennsylvania, on March 21.

Frederick W. Taylor, 1856–1915. Taylor consolidated a system of managerial authority, often referred to as scientific management, that encouraged a shift in knowledge of production from the workers to the managers. *(© Bettmann/Corbis.)*

Taylor's Studies

Taylor began by systematically studying machinery and human beings to discover precisely how much a diligent worker, using the best machines and procedures, could produce in a day. For example, his empirical analysis of metal-cutting machinery allowed him to more than double the machine's speed, and by analyzing the machinist's procedures into elementary motions, and timing them with a stop watch, he was able to minimize wasteful motions and optimize beneficial ones. This led to a belief that all tasks, from the lowliest to the highest, could be made more efficient, and the resulting increase in productivity would optimize everyone's compensation and job satisfaction. He argued that a "single best way" existed for accomplishing every task, and that his scientific analysis of human technology interventions achieved an ethical goal: the resolution of the age-old conflict between labor and management.

After Taylor left Midvale in 1890, he spread the gospel of scientific management while occupying a series of positions from Maine to Wisconsin. He lived at a time when many Americans believed science and technology had the solution to many problems of humanity, but also during a time when bitter strikes sometimes resulted in the deaths of workers. Labor leaders and politicians criticized Taylor's claim that his system would end owner-worker hostility and render unions and strikes unnecessary. They pointed out that workers could not be treated in the same way as machines, and that several creative ways existed for accomplishing tasks rather than Taylor's one best way. Others questioned Taylor's yoking of productivity and morality. Taylor emphasized that wise work produced ethical workers, whereas others insisted that human morality motivated hard work.

During the final decades of Taylor's life, his obsession with efficiency deepened. Managers as well as laborers often resented his despotic attempts to change traditional methods of work and management. To those who said that scientific management was antidemocratic, he insisted that his techniques energized workers, promoted their self-reliance, increased their wages, and shortened their work week. To those who said that scientific management was unethical, he emphasized that his methods enhanced fellow feeling among workers and between workers and managers because he promoted true justice by encouraging the maximum efficiency and prosperity of all those involved in his system. But labor leaders and some politicians saw scientific management simply as a tool for maximizing production and profits to the neglect of the emotional and physical health of the workers. For them, Taylor's methods debilitated workers and increased accidents.

Taylor's Influence

In the early decades of the twentieth century, Taylor's ideas continued to generate both critics and advocates. In 1911 Taylor's disciples founded the Society to Promote the Science of Management (called, after his death, the Taylor Society) and he himself published *The Principles of Scientific Management*. In 1912 Taylor's system was debated at a Congressional hearing during which he defended his system as a force for good, but some committee members felt that he did not grasp the deep asymmetry between labor and management. Nevertheless, in its report the committee found some things to praise in scientific management—for example, standardization.

In the years after Taylor's death, Taylorism spread around the world. Taylor's disciples preached the gospel of efficiency to a wider audience than just businessmen—including housewives, teachers, even clergy. Like Taylor, his disciples viewed his doctrines as a means of transforming society, because the pivotal point differentiating civilized from uncivilized societies was productivity. Some of Taylor's disciples criticized their master—for example, Frank Gilbreth advocated replacing stopwatch studies with "micromotion" analyses in which each minute of a worker's activities was filmed and divided into a hundred units. Even Vladimir Lenin was influenced and thought Taylorism compatible with communism.

However, humanists such as Lewis Mumford (1895–1990) felt that Taylor's system got it backward: Humans come before and transcend systems. Some even saw Taylorism as deeply unethical, because its mechanistic treatment of workers was both an illusion and a delusion. During the twentieth century scientific management evolved and diversified, and it was no longer a unified and consistent body of thought. Although Taylor's goals of establishing social and economic justice and ending class conflict have not been achieved, his ideas, transformed and diversified, continue to influence various ideologies of science, technology, and ethics.

TECHNICAL FUNCTIONS

One common way to describe artifacts is in terms of how they technically *function*. In a telephone sound is transformed into electronic signals that are then transmitted over some distance and transformed back into sound by another telephone. Such technical functions are strongly related to human uses. Telephones are designed and built so that they can be used for transmitting the human voice over distances well beyond its normal range. Because references to technical functions are often the basis for assessing human uses of artifacts, and insofar as such assessments express certain values, the relation between technical functions and uses is an issue for any ethics of technology.

Judging Actions and Artifacts

All intentional human behaviors or actions are subject to normative judgments. These judgments are of two sorts: deontic and evaluative. Deontic judgments express what one ought and ought not to do or what one has reasons for doing. Evaluative judgments describe something as good or bad. Using an artifact is subject to these types of judgments, in the first place because it is a form of action. It is generally wrong, for example, to hurt another person with a knife, which is merely a specification of the judgment that one ought, generally, not to hurt someone.

Additionally, however, the use of artifacts is subject to judgments that relate directly to the particular function of the artifact. For instance, one may say that it is wrong to use a Phillips screwdriver to open a paint can. Assuming that the attempt to open the can is itself perfectly in order, the *wrong* here is not morally wrong but *instrumentally* or functionally wrong: Using the Phillips screwdriver will not smoothly lead to the desired outcome. Typical for artifact use, such judgments may be translated, so to speak, to the artifacts themselves. An artifact is said to perform its function well or to function poorly or to malfunction. One can also say that a particular artifact, in the prevailing circumstances, *ought to do such-and-such a thing*. Even natural objects can, in a context of use, be subject to such judgments, for instance when one says that a particular stone is *a good stone to use as a hammer*.

Functions

The use of the term function in the previous paragraphs sets aside a considerable philosophical debate about the meaning of functions, one that has taken place largely in relation to the analysis of functions in biology (the function of the heart is to pump blood) and the social sciences (the function of religion is to create social cohesion).

Briefly there are two major competing concepts of functions: system functions as first stated by Robert Cummins, and proper functions as first stated by Larry Wright (1973) and further analyzed by Ruth Millikan, Karen Neander, and others. According to Cummins (1975), who is primarily concerned with biological systems, something has a function insofar as it contributes to the capacity of some system. According to Millikan, by contrast, the *proper* function of an organ or system is what helps to account for the survival and proliferation of its ancestors (1993). Millikan aims for a theory of functions that applies to artifacts as well as organisms.

Against these attempts to bring all uses of the notion of function under a single theory, Beth Preston (1998) argues for a *pluralistic theory of functions* that includes Cummins's system functions and Millikan's proper functions. Wybo Houkes and Pieter Vermaas (2004) hold that theories of artifacts are overly function-oriented and that a theory of artifact functions can be derived from a theory of artifact actions. For Preston, as well as for Houkes and Vermaas and for many others, functions often become the locus in both science and technology for the uniting of deontic and evaluative judgments.

Uniting Deontic and Evaluative Judgments

There is, however, no consensus of what precisely unites deontic and evaluative judgments insofar as they jointly comprise the realm of the normative. One account proposed by Joseph Raz (1999) and Jonathan Dancy (2005) holds that normative facts are facts expressing how other facts—natural or positive facts—matter to the question how to act. The deontic judgment that *To do X is right* then expresses the normative fact that there is the positive fact of X possessing certain features, *and* that these features are such that, in the circumstances at hand, the balance of reasons points toward the doing of X. The evaluative judgment that *X is good* similarly expresses the normative fact that the features of X are such that one has reason, perhaps even a compelling reason, to adopt a certain positive attitude toward X. What this positive attitude could be depends on the nature of X.

In contrast to a lack of clarity concerning the normative in general, there is wide agreement among philosophers that *instrumental* value should be sharply distinguished from *moral* or *ethical* value. To see the difference between these two forms of value, consider the statement: This is a good knife to kill Mrs. Robinson with. The knife is instrumentally good as a *means* to an end, but the *end*, the killing of Mrs. Robinson, is *morally bad.* One has reason to disapprove of Mrs. Robinson's violent death, and ought to prevent it. But *given* that the killing of Mrs. Robinson is sought, to do it with this knife may be considered a good and recommendable choice. Instrumental value is therefore in a sense conditional: It concerns the fitness of a particular means to the realization of an end once that end is given, whereas it is not concerned with any pros or cons regarding the end itself.

The distinction between moral value and instrumental value is closely related to a distinction among the sorts of reasons that back up an act or an attitude or a belief. If means M is fit to end E such that one ought to choose M or choose to do M, this concerns an ought on rational grounds. By contrast, if M is morally good or bad, such that one ought to approve or disapprove of M, this concerns an ought on moral grounds. This way of distinguishing rational grounds from moral grounds sees the notion of rationality exclusively as instrumental rationality. Not all philosophers will agree, however, that rationality should be viewed thus.

Designing and Using Artifacts

The design and use of artifacts is involved with both kinds of grounds for normative judgments, but in particular cases it is not always obvious whether one or the other kind is at issue. Malfunction judgments and judgments of poor or proper functioning certainly have a special relation to considerations of rationality. A statement such as *Artifact A malfunctions* expresses the positive fact that A does not or will not show the behavior it was designed to show. However, this positive fact does not exhaust the meaning of the statement. It also seems that when an artifact malfunctions or functions poorly, human beings *by definition* have a reason not to use it, or at least not to use it as designed, on rational grounds. One cannot go as far as saying that the notion of malfunction or of poor functioning semantically implies that the item ought not be used. There may be reasons such that, on balance, it is rational to use the thing anyway. But if one applies the judgment of malfunction prior to any considerations of use, as a mere factual statement of the artifact's failure to show a certain behavior, it makes no sense to then ask whether that fact means anything about what one will do with the artifact. When an artifact is said to malfunction, one necessarily has at least *a* reason not to use it as designed.

Similarly to say that a particular artifact functions well is not just to say that it shows a certain behavior, as a positive fact, regardless of anything that one might do with it. This judgment implies that the item shows a particular behavior and that one has a reason to use it as designed. In this case, however, the conditionality of instrumental reason really has a bite: One has an overall reason to use something to produce the result that using the artifact in question produces. If one does not have a reason to use a car in the first place, because one is not going anywhere, then neither does one have a reason to use this particular car, which happens to be a very good car.

Whether one also has a reason *on moral grounds* not to use a malfunctioning or poorly functioning artifact, or even ought not to use such an artifact on moral grounds, is a question that raises different issues. The judgment might be motivated, for instance, by fear that the artifact's use would pose a hazard for other people. But such judgment often depends on the particular case at hand and thus is not covered in the *meaning* of malfunction. It is hardly worthwhile to discourage someone from using a Phillips screwdriver to open a paint can on moral grounds.

The rationality of artifact use depends critically on knowledge. To judge that the use of a particular object is the best means to achieve a certain goal requires an adequate knowledge of the object's properties and the effects of manipulating it in the prevailing circumstances. The use of the object can be rational only to the extent that the user's beliefs about the object are rationally justified. Rationally, in this sense, refers to *epistemic* rationality, and not *practical* rationality, which was the form of rationality relevant in the preceding considerations. In practical rationality, the issue is what it is best to *do,* or what one has a reason to do, given one's end of realizing a particular situation. For epistemic rationality the issue is what it is best to *believe,* or what beliefs one has a reason to adopt, given the end of holding as many true beliefs as possible or holding only true beliefs.

Proper Use and Good Design

When someone uses an artifact in disregard of its designed function, that is, according to some privately conceived use plan, reasons of epistemic rationality seem all that matter. (The concept of function as a use plan is developed at length by Houkes, Vermaas, Dorst and de Vries, 2002.) When the artifact's use fails to have the desired result, there is no one to blame. This is no longer true when an artifact is used for its designed function, in circumstances that are consistent with the artifact's use plan as explicated in the instructions for use. When handing over an artifact to a client who ordered it, or to the market, the designer/producer is committed to the veracity of the predictions made about the artifact's behavior. These predictions have the force of a promise, and the commitment accordingly has the character of a moral obligation. One could say that a designer ought, on moral grounds, to be epistemically rational. In practice the extent of this obligation is articulated in the form of standards that say how much research and testing is sufficient to vindicate the claims that are to be made about the artifact's performance.

It is part of the human condition that neither the criteria of epistemic and practical rationality nor the criteria of moral obligations can guarantee the realization of plans. One may be disappointed by fellow human beings as well as, metaphorically speaking, by nature. The ubiquity of uncertainty shows in the use of language when one says that a particular artifact *ought to do* something when handled in a certain way. This may express the idea that one is epistemically justified in one's belief that the artifact will perform as expected, given the amount of research and testing adopted in designing or in repairing the artifact, but at the same time there is a recognition that there is always the possibility that something was overlooked. The statement may also express the idea that one *has a right* to the artifact's performance, on the basis of a promise by a designer/producer, retailer, or repair service person, while there is at the same time the awareness that such promises are occasionally broken.

It seems natural that in what is summarily described as *good design* the grounds distinguished above play a role. An artifact that can be termed a good design must be instrumentally fit for its function in a range of plausible circumstances. However a well-designed artifact must also be one that it is morally vindicated to use. This can either mean that it is not likely to lead to outcomes of low moral value, for instance by being safe, or that it is likely to lead to outcomes of high value, which will often be a comparative matter.

Thus the features of a particular artifact may give rise to reasons, even compelling reasons, for its use in order to contribute to the realization of one's goals, by which such artifact is instrumentally good. It may also have features such that one has reasons, even compelling reasons, to approve and promote its use, by which it is morally or ethically good. Additionally, artifacts are often judged on the basis of a third criterion, previously not discussed, namely aesthetic appeal. Technical artifacts may have both instrumental and ethical value, or both instrumental and aesthetical value, or even all three. Some trash receptacle for public use may not only function perfectly as a trash receptacle, but it may also encourage people to use it to a larger extent than another type of trash receptacle, and on top of that be considered a beautiful object.

TECHNICISM

The term *technicism* is parallel in construction to "scientism" and serves many of the same purposes, although it is less common. While closely associated with the process of "technicization," technicism, like all "isms," offers a special perspective on the world and its character. The belief in technology as central to the world can take different forms, but is most commonly manifest in what may be called ethical technicism.

Origins

In the *Gorgias* Plato (c. 428–347 B.C.E.) already identified the character of technicism, the belief in means as in some sense primary over ends. Gorgias, a sophist, has separated his rhetorical skills (*technai*) from any firm subordination to substantive social or cultural traditions, not to mention to the good. This is a position that Socrates (c. 470–399 B.C.E.) strongly criticizes, but according to Karl Polanyi (1886–1964), Lewis Mumford (1895–1990), and other historians, it is precisely such a project of separating culture into various components and then pursuing each on its own terms that is the foundation of modern technology. When technics is pursued in terms of its own logic it becomes technology.

According to Max Weber (1864–1920), in his posthumously published studies titled *Economy and Society* (1922), traditional societies contain "techniques of every conceivable types of action, techniques of prayer, of asceticism, of thought and research, of memorizing, of education, of exercising political or hierocratic domination, of administration, of making love, of making war, of musical performance, of sculpture and painting, of arriving at legal decisions" (vol. 1, p. 65). But in traditional societies these techniques are embedded in mores and counter-mores institutions. The planting of crops is done efficiently, but also in accord with certain religious rituals. The building of houses is done effectively, but also with respect for various craft traditions and social distinctions. Efficiency and effectiveness do not operate independently of other social, culture, religious, aesthetic, ethical, and political constraints.

In the German tradition Max Scheler (1874–1928) was among the first to use the term *Technizismus* (technicism) to name an attitude toward the world that takes the pursuit of material effectiveness in means as itself a fundamental ideal. The term appears in Scheler's 1926 book *Die Wissensformen und die Gesellschaft*, but was also used in papers as early as 1914 in which he provided phenomenological sketches of different types of persons and leaders. For Scheler, it is the historical development of modern technological civilization that gave rise to technicism as a form of discourse (Janicaud 1994) or consciousness (Stanley 1978) that chooses to privilege means over ends—that is, to center public life around the pursuit of ever more effective means, while relegating questions of ends to issues of personal or private choice and decision-making. From this perspective, technicism has become a pejorative term especially among nonbehavioral social scientists.

Ethical Technicism

Among the first philosophers to analyze the ethical implications of separating out means from ends was José Ortega y Gasset (1883–1955). In the English translation of his *The Rebellion of the Masses* (1929), Ortega identifies three principles as fundamental to the twentieth century: liberal democracy, scientific experiment, and industrialism. "The two latter may be summed up in one word: technicism" (1932, p. 56). In fact, insofar as liberal democracy is also committed to public policies that promote the maximization of means, leaving ends to be determined by individuals, technicism covers the first principle as well. (In Spanish Ortega actually used the word *técnica*, but the translation "technicism" is significant as one of the earliest English occurrences in a new sense. In the previous century "technicism" meant simply excessive reliance on technical terminology.)

The next decade, in *Meditación de la técnica* (1939), Ortega outlined a historical movement from the chance inventions that characterize archaic societies, through the trial-and-error techniques of the artisan, to the scientific technologies of the engineer. According to Ortega, the difference between these three forms of making lies in the way one creates the means to realize a human project—that is, in the way technicalness or technicity is manifest. In the first epoch technicity is hidden behind accidents, whereas in the second, technicity is cultivated and protected in craft traditions. In the third, however, the inventor has undertaken scientific studies of technics and, as a result, "prior to the possession of any [particular] technics, already possesses technics [itself]" (*Obras completas* V, p. 369). It is this third type of technicity that constitutes "modern technicism" (and here Ortega himself uses the term *tecnicismo*).

But technicism understood as the science of how to generate all possible means independent from any lives making and using context creates a unique existential problem. There is a temptation to pursue technical invention as a good in itself, to become lost in the technical means as exciting or valuable in their own right. Prior to the modern period human beings were limited by circumstances in which they at once acquired a way of life and the technical means to realize it. Now in liberal societies they are given in advance a plethora of technical means but no well-defined sense of the good other than personal choice. "To be an engineer and only an engineer is to be everything possibly and nothing actually" (*Obras completas* V, p. 366). In the midst of modern technicsm Ortega discovers a crisis of imagination and choice. Insofar as people can be anything at all, why should they be any one thing? What Ortega imagined has become real in the case of those who play with their avatars in cyberspace while failing to become something in the world.

Epistemological Technicism

The engineer Billy Vaughn Koen, however, proposes the engineering method as the fundamental way of knowing and acting in the world in a way that turns technicism from an ethical problem into an epistemological method. Koen does not use the term technicism, perhaps because of its negative connotations. But his argument is that engineering is the method that all human beings use, and indeed must use, whenever they solve problems. "*To be human is to be an engineer*" (2003, p. 7; italics in original) whether one knows it or not. There is simply no alternative.

For Koen, "The *engineering method* is the use of heuristics to cause the best change in a poorly understood situation within the available resources" (p. 59). Heuristics are simply strategies based on some hunch, rule of thumb, or intuition, about what might work, that include both a rejection of any absolute sense or certainty and a willingness to revise in response to experience in order to make things better. In Koen's perspective, the engineering method is universal precisely because it does not claim to be universal. The engineering response to Ortega's problem is simply to try something. No situation of even apparently unlimited possibilities can remain that way forever. There is in the end an excitement about an epistemological technicism that sees necessity as unnecessary and is therefore willing to play with possibilities and see what happens.

TECHNICIZATION

The challenges posed by modern science and technology to ethics include the challenge of technicization. Technicization is a process that some contend infects and thereby corrupts ethics. To understand this claim requires an understanding of the process of technicization (related terms: technicism, technization, technicalization, scientism, scientization, mechanization) in relation to the task of ethical reflection.

Technological civilization is made up not only of machines but also and more importantly the methods or "techniques" that produce machines. Technique is rooted in the human capacity for language that gives humans the ability to imagine ever-new goals and the means to achieve them. For most of human history techniques were embedded in a wider array of cultural beliefs and practices and passed on as part of the culture from one generation to the next. One did things in a certain way because that was how one's ancestors did them. Such techniques were not inherently related to science.

When modern science intersected with ancient technologies beginning in the seventeenth century, the result was the technicization of society. This occurred when scientific investigation systematically evaluated not only the array of techniques historically available from all cultures for accomplishing human ends but also systematically studied the process by which techniques come to be invented, so as to refine the efficiency and effectiveness of the invention process itself. The ultimate goal of the science of technical development is the creation of the most efficient techniques in all areas of human endeavor so that every aspect of life is shaped by technical norms of efficiency.

The application of science to technique transforms the way human beings understand themselves and human societies organize themselves and their tasks. In premodern societies "essence" was thought to precede "existence"—that is, human beings thought of their selves and their institutions as having a preordained natural course of development (their *telos*) as part of an unchanging sacred natural order established by the gods and ancestors and/or nature itself.

From the ancient Greeks right on through the Enlightenment, social, political and ethical theory was dominated by the assumption that there is either a supernatural (the Platonic tradition and its successors) or a natural (the Aristotelian tradition and its successors) telos or archetype that must be discovered and implemented in human society. Society, as the Greeks said, is the cosmos writ small and later thinkers such as Hobbes and Rousseau still gave assent to such a view although there understandings of "nature" certainly differed. Even when Kant split noumena from phenomena he still assumed a universal rational human nature. Hence, whereas there was comparative reflection on social organization and speculation as to the best order for society from the time of the ancient Greek philosophers, it was assumed that the best order could not be discovered in the practices of social convention (the artificial) but only through the discovering the right order of nature (its true essence and telos).

Society is not an empirical object. The awareness of society as a realm separate from nature is a work of the human imagination. It was only with the emergence of the comparative and cross-cultural studies of the social sciences in the nineteenth century that society came to be imagined as existing as a distinct realm apart from nature, an artificial or humanly made order that had no inner telos. Society came to be understood as a technological or artificial product, Existence precedes essence and society is what humans make of it.

In this way, with the emergence of the critical historiographical and ethnographical techniques of the social sciences in the nineteenth century, the mythic stories of "natural order" were demythologized and replaced with a technological understanding of society. This transformation came to be expressed in four new ways of thinking about self and society: (1) the *existential self*, (2) the *managerial society*, (3) *public policy*, and (4) *social ethics*. Because the order of society is not fixed and given with the order of nature, humans must (1) choose who they shall become individually and as a society (2) reorganize the structures of society to make such choices possible, (3) engage in public debate in order to make choices about what kind of society they want to create and (4) therefore engage in social ethics as the attempt to define the norms by which they shall make such choices and so invent themselves.

In premodern societies ethics is primarily the ethics of virtue and so is concerned with individual choices. The task of ethics is to actualize one's essential "human nature" in accord with one's *telos*, within the social order as the cosmos writ small. Once institutions are seen as human creations based on choice rather than being fixed and given as part of a sacred cosmic order of nature, ethics is forced to enlarge its horizons to engage in the critique of institutional behavior without reverting to the essentialist model of cosmological thinking. A technological civilization fundamentally transforms the understanding of the task of ethics by introducing the novel idea of social ethics as a post-essentialist critique of society as a technological artifact through those public policies or social choices that shape one's personal identity and institutional life.

For some (for example, Niklas Luhmann, 1927–1998) the technological civilization that emerges out of the new social scientific consciousness of the artificiality of society seems to promise greater freedom and control, and so a greater scope for ethics through managerial social policy. However, others (such as Jacques Ellul 1912–1994, Jürgen Habermas b. 1929) argue technicization threatens to undermine that freedom and the practice of ethics by producing the technobureaucratic rationalization and mechanization of society.

Indeed, a major motif among the giants of sociology (Karl Marx, Émile Durkheim, Max Weber) is the mechanization of society so as to create what Weber called "the iron cage" of technobureaucratic societies. In this view, managerial societies are dominated by bureaucracies of scientific-technical experts who identify and promote the most efficient ways to meet human needs in all areas of endeavor (that is, maximizing results while minimizing costs and energy expenditures), and technical efficiency eliminates choice. The focus shifts from ends to means. The less efficient society cannot compete with the more efficient society any more than the less efficient business can compete with the more efficient business.

This process of technicization threatens the human ability to think and act ethically. Insofar as ethics entails the Socratic question—*Is what people call good really the good?*—how can that question be raised and acted on in a society that defines efficiency as the ultimate good? How can ethicists expect to succeed in introducing nontechnical norms such as justice and compassion in a society that seems to make acting on nontechnical norms virtually impossible? And how can norms be asserted at all in a post-essentialist technological society?

The seriousness of this problem is evidenced by the technicization of ethics itself. In a technical civilization only people who have technical expertise command respect and are socially and financially rewarded. In response ethicists' reflections have become increasingly too technical and specialized to be understood by society at large and so must be left to the calculations of technobureaucratic experts. As a consequence the Socratic task of the "gadfly" who calls into question what people call "good" in order to introduce a broader (nontechnical) vision and practice of "the good life" is in danger of being neutralized as irrelevant. If the ethical task of the gadfly is to be possible, it will have to begin by calling into question the "technological bluff" of the adequacy of technical language and norms as sufficient for realizing the good life.

TECHNOCOMICS

Technocomics are illustrated narratives in which science and technology play a major role in the determination of character and action. Superhero comics are often good examples, insofar as many of their protagonists receive superpowers as an unexpected consequence of some scientific phenomenon. Peter Parker becomes Spider-Man, for instance, during a school outing to a science museum where he is accidentally bitten by a radiated spider; the X-Men all experience genetic mutations as a result of environmental contamination and thus confront problems of social prejudice and responsibilities between generations. Technocomics as a genre are thus closely related to science fiction and may serve to both mirror and shape popular reflection on questions related to science, technology, and ethics.

The comic book superhero first emerged from pulp fiction in the 1930s in what is known as the Golden Age of DC Comics and its protagonists such as Superman, Batman, and Wonder Woman, who were only marginally associated with science and technology. The post-World War II period saw a decline in the popularity of these figures. But in the 1960s, Marvel Comics brought about a Silver Age by creating a new pantheon of superheros including Spider-Man, the Incredible Hulk, and the X-Men, all of whom reflected a deeper concern for the ethical issues associated with science and technology in the nuclear age. The following analy-

Superman. *(AP/Wide World Photos.)*

tic introduction assumes some familiarity with this particular genre as it has developed in the United States, a genre that has also extended to movies, video games, and, in the early-twenty-first century, to some advanced simulations such as *Technocracy* (see Brucato, Long, and DeMayo 1999). For more general introductions to technocomics see the work of Mike Benton (1992), Richard Reynolds (1994), and Geof Klock (2002).

Radiation: Science as Savior and Scapegoat

Radiation has from the very beginning played a key role in technocomics, which perhaps reflects twentieth-century American societal fascination with, as well as aversion to, nuclear technology and its applications during times of both war and peace. Many superheroes of both the Golden and Silver ages of comics derived their special abilities from some type of radiation in one of three ways. The first, rarest, and perhaps most optimistic way is when the character comes to reside in a different environment and is exposed to a form of radiation that alters the physiology of his already existing anatomy. Superman, one of the earliest protagonists of the Golden Age of comics, is an example of this type of superhero. Originally the source of his special powers were unexplained; later, however, they were linked to the effects on his body of the light radiation from the Earth's yellow sun as opposed to that of the red sun of his home planet Krypton. Later comics involving Superman included a substance called Kryptonite (no relation to the element Krypton), whose green and other forms had various effects on him, including the nullification of his powers.

The second way in which radiation bestows superpowers in technocomics illustrates one of the most common fears of the nuclear age—mutation. This preoccupation with the unexpected, negative effects of radiation (which gave rise to a series of Godzilla movies in Japan), is manifested in such Silver Age technocomic protagonists as the X-Men, who are born with superpowers because ambient radiation from atomic bombs has changed their genetic codes.

Yet the third way in which superheroes derive their powers from radiation in these comics is the most prevalent—the alteration of an individual's genetic makeup through accidental or intentional exposure (such as nuclear accidents, atomic experiments, and others). Some of the most famous superheroes who have attained their powers in this way include Spider-Man, the Teenage Mutant Ninja Turtles, Dr. Manhattan, Daredevil, and Captain Atom. The most representative of this type of superhero, however, is the Incredible Hulk, whose alter ego, Dr. Bruce Banner, was a research scientist for the military-industrial complex who was attempting to develop a gamma bomb for the U.S. Army. During the first test of this bomb, Banner entered the testing area to save a civilian from the explosion, thus exposing himself to the gamma radiation that causes him, in a Jekyll-and-Hyde-like manner, to transform into the Hulk, a huge, immensely strong creature.

Human Response: Technology as Superpower

While superhuman characters such as Superman and Spider-Man experienced permanent changes that made their special powers innate, other characters have developed and employed technology in an attempt to achieve superhero status. Technological research and development organizations began to appear in superhero comics (such as Advanced Idea Mechanics [A.I.M.], a criminal organization in the Marvel universe, and Scientific Technological Advanced Research Laboratories (S.T.A.R.), a scientific organization in the DC universe), creating new technology to both the benefit and detriment of society. Devices such as ray guns, flying cars, and power armor appear in myriad forms in these comics, in which technological processes and pharmaceuticals such as cloning and *supersoldier sera* are also common. The list of technologically assisted superheroes and supervillains is long, and the majority of them utilize special suits and gear. The most famous of these characters include Iron Man, Green Arrow, the Punisher, Nick Fury and the Supreme Headquarters International Espionage Law-Enforcement Division (S.H.I.E.L.D.), the Atom, Hank Pym, Blue Beetle, Owl Man, Doctor Doom, Lex Luthor, Booster Gold, Captain America, the Engineer, and Batman (who nevertheless would be a force to reckon with even without his Bat Computer and infamous utility belt).

One of the most unique of these superheroes, Booster Gold, is of special interest because his origins illustrate ambivalent feelings toward the corporate technological complex. Booster, a twenty-fifth-century football player banished from professional sports for illegal betting, steals a force field belt, flight ring, and a time sphere which he and a robot named Skeets use to travel back in time. He then becomes the CEO of Booster Gold International, a monolithic holding company and tax shelter, as well as *America's Most Popular Super Hero*.

Still other superheroes use technology in the form of symbiotes (organisms, alien or otherwise, that grant abilities to their hosts), chemical alterations of their bodies, and even artificially intelligent constructs. Perhaps the most famous example of a chemically enhanced superhero is Captain America. According to the account of his origins, during World War II the United States developed an experimental supersoldier serum. It was first tested on Steve Rogers, a frail man unfit for combat, to whom it gave increased mental and physical capabilities. The doctor who created the formula was soon after killed by a Nazi spy, leaving Rogers as the first and only supersoldier—Captain America.

Still other superheroes and supervillains have obtained their powers through a combination of the effects of radiation and technological enhancement. A good example here is one of the X-Men, Wolverine, a born mutant who is later *improved* with technology. Wolverine's original mutations included animal senses and an amazing capacity for self-healing. This latter power enabled the Weapon X Program to implant the unbreakable metal adamantium into his bones without killing him, thus making him virtually indestructible.

The Ethics of Power

Ethical questions regarding science and technology make natural themes for technocomics, given the great number of technologically created superheroes and supervillains who serve as their protagonists. One of the most common of these questions is that regarding the limits of scientific experimentation. J. Robert Oppenheimer's concern about the atomic bomb finds its echo in technocomics: Does ability imply permission? Do humans have the right to use technology just because they have invented it? These questions are debated time and again in the pages of technocomics (for example, in the cases of the Weapon X Program, the origin of the Hulk, and Brainiac 5's creation of Computo). Such comics play an important ideological role, because they are often a young person's first introduction to these questions, and furthermore offer a safe, fictional representation that spurs critical thinking about the real dilemmas (such as human cloning) faced by contemporary society.

Many technocomic superheroes demonstrate the desire to use their powers ethically and strive to accept a responsibility to others that they believe accompanies their special gifts. For example, heroes such as the almost omnipotent Professor X and Spider-Man (whose message "With great power comes great responsibility" has become a mantra for generations of comics fans) seem to be always defending and disseminating their belief that those who possess special abilities must not exploit those who do not.

Homo Superior: Social Darwinism in Technocomics

Although Social Darwinism is a misapplication of a scientific theory, it generates many debates in technocomics, especially given their superhuman protagonists. Should the strongest, most talented, and most intelligent rule the world to the detriment of the weak? Perhaps the most important site of this debate in the technocomic world is found in the X-Men comics, in the conflict between Professor X and his archrival, Magneto. Magneto is a superpowerful mutant who survived life in a concentration camp during World War II, and has therefore experienced firsthand the horrors that humans are capable of inflicting on one another. He is convinced that mutantkind (human beings who have mutated and developed superior abilities) is the next step in human evolution and that mutants should therefore take their place as the new rulers of the world. Professor X, however, takes the stance that mutants—however different they may be—are still humans and must learn to live alongside less-gifted humans.

Technoscientific Authoritarianism

Ethical questions surrounding technoscientific authoritarianism are often present in technocomics, given

Spider-Man. *(AP/Wide World Photos/Courtesy Marvel Comics.)*

that absolute power is a goal that many technically enhanced supervillains strive for. A particularly relevant instance of this debate, albeit ultimately unresolved, appears in those Marvel comics dealing with Doctor Doom, the supreme ruler of a fictional country called Latveria. This country is described as being free from racism and social unrest; its inhabitants enjoy economic prosperity while remaining ecologically and physically safe and sound. But while the government of Latveria is considered to be an *enforced monarchy* by Doom and his subjects, all others consider it a dictatorship. The question of whether it is acceptable to give up democratic and personal freedoms to a technocrat in return for safety and security arises. At one point in the Marvel universe, Doctor Doom manages to take control of the entire world after which he eliminates disease and hunger and brings about world peace with an iron hand. Even the staunch defender of democracy, Captain America, has to admit that, while the method Doom uses is unacceptable, the changes he brings about are in the best interest of humanity. Nevertheless, at the end of the series, Doom is removed from power and the world reverts to its previous state, with relief food rotting on the docks in Africa, arguments breaking out in the United Nations, and the winds of war again stirring worldwide. Readers are left to decide for themselves which type of government is preferable.

Subsequently, in 2004, Captain America, the technologically enhanced supersoldier, was involved in a critique of the very military industrial complex that created him. He is sent to Guantanamo to oversee the treatment of the Taliban and Al-Qaeda prisoners being held there by the heavily armed, technologically superior U.S. soldiers, and is shocked at the human rights abuses he witnesses being committed by members of his own team.

Questionable Experimentation and Creation: Progress versus Safety

Questions surrounding the ethical ramifications of experimentation, especially experimentation on living beings, arise frequently in technocomics. Should experiments be done if they are not safe for the individuals involved? Is questionable scientific experimentation ethical if it causes human and/or animal suffering in pursuit of the alleviation of future suffering? Are technological processes that extend the quantity of life worth their possible toll in quality of life? The previously mentioned Weapon X Program in which Wolverine gains his adamantium skeleton, along with the ambivalent feelings many superheroes have toward their own powers, is only one of the ambiguous situations in technocomics that promote such ethical pondering.

Artificial intelligence (AI) plays a central role in many technocomics. The philosophical questions raised in this regard range from the ontological (Is a machine that can think a living creature?), to the epistemological (How does one recognize life?), to the ethical (Is it ethical to try to create a machine that can think? If a thinking machine has accidentally been created, should it be shut off? Should humans allow themselves to become so dependent on machines in general, and on artificial intelligence in particular?).

Not only does sentient AI life exist in the world of technocomics, but it is also often imbued with the theological categories of good and evil. One example can be found in the *Avengers* series of comics, in which the scientist/Avenger Hank Pym accidentally creates Ultron, an evil, artificially intelligent being who is able to remodel himself as well as to create other AI machines. The Vision, one of the machines modified by Ultron, using his newly acquired free will for more noble purposes, rebels against his programming, joins the Avengers, and even marries. Similarly, in the *Brainiac* series of stories, Brainiac 5 creates an AI machine named Computo, that ends up killing dozens of people before being turned off.

Using Technocomics

Technocomics have introduced many scientific and ethical questions into the minds of readers, and can be expected to continue to do so by incorporating into fiction new technologies and scientific theories as they emerge in the real world. Technocomics have been a source of entertainment for so long that their value as teaching tools are often overlooked. Nevertheless, in the early-twenty-first century, there is increasing awareness of the effectiveness of using technocomics to spark scientific and philosophical debate in the classroom. The Department of Chemistry at the University of Kentucky, for example, supports a web site linking science to technocomics that lists, in periodic table structure, the occurrences of elements in comic books, both in the form of facts and misconceptions. At times the superpowers portrayed in technocomics, as well as the scientific errors that they frequently entail, can be as useful as scientific facts for teaching purposes. James Kakalios, a professor at the University of Minnesota, incorporated such misconceptions in a course titled "Everything I Know of Science I Learned from Reading Comic Books," which compares and contrasts the science portrayed in technocomics with real-world physics, including thermodynamics and the material sciences. Kevin Kinney of DePauw University discusses many misconceptions of biology in comic books, such as those related to superpowers and the amount of nutrients that would be needed to fuel them.

Interestingly while science fiction in general has logically been appropriated by teachers of ethics as a springboard for debates about ethical issues in science and technology, the use of technocomics for these same purposes appears to have been overlooked. Nevertheless the success of film adaptations of such technocomics as *The Hulk* (2003), *Spiderman* (2002, 2004), and *X-Men* (2000, 2003) will almost certainly guarantee serious reconsideration as to how these works both reflect and mold popular opinions and conceptions about the nature—ethical or otherwise—of scientific investigation and technological innovation.

TECHNOCRACY

Technocracy may be generally described as an organizational structure in which decision makers are selected based on their specialized, technological knowledge, and/or rule according to technical processes. It has also been defined more simply as rule by experts. In all such cases technocracy constitutes a particular interaction between science, technology, and politics that has led to significant ethical debate.

Historical Development

The concept of technocracy needs to be qualified because the idea of rule by experts is at least as old as Plato's proposal for philosopher kings. Similarly, in his *New Atlantis* (1627), Francis Bacon envisaged an ideal society directed by scientists. But the contemporary meaning of technocracy presupposes the existence of complex industrial societies and the large-scale production and consumption processes that arose at the beginning of the twentieth century. It is only under these conditions that a class of experts in organization and production, namely engineers or technologists, could form. Technocracy, then, is rule by this particular type of expertise. Its advocates either assume or explicitly state that the efficient, rational production and distribution of goods for material abundance is the primary or even exclusive goal of society, because only in this way could they justify expert governance in these fields.

Early in the nineteenth century, the French writer Henri de Saint-Simon (1760–1825) foreshadowed calls for modern technocracy by arguing that the organization of production was more important to society than any other political end. By the 1890s, an emerging ambiguity in the social role of engineers led some to question their traditional subservience to employer goals. Unlike doctors, lawyers, and most other experts, engineers used their expertise to shape productive and technological systems, thereby transforming entire societies. Many began to feel that their power enabled or even obliged them to bring about social progress. With his idea that scientific laws would govern the efficient management of labor and use of resources, Frederick Taylor (1856–1915) provided a practical platform to extend the domain of engineering expertise into management and politics.

Henry Gantt (1861–1919) and James Burnham (1905–1987) further argued for the independence of engineers in their critiques of societal irrationalities and inefficiencies. Thorstein Veblen (1857–1929) critiqued wastefulness in the dominant political and economic system (i.e., the capitalist price system) and argued that engineers were best suited to direct society, because their objectivity was preferable to the short-sighted greed of business leaders. One of his disciples, Howard Scott (b. 1926), formed the Technical Alliance (in 1918) and later—rivalling with the "Continental Committee on Technocracy" (led by Harold Loeb and Felix Frazer)—Technocracy Inc. (in 1933). Members of Technocracy Inc. advocated a transition away from the price system and the establishment of a "governance of function," or a Technate, on the North American Continent. They argued that the scientific design of social operations would guarantee abundance for all.

Types of Technocracy

Analytically there exist at least seven variations on the technocracy theme. First, there is the notion of "expertocracy," or a conspiracy of experts who usurp decision making powers from democratically elected representatives. Second, technocracy can serve as a form of social engineering, where administrative procedures and organizational contrivances, rather than experts, gain power and form a "technological state." Third, there is a technocracy of work best articulated by Taylor's *Principles of Scientific Management* (1911). Fourth, the technological imperative of "can implies ought," in which means and feasibility determine goals, may create a technocracy that values the improvement of instrumentalities as a primary end. Fifth, there is the systems technocracy that may emerge from dynamic, interdependent systems engineering and by thereby administrating soci(et)al and political systems. Sixth, technocracy can refer to a situation in which laws are enforced by designing systems such that it is almost impossible to break them and that societal decisions and developments are totally streamlined by them and/or computerization. Finally, there is the technocratic movement spearheaded by Technocracy Inc. Additionally, the term has also been applied to a number of dictatorship governments and to a virtual reality game that claims to be based on "the inexorable advance of real-life technocracy" (see the web site at www.white-wolf.com/Games/Pages/MagePreview/technocracy.html).

Nevertheless, only four of these possibilities exhibit continuing viability. The idea of technocracy as expertocracy remains the most popular: a conspiracy of experts taking power through their personal, knowledge-based control of complex decision making. In the version promoted by Veblen (1925) this would involve rule by engineers especially in industrial corporations. But other alternatives might stress the intelligence and efficiency of more localized expertise, such as medical doctors to run health care systems. In all instances, expertocracies are argued to increase intelligence and efficiency in technical action—but threaten democracy.

A second widely discussed possibility focuses on the scientific optimization of social engineering through public administration. Here it is not experts as persons but administrative procedures and organizational structures that would exercise power. No individual or group would rule; individuals or groups would at most have a role in properly managing institutions and processes. This is the vision of technological politics presented by Jacques Ellul and others in which technological and administrative decisions replace political deliberation. Legislation by elected officials would wither under such an automated bureaucracy.

During the 1960s the idea of a technological imperative led to the articulation of another important version of technocracy, although one that has declined in intellectual salience. According to critical social theorist Herbert Marcuse (1898–1979) and science fiction writer Stanislaw Lem (b. 1921), there is a strong tendency for technical possibilities to determine social or political goals. Anything that can be done or produced will be done or produced, even becoming a matter of need. Means would determine ends; can implies ought. In a society established along these lines, improvement of instrumentalities becomes of singular value; the constant improvement of technology becomes the goal.

A fourth form of technocracy that continues to be examined conceives it in system terms. This is an important new variation on the technocracy theme. Systems engineering as well as systems analyses of the interconnections and complexities of society (as in the work of Niklas Luhmann) suggest a new kind of systems-technocracy. Discussions of systems-technocracy and the special case of "computerocracy" have emerged as serious issues in association with the rise of the so-called era of "information and systems technology" (Hans Lenk 1971, 1973).

Is systems-technocracy the wave of the future? There certainly are trends pointing in this direction, and the discussion should not be left to sociologists and politicians only. Instead, the single-focus framework of the social sciences should be combined with historical, engineering, and philosophical approaches to create an adequately interdisciplinary perspective. From such a perspective it can be argued that in a pluralistic technoscientific society the best way forward is to steer a pragmatic middle path between the extremes of an inhumanly efficient technocracy, a ruthless power politics, and a vulgar democracy devoid of intelligence.

Assessment

As Jean Meynaud (1964) summarized the issue, the decades-old debate on technocracy comes down to the fact that there is no conspiracy on the part of the technical community to usurp political power, though technical matters have taken on ever increasing importance.

Because the complexity of social, technological, economic, and ecological systems has increased, there is a progressive demand for technological, scientific, and organizational expertise. At the same time, narrow expertise calls forth a complementary needs for generalists, people with a broad view ("specialists of the general") of interdisciplinary complexes who can take a systems approach toward problems.

Historically speaking, the technocracy debate simply continued the social criticisms of technology from the early part of the twentieth century. Its dominant characteristic has been a pessimistic attitude that ignores the extensive ways technology has humanized the world. But the privileged position of experts in particular cases has not led to the demise of politics in the so-called "technolocal state" (Helmut Schelsky) or of the importance of its interplay between conflicting and overlapping interest groups and power structures. The opposite seems to be the case. The most significant outcome of the technocracy debate is thus an awareness that complex political decisions cannot be replaced by the technological or "computerocratic" procedures of optimization and maximization.

There are several explanations for this. Most significant is the fact that complex political decisions involve both information and the adjudication of a plurality of values. The inexplicable and undecidable character of political questions in contrast to technological answers, as was argued by Hans Lenk (1973), has largely been confirmed by experience. Society and the state are not machines with mere objective standards of performance, and there is no scientifically generated "one best way" (as Schelsky believed) to solve many technical, let alone political, problems. Attempts to apply science to societal problems with this intention often lead to interminable debates among competing experts, while the underlying values at stake remain unexamined.

Yet it remains true that technical matters have taken on ever increasing importance in the complex problems of modern societies and computerocracy as a virulent version of systems technocracy is an imminent danger in our hi-tech societies. The challenge for democratic governance is to integrate technical experts with non-expert participants to strike common interest solutions in contexts where many elements are beyond the comprehension of all but a few specialists. These interdisciplinary contexts may even demand generalists capable of integrating diverse sets of knowledge and perspectives.

TECHNOETHICS

Technoethics is a term coined in 1974 by the Argentinian-Canadian philosopher Mario Bunge to denote the special responsibilities of technologists and engineers to develop ethics as a branch of technology. However, in 1971 the chemical engineer and theologian Norman Faramelli had used a word of only one less letter, *technethics*, to argue for a general ethics of technology from a Christian theological perspective. In 1973 the *Britannica Book of the Year* defined the same term, without referencing Faramelli, as indicating "the responsible use of science, technology and ethics in a society shaped by technology."

Bunge's use is the more significant and radical. For Bunge engineers and managers, because of their enhanced powers, acquire increased moral and social responsibilities. To meet these responsibilities they cannot rely on traditional moral theory; since moral theory itself is underdeveloped having "ignored the special problems posed by science and technology" (Bunge 1977, p. 101). Instead, engineers must adapt science and technology, tools that are foreign to most philosophers, to construct a new theory of morality.

According to Bunge, rational moral rules have exactly the same structure as technological rules. Technological rules come in two types: ungrounded and grounded. Ungrounded technological rules either are irrational or are based on empirical evidence that has not been systematized. Grounded technological rules are based on science. According to an earlier argument, Bunge (1967) sees technology as being constituted by scientific theories of action. Modern technology develops when the rules of prescientific crafts, which are based on trial-and-error learning, are replaced by the scientifically "grounded rules" of technological theories.

During the late 1990s and the early 2000s the term *technoethics*, especially in Spanish and Italian cognates, appeared anew in an effort to parallel another coinage from the 1970s: *bioethics*. However, the prefix *techno* has connotations that are at odds with *bio*, which references life and its nuances. Ethics is a living field. *Techno* denotes the hard-edged and loud, as in *technomusic*, *technoart*, and *technoeconomics*. Given these uses, *technoethics* fails to connote as readily the broad concerns that have been easy to include in bioethics. Indeed, Bunge's use of the term seems more appropriate.

In the preparation of the *Encyclopedia of Science, Technology, and Ethics* there was some initial debate about making it an "Encyclopedia of Technoethics." The conclusion, however, was that such an alternative would have been inadequate in building bridges between a number of applied ethics fields ranging from computer and engineering ethics to research and environmental ethics, including history, literature, and philosophy along the way. The expansive if less catchy title *Encyclopedia of Science, Technology, and Ethics* defines in a more inclusive way the scope of a reference work that should appeal to scholars; professionals in the sciences, engineering, and the humanities; and general readers.

TECHNOLOGICAL FIX

Technology is often couched in terms of solving problems such as curing disease, providing for reliable food production, or affording efficient means of transportation. Indeed, technology has proved powerfully effective for solving any number of problems, from the massive project of sending people into space to the minor chore of fastening pieces of paper together. But in a 1966 article, atomic physicist Alvin M. Weinberg raised the following question: Are there some types of problems that cannot—or should not—be *fixed* by technology? Weinberg coined the term *technological fix* to describe the use of technology to respond to certain types of human social problems that are more traditionally addressed via political, legal, organizational, or other social processes. Although Weinberg advocated the use of technological fixes in some cases, the term has come to be used frequently as a pejorative by people critical of certain uses of technology.

Writing during the cold war, Weinberg cites nuclear weapons as an example of a technological fix for war. The technological ability to unleash global devastation serves as a deterrent to international aggression. But critics argue that such a solution is at best tenuous, and at worst lessens people's resolve to work diplomatically at ameliorating the underlying clashes of ideology, economy, and culture that lead to war. Nuclear weapons also served as an alternative to maintaining a large standing army such as that of the Soviet Union, thus shifting social sacrifice from the less to the more democratically acceptable—from personal service to government investment in advanced technological weapons research and development. It is this aspect of technological fixes—their tendencies to mask the symptoms of complex social problems without addressing their causes or true costs—that generally evokes ethical concern.

For example, if large numbers of children are being disruptive or having trouble concentrating in school, is the liberal prescription of psychotropic drugs a viable technological way to ease the problem, or does this simply allow parents and teachers to abdicate their responsibilities for good parenting and maintaining discipline, respectively? If employees are using company computers for personal business or entertainment, is installing software to monitor and curb such behavior a viable technological solution, or does this simply foster an atmosphere of distrust without addressing the causes of the problem, perhaps poor morale or inefficient tasking?

These are difficult questions because there are surely some children who could benefit from psychotropic drugs, and there are arguably certain situations in which an employer has a legitimate need to monitor an employee's use of the computer. But once such technological fixes become available, they run the risk of proliferating into universal *easy ways out*. Or they may simply shift the locus of the problem; in the case of the work computers, spy software does not guarantee greater employee productivity, only that employees will not be unproductive in a particular way.

Despite these criticisms, sociologist Amitai Etzioni (1968) defended the use of what he called technological *shortcuts*. Etzioni argued that many of the concerns levied against such shortcuts were based on conjecture rather than hard evidence. For example, when better lighting is installed on city streets in an effort to discourage crime, critics claim that this approach treats only the symptoms and does not do anything to address the underlying motivations for crime, nor does it necessarily reduce crime overall; rather, they claim, it just shifts the criminal activities to other locations. But while sounding plausible, such criticisms are typically unsupported by any definitive data. The questions to be asked in this example are, where do criminals go, and what do they do, when their previous stalking grounds are illuminated? "No one knows," writes Etzioni, but "[t]he one thing we do know is that the original 'symptom' has been reduced" (p. 45).

Etzioni also pointed to the deep-seated and intractable nature of many social problems, which suggests the near impossibility of ever implementing any comprehensive solutions via social transformation, particularly given fervent political disagreement about the propriety of various transformation strategies. Thus stopgap shortcuts may be the only recourse. "Often," writes Etzioni, "our society seems to be 'choosing' not between symptomatic (superficial) treatment and 'cause' (full) treatment, but between treatment of symptoms and no treatment at all" (p. 48).

The fundamental difficulty with technological fixes—or shortcuts—is the inherent incompatibility between problem and solution. Technologies are most useful for solving specific, well-defined, and stationary problems, such as how to get cars from one side of a river to the other (for example, using bridges). In contrast, social problems, such as crime, poverty, or public health, are broad, ill-defined, and constantly evolving. Weinberg, like Etzioni, was not naïve about this difficulty, writing, "Technological Fixes do not get to the heart of the problem; they are at best temporary expedients; they create new problems as they solve old ones" (p. 8).

An atomic scientist discusses the merits of using technology to eliminate or attenuate social problems as an alternative to pursuing the more difficult strategy of changing prevalent social attitudes.

TECHNOLOGICAL INNOVATION

Technological innovation has been a leading agent of social change, worldwide, since the late 1700s, serving as the conduit into society of developments in science and technology. As such, it has been at the center of ethical issues ranging from the morality and justice of the early Industrial Revolution to the consequences of genetic engineering, nanotechnology, and artificial intelligence (AI). In spite of its extraordinarily high social visibility, however, innovation is almost universally misunderstood and misrepresented, typically as synonymous with invention. Invention, in turn, is presented as a value-free, hence ethically neutral, application of new or existing technical knowledge. Treating innovations as inventions implies that ethical issues associated with their implementation derive not from factors intrinsic to innovations, but from how society chooses to implement them. Such an interpretation frees innovators from moral responsibility for the ethically problematic consequences of their activities, as well as buffering these activities from public assessment.

What Innovation Is

Innovation is a social process in which technical knowledge and inventions are *selectively* exploited on behalf of (corporate or government) institutional agendas driven by marketplace values or political policies. Inventions, and more broadly scientific and engineering expertise, are merely raw materials for technological innovation, which is the value-laden, ethically provocative process that determines *whether* an invention is introduced into a society, the *form* in which it is introduced, and the *direction* of its subsequent development as society responds to the innovation. The introduction of the automobile, television, nuclear power plants, and the Internet are examples of the value-laden innovation process, including how societal responses feed back into the course of innovation developments over time.

Conceptual Emergence and Practical Engagement

The beginning of the twentieth century saw leading economists focused on determining the conditions for supply-demand equilibrium. For Austrian economic theorist Joseph Schumpeter (1883–1950), however, what needed to be analyzed was not equilibrium but the disequilibrium created by economic growth. Looking back over the nineteenth century and the first decade of the twentieth, Schumpeter argued that entrepreneurship in combination with technological innovation—that is, risking capital by creating new businesses that transform inventions into innovations—was the engine of economic growth in modern societies. This combination of innovation and entrepreneurship created new wealth, destroyed old wealth, and created new concentrations of social and political power. Schumpeter defended what he called the *creative destruction* that often accompanied implementing innovations. The creation of synthetic dye, electric power, and the automotive industries, for example, undermined established industries based on natural dyes, steam and water power, and horse drawn transportation. Businesses were indeed destroyed, jobs were lost, people suffered but, Schumpeter claimed, *better* businesses were created, employing more people in *better* jobs. Schumpeter eventually also defended the wasteful and often frivolous character of the combination of innovation and entrepreneurship in an industrial capitalist environment driven by opportunistic profit-seeking.

After World War I, individual thinkers, among them the American economist Thorstein Veblen (1857–1929) and future U.S. president Herbert Hoover (1874–1961), argued that technological innovation would be central to national security and industrial competitiveness. Only in Germany, however, was there a strong national commitment to an innovation-driven military and industrial agenda, initiated by Prince Otto von Bismarck in the 1860s and developed further by all subsequent German governments, especially the National Socialists. In the United States and Great Britain, by contrast, calls for such national commitments were repeatedly rejected. For example, George Ellery Hale (1868–1938), one of the world's leading astronomers and the person responsible for maintaining America's leadership in telescopy from 1897 into the 1980s, failed in his attempt to win government acceptance of his plan to harness academic scientists to the nation's war effort during World War I. He failed again in his postwar attempt to create a national research foundation to be cosponsored by the federal government and major corporations.

World War II changed all this. The role that technology and science played in waging and winning the war for the Allies, especially the role of the U.S. Office of Scientific Research and Development (OSRD) headed by Vannevar Bush (1890–1974), led if anything to an overestimation of the power of innovation in the postwar period. In his report titled *Science: The Endless Frontier* (1945), Bush argued that U.S. industrial prosperity and military security would in the future be critically dependent on continuous science-based technological innovation. The federal government needed to create mechanisms for government-subsidized basic research, primarily at universities, to *feed* the commercial innovation process. For Bush, this was the lesson of such OSRD accomplishments as the Manhattan Project, of the Massachusetts Institute of Technology's (MIT) Radiation Laboratory or RadLab that produced a constant stream of electronic warfare and counterwarfare technologies, and of mass-produced cheap antibiotics and blood products. Yet as Bush later acknowledged, this *push* or linear model, in which basic research leads to applied science, which then leads to commercial technological innovations, overestimates the dependence of innovation on basic science. This view was confirmed in Project Hindsight (1966), a Department of Defense study of twenty weapons systems, introduced since 1946, that concluded that basic science affected less than 10 percent of these systems. A follow-up study by the National Science Foundation (NSF), TRACES (Technology in Retrospect and Critical Events in Science [1968]), defended the basic research-driven model in the Bush report by looking back fifty years instead of twenty.

Since 1970 research by historians of technology has supported a version of the Project Hindsight conclusion. While basic research sometimes *pushes* innovation, innovation far more often *pulls* research, which may then enable further innovation. The exponential growth of innovation in the semiconductor and computer industries exemplifies this relationship.

Bush's report and its basic science push model nevertheless anchored postwar-U.S. science and technology policy. For the first time in U.S. history, there was a mandate for large-scale federal support of basic as well as applied scientific research. The ethics of giving scientists public funds to do research on subjects of their choice gave rise to contentious political debates that held up creation of the NSF in 1950. But the NSF budget for basic research was then and has remained modest compared to the budgets for applied research linked to innovation, which until 1989 was driven primarily by Cold War military agendas and secondarily by the evolving war on cancer, war on AIDS, and Human Genome Project agendas of the National Institutes of Health (NIH) and the U.S. space program.

In the 1960s leading political figures including Presidents John F. Kennedy, Lyndon B. Johnson and Richard M. Nixon promoted innovation as the key to U.S. economic growth. In 1962 President Kennedy explicitly identified industrial innovation as the source of new jobs and new wealth that would be shared by all. But it was only in the 1970s and after, in the wake of the Silicon Valley phenomenon and the astonishing pace of wealth creation in the semiconductor and computer industries, that a national consensus recognized the civilian economy as critically dependent on innovation for growth. It was in the 1960s and 1970s that Schumpeter's identification of innovation and entrepreneurship as engines of economic growth was rediscovered. It had sparked little interest when published in 1911 or even after Schumpeter's migration to Harvard University in the 1930s. Nor did University of Chicago economist Frank Knight (1885–1982) stimulate interest in the link between innovation and entrepreneurship with his pioneering 1921 study of the dynamic role played by risk in creating new businesses. Knight coupled a penetrating analysis of the economics of innovation-driven entrepreneurship to a stinging moral critique of the wastefulness of innovation in a capitalist economy. The importance of the ideas of Schumpeter and Knight would be appreciated only when innovation had engaged the general political consciousness and conscience. Early-twenty-first-century American economist Paul Romer is an influential neo-Schumpeterian, arguing that growth is generated by ideas of which innovation is a symptom and defending the virtues of the unmanaged U.S. innovation model over the managed innovation models in Japan and east Asia.

The Ethics of Innovation

Recognition of the scale and scope of innovation-enhancing policies provoked broad criticism of social and ethical implications of the dependence of society on innovation. Jacques Ellul in *The Technological Society* (1954), for instance, argued that such dependence reflected a gamble that would compel societies to transform themselves into vehicles for supporting continuous innovation at the expense of traditional personal and social values. Ellul's ethical and political critique of technology-based society attracted many followers who developed it further in the 1960s and 1970s, and were significantly responsible for the creation of university-based science, technology, and society (STS) studies programs as an academic response to the new institutionalization of innovation by government and industry. Alvin Toffler's *Future Shock* (1970) was a more popular caution against and criticism of the personal as well as social disorientation caused by continuous innovation. Its commercial success suggests a responsive chord of concern in the general public, which nevertheless embraced the flood tide of innovations affecting every aspect of personal and social life, locally, nationally, and globally, that poured into the marketplace during the last third of the twentieth century.

By the turn of the twenty-first century, that economic prosperity was keyed to continuous technological innovation in a global competitive environment was enshrined as an ineluctable fact, a principle of nature, a kind of categorical imperative. *Innovate or stagnate* not just economically, but culturally as well. Open to serious debate in principle were such questions as whether innovation-induced social change constituted true growth or was just change; whether such change was progressive, improving the quality of life, or just sound and fury busyness signifying nothing very deep. Yet public debates on such questions rarely took place. What was broadly recognized as inescapable, though, was that the innovation-driven economic growth process institutionalized after World War II and adopted globally by 2000 was characterized by a kind of positive feedback. Only *continuous* growth was possible; stasis, with the loss of the expectation of growth, threatened economic collapse.

Meanwhile the accumulated scholarship of the STS studies community generated new insights into the innovation process. Contrary to the inherited wisdom that technical knowledge was value-free, innovation is in fact ethically *preloaded*. Innovations enter the marketplace incorporating a broad range of value judgments primarily determined by the agendas of the commercial institutions and governmental agencies pursuing innovation on behalf of those agendas. The so-called *negative externalities* of innovation—including Schumpeter's *creative destruction* of superseded technologies along with their institutions, facilities, and people—also include negative environmental impacts, the introduction of new forms of personal and social life, and the creation of new vested economic, social, and political interest groups and power centers, each committed to perpetuating itself. All such concomitants of innovation raise ethical concerns that dwarf the public processes available for addressing them.

Organizational theorist and Nobel economics laureate Herbert Simon noted in the 1960s that complex systems are by definition ones whose behaviors include unpredictable outcomes. Technological innovations often result in the implementation by society of complex systems to support them. As a result, even with the best of corporate, governmental, and public intentions, it is impossible to predict in advance all of the consequences, negative or positive, of innovations in, for example, antibiotics, television, the Internet, and cell phones. Such unpredictability motivated Bill Joy—a cofounder of Sun MicroSystems Corporation, its chief scientist, and a cocreater of the Java programming language—to issue a passionate call in 2001 for a moratorium on innovation in biotechnology, nanotechnology, and robotics. Joy's argument was that these three technologies were converging and had the potential for unpredictable consequences that posed profound threats to human survival. Joy stumped the nation warning academic, industrial, and public audiences of the potential for catastrophic harm from continuing our postwar policy of unfettered innovation followed by catch-up attempts at regulation as problems arose.

A similar moratorium had been argued for in 1974 by Paul Berg, inventor of recombinant DNA technology. Berg's call, following a year-long cessation of research in his own lab, led to the 1975 Asilomar Conference, which substituted heightened laboratory safeguards for a moratorium, and subsequently sanctioned a biotechnology innovation free-for-all. In the 1980s, Jeremy Rifkin and others attempted to block innovation in genetically modified food crops and plants, to little if any avail. Joy's call did provoke a substantial response within the technology community. Raymond Kurzweil, an eminent engineer-inventor, debated Joy on a number of occasions, orally and in print, championing unrestricted innovation as both progressive and capable of containing any unanticipated harmful consequences of innovation. In spite of rapid commercial development of biotechnology and nanotechnology industries at the start of the twenty-first century, the public was not engaged in the ethical issues raised by innovations that were under research and development, in the prototype stage, or being introduced into the marketplace.

TECHNOLOGY ASSESSMENT

SEE *Constructive Technology Assessment; Technology Assessment in Germany and Other European Countries; United States Office of Technology Assessment.*

TECHNOLOGY ASSESSMENT IN GERMANY AND OTHER EUROPEAN COUNTRIES

From its mid-1970s origins, technology assessment (TA) in Germany and in Western Europe has been presented as a methodical, ethical, and theological as well as natural-, engineering- and social-science-oriented reflection on the technological preconditions for the formation and design of modern societies and the impacts of technology on such societies. TA analyzes both the development of technologies and the entities that have the competence, resources, and strategic potential to create them. Using prediction procedures, decision-theory approaches, and model simulations—all of which resemble economic models—the goal is to raise awareness of the desired and undesired, synergetic, and cumulative consequences of new technologies, if possible before they become issues of public debate. TA further aims to reveal the basic values underlying any *assessment*.

Representative Institutions

Understood as a form of *political counseling,* a series of TA institutions were founded by some Western European parliaments. Among these institutions are the following:

- Scientific and Technical Options Assessment (STOA), by the European Parliament (1985)
- Office Parlementaire d'évaluation des choix scientifiques et technologiques (OPECST), France (1983)
- Büro für Technikfolgen-Abschätzung beim Deutschen Bundestag (TAB) or Office of Technology Assessment at the German Parliament (1990)
- Rathenau Institute, Netherlands (1986)
- Parliamentary Office of Science and Technology (POST), United Kingdom (1989)

There are also parliamentary institutions in Denmark, Austria, Finland, Belgium, Greece, Norway, Switzerland, Sweden, and Spain, which in the near future will join this circle of parliamentary counselors in the cooperative European Parliamentary Technology Assessment (EPTA). Some Eastern European countries, in particular Poland, Hungary, and the Czech Republic, have also established independent TA institutions. Of the independent institutions founded in Germany, of particular interest is the Institut für Technikfolgenabschätzung und Systemanalyse (ITAS or Institute for TA and System Analysis) of the Karlsruhe Research Center (RZE), a member of the Helmholz-Gemeinschaft Deutscher Forschungszentren (Helmholz Association of National Research Centers), the largest scientific organization in Germany. ITAS is also the operating authority of TAB. ITAS publishes the only significant TA journal in Germany titled *TA in Theory and Practice*.

Two major research institutes in the Helmholtz Community Association of National Research Centers among those that conduct projects on sustainability research relating to TA, should be mentioned: Forschungszentrum Jülich (Juelich Research Institute) and the Deutsches Zentrum für Luft- und Raumfahrt (DRL) (German Center for Aviation and Space Flight), Cologne. Another national organization is the European Academy for Research on the Consequences of Scientific/Technical Development, which is located in Bad Neuenahr and primarily supported by the state of Rhineland Palatinate and by the DLR. It is less technology-transfer oriented than, for example, the ITAS or TAB because its research is focused more on basic questions concerning the acceptability of technology use as an element of forward-looking policies. The Academy for TA, founded in Stuttgart in 1991, was closed by the state of North Rhine-Westphalia at the end of 2003. This was a severe setback for TA research in Germany, in particular because the academy had an impressive public profile as a result of its efforts to link socially relevant discourse with areas of science, economics, and politics.

Research Themes

Among the important TA topics in Germany, sustainability dominates current research. Indeed efforts are aimed at institutionalizing the principles of sustainable development at all levels of national and transnational political systems.

In addition to biotechnology (as related to agriculture, pharmacy, textiles, and food), research into gene technology, diagnostics, and therapy are at the center of public interest. In Germany discussions have concentrated on the fields of biomedicine, and in particular on the ethical justification of research using human embryos and preimplantation diagnoses (PID). Stem-cell research is examined in terms of future application to tissue and organ regeneration. The acquisition of stem cells from embryos, or so-called therapeutic cloning, is the subject of numerous investigations. The compatibility of biomedical developments with the principle of human dignity as defined by the German basic law (or constitution) and the EU constitution is an especially important issue.

The development of nanotechnology is also of interest, especially because this field has frequently been presented as a key technology for the twenty-first century. Applications of nanotechnology are projected in the fields of space flight, agriculture, information processing, and medicine. The implementation of nanotechnology materials is discussed in relation to ecological and medical issues.

In the context of the process of globalization—especially in university research projects—there are TA questions about the consequences and effects of the virtualization of social life—politics, economics, ecology, culture, and law. With regard to politics, studies have focused on e-government, electronic democracy, and the dismantling of nation-states. With regard to economics, TA has concerned itself mainly with the transformation of work. In addition, TA continues to address classic issues such as traffic, new energy sources (nuclear fusion), privatization of health systems, pharmacology, food technology, multimedia technology, and information or data processing.

Evaluation

The German and European TA landscape deserves evaluation on the basis of the following: Have the numerous TA activities had any influence? If so, what kind of influence have they had on technological developments and on related underlying decisions? *Technological Assessment in Europe: Between Method and Impact* (2003), a study by ITAS and the European Academy, is a useful guide in answering these questions. This study presents a typology of three types of impacts: the generation of knowledge; the alteration of opinions and forms of behavior; and the initiation of action.

The study concludes that: "Based on the typology of the impacts on TA it is shown that the impacts of TA present more than just the direct influences of political decisions . . . TA—independent of whether it is more classically scientific or participatory—contributes in various ways to society's communication process and to the political decision process: Through the preparation of a balanced basis of knowledge, through the initiation of a new discussion in a gridlock situation, through the working out of new perspectives on a problem" (Decker and Ladikas 2004, p. 78).

Finally the report of the European Science and Technology Observatory (ESTO), an association of twenty European institutions, should be mentioned. In 2002 at the direction of the Institute for Prospective Technological Studies (JRC-IPTS) of the European Commission, ESTO produced an overview of technology-forecasting activities in Europe.

This working document arose within the frame of the ESTO project "Monitoring of Technology Forecasting Activities," funded by the Joint Research Center Institute for Prospective Technological Studies (JRC-IPTS) of the European Commission. This project was part of a larger ESTO monitoring activity, which ran from February 2000 until June 2001. The main results of this ESTO activity are published in "Strategic Policy

Intelligence: Current Trends, the State of Play Perspectives, IPTS Technical Report series, EUR 20137 EN.

TECHNOLOGY LITERACY

SEE *Public Understanding of Science.*

TECHNOLOGY: OVERVIEW

Technology may be broadly defined as the making and using of artifacts. In its simplest forms, however, use will involve no more than natural objects, and in more abstract instances fabrication and use can both be of concepts—in which case logic may be described as a technology. The etymology of the word leads back to the Greek *techne,* from which is derived *technique* and *technics.* In the opening lines of *Nicomachean Ethics,* Aristotle (384–322 B.C.E.) observed that "Every *techne* and every inquiry, and similarly every *praxis* and pursuit, is believed to aim at some good" (1.1.1094a). Thus the centrality of human ends or intentions to technology makes ethical analyses vital. Ethical inquiry is made difficult, however, by the diversity of ways technology can be understood. According to one proposed analysis, technology may be distinguished into objects, knowledge, activities, and intentions (Mitcham 1994). Each of these types of technology constitutes a source and challenge for ethics.

Historical Dimensions

Before considering these different types of technology, which are covered in a plethora of entries in this encyclopedia, there are historical transformations from technics to technology to acknowledge. These transitions, which are also often described as shifts from ancient to modern or from prescientific to scientific technology, can be discussed in terms of artifacts and attitudes. In relation to artifacts, humans used lithic (or stone) tools from the early Paleolithic period (about 2.6 million years ago) up to the close of the Neolithic period around 5,000 years ago. The widespread control of fire occurred roughly 124,000 years ago and crops were domesticated around 10,000 years ago. Up until approximately 40,000 years ago, the interplay between human physiology and technics no doubt influenced the evolution of human cognitive and other physical capacities.

The development of bronze and iron tools marked the end of the Neolithic and the transition into the classical age, in which technological artifacts in the form of structures became increasingly significant. Premodern structures, initially in the early civilizations of Egypt, Mesopotamia, India, and China, then especially in China's Han dynasty (206 B.C.E.–220 B.C.E.) and the Greek and Roman periods in Europe, became interrelated with governance, and the works of architects began to influence daily life. In the European Middle Ages progressive developments in mechanics and the harnessing of nonhuman sources of power promoted further change in artifactual history.

The emergence of technology in a distinctly modern sense is correlated with the rise of modernity itself. Through the Industrial Revolution tools, machines, structures, industrial processes, and mass-produced consumer goods increased in complexity and number, acquiring an unprecedented societal influence. Additionally, during and after the Enlightenment, technology became progressively associated with accumulating scientific knowledge, to the point where, in the late twentieth century the connection was occasionally denominated with the term *technoscience.*

In relation to attitudes, which exhibit inherently ethical components, history may be broken out into a threefold taxonomy of arguments about technology and its proper role in the good life. Although partially historical, these basic attitudes (with countless gradations) nevertheless continue to coexist today. First, ancient or premodern attitudes about technology were generally skeptical, tending to view it as a necessary but dangerous turning away from God or the gods. Artifacts were judged to be less real than natural objects, technical information was not considered true wisdom, and technical affluence was thought to undermine higher goods such as individual virtue and political stability.

Second, modern Enlightenment attitudes about technology were optimistic, viewing it as a means of socializing individuals and creating public wealth. The will to technology was ordained by God or nature. Technical engagement with the world provided true knowledge, and nature and artifice were judged as operating by the same mechanical principles.

Finally, Romantic attitudes about technology reintroduced a degree of premodern uneasiness to constitute an ambivalence that tried to strike a middle ground between premodern skepticism and modern enthusiasm. Technology was viewed as one manifestation of human creativity, and thus to be affirmed, but also as manifesting a lamentable tendency to crowd out other forms of creativity. Technology engendered freedom but simultaneously alienated individuals from affective strength, weakened cultural bonds, and introduced new forms of social control. Artifacts expanded the processes of life, but imagination and vision deserved to be defended against the encroachments of technical knowledge.

Technology as Object

Technology is most commonly thought of in terms of artifacts, physical objects designed and produced by human beings. Ethical issues related to artifacts include the concerns of health and safety. These are especially illustrated by elements of risk and uncertainty, because it is often impossible to predict how objects will interact with the complex physiological, social, and ecological contexts in which they are deployed. Important work in engineering design seeks to integrate safety concerns throughout the process, but in some sense accidents and failures may be an inevitable part of complex modern artifacts.

Other ethical issues stem from justice and equity concerns that arise, for example, in cases of technology transfer and other manifestations of globalization. Matters of justice and equality are also involved in the representation of females and minorities in technology development and application policies. Freedom is a further important consideration in debates about technological determinism (in the thought of Jacques Ellul) or the liberating potential of technology (as argued by Julian Simon). Moreover, philosophers such as Langdon Winner have argued that artifacts have politics, in that they may be intentionally designed to limit the freedoms of certain groups. Other objects inherently lead to different political systems of control along the spectrum from authoritarianism to democracy.

Technological objects raise additional ethical and phenomenological questions about how they influence individual and group self-identities. For example, the design of buildings and public spaces in urban environments, in addition to impacts on safety, health, and equity, influence community character and quality of life. Finally, there is a sense in which technological objects as consumer goods can alter both culture and, through pollution and waste, the natural environment.

Not only do many of the key themes just mentioned have their special entries, but sample encyclopedia entries on almost any technology—from "Airplanes" and "Biological Weapons" to "Movies" and "Television"—illustrate these issues. Entries on thinkers such as "Anders, Günther," "Ellul, Jacques," "Illich, Ivan," and "Simon, Julian" present particular arguments. Slightly more general discussions that emphasize structures and hardware can be found in "Architectural Ethics" and "Computer Ethics," respectively.

Technology as Knowledge

Much of the philosophical work on technology as knowledge has naturally been epistemological, but ethical issues have also received consideration. One of these concerns freedom of speech and censorship. For example, terrorist threats highlight the dual-use character of technical knowledge, which may often be used for beneficial as well as nefarious purposes. This raises age-old questions about whether some knowledge should be forbidden, or if not, how its production and exchange should be regulated. Because technoscientific knowledge is not easily separable from applications, it may not be feasible or wise to argue that ethical considerations need only take place after knowledge has been produced.

With advances in genetics and information technologies, the issue of intellectual property rights has sparked debate about the ethical and societal implications of the private ownership of technical knowledge. Pertinent topics in this area are open-source software and the patenting of genetic material. In agriculture, the latter area has raised difficult questions about the legal status of indigenous technical know-how. Another important topic is the increasing privatization of academia driven by incentives for university researchers to patent the technological products that result from their research. This raises ethical issues about the proper role of the academy and the value of open information exchange in science.

One last broad set of ethical issues is raised by the theme of expertise and the role of experts, especially engineers, in a democracy. Many problems in modern industrial societies require the specialized knowledge of engineers, but most would claim that a technocracy, or rule by experts, represents an undesirable departure from democratic ideals. (It is worth noting, however, that in some cases technocrats are praised because of their lack of attachment to fundamentalist political or religious ideologies; technical knowledge and competence has its virtues.) Although engineers have much to offer regarding management and policy decisions, many nontechnical or political issues tend to become unproductively debated as if they could be resolved by technical knowledge. Other issues related to the accumulation of specialized knowledge by experts are the deskilling of the workforce, equity concerns about access to education, and widespread technological illiteracy even in societies utterly dependent on the smooth functioning of technological systems. All of these issues raise important questions about knowledge as a form of power.

Encyclopedia entries that deal directly with technology as knowledge thus include those on "Expertise," "Intellectual Property," "Public Understanding of Science," and "Technocracy." Related questions are also addressed in more general entries on, for example, "Computer Ethics" and "Information Ethics."

Technology as Activity

Technology as activity shades from personal to institutional and social modes. It may conveniently be divided into the two broad themes of production and use. With regard to production, most of the ethical issues are internal to the various technical professions. They raise issues of professional, engineering, and management ethics, which are often formalized in codes of ethics and are being increasingly integrated with professional training and education programs. Different ethical issues arise along the spectrum of engineering functions from the initiating actions of inventing and designing to the subsequent processes of testing, constructing, and operating. But across the board one common theme is that of the social responsibility of engineers, managers, and the organizations in which they are embedded.

Technology as activity is nevertheless more complex than a one-way flow of products from invention to application or use. Not only are engineers influenced in subtle ways by cultural norms, their work is often consciously informed and directed by formal and informal involvements of governments and publics. These take the broad form of technical standards, regulation, and technology policy, as various institutions and actors engage in decision-making procedures about which technologies to produce, ban, limit, or otherwise manage. Examples include regulatory bodies such as the Food and Drug Administration (FDA), advisory bodies such as bioethics commissions, and technology assessment agencies such as the Office of Technology Assessment (OTA) or tools such as environmental impact statements. Public decisions about the production and use of technology raise manifold ethical issues about who should be involved, how involvements should be structured, how risks, costs, and benefits should be measured, and what goals should drive the policymaking process. Broader debate occurs over the proper roles of market mechanisms and government control.

Ethical analyses of the use of technology flow naturally from the fact that such uses are subordinate to, or in the service of, some goal. Issues of use often raise the question of whether artifacts can be considered ethically neutral. For example, computer technology can be used to help researchers find cures for diseases, or it can be used to hack into financial systems and steal money. Although it is common to conceptualize technology in this way, there is significant evidence for the nonneutrality of technology.

Indeed technological changes fundamentally alter human experiences in ways that can be judged good or bad, but certainly not neutral. Such changes are best illustrated by work, the most prominent form of technology as activity. The large-scale production and use of modern technologies has brought about the transformation of craftwork into industrial labor, which is marked by division of labor, mass production standardization, and bureaucratic organization.

For more analysis of the ethical issues related to technology as activity it is thus useful to consider encyclopedia entries on "Professions and Professionalism," specific professional organizations such as the "Institute of Electrical and Electronics Engineers," and regulatory agencies such as the "Food and Drug Administration" and the "Federal Aviation Administration." Also relevant would be entries on the principles that are said to guide much technical activity such as "Efficiency," "Safety," and "Reliability."

On a philosophic note, it is also important to consider how technological activities or processes of a more impersonal sort alter human relationships and relationships between humans and nature. The entry on "Tools and Machines" makes suggestions with regard to human–human relationships. The entry on "Arendt, Hannah," provides further background to her argument about the ways traditional technics or premodern technology was limited by the materials and energy given in nature. The development of steam, electric, and nuclear power qualitatively changed this human–nature relationship. Finally, Arendt noted how technology as action is a deeply troubling contradiction. Traditionally, action was associated with the political realm and its qualities of plurality, indeterminacy, and choice. Modern mass society has subordinated this realm to the pursuit of scientific technology and technologically mediated work, an effort that seeks to replace the contingencies of nature and the polis with the control and certainty of technology. Ethical and metaphysical quandaries result about the modern attempt to control, manage, and even make nature. Much of the rhetoric around the notion of ecological sustainability, for example, is dominated by concerns of control and efficiency rather than political and ethical considerations of the meaning of the good life and humankind's proper relationship with other species. And contemporary worries about the uncertainty of much scientific and technical knowledge would arise only in a world that aspired to certainty in human affairs.

Technology as Intention

Technology as intention is at once the most basic yet the most difficult to consider. As Aristotle noted, neither technics nor technology can exist without the exercise of intentionality. Moreover, because ethics is itself so closely tied to the idea of intentions and their assessment, to think of technology as intention would seem to bring technology more closely into the ethical realm than to think of technology as object, knowledge, or perhaps even action. At the same time, the slipperyness of intentionality presents its own difficulties, especially in relation to technology. Is there any such thing as a distinctively technological intention in the same way there are technological objects, forms of knowledge, and activities? Is it possible, for instance, to distinguish between religious, political, and technological intentions—or between premodern and modern technology in terms of intentionalities? Or are intentions just mental states to which technical activities are necessarily subordinated? Is there one intention to procure food, which can then be achieved by, say, political or technological means? But surely the intentional selection of technological over political means constitutes a kind of technological intention. (See, in this respect, the entry on "Technological Fix.")

The most common way in which intentionality has been invoked when examining the ethics of technology is in fact in relation to the idea of modern technology as emanating from a distinctive will or volition, a philosophical argument more common to phenomenological than to analytic traditions in philosophy. Discussions of technology as volition span the spectrum from technology as a creative life force to technology as a restricting urge to control. Technology can be celebrated in a Nietzschean aesthetics of self-making in the project to wrest control of life from the vagaries of nature and even achieve immortality. But there is a sense in which technologies have a "will of their own" and are not infinitely plastic to the impress of different human intentions. Perhaps it is not just human intentions or volitions that shape technology, but technologies that also influence human intentions. There are limits to what one can do with any particular technology: It is difficult to use a hammer to screw a nut onto a bolt.

To analyze technology as a form of intentionality further requires that ethical assessments of use be coupled with empirical work on the properties of technologies. One form this has taken is to conceptualize intending as a form of decision making, which may in turn be undertaken by rational analysis. More generally, the increasing powers unleashed by modern technology suggest a need for increased knowledge of what ends they are to serve and knowledge of the consequences before they are put into use. But such needs must themselves be translated into action. And failure to take action is a form of weakness of intention or will that recurs frequently in situations of public and personal decisions about technology.

Most discussions of the ethics of technology deal with specific technologies: biomedical technologies, computers, nuclear weapons, and more. But in a few instances philosophers working in the phenomenological tradition have sought to bridge technological divides and consider the parameters of technology as a whole. Here the contributions of such thinkers as "Anders, Günther" and "Jonas, Hans" as well as "Heidegger, Martin" are especially significant. Related discussions can be found in entries on such philosophical schools as "Existentialism" and "Critical Social Theory."

Generalization

The distinctions between ethical issues in technology as object, as knowledge, as activity, and as intention should not serve to excuse anyone from thinking about ethics and technology in other ways as well—or for seeking to integrate these four modes of the manifestation of technology. For instance, Albert Borgmann's provocative interpretation of modern technological objects as tending toward what he terms the "device paradigm" of supplying some commodity with minimal human engagement and contextual dependency at the same time depends on a unique form of (virtual) knowledge and sponsors a distinctive type of (unfocused) activity. Borgmann's ethical assessment of technological devices is coordinate with his ethical judgment regarding technological knowledge and activity. To distribute ethical issues across a spectrum of manifestations of technology may serve simply as a provisional means for appreciating the breadth of concerns that fall under the idea of relating technology and ethics. Similarly, Don Ihde's analysis of different forms of human engagement with technology—from embodied extension to perceptual transformation—crosses the boundaries of technology as object, knowledge, and action in ways that invite scientists, engineers, and the general public to ask broad ethical questions about the techno-lifeworld they are in the process of creating.

Finally, the breadth of concerns must not be thought of as one determined only by problems. The praise of technology that is distinctive of the modern project and Enlightenment aspirations invests technology with rich ethical promise for better goods and services, understanding, human health, and intentional fulfillment. From this perspective the ethical problems are addressed so that they can be negotiated with that distinctively human behavior that originally gave rise to all technology, ancient and modern, in order to pursue and promote true human flourishing. Problems need not be limitations; they can also be conceived as the stimulus to new achievements.

TECHNOLOGY TRANSFER

Technology transfer is a complex and multi-faced process. Initially, transfer occurs from research laboratories such as universities to the market. Prior to 1980 when The Patent and Trademark Laws Amendment Act, more commonly know as the Bayh-Dole Act was passed, there was limited flow of government-funded inventions to the private sector. In 1980, the federal government held title to approximately 28,000 patents. Fewer than 5 percent of these were licensed to industry for development of commercial products (U.S. Government Accounting office, 1998). The Bayh-Dole Act permitted universities to retain title to inventions developed under government funding and encouraged universities to collaborate with companies to promote the utilization of invention arising from federal funding. Since the passage of this Act, partnerships between universities and industry have moved new discoveries from the laboratory to the market place for the benefit of society.

There is substantial evidence to suggest that the Bayh-Dole Act has promoted a considerable increase in the technology transfer from universities to industry, and ultimately to the people around the world. However, it is obvious that economic interests were the driving forces for the change in governmental policy. Licensing by universities, National Institutes of Health or other governmental agencies in life sciences has yielded substantial profits to pharmaceutical companies, sometimes at the cost of human suffering. If the public good is not served by, or is undermined by technology transfer, then it is ethically justified to change public policy.

Historically, and to a large extent even in the early twenty-first century, the transfer of technology occurs between and among developed nations. However, new forms of multi-national enterprise imply a dispersion of production tasks across globe. In the case of developing countries, the technology must meet the local needs and be socially accepted. If the technology is not appropriate it may cause negative economic, social, and environmental impacts. The chemical disaster in Bhopal, India, is a case in point. Methylisocyanate (MIC) leaking from a Union Carbide corporation pesticide plant immediately killed more than 2,000 people and injured or disabled more than 200,000 others. The death toll has reached 20,000 since December 3, 1984, when the accident occurred. Information about hazardous technologies was lacking, workers were poorly trained, and major safety equipment was inoperative because of poor maintenance. In this case the technology should have been modified to make it adaptable to the new environment.

Mechanisms of Technology Transfer

The most important legitimate channels for technology transfer are licensing, foreign direct investment, and joint ventures. Most technology transfer takes place in the form of licensing under specific terms and conditions agreed to by both suppliers and recipients. The suppliers gain monetary rewards, whereas the recipients expand their economic opportunities.

Foreign direct investment refers to a process by which multinational corporations (MNCs) transfer production operations to the developing countries through wholly owned subsidiaries. In this context, the transfer of technology takes place internally between parent MNCs and their branches and subsidiaries in different countries. This enables MNCs to retain technology within the corporations.

Joint ventures have emerged as an alternative to foreign direct investment because most developing countries have issued investment laws that regulate foreign investment. These laws promote joint ventures between local and foreign partners. Consequently, with greater emphasis on national participation and control by the developing countries, technology transfer has assumed a new meaning, although control over proprietary technology and know-how has remained with MNCs.

Technology Transfer and Ethical Issues

Given these basic mechanisms of technology transfer, one may nevertheless ask: Why technology transfer? Can technology transfer improve the economic conditions of people living in the developing countries? Can technology transfer create global equity?

Proponents of globalization have suggested that technology and its diffusion can improve living standards, increase productivity, generate employment opportunities, improve public services, and create competitive markets for products. Have these goals been achieved? There are two contending theories: the dependency theory and the bargaining theory.

DEPENDENCY THEORY. Proponents of this theory (Cardoso and Faletto 1979) claim that, because of the insistence of multinational corporations on foreign direct investment (which transfers technology from the parent companies to the foreign subsidiaries), developing countries are denied access to modern technologies. These theorists contend that technology is key to development and, if denied, developing countries will remain dependent on developed countries. This will create negative economic outcomes, such as increased inequality and wage stagnation. Consequently, the balance of trade between developed and developing societies will remain unequal and therefore exploitive. Sunil K. Sahu (1998) suggests that such technological dependence creates an enclave economy for the developing countries, and that it will be difficult for their economies to expand or even survive.

BARGAINING THEORY. This theory takes a view opposite that of dependency theory. Bargaining theory recognizes the potential benefit that MNCs can bring to their host countries. In other words, the technologies of the advanced countries do not have adverse effects on the economy of the developing societies. Raymond Vernon (1971), an advocate of this theory, has developed a concept known as "obsolescing bargaining" that explains the relationship between MNCs and host countries. The bargaining power of the developing countries tends to increase after a certain period, specifically when technology becomes stabilized and competition for the same technology by other developed countries intensifies. The competition among developed countries increases the choices available to the developing countries. Additionally, once the foreign investment is "sunken," the host country is in a much stronger position to negotiate a better deal, and at this point MNCs cannot credibly threaten to withdraw (Stepan 1978). Vernon also suggests that the monopoly of the innovator is not permanent because most products tend to pass through a transition from "monopoly to oligopoly to workable competition" (Vernon 1971, p. 91). This is also known as the product life-cycle theory.

Can Technology Transfer Create Global Equity?

Technology transfer has accelerated the process of globalization, and it is suggested that it may lift all people and raise their living standards. The Industrial Revolution brought new wealth first in Europe and then in the United States. Since the Industrial Revolution, the difference between the rich and the poor in the world has increased. It is estimated that the difference between the per capita incomes of the richest and poorest countries was 3 to 1 in 1820, 11 to 1 in 1913, 35 to 1 in 1950, 44 to 1 in 1973, and 72 to 1 in 1992 (UNDP 1999). The gap is further reflected in how the world's wealth is distributed. The wealthiest 20 percent of the world's people—all from developed countries—control 85 percent of global income. The remaining 80 percent of people share 15 percent of the world's income. Such disparity has led to greater poverty in the developing countries. Statistics show that the number of people who are living on less than $1 per day (a frequently used poverty line) was rising in the late twentieth and early twenty-first centuries. The number of these people grew from 1.2 billion in 1987 to 1.5 billion in 2000, and there could be nearly 2 billion poor people by 2015. In addition, approximately 45 percent of the world population live on $2 per day (World Bank 2000). Some countries such as South Korea, Taiwan, Singapore, Hong Kong, and China have benefited from global economies, but others have not. The growth of proprietary technology, covered by patents and industrial property rights, has served as a major barrier to new entrants, and it will continue to do so unless proprietary rights are modified.

TECHNOSCIENCE

Technoscience refers to the strong interactions in contemporary scientific research and development (R&D) between that which traditionally was separated into science (theoretical) and technology (practical), especially by philosophers. The emphasis that the term *techno(-)science* places on technology as well as the intensity of the connection between science and technology varies. Moreover the majority of scientists and philosophers of science continue to externalize technology as *applications and consequences* of scientific progress.

Nevertheless they recognize the success and efficiency of technology as promoting realism, objectivity, and universality of science.

The prehistory of the concept of technoscience goes back at least to the beginning of modern science. Francis Bacon (1561–1626) explicitly associated knowledge and power; science provided knowledge of the effective causes of phenomena and thus the capacity for efficient intervention within them. The concept became clearer during the first half of the twentieth century. Gaston Bachelard (1884–1962) in *Le nouvel esprit scientifique* (1934; The new scientific spirit) places the *new scientific spirit* under the preponderant influence of the mathematical and technical operations, and utilizes the expression *science technique* to designate contemporary science. However the term techno(-)science itself was not coined until the 1970s.

The History of Techno(-)science

The first important occurrence of the term appears in the title of an article titled "Ethique et techno-science" by Gilbert Hottois, first published in 1978 (included in Hottois 1996). This first usage expresses a critical reaction against the theoretical and discursive conception of contemporary science, and against philosophy blind to the importance of technology. It associates technoscience with the ethical question, What are we to make of human beings? posed from an evolutionist perspective open to technical intervention.

Throughout the 1980s two French philosophers, Jean François Lyotard and Bruno Latour, contributed to the diffusion of the term in France and North America. For Lyotard technoscience realizes the modern project of rendering the human being, as argued from the work of René Descartes (1596–1650), a *master and possessor of nature*. This project has become technocratic and should be denounced because of its political association with capitalism. As a promoter of the postmodern, Lyotard thus facilitates diffusion of the term within postmodern discussions.

In *Science in Action* (1987), Latour utilizes the plural *technosciences* in order to underline his empirical and sociological approach. The technosciences refer to those sciences created by human beings in real-world socioeconomic-political contexts, by conflicts and alliances among humans and also among humans and nonhumans (institutions, machines, and animals among others). Latour insists on networks and hybrid mixtures. He denounces the myth of a *pure science*, distinct from technologies susceptible to good and bad usages. In reality it is less technology that Latour internalizes in the idea of science than society (and therefore politics), of which technologies are part in the same ways as other artifacts. He rejects any philosophical idea, whether ancient or modern, of a science that is supra- or extra-social and apolitical. The worldwide successes of the technosciences are a matter of political organization and will, and do not derive from some universal recognition of a rational and objectively true knowledge that progressively imposes itself. Latour has contributed to the success of the term technoscience in social-constructivist discussion since the 1990s.

The work of Donna Haraway illustrates well the diffusion of technoscience crossed with the postmodern and social-constructivist discussions in North America. Technoscience becomes the word-symbol of the contemporary tangle of processes and interactions. The basic ingredients are the sciences, technologies, and societies. These allow the inclusion of everything: from purely symbolic practices to the physical processes of nature in worldwide networks, productions, and exchanges.

In France, in continental Europe, and in the countries of Latin America, the use of the term technoscience has often remained closer to its original meaning that involves more ontological (as with German philosopher Martin Heidegger (1889–1976)), epistemological, and ethical questioning than social and political criticism. Indeed in a perspective that complements the one provided here, in *La revolución tecnocientífica* (2003; The technoscience revolution), Spanish philosopher Javier Echeverría provides an extensive analysis of technoscience as both concept and phenomenon. A political usage is not, however, rare, especially in France where there is a tendency to attribute to technoscience a host of contemporary ills such as technicism and technocracy, multinational capitalism, economic neo-liberalism, pollution, the depletion of natural resources, the climate change, globalization, planetary injustice, the disappearance of human values, and more, all related to U.S. imperialism. The common archetype of technoscience is Big Science, originally exemplified by the Manhattan Project, which closely associated science, technology, and the politics of power. In this interpretation, technoscience is presented from the point of view of domination, mastery, and control, and not from that of exploration, research, and creativity. It is technocratic and totalitarian, not *technopoiétique* and emancipating.

The Questions of Technoscience

What distinguishes contemporary science as technoscience is that, unlike the philosophical enterprise of science identified as a fundamentally linguistic and theoretical activity, it is physically manipulative, interventionist, and creative. Determining the function of a gene whether in order to create a medicine or to participate in the sequencing of the human genome leads to technoscientific knowledge-power-doing. In a technoscientific civilization, distinctions between theory and practice, fundamental and applied, become blurred. Philosophers are invited to define human death or birth, taking into account the consequences of these definitions in the practical-ethical plans, that is to say, in regard to what will or will not be permitted (for example, the harvesting of organs or embryonic experimentation).

Another example is familiar to bioethicists. Since the 1980s there has existed a line of transgenic mice (*Onco mice*) used as a model for research on the genesis of certain cancers. Here is an object at once natural and artificial, theoretical and practical, abstract and concrete, living and yet patented like an invention. Their existence and use in research further involves many different cognitive and practical scientific questions and interests: therapeutic, economic, ethical, and juridical. It is even a political issue, because transgenic mice are at the center of a conflict between the European Union and the United States over the patentability of living organisms.

The most radical questions raised by technosciences concern their application to the *natural* (as a living organisms formed by the evolutionary process) and *manipulated* (as a contingent creation of human culture). Such questions acquire their greatest importance when one takes into account the past and future (unknowable) immensity of biological, geological, and cosmological temporality, in asking, for example: What will become of the human being in a million years? From this perspective the investigation of human beings appears open not only to symbolic invention (definitions, images, interpretations, values), but also to techno-physical invention (experimentation, mutations, prosthetics, cyborgs). A related examination places the technosciences themselves within the scope of an evolution that is more and more affected by conscious human intervention. Both approaches raise questions and responsibilities that are not foreign to ethics and politics but that invite us at the same time to consider with a critical eye all specific ethics and politics because the issues exceed all conceivable societal projects.

TELEPHONE

Telephone technology allows a person to talk to nearly anyone in any place who has similar equipment. There are substantial ethical questions related to the uses and abuses of the telephone. Among other things, the telephone is a communication system that provides political leaders, pollsters, and social science researchers with some understanding of public attitudes and behaviors. It gives voice to the needs and wishes of citizens as they attempt to make their views known to governments and corporations. Additionally, the telephone is a conduit for the delivery of professional services. As a result of these aspects of what has been an everyday but rapidly changing technology, considerable attention has been devoted to the telephone from ethical, legal, and policy viewpoints.

Historical Development

The term *telephone* is based on the combination of the Greek words, *tele* ("distant" or "afar") and *phon* ("sound" or "voice"); it was first used in France in the 1830s to name a crude acoustic device. By the mid-1800s something akin to a pair of tin cans connected by a taut string was known in the United States as the "lover's telephone." In 1876 Alexander Graham Bell (1847–1922) won a patent for a device that has come to be known as the telephone.

Alexander Graham Bell testing his telephone invention in front of onlookers. Graham won a patent for the device in 1876. *(U.S. National Aeronautics and Space Administration.)*

The traditional telephone operates by converting the mechanical energy of sounds carried in the air (the speaker's voice) into electrical impulses for transmission to a receiver. The receiver reverses the process, changing the electrical impulses back into vibrations. Those vibrations are heard as sounds. The original telephones transmitted electrical impulses by wires. Radio and other portions of the electromagnetic spectrum subsequently supplemented or supplanted wires as digital forms replaced analog.

The uses of the telephone have expanded to include multiple forms of data transmission, including fax, photo, and video image formats. Ancillary services have been created and have been widely adopted, including answering machines, caller-ID boxes, and telephone-based security systems. The Internet owes much of its success to the ability of users to go online by means of telephone lines.

In the early period of the telephone myriad uses were explored, including the "broadcasting" of news, opera, weather reports, and religious services. Some contemplated services never materialized: Bell speculated that the telephone might be used to communicate with the deceased. Other services did not materialize because they were outdated before they could deployed: France's national telephone company conducted extensive research in the 1960s to see if the telephone touch-tone pad could be adapted to serve as a home calculator. Yet other services were initially innovative and popular, but then, as technology continued to advance, they were left in the backwater. The fax machine and the French Minitel system are examples of this phenomenon.

Ethical Issues

PRIVACY, SECURITY, AND SURVEILLANCE. Among the early ethical questions was the way the telephone was used to invade privacy in the household and give outsiders access to household members. In particular the telephone allowed outsiders to make social connections with the members of a household, thus violating rigid gender and class roles. Ethical questions relating to various roles in the household, along with the power relationships among those roles, have been exacerbated by the telephone. For example, teenagers and parents come into conflict over appropriate norms for telephone use.

The telephone often leads to disruption of household routines and may allow for social subversion through practical jokes and harassing or obscene phone calls. Women especially have been victimized by such calls, though a surprisingly large number of men have been as well. Although commentators see great net benefits arising from the telephone, they also recognize the moral dilemmas that result from the "distant presence" (a phrase popularized by Kenneth J. Gergen) the telephone allows. The American humorist Mark Twain (1835–1910) was an early acerbic critic of the way the telephone could disrupt trains of thought and ordinary social interaction. In addition, characteristic of early telephone technology was the large proportion of homes that shared local service party lines; this meant that neighbors could listen in to conversations and learn family secrets.

Larger questions of privacy surrounded systematic wiretapping conducted by both licit and illicit organizations. Only a few years after the telephone was invented numerous devices were built to allow not only tapping but also recording of telephone conversations. (Many of these microphone devices also can be used to listen in on in-room conversations.) A wide variety of practices legal and illegal, moral and immoral, could be identified and documented.

Police forces and other governmental agencies sometimes carried out large-scale wiretapping not only in pursuit of wrongdoers but also to monitor those perceived as opposing government policy. In what has become a well-established cycle of innovation, new ways to communicate were followed by new ways to penetrate those forms, followed by steps to enhance privacy. Often a variety of codes would be devised to hinder attempts to collect data and conduct surveillance. The question of the areas in which people had a "reasonable expectation" of privacy was brought to a head when the U.S. Supreme Court decided in *Katz* v. *United States* (389 US 347 [1967], docket number 35) that public phone booths were not eligible for systematic tapping by the police.

Although monitoring of workers has been a perennial workplace issue, the telephone gave that issue added impetus because it greatly expanded the ability of managers to tap into the conversations of employees. Telephone companies often have conducted extensive monitoring, sometimes to the point of abuse, when they have used their own technology to monitor employees' behavior and comments. Switchboard operators once were notorious for eavesdropping, though sometimes that allowed them to interrupt the execution of crimes. (Eavesdropping, as opposed to service monitoring or surveillance by officials, is generally prohibited everywhere.) Many companies, including especially telephone companies, have published rulebooks and etiquette guides directed to their employees and managers regarding eavesdropping. While these efforts presumably reduced the problem, they have not been sufficient to extinguish the practice.

TELEMARKETING AND RESEARCH. Telemarketing is the offering of goods or services through sales presentations on the telephone. Because it can be a low-cost, high-profit enterprise, its rapid proliferation has become a source of general annoyance to the targeted public. The Direct Marketing Association and the American Marketing Association instruct their members not to use approaches that might be considered illegal. Moreover, there are numerous laws that regulate telemarketing at the national and local levels. Major moral dilemmas are related to this situation.

On the one hand, there are the claimed rights of businesses to "freedom of commercial speech," which includes the freedom to communicate with potential customers and participation in "fair and efficient markets." (These rights are protected strongly in the United States.) These rights often are carried out with increasingly powerful telephone support technology and database-mining software. On the other hand, individuals have a right to be left alone and not to have information about them collected in secret and without their permission. (These rights are protected strongly in the European Union nations and not as well protected in the United States.) Despite such efforts on both the technological front (such as caller-ID and call blocking) and the legal front (such as the compilation of "do not call lists" and the regulation of times when sales calls may be made), this problem persists.

Social science research and public opinion surveys often are reliant on polling by telephone. Numerous agencies and associations, such as the American Sociological Association (ASA) and American Association for Public Opinion Research (AAPOR) have created codes of conduct for their members, and in some cases governments have stepped in to create regulations in this area. Criminal penalties can be imposed for collecting data improperly by telephone. Many institutional review boards (IRBs) at universities require that researchers demonstrate that they will protect the data and not cause psychological distress, and this applies to telephone surveys as well as to medical experimentation. In more extreme cases, such as at the University of Newcastle in Australia, researchers are required to notify the target population in advance with a written information sheet that warns that telephone contact will be made and includes complete contact information.

UNIVERSAL SERVICE, SOCIAL EQUITY, AND DEMOCRACY. An important ethical component of national and regional policies for telephone technology is equitable distribution. As Claude Fischer (1992) has noted, in its early years the telephone could be considered only a luxury. However, what was an expensive enhancement to lifestyle has in contemporary society become a near necessity for most people.

For much of the twentieth century national telecommunication policies were aimed at subsidizing low-income and rural populations by indirectly taxing (through higher rates) urban and nonpoor telephone subscribers. This was done under the rubrics of social equity and economic development. In fact, in the United States the promise of universal service at an affordable cost was accepted by the government in exchange for the granting of near-monopoly status to the American Telephone and Telegraph Company (AT&T). However, the initial moral clarity of those policies has been obscured as advanced telecommunication technologies have proliferated, especially in the case of the mobile phone.

Mobile phone. Mobile phones have a long and varied history that stretches back to the early 1970s. Due to their low establishment costs and rapid deployment, mobile phone networks have since spread rapidly throughout the world, outstripping the growth of fixed telephony. *(© Leland Bobbe/Corbis.)*

It is noteworthy that around the world hundreds of millions of subscribers have flocked to new mobile phone services. Those services allow subscribers to leapfrog the long waits and frequently high prices associated with wireline residential services. Moreover, cross-subsidization by ordinary telephone subscribers of low-cost services for schools and hospitals, as is the practice in the United States, means that many people with modest incomes are being penalized for the benefit of institutions in wealthy communities. (Mobile phone subscribers in the United States are exempt from these taxes.)

There can be little doubt that the telephone is an important adjunct to democracy on the level of political expression and as a bulwark against excessive governmental power. At the same time, terrorists and those seeking radical regime change can use the telephone to further their aims. In light of this situation many governments monitor telephone conversations and in some cases limit or prohibit mobile phone services. As instances, North Korea forbids civilian mobile phones on security grounds and Colombia's mobile phone networks were selectively turned off by the government in an effort to detect the location of cell phone-toting drug lord Pablo Escobar.

Public Use of Mobile Telephones

Each major advance in telephone technology has been accompanied by some social disruption. In most cases the disruptions have been transient. With the advent of the mobile telephone, however, high levels of conflict continue. These conflicts often may be understood in terms of what is known in psychology as the actor-observer paradox. The person who wishes to use the mobile phone (the actor) does so because he or she has good cause and with the expectation that others will understand and accept that necessity. However, the people around the user (the observers) view the situation differently. They feel that the mobile phone user is being selfish and self-indulgent and is failing to respect the conventions of polite society. The public use of mobile phones is likely to remain a source of normative conflict because the sources of irritation are not merely conventional but seem to go to the core of human cognitive processes. The result could be that as mobile phone users pursue the private pleasures of conversation there will be a reduction in civility and personal engagement in public places. Perhaps no better illustration of this process is the havoc wrought by drivers who are preoccupied by their mobile telephone conversations.

Provision of Professional Services

The ease and flexibility of telephone use have led many professional organizations to develop codes of conduct that allow their members to use the telephone, under appropriate conditions, to serve clients. This is the case with the many national and worldwide associations of lawyers, for instance. However, the potential for abuse also has led many organizations, such as the Legal Profession Advisory Council, to remind their members that whereas the telephone can be used to discuss and provide confidential information, both the professional and the client have to agree to this in advance. It further recommends that a scrambling device or other encryption technology be used. All advertisements for lawyers should bear the attorney's phone number prominently.

The question of recording telephone conversations is fraught with ethical and moral questions. In one instance (LEO 1738, 48/10 Va Lawyer Reg 23, April 13, 2000) the Virginia state bar association reexamined the subject of taping telephone conversations. That association concluded that all forms of wiretapping, along with one-party-consent recording of telephone conversations by lawyers, are prohibited. Although many people disagreed with that conclusion, it did arrive at the formulation that because wiretapping involves "deceit," the practice must be forbidden. This raises problems when, for instance, testers try to prove housing discrimination by pretending to be people other than who they are. The rules even make it unethical for an attorney who receives an obscene or threatening phone call to record it.

The American Medical Society counsels physicians that telephone advising and referral services should be used only to complement face-to-face interaction and that both the physicians and the clients should be well aware of the limitations of the medium. They urge that no physician make a clinical diagnosis or prescribe medications by telephone and at the same time be certain to elicit all-important information over the phone. They also should avoid generating large telephone bills that their patients or others have to pay.

Counseling by Telephone

Telecounseling has been defined as using the telephone for synchronous but distant interaction between counselors and clients for one-to-one conferencing. Obviously, such interactions are fraught with ethical issues. In response, the National Board for Certified Counselors (NBCC) says that its members should base the use of telecounseling on the needs and convenience of the client. The NBCC further stresses that telecounseling should only be a supplement to face-to-face counseling.

Confidentiality is an important consideration because it may be difficult to know precisely with whom one is speaking when one receives a telephone call. Thus, the American Psychological Association's guidelines warn counselors about privacy and confidentiality issues. The International Chiropractors Association of California has in its code of ethics the statement that its members "shall not discuss any patient information over the telephone with anyone without the patient's consent, preferably in writing." The International Association of Coaches instructs coaches to take precautions to ensure the confidentiality of telephone communications with clients.

In areas in which telephone counseling would be inappropriate professional codes of conduct underscore the importance of avoiding abuse. Thus, the Michigan Speech and Hearing Association urges that the telephone not be used for "diagnosis, treatment or re-evaluation of individual language, speech or hearing disorders." Medical and legal associations have guidelines that also are meant to avoid problems and underscore to their members that using the telephone may be construed as entering into a relationship with a client, with all the demands such a relationship entails.

More Complications Ahead

Because the telephone can obscure many of the ways in which people recognize each other or understand an evolving situation and can transcend distance, it opens new opportunities for ethically questionable or unethical behavior. In addition, as a result of the simplicity and power of the telephone, it has become a vital component of modern life. A variety of codes of conduct, laws, and corporate and governmental regulations have been developed to address these problems. However, these attempts have had incomplete success. Even as recent events are grappled with through norms and regulations, new telephone-based technologies that allow even more forms of use and abuse are complicating efforts to control telephone behaviors through technological countermeasures and moral and legal sanctions.

An eccentric but probing look at the deeper processes involved in the social and phenomenonological construction of the telephone. The volume is a wry postmodern achievement in both form and content.

TELEVISION

Along with the radio, television has become the primary means for broadcast communication and entertainment. As such it calls for ethical and political assessment.

What follows will thus focus on such assessments, noting a spectrum of views running from positive to negative in relation to both content and practice.

Background

The word *television,* a hybrid compound of the Greek *tele* (distance) and the English *vision,* names a technological invention from the 1920s in which electromagnetic waves are used to control a beam of electrons scanning a cathode-ray tube so as to create an image. The initially distinctive feature of this technology was that, unlike motion pictures but like radio, it could be personalized for home or individual use. Over the course of more than half a century the electronics underwent continuous modification: Vacuum tubes were replaced with transistors and then integrated circuits; the black-and-white cathode-ray tube became colored and was then replaced by a high-definition, flat, liquid crystal display; and analog transmission was transformed to digital. The information transmitted thus became increasingly rich in a technical sense.

The commercial development and regulation of television followed the pattern established by radio: Television was initially promoted by the same corporations, and existing regulatory agencies and frameworks were adopted to distribute a limited transmission spectrum among competing private interests. Some countries established national broadcast operations independent of or complementing private operations. But in all cases television viewers received programs free of charge, except for advertising time or taxes. With the advent of video recording systems, cable, and satellite television, however, transmission resources were greatly enlarged, and fundamental shifts took place within the industry that created pay-for-view television. Yet this further increase in technical information delivery and in regulatory regime change failed to alter the basic content, which has remained of two sorts: information and entertainment. Indeed, the TV is the centerpiece of home entertainment systems.

Moral Promise and Threat

From its post–World War II appearance, the promise of TV has been at once praised and criticized. As a new, more vivid and pervasive form of mass communication than anything that had preceded it (magazines, newspapers, radio, and movies) it was subject to intensified versions of both the hype of modernity, which sees technological innovation as inherently beneficial, and mass culture criticism, which argues technology's dangers and debasements. A love–hate relationship was manifest in tensions between promises of increased democratic enlightenment and worries about the commercialization of culture.

On the one hand, television brings diverse quality dramas into the home, and international news programs depict a variety of countries, cultures, and perspectives in a single broadcast. On the other, pop-culture programs, such as those on MTV, present fragmented images that draw from a multicultural mix of music, fashion, sexuality, and ethnic traditions. The moral significance of numerous "high" and "low" cultural programs can be attributed to their ability to deconstruct monolithic images and ideologies: "Implicit in pluriculture is a kind of *bricolage* relativism. One may pick and choose culture fragments, multiply choices, and in the process reflectively find one's own standards provincial or arbitrary—certainly no longer simply *a priori* obvious" (Ihde 1995, p. 155).

While traditional cultures find themselves forced to confront modern secular images, so too are provincial U.S. (and other Eurocentric) audiences forced to question their own identities when confronted with traditional religious images. Television thus presents viewers with the opportunity to engage the global "community of those who have nothing in common" (in Alphonso Lingus's formulation) such that they may become more reflective about the arbitrary nature of their own cultural identity. Any particular cultural position is but one of many such perspectives within the wider cultural arena. For example, the multiperspectival international coverage of the "War on Terrorism" suggests that the conflict between East and West cannot be adequately explained by the partial metanarratives of either side.

Criticism

For present purposes television criticism may be distinguished into three types: those not influenced by Marshall McLuhan (1911–1980), those influenced by McLuhan, and those reacting against or going beyond McLuhan. As the typology suggests, the ideas of McLuhan, who argued the primacy not of television content but of its formal properties, have played a central role. "The medium is the message" was the sound-bite summary of his theory in *Understanding Media* (1964).

Prior to or subsequently ignoring McLuhan have been studies focused on issues related to the content of television and the social influence of this content. Does television advertising work? Do the attitudes and opinions expressed on TV influence or just represent those of the viewers? In the 1950s concern often emphasized the impact of television on leisure and culture. In the early 2000s the concern shifted to the political or cultural biases of television programming. This tradition of criticism also distinguishes different genres—news, cultural programming, sports, soaps, and so on. Most television criticism in the mass media has been of this type, which thus represents the most common critical approach. Studies by Cecelia Tichi (1991) and Lynn Spigel (1992) are scholarly contributions to this tradition.

Among criticisms that have been influenced by McLuhan's work are more intellectual studies, some of which have become classic references. Examples include Tony Schwartz's *Media: The Second God* (1981), Neil Postman's *Amusing Ourselves to Death* (1985), and Joshua Meyrowitz's *No Sense of Place* (1985). More thickly analytic than McLuhan, but in the same vein, Stanley Cavell (1984) contrasts the basic experience of movies as viewing with that of television as monitoring. All successful TV formats—from sitcoms and game shows to sports coverage and news—are forms of monitoring. For Cavell it is no accident that the television receiver is called a monitor, and that TV is used to monitor everything from banks to parking lots.

Most representative of the reaction to McLuhan is the work of Brian Winston (1998), who originally titled his work *Misunderstanding Media*. For Winston television is not the radically new medium envisioned by McLuhan, but simply another instance of technological performance based on progressively developing scientific competence. Moreover, "there is nothing in the histories of electrical and electronic communication systems to indicate that significant major changes have not been accommodated by preexisting social formations" (p. 2). Building on but transcending McLuhan is the teletheory of Gregory L. Ulmer (1989) and the concept of the televisual as developed by Tony Fry (1993).

Cutting across these three types of criticism are negative and positive assessments that focus either on the physical aspects of the technology or its content/form. Although there is no proof that a person can become physically ill from watching television, conclusive scientific evidence does not exist that details what challenges to health are likely to arise from exposure to extremely low doses of low-level radiation over long periods of time. Indeed, critics suggest that there is no threshold of exposure below which radiation may not harmfully affect humans. From an environmental perspective, critics further note not only that the process of manufacturing televisions generates toxic problems, but also that the level of electronic waste is growing rapidly. This dilemma is exacerbated by the fact it is often less expensive and more convenient to replace rather than fix a malfunctioning television.

Negative assessments of the content of television programs vary. There are psychological worries about exposing children to violent and sexually charged programs, feminist and multicultural arguments about how television programs routinely stereotype women and other minorities in adverse ways, and sociopolitical concerns about the connection between television and political propaganda. Whereas the televised coverage of the Vietnam War in the 1960s facilitated a negative public reaction of the conflict because of its association with the "real" coverage of battlefield and civilian casualties, recent critical works that exemplify McLuhan's famous pronouncement that "the medium is the message," such as Jean Baudrillard's provocatively titled *The Gulf War Did Not Take Place* (1995) and Paul Virilio's *Strategy of Deception* (2000), suggest that the selective presentation of events during the Gulf War and the Kosovo conflict are indicative that people now live in a "hyper-real" time in which ever proliferating images are produced that are dissociated from reality. For example, during the Gulf War the impression that indiscriminate bombing and civilian causalities were minimized was fostered through the media's constant presentation of "smart bombs" that that destroyed only deliberately chosen and carefully delimited targets. A more recent argument, presented by Michael Moore in his Oscar-winning documentary *Bowling for Columbine* (2002), is that the media distortion of topics such as urban violence has produced a culture of fear in which American citizens routinely mistake deliberately sensationalized reporting for the presentation of unbiased facts.

In *Four Arguments for the Elimination of Television* (1978), Jerry Mander, a disillusioned advertising mogul, goes so far as to argue that because television is biased in favor of corporate interests and because it functions best when conveying simplified linear messages, it is beyond reform; the power of television to discipline people into accepting repressive control can be combated only by eliminating it completely. Mander also contends that television bolsters the tendency toward living in an artificial environment. This argument is given more in-depth philosophical examination by Albert Borgmann.

Ethical Criticism

Considering the sociological reports concerning how highly people esteem their televisions, Borgmann insists that the "telephone and television are the technological devices that have weakened literacy and impoverished the culture of the world" (1995, p. 90). Writing letters, telling stories, engaging in conversations, attending plays, reading to one another, and silently reading books and periodicals to oneself have all taken a backseat to watching television. Television routinely provides an alienating experience that disengages subjects from one another and inhibits genuine intersubjective connection by promoting self-oriented comportment. Whereas the scattered family once gathered around the "culture of the table," today TV dinners dominate. Not only is food reduced to a meal to be grabbed, but the festive and conversational context of dining—a focal practice—is lost. Seduced by the soothing presence of the television, people have come to experience engagement with others and with nature as exertion, as a cruel and unjust demand. When their favorite show is on, they do not want anyone to interrupt and pull them away from their passive contentment.

Borgmann grounds his negative assessment of television in an ontological distinction between two kinds of reality: *disposable devices* and *commanding things*. Disposable devices are readily available commodities that make technologically mediated experiences instantly available without the use of much skill. Indeed, learning to watch television requires little effort; young children ascertain how to do it, often without any formal instruction. Disposable devices thus belong to a world of pliable material; their emotional and moral significance is subjective and flexible. Their use, as Borgmann takes the example of television to illustrate, encourages a shallow life of distraction and isolation.

By contrast, commanding things are focal objects that express meaning on the basis of their own intrinsic qualities; the emotional and moral significance that people invest in them is largely based on the sense-bestowing capacity of the objects themselves. Commanding things direct one's attention because they require skill to use and we treat people who can adroitly operate them with respect. Whereas one does not value someone because they know how to operate a television, one admires musicians whose disciplined training allows them to create beautiful, memorable music. Furthermore, in contrast to the withdrawn and individualist behavior that disposable devices such as television encourage, commanding things further the end of communal engagement. One of the reasons why a person learns to use an instrument is to be able to extend the range of communication, to be expressive to others through the sounds that the instrument makes possible.

Assessment

Borgmann's criticisms, along with many others, have themselves been criticized as failures to appreciate the potential for enriching one's world through multivalent monitoring. From aesthetic installations of multiple television monitors to sports bars and space probe transmissions, television has the power to extend the human sensorium in ways not unlike the telescope and microscope. The ultimate promise of television may not be its utility to preexisting cultural ideals (such as democracy) but its performative presentation of scientific experience in ways that cannot help but insinuate science and technology ever more deeply into culture. To the extent to which science and technology may themselves be viewed as morally worthy projects, so too may television be viewed throughout its increasingly information-rich manifestations.

TELLER, EDWARD

Edward Teller, 1908–2003. The Hungarian-American physicist—sometimes called the "father" or the "architect" of the hydrogen bomb—was for decades on the forefront of the nuclear question and in the 1980s was an advocate of the Strategic Defense Initiative (SDI), also known as "Star Wars." *(The Library of Congress.)*

Edward Teller (1908–2003) was born in Budapest, Hungary on January 15, emigrated to the United States in 1939, and became known publicly as the "father of the hydrogen bomb." From the late 1940s until his death, he defended the U.S. development of nuclear weapons and the ethics of nuclear deterrence; as a public policy adviser he argued for the peaceful use of nuclear power and advocated national missile defense. He died in Palo Alto, California (September 9).

Education and Hydrogen Bomb Development

Teller worked with many of the early physics greats in Europe between the two world wars, distinguishing himself first in atomic and molecular physics (the Inglis-Teller and the Jahn-Teller effects), and then in nuclear physics. After serving at several universities, he eventually established permanent residence at the Lawrence-Livermore National Laboratory, of which he was one of the principal founders. (Livermore was originally dedicated to military research and development, although its work is now more general.) Teller also served as a senior researcher at Los Alamos during World War II, although his efforts were directed more toward development of fusion (hydrogen) bombs rather than fission (uranium and plutonium) devices, which were the highest priority.

In the early postwar years Teller became a principal advocate for the development of the hydrogen bomb by the United States, on the basis of strong belief in the deterrence concept, and distinctly conservative political views, which made him unpopular among many physicists. A centerpiece of his political ideology lay with his extremely strong antipathy to Communism. It was his fear that the Soviet Union would develop fusion weapons first and then use them to blackmail North American and Western European countries, especially the United States, that drove him into advocating their development. Along with Stanislaw Ulam (1909–1984), he is credited with coming up with the scheme that led to successful development of the H-bomb.

Teller's advocacy of the H-bomb placed him in direct disagreement, even confrontation, with many of the leading weapons scientists, most notably J. Robert Oppenheimer, who had been the scientific director at Los Alamos. The confrontation reached its climax during security hearings for Oppenheimer in Washington, DC, in 1954. Whereas most of Oppenheimer's contemporaries acted as friendly and supporting witnesses, Teller was a notable exception. He did not state categorically that he was in favor of denying Oppenheimer clearance, but he did say that he would be uncomfortable having Oppenheimer privy to important weaponry secrets. Partly as a result of Teller's testimony Oppenheimer was denied clearance. This act led to what amounted to a permanent ostracization of Teller by the mainstream U.S. physics community, although he remained friendly with a number of important, loyal friends, including Hungarian colleagues.

Later Work and Assessment

Teller was an innovative, energetic, talented individual, well liked on a personal level by most who knew him. He was the source of innumerable ideas concerning both military and peaceful uses of atomic energy, though many of these turned out to be impractical. He was a strong advocate of the deterrence concept and a principal spokesperson for the concept of strategic missile defense, although his advocacy was diluted by his unwarranted claims concerning its effectiveness. He was a leader in "Project Plowshare" during the late 1950s and 1960s, whose goal was to utilize nuclear explosions for peaceful purposes. For example, he proposed creating artificial harbors and canals by this means, which he termed "geological engineering." None of these schemes was realized, and the idea eventually died.

Despite the contrary opinions of many distinguished scientists, including Albert Einstein as well as Oppenheimer, there appears to be little if any doubt that the Soviet Union would certainly have proceeded to build its own hydrogen weapons. Without U.S. equivalency, the twenty-first century world would likely be very different. In hindsight Teller's strong advocacy seems to have been warranted.

TERRORISM

Terrorism was first used to define a systematic policy of violence during the French Revolution and has since undergone important transformations that have been topics of both scientific investigation and efforts at technological control. What is now called terrorism is an old practice that has acquired new dimensions as a result of science and technology in at least three respects: rationale, publicity, and weapons (and other means). Any adequate ethical or policy assessment of terrorism requires consideration of all three aspects of the problem.

Historical Aspects

Terrorism is an ill-defined but ethically charged term, which generally refers to the highly public, calculated use of violence, destruction, or intimidation to gain political, religious, or personal objectives. Yet in this sense many wars and even some police actions might be described as terrorist insofar as they seek to induce or exploit fear. Some observers also argue that there is little principled difference between official U.S. definitions of terror and counterinsurgency measures described in U.S. armed forces manuals (Atran 2003).

From certain Roman emperors to the Spanish Inquisition (beginning in the fifteenth century) and the French Revolution's Reign of Terror (1793–1794), early forms of terrorism were primarily conducted by the state or other parties with high political power such as the Catholic Church. The nineteenth century, however, witnessed the development of complementary efforts by individuals or small groups such as the small band of Russian revolutionaries known as Narodnaya Volya (People's Will) who grew impatient with the slow pace of tsarist reforms. Members of this group are among the few to refer to themselves as terrorists, and, aided by the development of powerful and affordable explosives, they assassinated Tsar Alexander II in 1881. The Fenian Brotherhood, an Irish-American group, planted explosives around London in the mid-1800s to protest the British occupation of Ireland, thus demonstrating one of the main objectives of many terrorist organizations, namely, to attempt to reacquire territory that they feel is legitimately theirs. On June 28, 1914, Gavrilo Princip, a member of the Serbian nationalist terrorist organization called the Black Hand, assassinated Archduke Francis Ferdinand of the Austro-Hungarian Empire, thus triggering the social and political upheavals of World War I.

World War II witnessed the uses of state terrorism by both the Allied and Axis powers. After the war, terrorism continued to broaden beyond the assassination of political leaders. Terrorist movements developed in certain European colonies to both pressure colonial powers and intimidate indigenous populations into supporting a particular group. After colonialism had waned in the 1950s and 1960s, terrorism continued in several areas and for a variety of purposes. These attacks often targeted civilians, as in the case of the murder of eleven Israeli athletes at the Olympic Games in Munich in 1972.

Although suicide terrorism has deep historical roots (Atran 2003), it has played a major role in Middle East politics since the early 1980s. Since at least 1993, suicide attacks by groups such as the Islamic Resistance Movement (Hamas) have continually thwarted peace efforts between Israel and Palestine. Although Islamic religious extremism is involved in many of these terrorist attacks, it should be noted that other religious groups have committed acts of terror. The same holds true for secular groups, such as the Liberation Tigers of Tamil Eelam in Sri Lanka.

In the 1990s, Osama bin Laden, a member of a wealthy Saudi family, rose to prominence as the leader of al-Qaeda (the Base), an Islamist terrorist organization. Determined to resist Western influence in Muslim countries, members of this group killed hundreds in bombings of U.S. embassies in Africa in 1998. Al-Qaeda members have been able to create a complex, networked organization capable of transcending national borders. Such capabilities allowed them to hijack commercial airplanes and crash them into the World Trade Center towers in New York City and the Pentagon in Washington, DC, on September 11, 2001. Passengers onboard a fourth plane forced it to crash in a Pennsylvania field. These attacks caused approximately 3,000 deaths and extensive social, psychological, and economic damage, and set off major political changes around the world, much of which bears on the use of science and technology both as potential security threats and as sources of counterterrorist measures.

Rationales

The justifications that terrorists give of their actions are perhaps even more difficult to consider than the definition of the actions themselves. It is easier—and initially appears more accurate—to describe terrorists as cowards or insane. But such a reaction runs the danger of misconstruing the phenomena and feeding into counterproductive responses.

Works by al-Qaeda and Theodore Kaczynski (the Unabomber) suggest that a major underlying rationale for some contemporary forms of terrorism is a condemnation of the dangers and depravity of modernity, including liberalism, capitalism, and a technological materialism divorced from spiritual or ethical guidance. Paul Berman (2003) traces much of the ideological impetus of al-Qaeda back to Egyptian Islamic fundamentalist groups and their "intellectual hero," Sayyid Qutb (1906–1966), who presented an extended critique of the modern world and the tyranny that technology holds over life. Qutb traced the source of error back to a split between the spiritual and material realms, which put humans out of touch with their own nature. He did not lament science but did decry the alienating effects of scientific "progress" (and the attendant consumerism) divorced from spirituality. The split between the secular and the sacred, he argued, was the fatal error that rendered the modern world inhospitable to a meaningful human existence and relationship with God.

Qutb's cultural critique also offered a revolutionary program to save humankind by calling for a small vanguard to establish sharia, the religious law of Islam, for all of society. Competing interpretations of the Koran and the meaning of Islam have created conflicts along the spectrum of liberal and extremist Muslims. For Berman Islamic terrorists are heirs to modern European fascism, with their ideals of submission, absolutism, and "the one instead of the many." William A. Galston (2003) suggests that such an interpretation erases key distinctions such as that between the meaningless self-annihilation of nihilists and the politically motivated acts of suicide terrorists. Furthermore, the thesis of liberalism versus totalitarianism reinforces the belief that terrorists "hate us for what we are, not what we do," which curtails critical scrutiny of policy decisions.

Kaczynski developed a related rationale in his manifesto, *Industrial Society and Its Future* (published by the *New York Times* and *Washington Post* in 1995). Whereas Qutb placed the problems of modernity in religious history and sought solutions in religious texts, Kaczynski appealed to human evolutionary history to explain modern social and psychological problems and relied on Western philosophers to buttress his critique. Nonetheless, both provided similar justifications for taking radical steps to undermine modern techno-industrial society. Alston Chase (2003) argues that (just as with Qutb) Kaczynski's writing cannot be simply dismissed as fringe lunacy or simple-minded Luddism. His ideas were shaped by real experiences as a mathematician at Harvard University in the late 1950s and early 1960s.

First, Kaczynski was subjected to dehumanizing psychology experiments at the hands of Henry A. Murray. Second, the climate of academia (and the wider culture) was saturated by the tenets of logical positivism, which held that ethical claims are meaningless, because science cannot prove them either true or false. Ethical and other values are purely matters of private emotion. As with Qutb, Kaczynski saw this separation of private (moral) and public (material) and other such fundamental schisms in modern industrial society as the root cause of unethical science and technology, vacuous consumerism, and massive human indignities and feelings of meaninglessness. Finally, Kaczynski held that science and technology had become servants of a military-industrial complex in ways that echoed the arguments of other critics such as the American mathematician Norbert Wiener (1894–1964). Such an argument justifies Kaczynski's rejection of the combatant/civilian distinction, because virtually all academic scientists and engineers could be perceived as caught up in a web of culpability. There is no doubt that acts of terror are objectionable, but this does not erase the possibility that their underlying rationale may at least be intelligible.

Although one major way to avoid considering the reasons that terrorists give for their actions is to reject terrorists themselves as irrational, another is to propose a sweeping historical thesis such as Samuel P. Huntington's "clash of civilizations" (1996). In response, Amartya Sen (2002) has argued that the "clash thesis" dangerously oversimplifies the heterogeneity of motives and objectives behind terrorist acts by reducing complex people and organizations to one dimension. Huntington's thesis paints a patina of coherence over the messy reality—that rationales for terrorism are diverse, complex, changing, and poorly understood. Context matters and terrorism cannot be reduced to a single "root cause" such as poverty, political conflict, or the intrusion of Western values on other cultures.

As an alternative to reliance on a large-scale historical thesis, it would perhaps be useful to undertake more detailed psychological and social scientific studies of terrorists and terrorist organizations. According to Scott Atran (2003), for instance, suicide terrorists have no appreciable psychopathology and are at least as educated and economically well-off as their surrounding populations, although there is a fairly strong negative correlation between civil liberties and suicide terrorism. In their studies attempting to uncover the causes of terrorism, Alan B. Krueger and Jitka Maleckova (2003) conclude that "any connection between poverty, education, and terrorism is, at best, indirect, complicated, and probably quite weak" (p. B10). They suggest that terrorism is a response to political conditions and feelings of indignity and frustration that are only weakly linked to economic circumstances. Marc Sageman (2004) similarly claims that people join terrorist organizations to escape a sense of alienation.

Atran also notes a correlation between U.S. involvement in international situations and terrorist attacks against the United States. Adolf Tobeña and Scott Atran (2004) suggest that understanding terrorists' motivations requires research both on social conditions and individual traits. Hector N. Qirko (2004) proposes a model from evolutionary psychology to explain suicide terrorism. He suggests that this non-kin altruistic behavior can be explained in terms of inclusive fitness, because institutions that train suicide terrorists essentially create "fictive kin."

Contemporary terrorists are usually young males who feel that they have no alternative path to influence and power and that their voice will otherwise be ignored. Humiliation, despair, and loss of economic or social advantage are factors that often play into motivations to join terrorist movements. In many Muslim areas, expanding youth populations cannot find opportunities because of rigidly authoritarian regimes. For many, the allure of martyrdom becomes a strong case for carrying out suicide missions. Indeed Nasra Hassan (2001) reports that there is an excess of young recruits hoping for martyrdom.

Publicity

A primary terrorist objective is the creation of fear in a targeted population in order to use the psychological impact of actual or threatened violence to effect political change. The capability to cause terror has been multiplied not just by more powerful weapons, but also by the expanded media coverage of terrorist acts made possible by innovations in communication technologies. Knowledge of terrorist acts is much more immediate, vivid, and widely disseminated than ever before.

Before the advent of mass media and modern communication technologies, acts of terror were committed in crowds in order to gain publicity. This led Brian M. Jenkins (1974) to describe "terrorism [as] theatre," which was vividly confirmed by the September 11 attacks, designed in part to provide billions of television viewers with images symbolizing the weakness of the United States. Timothy McVeigh, who bombed the Alfred P. Murrah Federal Building in Oklahoma City in 1995, chose that target for the open space surrounding it, which allowed for extensive television coverage. The Colombian leftist terrorist group known as the Revolutionary Armed Forces of Colombia (FARC) has its own radio broadcasts, and there are more than 4,000 terrorist websites (Wright 2004). Terrorists have adapted strategies with the emergence of satellite networks such as the Arabic news network Al Jazeera and the video capabilities of the Internet to expand their abilities to gain publicity.

Brigitte L. Nacos (1994) has explored the relationship between terrorism and the media, and suggested that the media unintentionally help terrorists achieve goals of publicity, recognition, instability, and respect. Focusing on the Iranian hostage crisis (1979–1981) and the downing of Pan Am Flight 103 (1988), Nacos argued that terrorists successfully manipulated the linkages between the news media, public opinion, and presidential decision-making by staging spectacles of terror. The opposite view is that media attention harms terrorist causes. Images of death and destruction focus attention not on the group's message but on its method, which can delegitimize its cause and alienate potential supporters.

What is not controversial, however, is the fact that media attention can and often has shaped the outcome of terrorist activities. It can disrupt counterterrorist operations and influence the dynamics of hostage situations. Terrorist groups increasingly target the media, which attracts attention and shapes coverage. The decision by managers of two U.S. newspapers (as urged by the Federal Bureau of Investigation) to publish the Unabomber's manifesto led to his identification and capture. Nacos argued, however, that this was a shameful act of government acquiescence to mass-media pressure, which might eventually encourage more terrorism. The mass media holds wider powers too, in the sense that its public representations partially define what counts as terrorism and what counts as legitimate acts of violence.

Such issues raise questions about the responsibility of the media in covering terrorism. Excessive coverage may further terrorist causes and encourage more attacks, but it is also true that too little coverage would not fulfill the media's goal of informing the public. One specific example of this dilemma is posed by the occasional audio and videotapes released by bin Laden. How much coverage should he be granted? An example of self-imposed limits on media coverage emerged in the aftermath of the 2003 U.S.-led invasion of Iraq, when the major media organizations declined to air images of beheadings performed by terrorists. But the explosion of media outlets, especially on the Internet, makes it easier for terrorists to publicize their message.

Media coverage of terrorism also raises the important ethical issue of tradeoffs between freedom of the press and security interests. Democratic governments must walk a fine line to find the proper balance for controlling media actions. In the 1980s the British government banned the broadcasting of statements by members of terrorist organizations and their supporters. Margaret Thatcher, the then prime minister of Britain, justified this policy by claiming that the surest way to stop terrorism was to cut off "the oxygen of publicity." Some argue that coverage of vulnerabilities in U.S. national security (e.g., the susceptibility of nuclear power plants to terrorist attacks) might also help terrorists prioritize future acts.

Finally, the publicity received by Islamic fundamentalist groups has given the impression that they commit the majority of suicide terrorist acts. But Robert A. Pape (2003), in a quantitative study of the 188 documented acts of suicide terrorism from 1980 to 2001, concluded that this impression was false. The leading instigator of suicide attacks was the Tamil Tigers in Sri Lanka, a secular Marxist-Leninist group that was responsible for seventy-five of the incidents.

Weapons and Other Means

As in many other areas of interaction between science, technology, and society, the most dramatic transformation in contemporary terrorism is new technological means. These means come in two forms: means of communication among terrorists that facilitate their planning and execution, and means in the form of weapons. The thousands of deaths resulting from the September 11 attacks signal terrorists' abilities to manipulate modern technologies to cause ever greater devastation. Contemporary terrorist attacks highlight the fact that not just the use of individual technological instruments is at stake. Developed societies' dependency on centralized, complex technological systems looms as a source of vulnerability that gives terrorists enormous power.

Lawrence Wright (2004) uses the March 2004 Madrid train bombings by al-Qaeda to detail the importance of the Internet to terrorist organizations. He argues that the Internet serves two interrelated purposes. First, it is a vehicle for strategic and tactical goals such as planning and organizing attacks, raising funds, and training recruits. The Internet and other communication technologies (e.g., cell phones and satellite phones) allow for highly coordinated international attacks. Al-Qaeda even publishes two online magazines that feature how-to articles on kidnapping and other terrorist tactics. Coded communications are used, and web sites are continually moved in order to avoid detection.

The second purpose served by the Internet is more fundamental. Muslim immigration in Europe is creating massive social and psychological disruptions. Many young Muslims have trouble adapting to their new situations and are confused about whether their adopted homelands are part of "the land of believers" or "the land of impiety." The Internet provides a virtual community and a compassionate, responsive forum that "stands in for the idea of the *ummah*, the mythologized Muslim community" (Wright 2004, p. 49). This virtual community strengthens feelings of common identity and provides mutual emotional support to combat feelings of alienation. Arabic satellite channels are being replaced by the Internet as the main conduit of information and communication among a growing global "jihadi subculture."

Marc Sageman (2004) sees further implications of the new Internet culture. Al-Qaeda, for example, is a nonhierarchical network, which increasingly uses bottom-up, self-selected recruitment strategies (rather than top-down selection) as a result of emerging Internet communities. Various levels of adherents form according to different interpretations of the ideology and purpose of al-Qaeda. Top-down control is diminished, as leaders no longer approve all attacks. After losing its Afghan sanctuary, the leadership of al-Qaeda is more reliant on such semi-independent cells in diverse regions. Sageman sees such local cells as the wave of the future, a theory supported by the Madrid bombings, which were carried out by a semi-independent cell. Because of the Internet, al-Qaeda is becoming a virtual community (not dependent on any one geographical locale) in the global space of the Internet. It is a "virtual Islamist state that is trying to find a place for itself in the actual world" (Wright 2004, p. 53). The cohesiveness of this virtual community presents fundamental questions about its legitimate recognition in the international arena.

The use of the Internet and other communications technologies has sparked a technological arms race as government entities develop their own innovations to track and monitor terrorist activities. Government intervention such as shutting down web sites that are judged to support terrorism has sparked controversies about the proper limits to free speech (e.g., should instructions on bomb making be available online?).

Terrorists also use technologies in the form of weapons, which span the spectrum from simple to complex. Nasra Hassan (2001) explains that the materials used to build suicide bombs (nails, gunpowder, light switches, acetone, etc.) are not only readily available but so affordable that the most expensive part of some Palestinian suicide missions is the transportation to the site of the attack. Similarly, very little expertise or high-tech equipment is needed to make effective agricultural bioterrorist weapons (Wheelis, Casagrande, and Madden 2002). Timothy McVeigh used an ammonium nitrate and fuel oil (ANFO) bomb, which was composed of many simple and readily available components (e.g., fertilizer) but was most likely fairly complicated to construct. So-called dirty bombs (combinations of TNT or ANFO explosives with highly radioactive materials) are similar in that radioactive materials are relatively easy to procure (significant quantities have even been found in scrap yards), but constructing and deploying an effective dirty bomb capable of widely dispersing radiation is difficult (Levi and Kelly 2002).

Nuclear weapons are extremely difficult to build and nuclear material is rare and hard to refine, but political unrest in nations possessing them has increased fears that terrorists could acquire existing nuclear weapons. The term *loose nukes* refers to nuclear weapons, materials, or knowledge that could fall into terrorist hands. The black market in uranium and plutonium and poorly paid Russian scientists are of special concern. Al-Qaeda has repeatedly attempted to purchase highly enriched uranium, and states that sponsor terrorism continually try to build nuclear weapons. The threat of nuclear terrorism raises the old "nuclear dilemma" former U.S. President Dwight Eisenhower noted in the 1950s, namely, how to ensure atomic power is used to promote peace rather than threaten war. Fear surrounding these possibilities also spreads rumors of new weapons, such as "red mercury," which could make nuclear fusion weapons easier to build. Controversy surrounds the nature and very existence of red mercury, however (Edwards 1995).

Biological and chemical agents have also been used to kill and terrorize targeted populations. At least one British officer gave blankets used by smallpox patients to Native Americans during the French and Indian War (1754–1763), and reports exist of similar acts by land speculators and settlers. In 2001 an unidentified terrorist mailed letters laced with anthrax to U.S. senators and media icons. Five people died as a result. In the late 1980s Saddam Hussein used a combination of chemical agents including sarin, mustard gas, and possibly VX to kill as many as 5,000 and wound another 65,000 Kurds in northern Iraq.

In addition to both simple and more complex weapons, terrorists have adapted other technologies to serve as weapons. The most dramatic example is the use of commercial airplanes and skyscrapers by terrorists on September 11, 2001. It could also be argued, however, that terrorists even use television as a psychological weapon by creating images that induce fear.

Perhaps the most frightening reality raised by contemporary terrorist acts is the inherent vulnerability of complex sociotechnical systems. As Langdon Winner (2004) argues, life in modern civilization increasingly depends on large-scale, complex, geographically extended, and often centralized technological systems. The Y2K scare vividly raised the specter of vulnerability, as citizens, governments, and businesses alike realized how fragile such highly integrated and tightly coupled systems are. Examples include information and computer networks, dams and water purification systems, nuclear power plants, the energy transmission and distribution infrastructure, the communications infrastructure, chemical plants, gas pipelines, railroads, the mail system, food supply chains, huge fields of monoculture crops, and the containerized cargo system.

The human demands and material costs of policing these systems are, in the long term, unsustainable. Totalitarian societies have "hardened" their technologies to provide the necessary surveillance and protection, but this destroys civil freedom. Reliable engineering can solve only some of the problems. The only alternative left for free, democratic societies, Winner argues, is to embrace an attitude of trust. Citizens expect that key technologies will always work reliably. The relationship is reciprocal as it informs the structure and operation of technological systems themselves. The upshot is that "Many key components are built in ways that leave them open to the possibility of inadvertent or deliberate interference" (p. 156).

When this attitude of openness and trust is undermined by a sense of vulnerability and dread, rights and democratic institutions are threatened. Fears of cyber-, bio-, eco-, and other terrorist plots lead to a society that begins to treat all citizens as suspects, because anyone could potentially cause massive damage given the vulnerability of high-density populations dependent upon tightly integrated systems of all sorts.

Winner speculates that "Although seldom mentioned in the mass media, the ultimate fear driving public and private policies in the post 9/11 [era] is an awareness that seemingly secure, reliable structures of contemporary civilization are, taken together, an elaborate house of cards" (p. 167). This taps into our deepest fears about technology: that the powers we seek to control will come back to destroy us. Winner presents a suite of options based on the premise of designing technical systems that are more loosely coupled and "forgiving." Environmental design and bioregionalism provide models for shifting to locally available resources and decentralized systems.

The vulnerability of sociotechnical systems presents a curious reversal of the technological and power asymmetries in the relationship between terrorists and the groups they attack. The latter are generally regarded as privileged in terms of technology and power, whereas the former must take recourse to terrorist tactics precisely because of their position of weakness. Certainly, many of these groups are oppressed. But power in this dynamic is revealed as a two-way, nonhierarchical affair. The massive vulnerability of technological systems (and the fact that many technologies are becoming easier to manufacture on small scales partially because of the wide dissemination of knowledge) gives to individuals and small groups an inordinate amount of power to inflict damage and spread terror.

TERRORISM AND SCIENCE

When the U.S. Department of Homeland Security (DHS) was proposed in 2002, President George W. Bush (b. 1946) noted that "in the war against terrorism, America's vast science and technology base provides us with a key advantage." What he failed to mention is that science and technology are also major sources of vulnerability to terrorist attacks, requiring decisions about censorship of publication and restriction of access to sensitive areas and materials. Thus terrorism poses special problems for the scientific and technical community in two respects: how to limit terrorist access to sensitive knowledge and technology, and what scientific research and technological developments to pursue in the interests of countering terrorist threats. Although scientists and engineers must bring their professional ethical responsibilities to bear on both tasks, it is equally important that decision makers understand the related limitations of science and technology.

Limiting Terrorist Access

Because of their multiple use capabilities, scientific knowledge and technological devices can be used by terrorists for purposes other than those originally intended. Preventing such misuse presents policy makers and the scientific and engineering communities with two challenges. First, they must insure that knowledge and information are not inappropriately disclosed. Second, they must secure existing and proposed technologies (e.g., nuclear power plants) and research materials (e.g., pathogens). In general, policies in the first case involve restricting the availability of sensitive information by the government, scientists, or both. Actions in the second case generally involve containment, monitoring, and restriction of access. Both actions raise tensions between the goals of security and scientific freedom and openness in the creation and exchange of knowledge and products. Striking the proper balance between these competing goods has taken on heightened importance since the terrorist attacks of September 11, 2001, and the responses by the governments of the United States and other nations.

The situation is made more complex by the notion that some degree of scientific freedom is necessary for national security, because it facilitates the creation of new knowledge and artifacts that may be useful in preventing or responding to terrorist attacks. Especially in the biomedical field, circumstances are further complicated by the potential twin effects of secrecy and restricted access. In some cases, these effects may protect public health by preventing terrorist from acquiring sensitive information or dangerous pathogens. In others, they may harm public health by preventing the development of cures and vaccines or inhibiting the coordination of response efforts to disease outbreaks. In some cases, the potential benefits of researching pathogens to mitigate the effects of terrorist attacks may not be worth the risks. This has sparked controversies about the creation and siting of biosafety laboratories that handle dangerous pathogens.

The free creation and exchange of knowledge by scientists can present dangerous, unintended consequences for society. A paper by Ronald Jackson and other researchers found that the insertion of IL-4 genes into mousepox viruses resulted in near total immunosuppression (Jackson, Ramsay, Christensen, et al. 2001). This advanced valuable knowledge about immune system functioning, but it also evoked fears that terrorists could use such knowledge to engineer hyper-virulent viruses. Similarly, the journal *Science* published a paper in 2002 that showed how to assemble a poliovirus from readily available chemicals (Cello, Aniko, Eckerd 2002). The threat of terrorist acts has caused political leaders and members of the scientific community to question whether such knowledge should be created, and if so, how its publication and exchange should be regulated.

In *New Atlantis* (1627), Francis Bacon (1561–1626) imagined the self-censoring activity of scientists in recognition of the fact that politically authorizing experimental science entails societal risks. The twentieth century provided several examples of tradeoffs between security and openness in the pursuit of knowledge. The Manhattan Project that produced the first atomic bomb cultivated a culture of secrecy. A similar culture developed among researchers studying microwaves during World War II. During the Cold War, the U.S. government attempted to constrain information exchange in some areas of mathematics and the physical sciences that may have aided Soviet nuclear weapons development (Monastersky 2002). Physicist Edward Teller (1908–2003) and others eventually persuaded policy makers that openness, rather than secrecy, was the best tactic for security during the Cold War.

In 1975, an international group of scientists held the Asilomar conference to debate the proper use and regulatory oversight of recombinant DNA research. During the late 1970s, the National Security Agency (NSA) regulated cryptographers developing new algorithms, but the two groups eventually agreed to a system of voluntary submission of papers for review. In 2002, the U.S. government began to withdraw from public release more than 6,600 technical documents dealing mainly with the production of germ and chemical weapons. In a controversial move, the U.S. national policy for the restriction of information that may threaten national security was altered in the wake of the September 11 attacks to include restrictions on publication of federally-financed research deemed to be "sensitive but not classified" (Greenberg 2002).

As these examples illustrate, limitations on research and the availability of technical knowledge can come in the form of self-imposed screening mechanisms by the scientific community or government regulation. The Asilomar conference, for example, led to a suite of self-policing mechanisms within the scientific community, including the decentralized system of Institutional Biosafety Committees (IBCs). This same mechanism has been proposed by the National Science Advisory Board for Biosecurity (NSABB) as a way to prevent the misuse of biological research by terrorists. The NSABB also works to develop codes of conduct for researchers and laboratory workers, which underscores the importance of ethical conduct by individuals, especially where no rules exist or where the precise meaning of rules is unclear. Some professional associations and journals, including *Science* and *Nature*, have instituted procedures to give special scrutiny to papers that raise security concerns (Malakoff 2003). Putting such control in the hands of journal editors has caused some to argue that an advisory group like the Recombinant DNA Advisory Committee (RAC) would be a better mechanism.

Mitchel Wallerstein (2002) points out that the dangers posed by terrorists acquiring sensitive science and technology information differ from the state-related threats that were of primary concern during World War II and the Cold War. Terrorists generally do not seek out and would not be able to use the results of most basic research, but states may possess the intellectual and financial capital necessary to turn basic research into weapons. Daniel Greenberg (2002) contends that terrorists do not rely on new science. Rather, readily accessible information that has long been available suffices to fulfill most of the goals of terrorist organizations.

Biological weaponry is the area of science that could most directly benefit terrorist organizations. Wallerstein writes, "Information that improves knowledge of dangerous pathogens, their safe handling, and their weaponization increases the likelihood that such weapons could be produced covertly on a small scale" (p. 2169). His general conclusion is that restrictions on scientific and technical communications need occur only on a much smaller scale than during the Cold War. In fact, many echo his conclusion that sensitive research is a very narrow slice of the scientific world, which allows for severe but highly targeted restrictions.

Restricting the publication of information deemed sensitive and controlling access to technologies and research materials can help achieve security goals, but not without costs (Knezo 2002a). Some impacts are relatively minor, such as new standards for the construction and management of laboratories. Other impacts are more severe, including the impact of national security policy measures on the research process. Tightened laboratory access policies, publication rules, and visa restrictions may reduce the number of applications by foreign students to U.S. universities and colleges. This could hamper cross-cultural understanding. According to State Department rules, consular officials may deny visas for study in the United States in sixteen categories specified on the Technology Alert List to students from countries listed as "state sponsors of terrorism." Additional exemptions to the Freedom of Information Act (FOIA) and the withdrawal of information from federal agency websites have also sparked concerns about constraints on legitimate scientific work and academic freedoms.

Economic losses are also a concern about some legislative responses to security risks posed by science and technology. Instituting security and tracking measures in academic laboratories entails additional costs for researchers. Restrictions on foreign researchers can damage technological developments and economic productivity. The U.S. Immigration and Customs Enforcement (ICE) agency operates "Project Shield America" to prevent the illegal export of sensitive munitions and strategic technology to terrorists. It is intended to prevent terrorism, but may also entail losses to economic competitiveness.

Science and Technology to Counter Terrorism

Since the September 11 attacks, science and technology have increasingly been advertised as ways to prevent terrorist attacks as well as reduce vulnerabilities and minimize impacts of such attacks (e.g., Colwell 2002). This is in part a response by scientists and engineers to the sizeable increases in homeland security and counterterrorism research and development (R&D).

The National Research Council's Committee on Science and Technology for Countering Terrorism issued a report in 2002 that described the ways in which science and engineering can contribute to making the nation safer against the threat of catastrophic terrorism. It outlined both short-term applications of existing technologies and long-term research needs. The report recommended actions for all phases in countering terrorist threats, which can be roughly ordered as awareness, prevention, protection, response, recovery, and attribution. Different threats pose different challenges and opportunities across these phases. For example, nuclear threats must be addressed at the earliest stages, whereas biological attacks are more difficult to preempt, but more opportunities exist for technological intervention to mitigate their effects.

Scientific research and technological innovations can improve performance of all phases, from threat analyses and vulnerability assessments to post-attack investigations and restoration of services. For example, the Bush administration established BioWatch, a nationwide system of sensors to detect the presence of certain pathogens, and a public-health surveillance system that monitors the databases of eight major cities for signs of disease outbreaks. Early warning systems can detect the presence of certain pathogens by utilizing computer chips and antibodies or pieces of DNA (Casagranda 2002). Explosives-detection technologies have also been spurred since September 11, 2001 in order to bolster airline security.

Other examples include the use of biometrics (e.g., fingerprints and retinal signatures) to develop national security identity cards. The shipping industry is slowly adopting new security measures such as sophisticated seals and chemical sensors. Other researchers are developing strategies for securing information systems. Military infrared countermeasures for surface-to-air missiles may be used on civilian aircraft. Technologies for decontamination, blast-resistant walls, and protective gear for first responders are other components of research programs. Increasing flexibility and innovating measures to isolate failing elements could increase security of more complex technical systems such as transportation and communication infrastructures. Researching and developing broader applications of renewable energy can harden the energy infrastructure. Social scientists and psychologists also provide research for understanding causes and motivations of terrorists as well as the dynamics of terrorist group formation. Some (e.g., Susser, Herman, Aaron 2002) have demonstrated that, because terrorists choose targets to maximize psychological impact, mental health must be considered a top response priority.

With all of these potential applications of science and technology, decision makers need to address questions about how to coordinate, organize, prioritize, and evaluate investments to serve the goals of security and public health. Genevieve Knezo (2002b) reported that prior to September 11, 2001, the Government Accountability Office (GAO) and other authorities had questioned whether the U.S. government was adequately prepared to conduct and use R&D to prevent and combat terrorism. Partially in response to the need to better coordinate counterterrorism efforts (including R&D), the cabinet-level Department of Homeland Security (DHS) was created by legislative act in 2002. This incorporated half of all homeland security funding within a single agency. In addition to legislative activity, new advisory bodies such as the NSABB have been formed to guide the creation of new rules and development of new institutions to maximize the benefits of science and technology while minimizing unintended negative impacts.

Since September 11, 2001, established institutions have benefited from significantly increased funding for homeland security and public health research. For example, in 2002 President Bush proposed a 2,000 percent budget increase for the National Institute of Allergy and Infectious Diseases (NIAID) from pre-September 11 levels. Other institutions and agencies have either received additional funding (especially the National Institutes of Health) or made attempts to restructure their priorities to take advantage of shifts in R&D funding priorities (Congressional Research Service 2002; American Association for the Advancement of Science 2004).

Investments in science to reduce terrorist threats raise several ethical issues. First, the scale of vulnerabilities outstrips resources to reduce them, which raises equity issues in the process of prioritizing investments. For example, bioweapons detectors are too expensive to deploy on every street corner, so locations must be prioritized. Likewise, not all areas pose equal risks from terrorist attacks, so efforts need to be targeted to match threats.

Second, Arthur Caplan and Pamela Sankar (2002) note the increase in "research protocols that call for the deliberate exposure of human subjects to toxic and noxious agents" (p. 923). Such dilemmas are not new, as many trials on U.S. Navy and Army crew members took place in the 1960s in an effort to document the effects of biological and chemical weapons. Many research subjects were neither informed of the details of the study nor issued protective gear (Enserink 2002). Such research needs clear guidelines and unequivocal justification for its relevance to national security. Professional ethical issues also arise when unemployed scientists and engineers face financial incentives to aid terrorist organizations (Richardson 2002).

Third, the integrated nature of socio-technical systems raises considerations of equity and civil liberties. For example, forty percent of all containerized cargo that arrives in the Long Beach harbor in Los Angeles is destined for the U.S. interior. How should the burden of increased security costs be distributed? Furthermore, the process of hardening these systems can reduce access and curtail certain civil liberties (Clarke 2005).

Finally, several analysts have criticized dominant U.S. counterterrorism science policies as ineffective. Bruce Schneier, security technologist and cryptographer, argues that managers too often seek technological cure-alls and rarely consider the consequences of system failures (Mann 2002). For example, all security systems require secrets, but they should be the components that are most easily changed in case system integrity is breached. Biometric identity devices that use fingerprints can centralize so many functions that they create "brittle" systems that fail poorly in case they are stolen. New banking account numbers can be issued in case of fraud, but not new fingerprints. Schneier contends that in airline security the only effective measures are the low-tech solution of reinforcing cockpit doors and the non-technical fact that passengers now know to fight back against hijackers. Both measures pass Kerckhoffs' principle, which occurs when a system remains safe even when almost all of its components are public knowledge. Schneier also holds that security systems are at their best when final decision-making responsibility is given to humans in close proximity to the situation, not computers. Security systems should be ductile, small-scale, and compartmentalized to mitigate the effects of inevitable failures.

Stephen Flynn (2004) focused less on the inherent limitations of technology as a means of countering terrorism; rather he critiqued government R&D prioritizations. Flynn argued that some high-tech solutions such as digital photographs of container loading processes, internal emissions sensors in cargo containers, and GPS tracking devices can improve security, but they have not been given adequate funding.

The 2002 report by the Committee on Science and Technology for Countering Terrorism openly recognizes the fact that science and technology are only one part of a broad array of strategies for reducing the threat of terrorism that includes diplomacy, cross-cultural learning, and economic, social, and military policies. Furthermore, as the U.S. experience in the Vietnam War and the Soviet experience in the 1980s invasion of Afghanistan demonstrate, technological superiority does not guarantee victory. Success in the war on terror is measured by accomplishments, not R&D budgetary numbers.

From communism to environmental problems and the challenges posed by a globalizing economy, science and technology have often been put forward as ways to protect national interests and secure prosperity (Jenkins 2002). Scientists, engineers, and politicians often define problems in ways that call for technical solutions, but they must be held accountable for such problem definitions. Scientists and engineers especially must exercise ethical responsibility by not unduly exaggerating arguments that their research will serve societal goals.

Assessment

The two sections of this entry are interrelated in that increased scientific research on counterterror measures will create new knowledge and opportunities for terrorist exploitation, which will create new challenges for securing that knowledge. Given that security, health, and civil liberties are at stake in decisions about science and terrorism, it is important that measures be taken to involve and inform citizens. This entry has focused on actions by the U.S. government because it plays a leading role in matters of science and terrorism. But other countries and international coalitions face similar ethical dilemmas and policy choices. Private companies own many of the infrastructures that are targets for terrorist attacks, so regulations may be required to induce the private sector to invest in counterterrorism technologies that may not have commercial markets. Some scientific research, however, may have viable market applications, meaning that some of the R&D burden can be privatized, which raises other ethical issues that partially mirror those involved in the privatization of war.

THEODICY

Theodicy is a concept developed by Gottfried Wilhelm Leibniz (1646–1716) to justify the existence and absolute perfection of God despite the evil that exists in the world. The term appeared in 1710 in the title of Leibniz's work *Theodicy—Essays on the Goodness of God, of the Freedom of Man, and the Origin of Evil,* and with it he coined an optimistic variant *par excellence* on theories of evil. Insofar as science and technology are often interpreted as responses to evil, theodicy is related to their modern emergence.

Background and Emergence

Theories of evil have been developed by Plotinus (204–270), Augustine (354–430), and others in which evil is seen as necessary for universal harmony. Within the framework of the complex theological discussions on the origin of evil, Leibniz's theodicy denies both the idea of God as a malevolent creator of the world (a position taken by certain Gnostics) and the refutation of this theory by Origen (c. 185–254) and Augustine who, in postulating human freedom, attributed moral responsibility for all the evils of the world to human beings, in the form of sin.

Leibniz's particular approach was to interpret perfection as the state of a thing when it attains its highest level of being. This definition highlights God's perfection. From the quantitative point of view, God has all perfections; from the qualitative point of view, these perfections reach their highest form in him. God is therefore omniscient and omnipotent. Despite the impressions that evil, injustice, and suffering give us of the world, God's perfection is necessarily expressed in his creation.

This theory is, paradoxically, a key philosophical element of transition to modernity, a vital bridge to the new philosophies that emerged in the second half of the eighteenth century: the philosophy of history, philosophical anthropology, and aesthetic philosophy. The advance of these philosophies is tied to a new understanding of human nature that rejects the naturalism of seventeenth century thought, as well as traditional Christian theology. All the images of the human that developed in the eighteenth century were optimistic in ways reflecting theodicy—as can be illustrated in moral humanity (Anthony Ashley Cooper Shaftesbury [1671–1713]), rational humanity (Jean-Jacques Rousseau [1712–1778], Immanuel Kant [1724–1804]), economic humanity (Adam Smith [1723–1790]), and perfectible humanity (Condorcet [1743–1794]).

Although the idea of a human fall did not immediately disappear, a new concept began to replace it—not exactly of human greatness, but of the ability of humans to do what was necessary to make the world better for the human species. To understand this situation is to recognize the significance of Leibnizian theodicy for modern science and technology, as well as for ethics in the era of modernity. Leibniz's theodicy was both necessary for and representative of the modern world, insofar as it gave expression to a vision of the human condition as one which, aided by science and technology, was no longer characterized by powerlessness, suffering, and evil. These were henceforth looked at outside Leibniz's own metaphysical framework as being essentially surmountable.

Collapse and Continuity

With the Lisbon earthquake of 1755, Leibniz's justification of God in the face of worldly evil collapsed, in a complex historical context where science began progressively to replace religion as the cultural frame of reference. Nevertheless, the semantic core of Leibniz's arguments, that to compensate for evil is in fact the purpose the divine creator had before him, held firm. As Odo Marquard (1989, pp. 38–63) argued, Leibniz provided the teleological framework in which science and technology could become both means and ends. In Leibniz's theology that basic principle is "*malum* through *bonum*": God does not make up for evil with good, but evil is rehabilitated by the good it pursues. Tolerance in the face of evil is justified by having the highest good as the end in view, insofar as evil is the condition that makes the good possible.

In this sense, the principle of theodicy is that the ends justify the means. With the collapse of Leibnizian theodicy in its original form, human beings take the place left vacant by the omnipotent creative will and theodicy is transformed into anthropodicy or human progress. Humanity as an end in itself is free to use everything else as mere means, inheriting God's role in order to realize and complete theodicy in history. Every goal achieved became a new means toward another end.

As a result of this teleological sequence of means and ends, what came to predominate was not the possible uses of the means, but the very means themselves. The ends no longer justified the means, the means justified the ends. This logic is linked to the cost/benefit compensation criterion of utilitarianism: Every good has its price. As Thomas Robert Malthus (1766–1834) wrote in his *Essay on the Principle of Population* (1798): "There is evil in the world, not in order to produce despair, but rather activity." This idea is equally present in other modern thinkers such as Bernard Mandeville (1670–1733): "There are 'private vices' [*malum*], but they are 'public benefits' [*bonum*-through-*malum*]."

The Example of Cournot and Teilhard

Among those who developed philosophies of history guided by an optimistic approach or who believed in humanity's ascending progress to an ideal state were the Frenchmen Antoine-Augustin Cournot (1801–1877), a teacher of mathematics and author of several works on the philosophy of history, and Pierre Teilhard de Chardin (1881–1955), a Jesuit priest, paleontologist, and philosopher of nature. Though sometimes neglected, these two thinkers developed unusual and powerful syntheses that reflect the subtle and penetrating influence wielded by the Leibnizian idea of an omnipotent creative will. Their work had significant repercussions during their own lifetimes, and their theoretical constructs are still surprisingly topical in the twenty-first century: Cournot as a prophet of post-historical technological civilization, Teilhard as the prophet of transhumanism.

For the century in which he lived, Cournot was the thinker who developed with the greatest persistence a philosophy of history in which science and technology take pride of place. His philosophy of history is based on a series of binary opposites: chance and necessity, reason and instinct, passions and interests. With these concepts, his reading of history was finalistic, and he argued for the likelihood or even the inevitability of what has come to be called "the end of history," a partly Hegelian premise that was revived at the end of the twentieth century in a world that claimed the end of ideology, of utopia, of politics, of the human. Hermínio Martins (1998), who has emphasized the importance of Cournot for the philosophy of technology, argues that Cournot's "end of history" semantics do not imply a form of necessitarianism, in the sense of extinction or termination, but more correctly exhaustion, completion, fulfillment, or consummation.

Cournot's temporal interpretation of collective human existence is based on a system of three great time-phases, as found in the work of Auguste Comte (1798–1857) and Karl Marx (1818–1883), and closely related to different kinds of discourse. The first phase has been labeled "ethnological" and is characterized by the subordination of reason to instinct, of the planful to the unreflective; habit and custom predominate, and are accompanied by natural or human disasters. The second stage is the phase of history itself. This is defined by an increase in rationality in thought and action, and by a combination of passions and interests as the springs of action with sufficient power to give rise to colossal events, of which the French Revolution is an example. The third and terminal phase is the closest possible approximation to the ideal, which humanity will never be able to attain. In this phase, "political faiths" decline, as occurred during the French Revolution, and give way to the peaceable play of economic interest and the *doux commerce*.

This third stage establishes a post-historic society that conquers nature by systematic scientific discovery, technological invention, innovation, and economic growth. Cournot anticipates positions that were further developed in the twentieth century, such as Joseph Schumpeter's routinization of economic innovation and what Alfred North Whitehead calls the "invention of invention," but does not show any significant concern with the possible intrinsic limits of scientific progress, which might bar further fundamental technological advance.

Teilhard's approach to human history also embodies finalism, and the role of scientific and technological advance within it, although his vision embraces different domains from those of Cournot. Teilhard's arguments have roots in the philosophy of Henri Bergson (1859–1941), and are part of the new theology of history that seeks to protect theology from the temptation of rationalist hermeneutics. Nonetheless, it did not shy away from dealing with "earthly realities," such as the relationship between humans and nature, the carnal nature of human beings, scientific humanism, and the theology of science. Teilhard's thinking embodied these contributions, and added a lively intuition of the evolutionist and voluntarist scientific and technological type that aroused serious suspicions in Rome. Contravening some basic postulates of Christianity, he argued for the "spiritual value of matter," and developed a conception in which humankind, with its artistic achievements, technological artifacts, and religions, is part of an overall evolutionary scheme in which there exists a progressive manifestation of biochemical complexity on the path to a growing unified consciousness.

In the tradition of the omnipotent creative will, Teilhard argued that perfection lies in the progress not of individuals, but of humanity as a whole, on a path toward unification with God who, being in essence supernatural, is at the same time the natural outcome of evolution. In his main work, *The Phenomenon of Man* (1959), he develops a suggestive synthesis of science and religion, in the context of a view of the universe as a system that develops from one phase to another with ever-higher forms of consciousness.

Teilhard's speculations anticipated those who favor a transhuman future which appears possible and desirable. These transhumanists are convinced that the new computational technologies are creating a collective human intellect, a kind of cognitive and mental hyperextension of the human mind. Cournot, by contrast, thought that organic life would remain fundamentally inaccessible to mathematical and experimental science, while postulating that increasing knowledge of inanimate nature would be sufficient to ensure technical perfectibility and material progress.

THERAPY AND ENHANCEMENT

It is common, in classifying interventions, to sort them into those that are therapeutic, that is, directed at diminishing the harms suffered by a patient, and those that are enhancing, that is, directed at increasing the goods experienced by a patient. At least three independent but related questions can be raised about the therapy/enhancement distinction: (1) Can the two terms *therapy* and *enhancement* be defined clearly, reliably, and accurately? (2) Assuming they can be satisfactorily defined, under what circumstances is it morally justified for a physician to engage in either activity? (3) Assuming they can be satisfactorily defined, what implications does labeling an intervention as therapeutic or enhancing have on the issue of whether the cost of the intervention should be borne in part or in whole by third-party funding agencies?

Defining Therapy and Enhancement

The distinction between therapy and enhancement can be most clearly made by first having available a clear definition of a third term: *malady*. The following definition of a malady, adapted from Gert, Culver, and Clouser 1997 (p. 104) classifies all clear cases of maladies as maladies and does not classify as a malady any condition that is clearly not a malady.

> An individual has a malady if and only if (s)he has a condition that is not normal for a person in his (her) prime, other than his (her) rational beliefs or desires, such that (s)he is suffering, or is at a significantly increased risk of suffering, a nontrivial harm or evil (death, pain, disability, loss of freedom, or loss of pleasure) in the absence of a distinct sustaining cause.

Therapies are interventions whose intention is to reduce or eliminate the harms that are a defining characteristic of maladies. If an intervention is not directed toward reducing or eliminating the harms associated with a malady, then it is not a therapy. Enhancements are interventions directed toward increasing the personal goods experienced by another person, such as abilities (including knowledge), freedom, and pleasure. If an intervention is not directed toward increasing another's personal goods, then it is not an enhancement. These definitions seem to correctly classify all cases of therapies and enhancements.

An extensive project ("The Enhancement Project") sponsored by the Hastings Center concluded that the two terms could not be defined clearly and could thus serve only as "conversation starters." In the words of the project coordinator, "Like many distinctions, the treatment/enhancement distinction is permeable, unstable, and can be used for pernicious purposes" (Parens 1998, p. 25). In contrast, the present authors think the two terms can be defined clearly and that one advantage of clear definitions is that they decrease the likelihood of any pernicious applications of the terms defined.

There are inevitable borderline cases. For example, how should one classify the administration of growth hormone to a child destined to be very short but who shows no evidence of an endocrinopathy? There is disagreement about this question, but not because of any avoidable vagueness in the definitions given here. Instead the disagreement is about whether this condition is a malady. If it is not, then administering growth hormone is not a therapy; if it is, then it is a therapy. Both Eric T. Juengst (1998) and Norman Daniels (1994) also use the concept of malady in distinguishing between therapies and enhancements, although Daniels's definition of malady differs from the one given here.

The Moral Justifiability of Administering Therapies and Enhancements

There is a general consensus that it is ethically justified to administer interventions when certain conditions are met. First, the intervention must be a rational one for the patient to choose under his or her circumstances. Second, patients must give valid consent to an intervention: They must be given adequate information about the intervention, must not be coerced into consenting, and must be fully competent to consent. If these conditions are met, then it is ethically justified to administer an intervention. If one of them is not met, then it may or may not be ethically justified to administer the intervention.

If an intervention can be accurately predicted to cause only an increase in the personal goods experienced by an individual, and the individual gives a valid consent to the intervention, then there is nothing morally problematic about administering the enhancement. What often makes enhancements problematic is that there is uncertainty about whether there might be significant harms that will, sooner or later, accompany the enhancement. Breast augmentation surgery may result in abscesses or in later disfiguring and irreversible structural lesions. Exogenous growth hormone administration might result in later endocrinopathies or even tumors. Mood-altering drugs might result in short-term tranquility or euphoria but long-term deleterious psychic (or neurochemical) effects. Even in cases of enhancements with possible risks, unless it would be irrational for the adequately informed competent patient to choose to have the enhancement, it seems morally justified to administer the enhancement if the patient has validly consented to it.

One moral problem that arises concerning enhancements is not the moral acceptability of enhancing with valid consent, but whether the resources spent developing enhancements detract from the resources that are available for therapy. Except when the harms suffered are trivial and the goods involved are extraordinary, it is almost universally acknowledged that it is more important to prevent or relieve harms than to promote goods. Thus if the enhancements that are developed and marketed decrease the resources that are available for therapy, then it might be argued that it is not morally acceptable to develop and market such enhancements. It is very doubtful, however, that preventing the development of enhancements would increase the resources used for therapy, so that it is not clear how much force this argument would have.

Another moral problem concerning enhancement is that it is sometimes used to gain an unfair advantage over others, such as the case of athletes who take prohibited drugs to gain a competitive edge. The problem here, however, is not with enhancements themselves but with their use to gain an unfair advantage. It might be claimed that the existence of enhancing drugs provides such a strong temptation that merely making them available is morally problematic. But most enhancing drugs are also used therapeutically and, in fact, were originally developed for therapeutic use. That enhancing drugs are sometimes used unfairly is no more of an argument against their morally acceptable use than the fact that automobiles are sometimes used in committing a crime is an argument against their morally acceptable use. Other arguments against the use of enhancements, such as that they cause envy, create social pressure for their use, and increase the disparity between people, are also arguments against elite colleges, expensive cars, and personal trainers.

A rhetorically powerful but completely mistaken argument against enhancement is that it is not natural. This argument has no force because almost the entire world humans now live in is not natural, if by *natural* one means independent of human artifice. Even most of the trees and plants humans use are not natural. Medicine is not natural. Before abandoning traditional ways of acting and doing, whether natural or artificial, it is certainly important to ensure that the undesirable unintended consequences will not overwhelm the desired consequences. The larger the change the more caution is appropriate, especially if the desired consequences are not the prevention or relief of evils, but only the promotion of goods, such as germ-line genetic engineering that is used solely for enhancing.

HUMAN GENETIC THERAPY AND ENHANCEMENT. An important application of the therapy/enhancement distinction occurs with genetic therapy and genetic enhancement, and examples of both processes may well proliferate in the future. It is important to distinguish germ-line genetic engineering from somatic-cell genetic engineering. Both involve directly altering the genetic structure of an organism, but somatic-cell genetic engineering, which is done by altering the somatic cells of an organism, is not intended to have any consequences for the descendents of that organism. Germ-line genetic engineering alters the genetic structure of an organism in ways that will or may have consequences for all of its descendents. Gene therapy is genetic engineering aimed at eliminating the genetic cause of (a) a serious malady or (b) a significantly increased risk of suffering that malady. Genetic enhancement is genetic engineering aimed at providing an organism with new or improved traits that are deemed useful or desirable by those doing the altering. Genetic engineering for plants and nonhuman animals is almost always genetic enhancement. Gene therapy is now being considered for human beings, but there is already talk of genetic enhancement for human beings.

If somatic-cell genetic engineering does not have any consequences for future generations, it is not considered controversial. Unlike the genetic engineering that is used in plants and animals, somatic-cell gene therapy alters only the genetic structure of the individual who receives the somatic-cell gene therapy; the altered genetic structure is not passed on to that individual's offspring. Although it is possible for somatic-cell genetic engineering to affect the germ line, this is not yet considered a serious risk, and so its effects are thought to end with the individual treated. Unless some argument is provided to show that somatic-cell genetic engineering has serious risks, there is no stronger reason not to have somatic cell gene enhancement than not to have plastic surgery to improve the appearance of normal people. Indeed, it is hard even to imagine an argument against somatic-cell gene enhancement that is not also a general argument against any kind of technological enhancement.

The moral controversy that is the main subject here concerns whether there is any morally significant difference between germ-line gene therapy and germ-line gene enhancement with regard to human beings. In what follows, gene therapy and gene enhancement will always refer to germ-line gene therapy and germ-line gene enhancement. Gene therapy is regarded by some as the best way to correct severe genetic defects such as thalassemia, severe combined immunodeficiency, or cystic fibrosis. One argument is that because there is no nonarbitrary line between therapy and enhancement, acceptance of gene therapy, even to cure a serious genetic malady, makes it impossible not to accept gene enhancement as well.

This argument is used both by those who are opposed to genetic engineering of any kind, and those who favor gene enhancement. The former argue that because scholars are unable to draw a nonarbitrary line between gene therapy and gene enhancement, people should protect themselves against the latter by not even beginning with the former. The latter argue that because it is clear that one ought to accept gene therapy, one ought to also accept gene enhancement. Nevertheless, the objection that gene therapy will lead to gene enhancement presupposes that there is something intrinsically morally wrong with gene enhancement. No one has yet provided a strong theoretical argument that shows that genetic enhancement to produce greater size, strength, or intelligence, or increased resistance to toxic substances, is morally problematic. Yet neither is it clear that one ought to accept gene therapy or that there is no morally significant distinction between gene therapy and gene enhancement.

In fact, it is possible to draw a nonarbitrary line that distinguishes gene therapy and gene enhancement because there is an adequate definition of a genetic malady, related to the above general definition of a malady:

> An individual has a genetic malady if and only if (s)he has a genetic condition that is not normal

> for a person in his (her) prime, other than his (her) rational beliefs or desires, such that (s)he is suffering, or is at a significantly increased risk of suffering, a non-trivial harm or evil (death, pain, disability, loss of freedom, or loss of pleasure) in the absence of a distinct sustaining cause.

Genetic conditions such as hemophilia, cystic fibrosis, and muscular dystrophy all share features common to other serious maladies, such as cancer, high blood pressure, and tuberculosis and so fit the definitional criteria of malady. Genetic conditions that do not meet the definitional criteria of a malady should obviously not be counted as a malady, and gene engineering for these constitutes gene enhancement. Examples of genetic nonmaladies might include blue eyes, widow's peak, freckles, O blood type, or curly hair.

Nonetheless, it is inevitable that there will be some genetic conditions about which there will be disagreement concerning their malady status. The number of such conditions is small, however, and the disagreement is based on the nature of maladies, not on vagueness in the malady definition. Borderline conditions, such as short stature or mild obesity, will be conditions about which people disagree on their malady status because it is not clear whether these conditions significantly increase the risk of suffering nontrivial harms. Because such borderline conditions are not very serious in the medical sense, they are quite unlikely to be candidates for gene therapy, at least initially. For all practical purposes gene therapy would be limited to the clear cases of genetic maladies. Indeed, the moral argument against gene enhancement, outlined below, is also an argument against genetic engineering for mild or borderline cases of genetic maladies.

The moral argument against gene enhancement is fairly straightforward. It is not morally acceptable to cause harm or a significant risk of harm to some people simply in order to create benefits for some other people. It is sometimes morally acceptable, however, to cause harm or a significant risk of harm to some people in order to prevent more serious or more certain harm to others. The government is allowed to quarantine people, that is deprive them of their freedom, even without their consent, if failure to quarantine would cause serious harm, as in the sudden acute respiratory syndrome (SARS) epidemic of 2003. This restriction of freedom, however, would not be justifiable simply in order to provide benefits to people. Gene enhancement does, at present, pose an unknown but possibly significant risk of harm to the descendants of the person who is being genetically enhanced. This genetic enhancement is not done to prevent a more serious or certain harm to this person. Therefore genetic enhancement is not morally justified. As noted, this same argument can be used against gene therapy for mild or borderline cases of genetic maladies. With regard to serious genetic maladies, this argument does not have the same force, for in these cases, the harm being prevented is more serious and certain than any harm that might be created. This does create a morally significant difference between gene therapy and gene enhancement.

Another completely different kind of argument can be given that leads to the same conclusion. Gene therapy simply aims to replace a defective gene with a nondefective allele of the same gene. If the technique for replacing genes is perfected, which at present it is not, then there is little or no chance that some unknown harmful side effect will result. The genetic structure of the organism will be identical in the relevant respect to the genetic structure of the majority of the human species. With gene enhancement, however, a new gene is being introduced with far greater chance of unknown harmful side effects. There are many genetic effects that do not show up for many generations. The identical gene inherited from the mother may have different effects when inherited from the father. There are expanding genes (triplet repeats) that do not have any effect until after several generations. Gene enhancement could create harms for the third or fourth generation, when it may not even be possible to track these individuals. This is another morally significant difference between gene therapy and gene enhancement.

Because preimplantation screening can eliminate almost all of the genetic maladies that would be eliminated by gene therapy, it seems clear that the primary reason for engaging in any kind of genetic manipulation is gene enhancement. Thus, although there is a morally significant difference between gene therapy and gene enhancement, given that the alternative of preimplantation therapy has less risks than gene therapy, it may be that there is at present no moral justification for engaging in either of these practices.

NONHUMAN GENETIC THERAPY AND ENHANCEMENT. As previously noted, genetic engineering is practiced on plants and nonhuman animals, and indeed has a long history in the nondirect forms of selective breeding and hybridization. In these cases what is almost always of interest is not genetic therapy for the good of the organism but genetic enhancement for the good of human users. On the basis of all the arguments already given, there is no reason to make a general objection to the genetic enhancement of plants and nonhuman animals.

Reimbursements for Therapies and Enhancements

Discussions of the therapy/enhancement distinction are sometimes linked to the question of third-party reimbursement for the two kinds of interventions. It may be assumed that therapies should be reimbursed and enhancements should not (see Parens 1998 for a discussion of these arguments). While there may be a societal consensus that most therapies should be reimbursed and that most enhancements should not, this is a contingent and not an invariant relationship.

Suppose two new managed-care companies start up and offer somewhat different ranges of benefits. Company A pays not only for essentially all therapies but also for most borderline cases whose therapy/enhancement status is a matter of dispute, and even pays for a few enhancements that are clearly specified in the terms of the contract. Company B pays only for therapies and states ahead of time that they will not reimburse for borderline conditions (which they might list) and will not reimburse for any enhancements whatsoever. Company A's premiums are higher, while company B is offering a lower cost, less-inclusive policy. Neither company is acting unethically or in an unjust fashion.

If, however, the issue concerns medical plans that are financed by taxes, then there may be an argument that only therapies, and not enhancements, should be covered. Yet even in this case, there is no obvious way to determine which, if any, borderline cases should be covered. In democratic societies decisions about government-financed medical treatments should reflect the prevailing public consensus, as determined through democratic political processes.

THOMAS AQUINAS

Thomas of Aquino (ca. 1225–1274), a philosopher and theologian, was born into an aristocratic family at Roccasecca, near Naples, Italy. He joined the Dominican order in 1245, taking a *licentia docendi* at Paris in 1256. He later taught at Paris, Rome, Orvieto, and Naples. Thomas died at the Cistercian abbey of Fossa Nuova on March 7 and was canonized in 1323 by Pope John XXII. The *Summa contra Gentiles* was completed about 1264. His longest and most influential work, the *Summa Theologiae*, was unfinished at the time of his death.

Ethics and Politics

Thomas was the foremost contributor to the thirteenth-century recovery of Aristotle. His achievement in ethics lies chiefly in the application of a Christianized version of Aristotle to politics and law. In most respects he departs from the Augustinian orientation of previous generations that found the present world sin-laden and disordered and its politics harsh and coercive.

Thomas accepted the rational, humane, ordered world depicted by Aristotle. There is no tension between the acquisition of present goods on earth and the achievement of eternal ones in heaven so long as the former are directed toward and subordinated to the

Thomas Aquinas, ?–1274. Aquinas was an Italian theologian and philosopher of the Dominican Order of the Catholic Church and is regarded as one of the greatest and most influential thinkers of the Church. He had an important influence on the intellectual awakening that occurred in western Europe during and after his lifetime. *(© The National Gallery, London/Corbis.)*

latter. Human beings have a final ethical end—eternal blessedness—that transcends all earthly ends, but earthly happiness is also possible and desirable. God has equipped human beings with the rational capacity to pursue earthly as well as heavenly goods, and although sin has impaired the will, it has not obliterated reason. Thomas believes, as Augustine (354–430) did not, that humans are capable, under proper governance, of cooperating with one another to achieve a common good.

For Thomas human beings are by nature political animals; government is not merely a consequence of sin. Even if the Fall of Adam had not occurred, no individual would be able to acquire all the necessities of life unaided; only cooperation can secure the benefits of divisions of labor. However, there are many ways to achieve human ends, and so a community must be guided toward the common good by just and wise rule. The best government is a "mixed" constitution of the kind that Aristotle called *politeia*. Kingship may be the most efficient form of rule, but it is also the most likely to deteriorate into tyranny. It therefore must be tempered by elements of democracy and aristocracy. A king should choose the best people as his counselors, and what he does should be ratified by the people. Thomas follows Aristotle in supposing that a government in which as many people as possible participate will be the most stable because it will commend itself to all sections of the community.

Law and Ethics

In the *Summa Theologiae* Thomas develops a typology of law as eternal, natural, human, and divine. This theory has a Platonic starting point insofar as law is defined as a rational pattern or form. In the political realm law thus serves as a "rule and measure" for citizens' conduct. When citizens obey the law, they "participate" in that order in the way a table "participates" in the rational pattern or form of a table.

Because God is the supreme governor of everything, the rational pattern or form of the universe that exists in God's mind is law in the most comprehensive sense: the law that makes the universe orderly and predictable. This rational pattern is what Thomas called eternal law, and to it everything in the universe is subject. The eternal law is similar in content to what science now calls the laws of nature.

Inasmuch as humankind is part of the eternal order there must be a portion of the eternal law that relates specifically to human conduct. This is the *lex naturalis*, the "law of [human] nature": an idea present in Aristotle to which Thomas gave extensive elaboration. In developing his natural law theory Thomas restored human reason to a central place in moral philosophy. For Thomas, as for Aristotle, human beings are preeminently reason-using creatures. The law or order to which people are subject by their nature is not a mere instinct to survive and breed. It is a moral law ordering people to do good and avoid evil, have families, live at peace with their neighbors, and pursue knowledge. It is natural in that humans are creatures to whom its prescriptions are rationally obvious. To all humans, pagans included, these precepts simply "stand to reason" by virtue of a faculty of moral insight or conscience that Thomas called *synderesis*.

However, humans act on the principles of natural law with the assistance of more particular and coercive provisions of what Thomas called human law. The natural law is too general to provide specific guidance. Part of this specific guidance can come from the moral virtues that equip people to achieve practical ends: prudence, justice, temperance, and fortitude. However, these personal guidelines are developed and reinforced by human or positive laws that that help cultivate such good habits. These particular, positive rules of behavior include civil and criminal laws of the state as formulated by practical reason, or what Aristotle called *phronesis,* in the light of the general principles of natural law and have a morally educative function. Human laws that are not based on natural law—laws that oppress people or fail to secure their good—have more the character of force than that of law. Obedience may be called for if disobedience would cause greater harm, but people are not obliged to obey unjust laws. Individuals may exercise independent moral judgment; they are not simply subjects but rational citizens.

The fourth kind of law—divine law—is part of the eternal law but, unlike human law, is not derived from rational reflection on more general principles and historical circumstances. It is a law of revelation, disclosed through Scripture and the Church and directed toward people's eternal end. Human law is concerned with external aspects of conduct, but salvation requires that people be inwardly virtuous as well as outwardly compliant. The divine law governs people's inner lives: It punishes people insofar as they are sinful rather than merely criminal.

Applying Thomism

The strongest implications of Thomas's thought for ethics, science, and technology are found in the doctrine of natural law and the underlying idea of human equality. For instance, Pope Leo XIII in his encyclical *Rerum Novarum* (1891) drew on law theory to criticize the conditions of labor under industrial capitalism. Insofar as it requires people to do good, avoid evil, pursue knowledge, and live at peace with their neighbors, the natural law suggests that governments should support scientific and technological research intended to have beneficial outcomes. By the same token, it supports the principle that governments should not sponsor such research when it involves the development of weapons of mass destruction or the exploitation of some human beings by others.

Natural law doctrine implies as well that governments should not harm, but seek to preserve, the physical environment of humankind: the natural world that God created and over which humans properly exercise dominion. In regard to biological and medical science, the idea of human nature as a repository of value implies a distinction between laudable biomedical research, which is a work of charity beneficial to the human race, and unacceptable research involving the manipulation or distortion of human nature. In this connection Thomas often is cited in support of the Catholic Church's prohibition of artificial (as distinct from natural) methods of contraception.

Finally, it may be noted that Thomas's insistence on citizen participation in government speaks against any suggestion that political decisions should be made by technocratic elites of scientists and engineers rather than by those who will be affected by those decisions. Thomas presided over a thorough revaluation of the capacity of human beings for autonomous moral action and hence for responsible political participation. In effect, he reinvented the Aristotelian ideal of citizenship after its long medieval eclipse, and that reinvention would apply today to scientific and technological decision making.

THOMISM

Thomism is a philosophical system of thought based on the writings of Thomas Aquinas, from his death in 1274 to the present. As a philosophy Thomism may be viewed as a moderate realism developed within medieval and Renaissance scholasticism that has been in continuous dialogue with alternate systems of thought in the modern and contemporary periods. The focus here is on Thomism specifically as it relates to science, technology, and ethics in the present.

Notion and Relevance

Thomas of Aquino (1225–1274) was a Dominican who studied under Albert the Great (c. 1200–1280) in Paris and Cologne and then taught at the University of Paris and in various Italian cities. Thomas was a prolific writer, known in his own day as a commentator on Aristotle, who adapted his thought to explicating the Catholic faith. Thomas was himself competent in the science of nature in the Aristotelian sense, and owed much to Albert's knowledge of the biological and psychological sciences. The relevance of both Albert and Thomas to modern science and its problems has been explored extensively by three contemporary Dominicans, Benedict M. Ashley, William A. Wallace, and James A. Weisheipl (1923–1984).

Modern science differs from *scientia* as understood in the Thomistic tradition, where it is defined as true and certain knowledge acquired by demonstration through prior knowledge of principles and causes. Modern science makes a lesser epistemic claim, only to knowledge acquired by hypothetico-deductive reasoning yielding conclusions with a high degree of probability but that fall short of certitude. Mathematical logic is instrumental for science, but science itself remains fallible and revisable. For Thomists this is too pessimistic. They would say that philosophers of science should rediscover the epistemology of Aristotle's *Posterior Analytics*, and rather than basing their reasoning on logic alone, could also focus on concepts provided by the philosophy of nature developed within the Aristotelian tradition (Wallace 1996).

For Thomism's relevance to technology a balanced view is that of a former Dominican and Wallace student, Paul T. Durbin. Durbin insists, first, that technology in the present day is essentially related to science, and second, that an identifiable social group is the carrier of technology. Thus the term *technology* can be taken to cover this scientific and technical community, including its inner structure and functions, its products, its particular values, and its implicit view of human nature. The term *philosophy of technology* then means a set of generalizations or a systematic treatment, in philosophical language, of one or another or all of the above social phenomena.

With regard to ethics, of the three terms—*science*, *technology*, and *ethics*—the last has the most explicit and enduring relationship to Thomism. There ethics is seen as the philosophical study of voluntary human action, with the purpose of determining what types of activity are good, right, and to be done, or bad, wrong, and not to be done, so that human individuals might live well. As a philosophical study, ethics treats information derived from a person's natural experience of the problems of human living. The term ethics is etymologically connected with the Greek *ethos*, meaning customs or behavior, and is the same as moral philosophy, similarly connected with the Latin *mores*, also meaning customs or behavior. It is a practical science in the sense that its objective is not simply to know, but to know which actions should be done and which should be avoided, so as properly to translate knowledge into action. Thus understood, only one thesis on ethics is listed among various theses seen as essential to Thomism. This states that humans have by nature the right to cooperate with others in society in the pursuit of personal happiness in the common good, and that this pursuit of happiness is guided by conscience, laws both natural and positive, and virtues both private and public. Briefly, Thomistic ethics is a virtue ethics that infers from nature what humans ought to do or be to achieve their proper perfection.

Historical Overview

Albert and Thomas wrote in the medieval period of high scholasticism. Albert was the first to appreciate the importance of the newly imported Greek-Arabic learning for science and philosophy, and he set himself to making encyclopedic summaries for his students, which earned for him the title "the Great" in his own lifetime. He had many followers among German Dominicans, including Meister Eckehart (c. 1260–1327) and Theodoric of Freiberg (c. 1250–1310), the second of whom worked out the first correct theory of the rainbow. But Albert's work bore principal fruit in the monumental synthesis elaborated by his pupil Thomas. Called the "Angelic Doctor," Thomas brought natural philosophy and metaphysics into the heart of theology to develop the unique synthesis known as Thomism. Its major teachings are that first matter is pure potentiality and its first actuation is by substantial form; that the human rational soul is the unique substantial form of the human body, endowed with powers that are really distinct from it; that human knowledge originates with the senses but is capable of attaining universals; and that humans can reason to the existence of God and some of God's attributes from the visible things of the world.

In later scholasticism Thomism became the official doctrine of the Dominican Order, where it was championed by Harvey Nedellec (1250 or 60–1323), John of Naples (d. 1330), and Jean Capréolus (c. 1380–1444). The Renaissance was the period of great commentaries on Thomas known as "Second Thomism," when Dominicans exerted strong influence at Paris and Salamanca as well as northern Italy. The more famous of the figures of Second Thomism were Thomas de Vio Cajetan (1469–1534), who debated the German religious reformer Martin Luther on the Eucharist; Francisco de Vitoria (1486?–1546), who developed the theory of natural law during Spain's period of colonial expansion; and Vitoria's colleague Domingo de Soto (c. 1494–1560), whose work foreshadowed to a degree Galileo Galilei's law of falling bodies (Wallace 2004). The same period saw the foundation of the Jesuits, who were initially trained as Thomists but then developed their own versions of Thomism. Jesuits and Dominicans later entered into prolonged controversy over the efficacy of God's grace on human free will and God's foreknowledge of human free actions, and were convinced that many modern evils stem from false philosophy, to which Thomas's thought would supply a needed corrective.

Developmental Thomism

The period from the mid-sixteenth to the late nineteenth century saw little development within Thomism. The system itself had received strong endorsement by the Council of Trent (1545–1563), and, as what may be referred to as Scholastic Thomism, it was taught in Catholic seminaries as a philosophical preparation for the study of theology. It was often seen as the "perennial philosophy," an integrated system that gave enduring answers to central questions about reality and knowledge. And it was largely unaffected by the scientific revolution of the seventeenth century, which was mainly concerned with physical sciences that seemed to have little relevance to Catholic teaching.

This situation changed dramatically after the issuance in 1879 of the encyclical *Aeterni Patris* of Pope Leo XIII (1810–1903), which gave rise to a movement known variously as neo-scholasticism or neo-Thomism (or, among Dominicans, "Third Thomism.") The stimulus came from the labors of medieval historians such as Maurice De Wulf (1867–1947) and Martin Grabmann (1875–1949), who had recovered works of medieval thinkers and focused attention on Thomas's thought as containing answers to pressing contemporary problems. With Pope Leo's endorsement, Thomism underwent extensive development in the twentieth century and came in dialogue with other philosophical movements. Arguably it is the most extensively developed systematic philosophy in the present day.

In this expanded sense, the term *Thomism* has itself undergone a change of meaning. An "ism" need not refer exclusively to an original system of thought. It might also refer to a system of thought that has taken on new meaning in light of developments that were unforeseen and unknown by its originator. In this alternate sense René Descartes could not be a Cartesian nor could Immanuel Kant be a Kantian. This sense would apply to those who came after them and assimilated new knowledge into their syntheses in ways consistent with the principles they had established, while rejecting matter that had been superseded in the interim. This is obviously a more speculative enterprise, but it is in this sense that one might speak of one or more developmental Thomisms.

Types of Thomism

The development of overriding importance is the growth of modern science in its classical and contemporary senses and how this affects Thomism as a whole. Allied to this are three subsidiary developments that may be characterized as different types of Thomism. Of these, two have already achieved the status of movements, namely, Existential Thomism, which arose from confrontation with existentialist thought, and Transcendental Thomism, which arose from the confrontation with Kantianism and other forms of idealism seen in the works of Continental philosophers. A third, resulting from the confrontation with Anglo-American philosophy, may be described as Analytical Thomism, though it is not yet regarded as a movement.

EXISTENTIAL THOMISM. The two philosophers most identified with this movement were the Frenchmen Jacques Maritain (1882–1973) and Étienne Gilson (1884–1978), both former students of Henri Bergson (1859–1941). Maritain became interested in the thought of Thomas after being converted to Catholicism. His most lasting achievements have been in the area of epistemology, in elucidating the different degrees of knowledge and their interrelationships, so as to constitute an integral, Christian humanism. He also made substantial contributions to social and political philosophy and to constructive critiques of modern culture and art. In his theoretical philosophy he stressed the authentic existentialism of Thomas, maintaining the primacy of existence in a realist philosophy of being, and seeing this as also providing the basis for an understanding of knowledge and of love.

Gilson did his early work on Descartes, which led him to a study of medieval philosophy and of Thomism in particular. He saw the philosophy of the Middle Ages as a Christian philosophy, one that, while keeping the orders of faith and reason distinct, considers Christian revelation as an indispensable auxiliary to reason. In Thomas he found a metaphysics of existence that conceives God as the very act of being (*Ipsum Esse*) and creatures as beings centered on the act of existing (*esse*). His disciples regarded his existential metaphysics as a corrective to the essentialism that had insinuated itself in Renaissance and rationalist versions of Thomistic thought.

TRANSCENDENTAL THOMISM. The roots of this movement can be traced to Désiré Mercier (1851–1926) and Maurice Blondel (1861–1949), and to the efforts of two Jesuits, Jean-Pierre Rousselot (1846–1924) and Joseph Maréchal (1878–1944), to rehabilitate critical philosophy in light of the teachings of Thomas. Maréchal's thought passed through several phases, but in a later formulation he proposed the act of judgment as an affirmation of absolute reality that objectifies the form or concept and so grasps it as being. Then, beyond the concept, the intellect is made aware of a further intelligibility by its own tending, in a dynamism unleashed by the concept itself, toward something infinite and absolute—actually the infinite act of existing that is God. The intellect thus "constitutes" its object as belonging, in a finite and participatory way, to the realm of the real.

Maréchal's innovative views gained new insights from dialogues with phenomenology by two German Jesuits, Karl Rahner (1904–1984) and Emerich Coreth (b. 1919), and by analyses of modern science by a Canadian Jesuit, Bernard Lonergan (1904–1984). From these have emerged a new metaphysics in which the being investigated is that which occurs in consciousness. So Coreth writes of an immediate unity of being and knowing in the very act of knowing, and Lonergan looks upon being as whatever is to be known by intelligent grasp and reasonable affirmation, and so extrapolates from the being of consciousness to the being of the cosmos. For Rahner an analysis of the performance of the human spirit discloses an innate drive to being as absolute and really existing, which itself is human nature as "spirit in the world" or finite transcendence. They elaborate these insights in various ways through the use of what is called a transcendental method.

ANALYTICAL THOMISM. Like phenomenology, analytical philosophy is more a method or way of doing philosophy than it is a philosophy itself. Bertrand Russell (1872–1970) was one of its pioneers, and after him came the logical positivists, with their anti-metaphysical programs, and finally a more relaxed conception of linguistic analysis, culminating in the work of Ludwig Wittgenstein (1889–1951). One of Wittgenstein's students, Elizabeth Anscombe (1919–2001), along with her husband Peter Geach (b. 1916) were the first analysts to attend to Thomism in their writings. A related thinker is Alasdair MacIntyre (b. 1929), whose work in Aristotelian politics and virtue ethics brought him to the study of Thomas. Also noteworthy is the work of John N. Deely, a former Dominican and student of Weisheipl, who recovered the work on semiotics of the early-seventeenth-century Thomist John Poinsot, known in the Dominican Order as John of St. Thomas. By the early twenty-first century, the most distinctive contributor to the emerging movement is John J. Haldane, of the University of Aberdeen, who has published extensively in the philosophy of mind and the philosophy of God from a Thomist perspective.

Areas of Continuing Research

Thomists in the United States seem more inclined to pursue the analytical route than the other two movements, and have two main areas of research. The first focuses on an analysis and critique of scientific concepts with reference to the Aristotelian-Thomistic heritage, particularly the latter's use of first matter and transient entities to develop a view of creation and evolution that concords with recent theories of cosmogenesis (the origin of the cosmos). The second focuses on problems in bioethics, particularly through a recovery of Thomas's teaching on delayed hominization as this relates to the study of homogenesis.

On the theme of cosmogenesis, this line of research associates God's creative act at the beginning of time with the "big bang" theory of cosmic origins (Wallace 2002). Time began some 13 billion years ago by the production by God, ex nihilo (out of nothing), of the primordial mass-energy of which the universe is now composed. Along with the act of creation, God as prime mover also initiated the "big bang," releasing the enormous energy of the primitive mass for the formation of the natures now found in the universe. These are, in order, transient natures, inorganic natures, plant natures, animal natures, and human nature. They correspond to the stages of evolution commonly accepted among scientists: the period of fundamental particles impelled at high energy; that of element and compound formation; the two periods of biogenesis, wherein first plants and then animals were generated; and finally that of hominization, when *Homo sapiens* first appeared. All of these stages except the last were accomplished by a natural process Thomas referred to as "the eduction of [substantial] form from the potency of first matter" (*Summa Theologiae* I, q. 90, a. 2).

The final stage of cosmic evolution would then be hominization, the appearance of humans with a special type of substantial form, an immaterial (and immortal) soul. Here there is a break in the line of causality extending back to creation, because, according to Catholic teaching, such a soul cannot be educed from the potency of matter. Up to this point the entire process of evolution can bring organisms to a level just below that of thought and volition, but they cannot progress to the final stage. Here God's creative act is again required. This second input of divine causality is the production, ex nihilo, of the immaterial souls of the first humans, tailored to match the ultimate disposition of first matter, as this has been prepared, over billions of years, for their reception.

With regard to bioethics, an important advance has been in the recovery of Thomas's teaching that the beginning of human life is a gradual process: that the human soul is not infused into the incipient organism at fertilization but rather is prepared for by a succession of substantial forms that dispose first matter for the reception of an intellective soul (Wallace 1995). Less well known is his speculation that the reverse process may occur at the ending of human life, namely, that the human soul may depart from the body well before all signs of life have disappeared from it. Both views are opposed to the notion of immediate hominization, commonly taught in Catholic circles, namely, that human life begins at fertilization, when the rational soul is infused by God into the body, and terminates at death, when the same human soul departs from the body.

With regard to human generation, Thomas followed Aristotle in holding that the conception of a male child was not completed until the fortieth day after intercourse, whereas that of the female child was not completed until the ninetieth day. The details of Thomas's treatment, now referred to as delayed hominization, were worked out on the basis of Aristotle's teaching as developed by medieval commentators, particularly Avicenna (980–1037). Little empirical evidence was available to support the various steps of the argument. In the early twenty-first century, however, the human reproductive process is being studied intensively, and much evidence can be brought to bear on the problem of hominization.

Catholic theologians have advanced two lines of argument that generally favor Thomas's solution. The first, proposed by Norman M. Ford (1988), is based on the possibility of twinning in the formation of the fetus and is essentially an argument from individuation. This would propose that the definitive individuation of the human fetus does not occur until fourteen days after conception, and thus that the intellective soul, and so the human person, need not be present before that time. The second argument, advanced by Joseph F. Donceel (1970), is based on the organ systems required first for sensitive life and then for the exercise of reason, which would involve the senses, the nervous system, the brain, and especially the cortex. The time when such organ systems are present in the human fetus must be ascertained by embryology. This probably occurs somewhere between several weeks and the end of the third month after conception, and so it is possible, on this theory, that human animation does not occur before this time.

Both of these conclusions, if accepted, would have far-reaching implications for future work in human genetics. Because the Catholic Church has thus far not taken a definitive position on the precise time when the human soul is present in the developing organism, the question remains open to discussion.

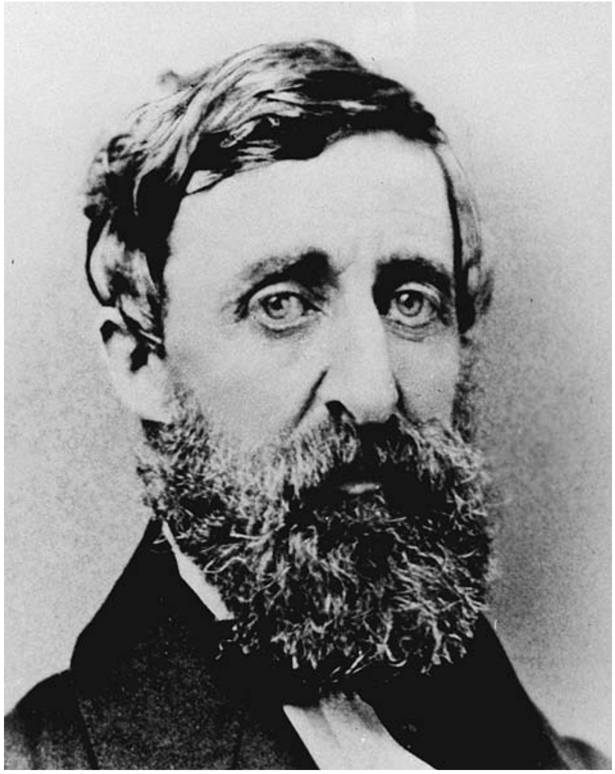
THOREAU, HENRY DAVID

Henry David Thoreau (1817–1862) was born in Concord, Massachusetts, on July 12, and died there of tuberculosis on May 6, two months shy of his forty-fifth birthday. He is best known as the author of *Walden* (1854), an account of the two years (1845–1847) he spent living in a cabin he built on the shores of Walden Pond (outside Concord), and "Civil Disobedience" (originally delivered as a lecture entitled "The Rights and Duties of the Individual in Relation to Government"), a polemical political essay describing the events surrounding, reasons for, and consequences of his arrest for nonpayment of taxes.



Henry David Thoreau, 1817–1862. Thoreau was an American writer, a dissenter, and, after Emerson, the outstanding transcendentalist. He is best known for his classic book, *Walden*. *(The Library of Congress.)*

Thoreau is often portrayed as an anti-modern romantic, placing him in strong opposition to the modernizing forces of science and technology. There is good evidence for this portrait scattered throughout his work. He wrote as an advocate of nature, and frequently suggested that the artifacts of civilization violated the goods and principles found in nature. For example, in his first book, *A Week on the Concord and Merrimack Rivers* (1849), he claimed that he would prefer to destroy the dams on the rivers and free the fishes; in a late essay, "Walking" he famously declared that "in Wildness is the preservation of the World" (Thoreau 1893, p. 275). He wrote in *Walden* of the need for people to simplify their lives ("Simplicity, simplicity, simplicity!" [Thoreau 1985, p. 395]), and many have interpreted this as an injunction to turn away from the world of modern science and technology in order to restore a more independent, even primitive lifestyle.

Despite the occasional evidence in support of this understanding of Thoreau's teaching, however, there is good reason to believe it is not a true picture of either his life or his intentions as an author. Any reader of Thoreau's books, essays, or fourteen volume *Journal* will be struck by his preoccupation with observing the natural world. He was a skilled, committed, and lifelong naturalist, and he provided field reports and specimens to the foremost biologist in the United States at the time, Louis Agassiz of Harvard University. He was also something of an archaeologist, gathering one of the most extensive collections of American Indian artifacts of his generation. Equally important *Walden* can be read as a philosophical commentary on modern economics, suggesting Thoreau's interest in social science. Thoreau was skilled as a surveyor and a carpenter, and proved his genius as a technologist by developing a new formula and manufacturing process for the graphite in the pencils manufactured by his family's business, which made these the highest quality pencils produced in the United States at the time. Thoreau's biography and writings reveal a man with a much more sophisticated view and knowledge of modern science and technology than is often acknowledged. While it is true that Thoreau often juxtaposed modern science and technology with what he took to be the wisdom or laws of nature, this does not preclude his being a serious natural and social scientist.

In fact Thoreau's complaint was not with science or technology in themselves, both of which he admired (and tried successfully to practice) in their proper place, but with the uncritical exercise and use of both. Although he was a skilled naturalist and technologist, he was most importantly a literary artist and a moralist. The message of *Walden* is not that modern science and technology are bad, but rather that they are bad as human beings currently practice them. This complaint is inspired by a concern for liberty, and is built on the fear that people are using science and technology to build wealth even if it costs them their freedom. He complained that people "have become the tools of their tools" (Thoreau 1985, p. 352) and that they would be more likely to learn "beautiful housekeeping" and "beautiful living" (p. 353) if they were willing to cultivate a more thoughtful poverty and independence. Ultimately Thoreau was a critic not of science and technology, but of the modern political economy and the way it employed these tools. His fear was that people were becoming morally ignorant about the cultivation of a good human life even as they were becoming scientifically and technically proficient.

As a social critic Thoreau has inspired many in the modern environmental movement who share his fear that society uses science and technology to war against nature rather than to learn to live in peace and harmony with it. Thoreau continues to be one of the most powerful literary voices in America. He is a reminder of the need to continually probe the purposes and ends to which science and technology are employed.

THREE GORGES DAM

The Three Gorges Multipurpose Water Control Project on the Yangtze River in China is one of the largest engineering projects in history. When complete, it will rival the Great Wall in technical and cultural significance. Unlike the Great Wall, however, and in accord with contemporary notions of scientific and technological decision making, the Three Gorges Dam has been the subject of considerable ethical and environmental assessment.

Historical Background and Description

The Yangtze River originates at 6,000 meters (20,000 feet) in the mountains of Tibet and then flows for 6,300 kilometers (3,900 miles) east through central China, passing through Nanjing, the capital of Jiangsu Province, before emptying into the East China Sea, through the port of Shanghai. From Shanghai, for the first 2,500 kilometers up the lower river is generally broad, calm,

and navigable, serving as a major transportation artery as it flows through the traditional rice basket of China. At Yichang there is a series of three, sheer-cliffed gorges, Xiling, Wu, and Qutang, that stretch up river for another 1,000 meters.

The idea of building the dam was first proposed by Sun Yat-sen in 1919, but it was not until 1994, with the backing of Deng Xiaoping, that construction actually began.

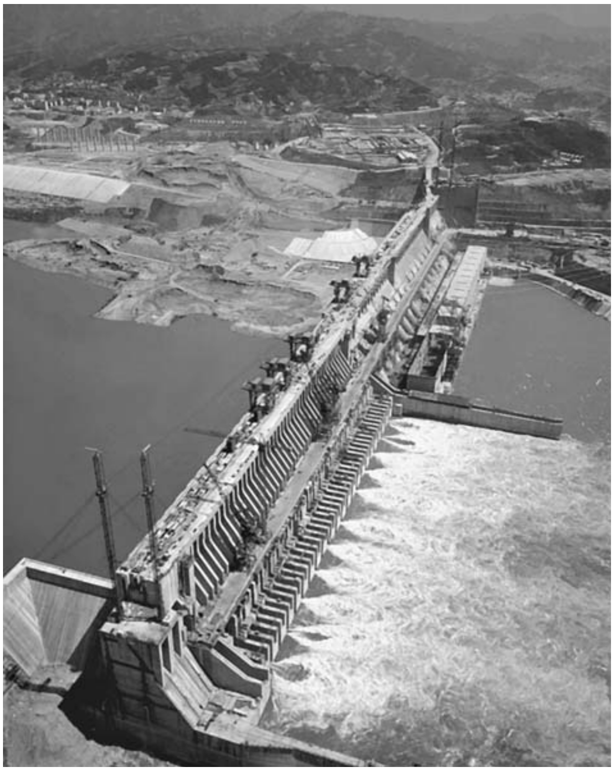
The project consists of three parts: the dam itself, hydroelectric stations located on each side of the dam, and navigation locks on the left side of the dam. When finished, the dam at the mouth of Xiling Gorge will be 185 meters high, 3,035 meters long at the top, and will create a reservoir that stretches 600 kilometers through each of the gorges in turn, with a surface area of 10,000 square meters and a volume of 39.3 billion cubic meters. It will provide flood control, generate electric power, and improve navigation.

Ethical Issues

The Three Gorges Dam project has been subject to three basic criticisms. It has been judged by the World Bank as economically unsound, by many environmentalists as ecologically destructive, and by some social scientists as socially and culturally disruptive. All of these issues have been discussed at length, and efforts have been made to address the objections.

Because of the negative judgment of the international financial community, China has raised the money for construction from its own resources. At the same time, it has tried to structure the project so that in the long term the investment will benefit Chinese economic development.

The Three Gorges Dam will indeed have significant ecological and social consequences. The ecological impact is justified not only by great social but also significant environmental benefit. When completed, for instance, the dam will provide for extensive flood con-



The Three Gorges Dam on the Yangtze River at Yichang, in China's Hubei Province. *(AP/Wide World Photos. Reproduced by permission.)*

trol on a river that has caused major disasters on an average of every ten years in the past. It will also produce 18.2 million kilowatts of electricity, the equivalent of ten standard coal-fired power plants that would together burn more than 50 million tons of coal each year, create 2 million tons of sulphuric oxide, 10,000 tons of carbon monoxide, and 370,000 tons of nitrous oxide, which would severely pollute the environment there. The dam will use an otherwise wasted, and sometimes destructive, energy source, water, to supply clean electricity for industrial and economic development.

But the Three Gorges project is also a means for scientific and technological collaboration at both the national and international levels, and thus an opportunity to exercise human self-realization or achievement by bringing science and technology together to cause a beneficial transformation of nature. The project is in fact utilizing and developing advanced construction techniques, and will install the highest quality power generation equipment available. On site concrete formulation takes place in Japanese machines, the hydroelectric generators come from Europe, and so on.

Finally the design of the Three Gorges Dam has been the subject of extensive ethical discussion and aims to contribute to the contemporary ideal of sustainable development. Where possible, biological preserves have been established to protect threatened species and to preserve water quality. Although more than 1 million people along the river are being relocated, they are being provided with new and better housing than they had in the past. Additionally efforts have been made to preserve materials of archeological value.

The Three Gorges Dam project is thus a major learning experience in China. It is teaching an important lesson in relating science, technology, and ethics.

THREE-MILE ISLAND

On March 28, 1979, a series of events took place at the nuclear reactor at Three Mile Island, Unit 2 (TMI-2), near Harrisburg, Pennsylvania, that resulted in an accident in which a significant fraction of the nuclear reactor core melted and a small amount of radioactivity was released to the environment. After more than twenty years of government-stimulated development of the nuclear power industry and in the context of increasing public objections, that accident became the focus for an intensely polarized debate about the wisdom of further construction of nuclear reactors. The accident at the Three Mile Island nuclear power station has taken on a key historical role in discussions concerning science, technology, and ethics.

Reactor Design

Understanding the accident requires a general understanding of the way the TMI-2 reactor worked. TMI-2 was a pressurized water reactor. A simple diagram of the system is shown in Figure 1.

The fission process—splitting the atom, with the release of energy—occurs in the reactor core. This generates heat, and so the core is cooled with water under high pressure, which is needed to prevent the water from boiling. The reactor is contained in a thick (ten inches) steel-walled reactor vessel. Two loops circulate the water. The primary loop carries the pressurized water through the reactor, where it is heated, to a device called a steam generator. In the steam generator heat is transferred from the primary loop to water in a secondary loop, which is not under pressure, and thus is converted to steam. Water in the primary loop does not mix with water in the secondary loop. Radioactivity in the primary loop never mixes with water in the secondary loop. The cooled water in the primary loop then is pumped back to the reactor for reheating. The steam produced in the secondary loop is piped to a turbine, where it hits turbine blades and causes them to spin. The turbine is connected to a generator that produces electricity. The steam then condenses below the turbine and is pumped back to the steam generator for its own reheating.

The primary loop is contained inside a steel-lined, steel-reinforced concrete building in which the walls are three to five feet thick. This containment building, as shown in Figure 1, is designed to prevent or at least minimize radiation leakage to the environment in case of a serious accident. It is a requirement in the United States that all commercial reactors be built inside a containment building. This is part of the "defense-in-depth" philosophy that has been required from the beginning in the design of commercial nuclear power plants in the United States.

The Accident

The accident began at 4:00 A.M., when maintenance activities caused secondary loop pumps to shut down, leading to a buildup of heat in the primary loop. The reactor shut down automatically, but the pressure in the primary loop increased significantly. As is shown in Figure 1, a pressurizer outside the reactor vessel monitors the primary loop. If the pressure gets too high, a valve opens and radioactive water escapes to the drain tank below the reactor.

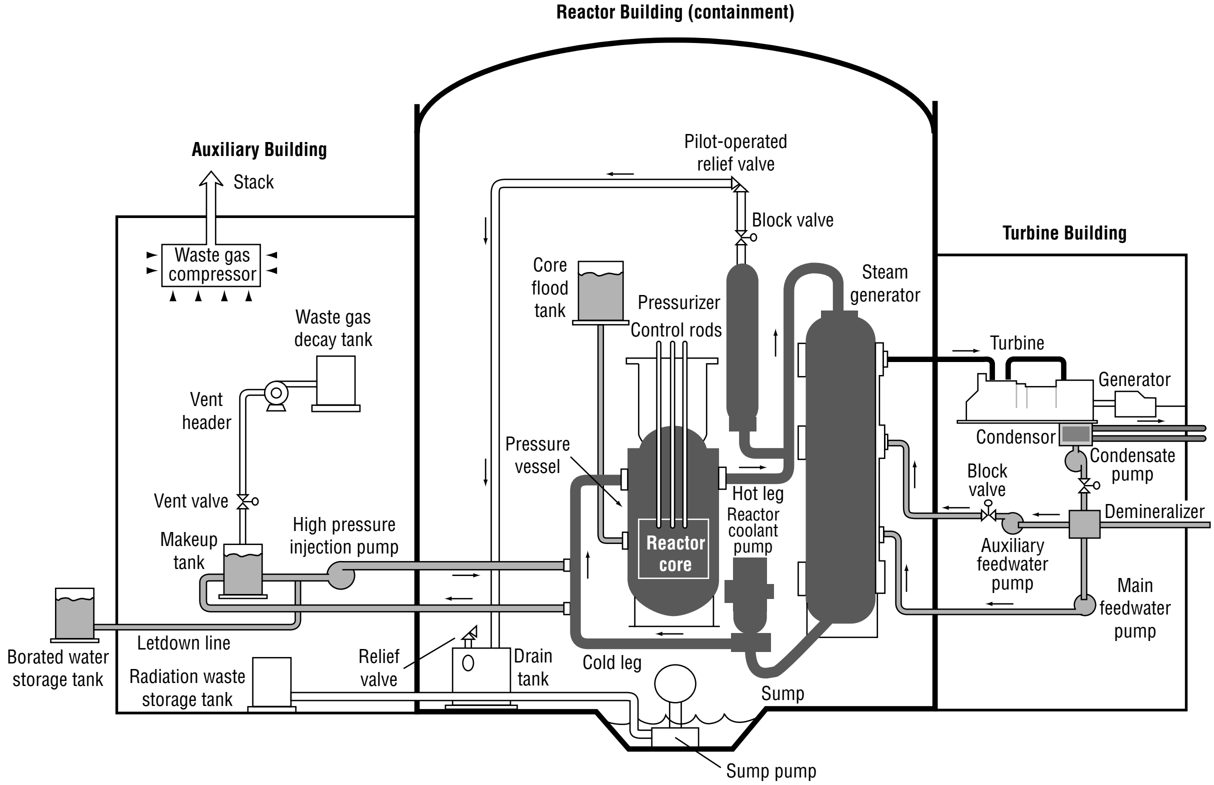
This is what happened at TMI-2. When the pressure returned to normal, the operator sent an electrical signal to the motor that closes the valve. An indicator light showed this action was taken, causing the operator to believe the valve had closed. Unfortunately the indicator did not show the actual valve position, which was partially stuck open. One of the changes resulting from the accident is an indicator that actually shows closure of the valves. Another sensor in the control room showed high pressure in the reactor drain tank, which indicated a leak, but this indicator was located behind a seven-foot-high instrument panel.

Alarms and warning lights began to go off in the control room, indicating problems in different systems. This confused the operators and made it difficult to diagnose the problem and choose the appropriate corrective action. Water continued to leak through the open valve from the primary loop to the basement, where it overflowed from the reactor drain tank onto the basement floor. It then was pumped to tanks in the adjacent auxiliary building. When those tanks overflowed, radioactive water spilled onto the floor of the auxiliary building, enabling the radioactive gas xenon, an inert gas that is not incorporated into the body tissue, to escape from the building through the ventilation system. This resulted in a low-level exposure to residents in surrounding communities.

Even when a reactor is shut down, residual radioactive fission products in the reactor core continue to produce heat that must be removed. An emergency cooling system turned on automatically and started pumping water into the primary loop. The operators, however, thinking that the valve on the pressurizer was closed and noting that the water level indicator in the pressurizer showed that the pressurizer was full, throttled back and then shut down the emergency cooling system because they feared that the primary loop would overfill with water and cause a dangerous overpressure in the loop.

FIGURE 1

Schematic Diagram of TMI-2



SOURCE: Adapted from *IEEE Spectrum* 16 (November 1979): 43–45. In Walker (2004), p. 72.

Schematic diagram of TMI-2. (© *IEEE 2004.*)

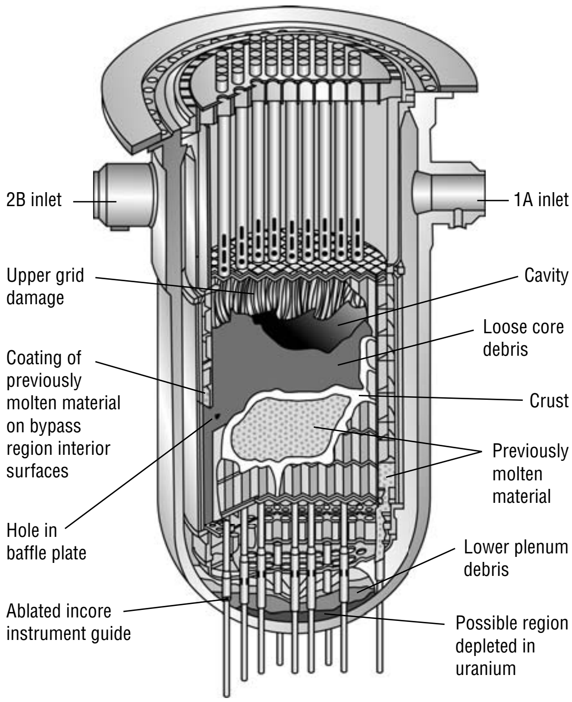
Actually, the pressure was dropping in the primary loop because of the open valve, and boiling of the remaining water began to occur. The large pumps for the primary cooling water began to vibrate heavily because they were filling with steam from the boiling water. Those pumps were shut down to prevent them from being damaged. Although the primary loop water was boiling off, with the steam going through the open valve, serious damage to the core still would have been avoided if the emergency core cooling system had continued operating.

After about 100 minutes enough water had leaked from the core through the open pressurizer valve that the top of the core was no longer covered with cooling water. The temperature in the uncovered parts of the core began to rise. The fuel is contained in tubes called cladding made of a zirconium alloy, and the uncovered tubes began to react with the steam, releasing hydrogen. Some of that hydrogen escaped into the containment building and later underwent a rapid burn (mild explosion) that caused some equipment damage. Some of the hydrogen accumulated in the top of the vessel that held the reactor and inhibited reactor cooling for several days. It also led to concern by some Nuclear Regulatory Commission (NRC) staff members that the hydrogen might explode. (It turned out that this was not possible because of an oxygen shortage in the system.) Because of uncertainty about the condition of the reactor two days after the accident began Pennsylvania Governor Richard Thornburgh advised pregnant women and preschool-age children within a five-mile radius of the plant to evacuate.

After 142 minutes the cause of the leak was determined, and a backup valve for the pressurizer was closed, stopping the loss of water. However, by that time about one-third of the primary loop water had escaped. Because of concern that introducing cold water into the intensely heated core would cause the fuel elements to fracture, the emergency core cooling system was not restarted until four and a half hours after the accident began.

FIGURE 2

Three Mile Island-2 Core End-State Configuration



SOURCE: Osif, Barrata, and Conkling (2004), plate 27.

Condition of the reactor core after the accident. (*Courtesy of the Pennsylvania State University Engineering Library*.)

As the core overheated and the cladding underwent chemical reactions as well as melting, the core structure began to lose strength and the top of the fuel elements collapsed into a pile, some of which heated to the melting temperature of the fuel, creating a large molten mass in the center. Some of that molten fuel eventually spilled over the side of the core and accumulated below the core. Altogether approximately 50 percent of the core melted. Fortunately, there was sufficient cooling water to prevent the molten fuel from rupturing the reactor vessel. Except for the radioactivity in the cooling water that leaked into the drain tank and then was pumped into the auxiliary building, from which there were small gaseous releases to the environment, almost all the radioactivity was contained within the containment building. The final state of the core at the end of the accident is shown in Figure 2.

Health Effects

The Nuclear Regulatory Commission, the Environmental Protection Agency (EPA), the Department of Health, Education and Welfare, the Department of Energy, and the state of Pennsylvania conducted studies on the health effects of the accident. All those studies concluded that the dose any member of the public received was far less than the natural background radiation. There was no increase in cancer in the surrounding communities.

Some nongovernmental groups and university researchers rejected those reports. Although the accident led to no generally accepted radiation injuries to the public or to workers, it did cause an emotional trauma to the local citizens and indeed to the nation. Without question it led to a loss of public confidence in nuclear power.

Lessons and Changes

Analysis of the accident revealed several significant operations problems in the industry as well as oversight problems at the NRC. Of particular importance was the finding that operator error had resulted from a lack of understanding of how the system behaved, a lack of information at the control panel to help operators make a correct diagnosis, and a control panel design that promoted confusion rather than understanding. Other issues in the accident included poor communication between the reactor site and NRC headquarters, ineffective communication with the public and the press, and an inadequate communication system for the NRC and industry to inform operators of safety problems identified at other plants. For example, the operators did not know that a similar stuck valve incident had occurred at another reactor eighteen months earlier.

In response the industry created an operations oversight organization called the Institute for Nuclear Power Operations (INPO). Among its activities are plant visits by expert teams on a regular basis (twelve to eighteen months), assistance to plant operators to improve their skills, and the creation of the National Academy for Nuclear Training, which accredits nuclear training programs in maintenance and operations to assure high standards. Simulators that replicate the behavior of the plant now exist at each site and are used to train operators on normal operations and accident scenarios. A key goal of INPO is the promotion of a culture at nuclear power plants that emphasizes "safety first" as the basis of decision making.

Finally, the NRC and industry used information from the accident to develop computer models that describe the progression of serious accidents. There are now emergency centers that conduct regular emergency exercises, including the use of local community response teams of emergency workers and fire fighters. All these efforts have transformed the U.S. nuclear industry and its regulation and have resulted in remarkable improvements in safe operations as well as economic performance, both of which were needed.

In the United States the nuclear power industry had developed rapidly in the 1960s and 1970s, with different companies involved and with diverse designs and changes in design with each new reactor. The power output of the reactors increased quickly from the early small reactors, with the belief that there would be an "economy of scale" with larger units. The regulatory process developed in parallel with industry growth, and changes in regulations were made as experience was gained and plants got larger. As a result each reactor was unique, and it was difficult to maximize learning in construction, operation, and maintenance. This contrasts with both the French and the Japanese nuclear power industries, which were initiated later and chose one or a small number of designs for their reactors, which contributed to facilitated learning in building and operations.

Accident Cleanup

Cleanup of the accident included the processing and storing of radioactive contaminated water in the auxiliary and reactor buildings and removal of contaminated building materials and the reactor core to a safe storage site at the Idaho National Engineering Laboratory (INEL). This was a lengthy, expensive, and contentious process. Numerous technical challenges, many of them first of a kind, had to be overcome. Those challenges included (1) building and operating systems to treat the radioactive water; (2) inspecting damage to the core, which revealed a collapse of the top five feet of the reactor material into a rubble bed, with a five-foot-thick section of solidified melted fuel below; (3) development and use of tools to break up the solidified section of the core so that it could be loaded into casks and shipped to INEL; (4) solving a biological growth problem that caused clouding of the water; and (5) the development and use of robotic equipment to decontaminate the reactor building basement. In addition to finding solutions to the technical problems, NRC approval was needed for each step in the cleanup. This often resulted in delays, partly because the NRC frequently sought general public input and acceptance.

Some of the contentious issues that arose delayed the cleanup. One was the venting of radioactive gas from the containment building to allow worker entry and building cleanup to begin. Two raucous public meetings were held before NRC approval of the plan. The public was angry, fearful, and mistrusting, and assurances that radiation exposure to the public would be negligible fell on deaf ears. The venting took place from June 28 to July 11, 1980, and was monitored by the NRC, the EPA, a state agency, the utility company, and a citizen's group. Radiation exposure was determined to be negligible.

Another issue was more technical and involved the use of a crane above the reactor vessel to remove the vessel head to allow access to the fuel. The conditions inside the containment were junglelike, including high humidity and even rain. Extensive maintenance was performed on the crane to ready it for use, but one engineer, Richard Parks, wanted to do a full load test before attempting to lift the multiton vessel head. When management decided against this, Parks went directly to the NRC with his concern and was fired for whistle-blowing by the general contractor, Bechtel. The NRC sided with his concern, and testing was performed before the head was lifted.

Additional public concerns arose about shipping canisters of highly radioactive waste off-site to INEL and about the disposal of the decontaminated water after the rest of the cleanup had been completed. The simplest and least expensive solution would have been to release the water gradually to the river. This would not have presented any hazard to the public, but there was strong citizen opposition to putting the water into the Susquehanna River. In the end the utility agreed to evaporate the water. That operation was completed in August 1993 after a two-and-a-half-year process.

It took approximately eleven years to complete the cleanup and place the building in a monitored shutdown state. The cost was approximately $1 billion. This does not include the cost of replacement electricity or the cost related to TMI-1 being shut down for six years before it was allowed to restart. The cost to the industry was also substantial because the NRC required numerous modifications to the safety systems of all pressurized water reactors as well as changes to operating procedures. Although those changes did enhance plant safety in most cases, making changes in response to a crisis is generally more expensive and undoubtedly drove up the cost of nuclear power generation in the 1980s.

Ethical and Policy Issues

Several ethical and policy issues have arisen regarding the safety of nuclear power plants and whether another accident might occur. The first issue is whether electric power generation companies might put economics before safety. Although the industry has found that the safest plants are also the most economical, decisions to keep a plant operating even though conservative safety considerations suggest it should be shut down occasionally still occur. One example was the Davis-Besse plant in Ohio in 2002, where evidence of continuous corrosion of the reactor vessel was not investigated thoroughly until the corrosion completely penetrated the head. Fortunately, the steel liner was able to hold the reactor pressure until the problem was discovered. The public will have to judge whether the safety record of the industry and the oversight of the NRC are sufficient to justify the continued operation of nuclear power plants.

Second, and perhaps more significant in the early twenty-first century, is whether, in light of potential terrorist attacks against nuclear power plants, the nation should continue to use nuclear power, which in 2000 supplied approximately 20 percent of the electricity consumed in the United States. Could a group of terrorists breach all safety systems and cause a significant radiation injury to the public? After the terrorist attacks of September 11, 2001, security has been enhanced at each nuclear site, including the hiring of additional guards. Also, studies have been made on the effect of an airplane crash into the containment building and other parts of the plant. These studies suggest that the use of standard evacuation procedures would be sufficient to prevent any serious injury to the public. Nonetheless, some public officials and critics of nuclear power lack confidence in the results and believe nuclear power plants should be eliminated.

There are, however, national security and environmental benefits of nuclear power that must be considered. Nuclear power does not require the use of imported fossil fuels such as oil or future imports of natural gas. Furthermore, there are no emissions of sulfur oxides, nitrous oxides, or carbon dioxide as there are with the burning of fossil fuels. Indeed, nuclear power is already the dominant method of avoiding carbon dioxide emissions in the nation. Any replacement of the 20 percent of electricity generated by nuclear power could increase the cost of electricity generation, reduce the reliability of the electrical grid system, and/or increase pollutants emitted to the environment. Nuclear power may be critically needed to reduce the potential consequences of global warming. Also, as the price of natural gas rises and as it is recognized that natural gas may be able to serve as a substitute for oil in transportation, nuclear power may be the most cost-effective means for producing electricity, especially for electrical generation that has a minimum of environmental consequences.

TILLICH, PAUL

Born in Starzeddel, Germany, on August 20, Paul Johannes Tillich (1886–1965) explored the theological

Paul Tillich, 1886–1965. The American Protestant theologian and philosopher ranks as one of the most important and influential theologians of the 20th century. He explored the meaning of Christian faith in relation to the questions raised by philosophical analysis of human existence. *(Harvard University News Office.)*

and philosophical depths of contemporary culture. His experiences as a German army field chaplain in World War I shook Tillich's confidence in Western civilization, leading him to question its cultural and religious assumptions. In a series of professorships culminating in an appointment at the University of Frankfurt he spelled out his "theology of culture," exploring the unconscious, self-evident faith implicit in ostensibly secular social thought and structures. After he was dismissed from his professorship on April 13, 1933, by the Nazi government, on November 3 of that year Tillich arrived in the United States, where he held positions at Union Theological Seminary, Harvard University, and the University of Chicago. He died on October 22 in Chicago.

Tillich understood technology as an adjusting of means to an end. That process is present in animal behavior such as the building of a nest, but human technology transcends organic processes by making tools for unlimited use. Tillich called the technical forms closest to natural processes "unfolding" technologies, for example, cattle breeding; those technical forms conserve and develop the potentialities implicit in natural forms. "Realizing" technologies such as musical instruments represent the direct expression of spirit in symbolic productions. "Transforming" technologies, exemplified by machines, destroy living connections by imposing purposes that are not implicit in natural forms.

Tillich defined science (*Wissenschaft*) as any methodologically disciplined cognitive approach to reality. In the subject-object structure of knowing, science separates itself from its object. For Tillich modern science is also a form of controlling knowledge or technical rationality because of its intimate connection to technological application.

Science and technology are "ambiguous," Tillich argued, both creative *and* destructive. They provide liberation from superstition and debilitating work but are enslaving in other ways. This shadow side of science and technological development arises not from their essential structures but from their isolation from wider contexts of meaning and their domination (what Tillich calls imperialism) over other ways of knowing and acting. In this fallen state of autonomy they achieve a quasi-religious status as "scientism" and "technicism." Along with capitalism they form a trinity of social forces that determine the religious situation of modernity.

The fulfillment of scientific and technological possibilities cannot come from their subjection to political or religious authority, however. That would constitute the imposition of "heteronomy," or determination from outside. Science must be free to question every presupposition, Tillich argued, or it loses its character as science. The creative potential of science and technology must proceed though an autonomy aware of its own depth to become "theonomous," or transparent to the ground of being (God), and thus reunited with broader conceptions of the meaning of life.

Ambiguity as the mixture of creativity and destructivity pervades technological production as the tools that liberate humanity also subject humankind to the rules of the making of those tools. Ambiguity is manifest in humanity's limited ability to adapt itself to limitless technical productivity, including atomic weapons. It is revealed in the emptiness created by the production of gadgets, which represent means that become their own end. It is manifest in an objectification of both natural objects and persons that transforms both into things. Neither the external restrictions of heteronomy (including religious determination) nor the fallen autonomy of running ahead indefinitely in a meaningless world is adequate to overcome these ambiguities.

Scientism and technicism must be overcome by what Tillich calls *theonomy*. Theonomy does not prescribe particular technological objects but instead calls for the creation of technical *Gestalten* (wholes) that people can love for the form and meaning embodied in them. It does this through production that follows rather than precedes human needs and maintains the intrinsic power in things. It would not halt scientific inquiry into the nature of the atom, for example, but would ban the destructiveness of inventions such as the atomic bomb by limiting the desire to create such devastation. Theonomy demands that people be treated as a ends rather than means, overcoming technological structures of dehumanization. It resists the attempt to control knowledge or monopolize the cognitive function, influencing science indirectly by determining the attitude and style of scientific creations.

Science is ambiguous in that the observer remains estranged from objects, examining them for the sake of domination. It proceeds through observation and conclusion. However, the observed changes, in the process of being observed, result in the discovery not of the "real" but of an encountered reality. Science carries unexamined assumptions into arguments that may influence its discoveries, with every statement about an object adopting concepts that require further definition, ad infinitum.

Autonomous reason, without the depth of reason (the true-itself), is driven to solve its dilemmas by combating relativism with absolutism, formalism with emotionalism, and subjectivism with objectivism. In theonomy, however, reason is grounded in the depth of reason, leading toward a more inclusive pattern of participation and insight, delving not only into the nature but also into the ultimate meaning and existential significance of things. Science tends toward a nominalistic form of methodological reductionism that is manifest in empiricism and positivism. Cut off from the depth of reason, scientism creates its own quasi-religious myth of a meaningless universe that swallows everything, including scientific passion. Theonomy, however, rejects an "objective" approach that loses its objectivity by grasping only one element of an object and not the whole, reducing reality to its own terms.

Contemporary technological society is ambiguous, Tillich states, just like the technological era that brought it into being. The task of a theonomous technological society would be to move autonomy to its own depth, making things and structures transparent to the ground of their being, thus making them not only useful but significant components of a meaningful world.

Few modern theologians have attempted the broad and deep conversation Tillich carried on with political, social, economic, and cultural phenomena. His distinctively neoclassical style of thought, however, is more intelligible to those steeped in the European intellectual traditions than to those grounded in pragmatic American thought. The theologian and ethicist Reinhold Niebuhr (1892–1971), in contrast, is more accessible to readers in the United States. For those who can negotiate his prose, however, Tillich provides a systematic and comprehensive ethical, philosophical, and theological assessment of modernity, from art and architecture to space travel.

Thomas, J. Mark. (1987). *Ethics and Technoculture*. Lanham, MD: University Press of America. This book reviews the evaluation of technological society in the thought of Talcott Parsons, Herbert Marcuse, Martin Heidegger, and Paul Tillich, arguing that the presuppositions of each thinker determine the terms of his social and ethical judgment.

Thomas, J. Mark. (1990). "Are Science and Technology Quasi-Religions?" In *Research in Philosophy and Technology*, vol. 10, ed. Frederick Ferré. Greenwich, CT: Jai Press. This essay uses thought within the "civil religion" debate and the work of Paul Tillich to analyze the proposition that science and technology constitute quasi-religions. It concludes that they are not quasi-religions but that scientism and technicism are.

Tillich, Paul. (1956). *The Religious Situation*. New York: Meridian. Originally written in 1926, this book explores the religious situation of modernity as it has been determined by the divine trinity of science, technology, and capitalism.

Tillich, Paul. (1963). *Systematic Theology*, vol. III. Chicago: University of Chicago Press. The third and final volume of Tillich's system explores the ways in which theonomy overcomes the ambiguities present in every dimension of finite life, including technological and scientific endeavors.

Tillich, Paul. (1988). *The Spiritual Situation in Our Technical Society*, ed. J. Mark Thomas. Macon, GA: Mercer University Press. This collection of essays brings together Tillich's writings on science and technology from his earliest German period (1927) until almost the end of his career (1963). It organizes those essays in five parts, describing the situation in technical society; the structure and meaning of science and technology; science, technology and human self-interpretation; dehumanization in technical society; and the symbols and ambiguities of a technical society.

TOCQUEVILLE, ALEXIS DE

Politician and author Alexis de Tocqueville (1805–1859), who was born in the village of Tocqueville in France on July 29 and died on April 16, is best known for his two politically minded books, *Democracy in America* (1835–1840) and *The Old Regime and the Revolution* (1856). Tocqueville was born into an aristocratic family and lived as an aristocrat. He had no children and no strong desire to perpetuate his family's noble name. His passion was to promote human liberty in democratic times, to keep alive what was best about the old aristocracies in societies devoted to the democratic understanding of justice. Tocqueville's political career was undistinguished, but he deserves to be remembered for his literary legacy.

Democracy in America, the outgrowth of an extended visit to the United States from May 1831 until February 1832, remains the best single book written on democracy and the best book written on America. It has in many ways become more true over time, as America has become more democratic. Tocqueville presents democracy not just as a form of government but as a way of life; the democratic ways of thinking, feeling, and acting, he correctly thought, had infused and would gradually continue to infuse themselves into every aspect of American and modern life.

Alexis de Tocqueville, 1805–1859. Tocqueville was a French political thinker and historian who championed liberty and democracy. *(The Library of Congress.)*

Tocqueville's explicit discussion of democratic science, technology, and ethics occurs in Part 1 of *Democracy* Volume 2, where his subject is the democratic mind. There he describes Americans as Cartesians without ever having read a word of Descartes. They are habitual skeptics; they view all claims of personal authority as nondemocratic claims to rule. Skeptical of the soul, Americans act feverishly on behalf of the body and its enjoyments. So they prize scientific knowledge far less for its own sake than for its applications or technological effects. The Americans dismiss the proud and pure desire to know characteristic of theoretical science as an aristocratic prejudice. Democratic peoples subordinate pleasures of the mind to those of the body.

Tocqueville himself embraces neither the aristocratic nor democratic views of science, but adopts the position of an umpire determining what is true and false about each partial or extreme view. The pride associated with the ruling class in an aristocracy leads scientific inquirers to confine themselves to the haughty and sterile pursuit of abstract truths. All scientific advances find their roots in such fundamental inquiry, but aristocrats inconsiderately or unethically neglect what applied science might do to improve ordinary human life.

Democrats, Tocqueville adds, are so selfishly enthralled with the benefits of technology that they neglect to provide for pure or theoretical inquiry. Democracies characteristically do not have a class that possesses the leisure required for the theoretical sciences; the mind needs relatively calm or unagitated social circumstances to achieve its possible perfection. The theoretical life is rarely possible for members of a merely middle class, for free beings who must work to earn a living.

For minds in democratic times, the most magnificent products of human intelligence are methods that quickly produce wealth and machines that reduce the need for human labor and the cost of production. Those who direct democratic nations, Tocqueville contends, must use their influence and power to go against the democratic grain by raising those minds on occasion "to the contemplation of first causes," to elevate them sometimes with the magnificence of the theoretical life. Their failure to do so might mean the near disappearance of scientific geniuses such as Blaise Pascal (1623–1662) and even the gradual decline of scientific progress itself. A nation with no theoretical passion at all might end up wallowing in the scientific stagnation characteristic of the China that Europeans discovered. The technical genius of America finally depends on the perpetuation of a way of life that disdains mere technology in the name of truth.

Tocqueville also worried about the effect of a democratic technological orientation on the souls of most human beings. He writes that if he had lived in an unjust, poor, and otherworldly aristocratic age, he would have attempted to turn people toward the study of physical science and the pursuit of material wellbeing. But in a democracy, people are readily pushed by social circumstances in that technological direction; there is no longer any need to promote applied science. Instead, the need is to raise souls in the direction of heaven, greatness, a love of the infinite, and the love of immaterial pleasures. The democratic danger is that "while man takes pleasure in [the] honest and legitimate search for well-being, he will finally lose the use of his most sublime faculties, and that by wishing to improve everything around him, he will finally degrade himself" (*Democracy in America,* Volume 2, Part 2, Chapter 14). So any comprehensive scientific claim for the truth of materialism—for the idea that there is no truth at all to claims for the soul's immortality—should be condemned by thoughtful human beings in democratic times as probably untrue and certainly pernicious.

Tocqueville was also a critic of the effect of applied science on language in democratic times. Language becomes progressively more vague and impersonal; human action is described using words more appropriate to mechanical motion. Precise personal distinctions and assertions become suspect, and metaphysics and theology slowly lose ground. Instead of saying, "I think," those who aim to influence democratic opinion say, "studies show." Having rejected personal authority, people in democratic times are far less skeptical concerning impersonal scientific claims about the various *forces* that shape their lives. Having freed themselves from aristocratic tyranny, people are seduced by the expertise of *schoolmasters* whose despotism is milder but exceedingly meddlesome. A democratic danger is the loss of any conception of free will or personal liberty; people will too easily be governed both by the claims of impersonal expertise and public opinion determined by no one in particular.

Tocqueville's significance is his account of all of modern life in terms of democracy. Many of his observations and fears anticipate, for instance, Martin Heidegger's account of all of modern life in terms of *technology*, and certainly modern democracy would be impossible without the liberation of technological progress for the most part from moral and political concerns. But Tocqueville emphatically refuses to equate technological progress with human progress. His judgments about democratic progress are friendlier to democracy and more judicious than Heidegger's. Democratic thought is partly true and partly not, and there is no reason to believe that people will not be able to correct some of its excesses in the directions of truth and liberty.

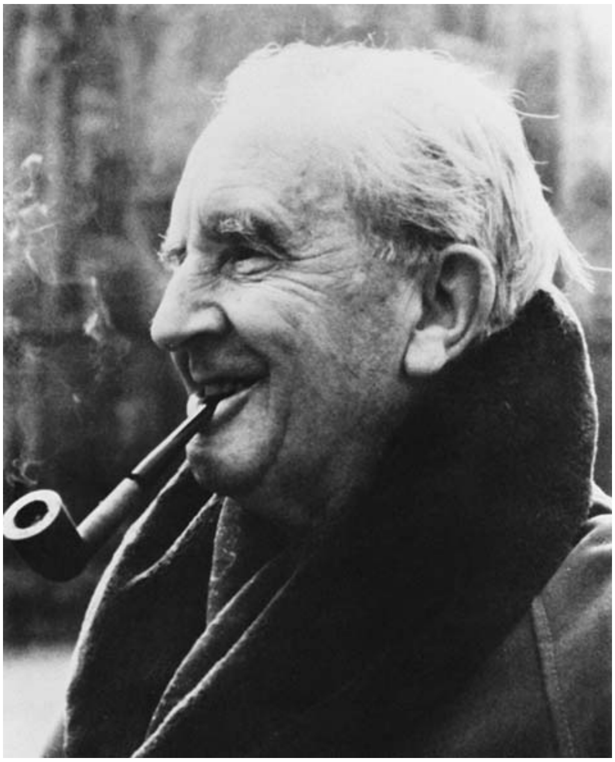
TOLKIEN, J. R. R.

Born in Bloemfontein, South Africa on January 3, fantasist, philologist, and critic John Ronald Reuel Tolkien (1892–1973) served in France during World War I and saw action at the Battle of the Somme. He completed his undergraduate studies at Exeter College, Oxford, in 1915, and from 1920 until 1924 was Reader and Professor of English Language at Leeds University. In 1925 Tolkien was elected Rawlinson and Bosworth Professor of Anglo-Saxon at Oxford University and Fellow of Pembroke College. In 1945 he was elected Merton Professor of English Language and Literature at Oxford. He published *The Lord of the Rings* in three volumes from 1954 to 1955 and retired from his professorship in 1959.

Man and Nature vs. Technology

In a 1951 letter to an editor, Tolkien commented that *The Lord of the Rings* and *The Silmarillion* (1977) were primarily concerned with "the Fall, Mortality, and the Machine." He explained that *the Machine* (or *magia,* magic) were plans or devices that dominated, either by



J. R. R. Tolkien, 1892–1973. Tolkien gained a reputation during the 1960s and 1970s as a cult figure among youths disillusioned with war and the technological age; his continuing popularity evidences his ability to evoke the oppressive realities of modern life while drawing audiences into a fantasy world. *(AP/Wide World Photos.)*

destroying the environment or by controlling the wills of people (Carpenter 2000, pp. 145, 146). His Middle-earth writings (*The Hobbit* [1937], *The Silmarillion*, *The Lord of the Rings*, the posthumously published *Unfinished Tales* [1980], and the twelve-volume *History of Middle Earth* [1982–1996]), can be understood as at least a partial response to a modern world that was embracing industry and technology. Tolkien believed the Machine (technology) was destroying his beautiful, rural, Edwardian countryside (represented in *The Hobbit* by the peaceful Shire) with wars, factories, cars, railroads, and pollution, and he saw no end in sight. He passed on his distaste for mechanization to his hobbits in the prologue of *The Lord of the Rings*: "They [hobbits] do not and did not understand or like machines more complicated than a forge-bellows, a water-mill, or a hand-loom . . ." (Tolkien 1994, p. 1). His two major villains in the story, Saruman and Sauron, are dependent on machines and use them to dominate and destroy the countryside. His descriptions of the realm of Mordor, with its desolate, scarred plains and history of being a stronghold of evil, were taken from his experiences on the battlefield.

Tolkien was not opposed to technology in itself, but he despaired of the motives behind it, which he saw as primarily concerned with speed, *immediacy*, and the desire for power and control. He compared the Machine with art, which created new worlds of the mind and imagination, and complained that labor-saving machines only added more and less effective work. He lamented that the *infernal combustion* engine had ever been invented, and expressed doubts that it could ever be put to rational use. He also disliked the fact that the Machine was increasingly associated with English daily life. He once owned a car, but found it difficult to drive in Oxford's traffic congestion, and commented that the *spirit of Isengard* (the evil Saruman's fortress) had led planners to destroy the city in order to accommodate more cars and traffic. Near the end of World War II he sarcastically suggested the war had been conducted by bureaucrats (*the big Folk*) who viewed most of it in *large motor-cars*.

Some critics suggested that *The Lord of the Rings* was an allegory and protest of atomic power and the dangers inherent in nuclear warfare. Tolkien emphatically denied this, saying that the story (which predated the nuclear age) was not about atomic power, but power exerted for domination. In his view nuclear physics could be used for domination, but it should not be used at all, and he further emphasized that the story was really about *Death and Immortality*. But he was stunned and outraged when he learned of the dropping of the atomic bomb on Hiroshima. He called the scientists who developed the bomb *lunatic physicists* and raged that it was idiocy to "consent to do such work for war-purposes, calmly plotting the destruction of the world!" (Carpenter 2000b, p. 116).

Tolkien's conservative Christian (Roman Catholic) beliefs contributed substantially to his attitudes about technology. In his seminal essay "On Fairy Stories" (1939, originally a lecture at the University of St. Andrews), he stated that human beings were *subcreators* who were created by God in his image to use their gifts wisely and in accordance with his wishes. The inclination of modern society toward domineering technology was, for Tolkien, a denial of God as creator. He called *The Lord of the Rings* a "fundamentally Christian and Catholic work" (Carpenter 2000b, p. 172), and his view of Christianity saw the universe as a place of conflict between good and evil.

Translation of *The Lord of the Rings* Into Film

In late 1957 Tolkien was approached by a group of American businessmen who gave him drawings and a story-line for a proposed animated film version of *The Lord of the Rings*. He wrote a member of the group a scathing letter of denunciation, explaining that the proposal and script, in whole and detail, was totally unacceptable, and that he did not want his story *garbled*. The early twenty-first century film versions of *The Lord of the Rings* have received generally favorable notices, particularly on the Internet and from young people. But several Tolkien scholars have written of their displeasure at the crass commercialization of the films, and the many liberties taken with characters and events. The films have been marketed by deploying the latest technology to sell to younger fans, and Tolkien's complex fantasy has been simplified into a visually stunning, character-driven action story with emphasis on spectacle rather than content.

Tolkien's son Christopher, the literary executor of his father's estate, did not disapprove of the film, but voiced doubts about the transformation of *The Lord of the Rings* into dramatic form. Tolkien, no doubt, would voice his displeasure over the films, and contend that technology has been used to reproduce and garble his narrative. He was resigned to the use of the Machine as a self-destructive tool of the modern world, which desired, in his view, to eliminate tradition and the past. He expressed his resignation in 1956, just a year or so after the publication of the final volume of *The Lord of the Rings*: "If there is any contemporary reference in my story at all it is to what seems to me the most widespread assumption of our time: that if a thing can be done, it must be done" (Carpenter 2000b, p. 246).

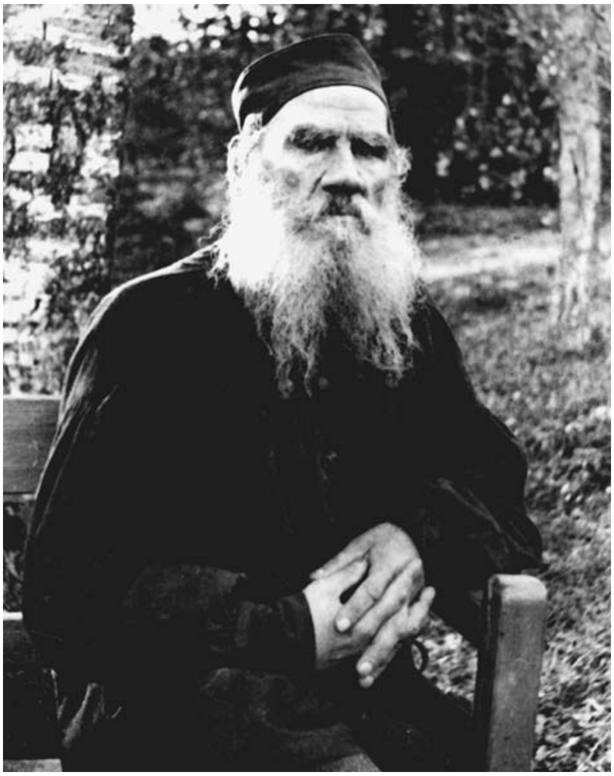
TOLSTOY, LEO

Lev Nikolaevich (Leo) Tolstoy (1828–1910) was born at Yasnaya Polyana, the Tolstoy family estate a hundred miles south of Moscow on August 28. He died on November 20 at a nearby railroad station, having fled in the night from an increasingly contentious marriage and a set of familial relationships that had been hardened in large part by Tolstoy's attempts to apply his radical moral beliefs to his own life. In the intervening eighty-two years Tolstoy became perhaps the most prominent novelist in an age and place of great authors as well as a vociferous critic of science and modernization.

Tolstoy's international fame rests primarily on two novels, *War and Peace* (1865–1869) and *Anna Karenina* (1875–1877). His fictional works also include short masterpieces such as "The Death of Ivan Ilyich" (1886), "The Kreutzer Sonata" (1889), and "Master and Man" (1895). In addition he wrote autobiographical accounts of his childhood (*Childhood, Boyhood, Youth* [1852–1857]) and his experiences as a soldier in the Crimean War (*Sevastopol Sketches* [1855]). With regard to issues of science, technology, and ethics Tolstoy's most relevant writings include a variety of short, passionate nonfiction works, particularly "What I Believe" (1884), "What Then Must We Do?" (1887), "On the Significance of Science and Art" (1887), "What Is Art?" (1898), and "I Cannot Be Silent" (1908), all of which address a confluence of moral and intellectual errors he perceived in modern life and thought at the turn of the twentieth century.



Leo Tolstoy, 1828–1910. Tolstoy was a Russian novelist, reformer, and moral thinker, notable for his influence on Russian literature and politics. *(The Library of Congress.)*

Tolstoy directed his most trenchant criticisms at the insensitive intellectuality of the urban elites, which he considered distant from the natural values of the land and its laborers; the modern Western adherence to science and its methods; and thinkers such as Auguste Comte (1798–1857), Georg Hegel (1770–1831), and simplistic interpreters of the philosopher Immanuel Kant (1724–1804) who built positivist historical and scientific doctrines on what he considered rickety evidence.

Despite his turn toward the simplicity of peasant agricultural values and the teachings of the Gospels, Tolstoy's commitment to a questioning, empirical worldview was deep. Tolstoy was never interested in a vague and disconnected mysticism. Those who consider themselves capable of circumscribing the infinite multiplicity of the world with their "scientific" theories were deluding themselves, he argued. People are not incapable of knowing or perceiving many of the causes or influences on which the natural and human world has been founded; it is simply that there are far too many influences, causes, and effects for people to remember and record, and to be able to integrate the available material in a scientifically conclusive manner. Positivistic science rests on a lack of respect for the multiplicity of the natural and human worlds. Assuming too much about human capabilities to know and understand is, in the world of social action and belief, morally dangerous.

Like his contemporary Fyodor Dostoevsky (1821–1881), whom he never met, Tolstoy was broadly concerned with the spiritual future of the human race. He attempted to confront the gradual movement away from traditional values with an almost Aristotelian emphasis on the permanent relationships of things, promoting the universality of natural and religious values of love and labor to which he believed the human heart responds. Although the West now knows him as the writer of large and perhaps infrequently read novels, his influence on writers and political dissidents such as Mohandas Gandhi (1869–1948) and Alexander Solzhenitsyn (b. 1918) has been enormous, and his thought provides resources for ethical assessments of science and technology that have not yet been explored fully.

TOOLS AND MACHINES

Tools and machines are almost universally thought of as beneficial, which would make their invention morally praiseworthy. Indeed, without tools it is difficult to see how human beings could survive, and the increasing adoption of machines shows that most people see them as salutary contributions to human affairs. Although isolated tools or particular machines may on occasion be criticized for their negative impacts, this is done mostly to improve technological implements or to reform their uses. Nevertheless, one may note important distinctions between tools and machines as such, and how these distinctions, independent of any particular uses, may be ethically significant.

Distinctions

What is the difference between a tool and a machine? This question is complicated by lexicographic shifts over time. The Greek and Latin words for machine (*mechane* and *machina*) name a kind of tool (*organum* or *instrumentum*) for lifting heavy weights. Classical mechanics identified six basic types of such machines: the lever, wedge, wheel and axle, pulley, screw, and inclined plane. Machines, unlike other tools, presented a conundrum: How do they enable human users to lift weights that would otherwise be beyond their power to move?

Unlike with a stick used for poking or scratching, which serves as a straightforward extension of some human operation, determining how machines work is more difficult. Aristotle's *Mechanical Problems* was an early attempt to solve the mystery concerning how machines do what they do, that is, how they work or operate. What happens is that all six simple machines function as machines by transforming a smaller force exerted over a longer distance into a greater force exerted over a shorter distance by means of a structured redirection of the force in question.

But machines in this premodern sense are just one kind of tool. All tools, even simple machines, require two types of direct human inputs: energy and guidance. The hammer is swung with the arm and guided by hand–eye coordination. By contrast, machines in a modern sense require only one type of direct human input: guidance. The difference is that between a human-powered and -guided bicycle and a human-guided car; a person does not pedal a car, but simply drives it.

After human beings have constructed them or found natural objects with properties such that they can be used as tools, any use will involve some energy and guidance from a user. The guidance, precisely because it constitutes the introduction of intelligence, involves skill. In this sense the skillful use of tools is different from the more passive use of other artifacts such as baskets, chairs, and houses. The coordination of human power inputs, as when a group of men operates a battering ram, and the substitution of animal and other nonhuman sources of power such as wind for human power, foreshadow the development of machines in the modern sense.

The standard definition for the modern machine is: "a combination of resistant bodies so arranged that by their means the mechanical forces of nature can be compelled to do work accompanied by certain determinate motions." Alternatively, a machine is an "assemblage of resistant bodies, connected by movable joints, to form a closed kinematic chain with one link fixed and having the purpose of transforming motion." (Both definitions are from Franz Reuleaux, who in the late 1800s formulated the modern science of mechanics.) Mechanics, or the science of machines, analyzes the ways forces are compelled and transformed to do work in terms of their structures (statics) and functional operations (dynamics).

Functions and Uses

Tools and machines have internal operations or workings that can be used for many different purposes. These operations are commonly analyzed in modular terms: Gears slow down or speed up motion. A cam transforms reciprocal into rotary motion. Although how tools and machines operate or function does not fully determine their uses, they place boundary conditions on or for possible uses. Indeed, when an inventor applies for a patent on a new machine, the inventor is required to specify both its (external) use and how (internally) it is designed to operate or function so as to make possible the intended use. Engineering design thus considers both extrinsic use and internal structure and operation, and is successful when it unites the two.

But just as with the tool–machine distinction, so that between function and use is difficult to nail down. In many instances the word *function* can be replaced by the words *working*, *operation*, or even *use*. One must be careful in speaking about functions not to create an imaginary ontological substance that is nothing more than projected use. But to say that the machine operations or functions of pounding, drilling, or rotating are the uses of pounding, drilling, or rotating shifts attention from the structure of the machine and how it works to the intentions or purposes of the user.

For engineers who focus on machines, then, machines and their component parts are as often distinguished by operations or functions as by uses. Indeed, it is precisely in this sense that classical machines are distinguished from tools. The machine works to increase force across decreasing distance in ways that other tools do not. Moreover, the working or functioning of tools as tools depends on human energy and skillful guidance; modern machines work or function with only human guidance. Because of this, using machines requires less human work and, by placing greater and greater power in human hands, makes consciousness or forethought an ethical imperative. One does not have to be nearly as conscious about what is going on when riding a bicycle as when driving an automobile.

In general the experience of using machines is different from that of using tools in terms of the decline in human energy input and a corresponding increase in human mental input. This transformation of the use experience is of ethical significance and is independent of any particular use. It is true no matter what kind of machine one is operating and what one is producing with it or where one might be traveling in it. No matter what kind of machines are involved, machine users are morally obligated to think more than tool users about what is going on. To some extent this shift in the character of the use experience may also be described as setting the pattern for living in a machine-dominated technological world.

TOTALITARIANISM

• • •

Totalitarianism is defined as a political system or regime in which the government seeks total control of society. This requires breaking down all the intermediate associations of civil society or turning them into agencies of the government, so that all that exists are, on the one hand, atomistic individuals and, on the other, the unity of the state.

Totalitarian systems have significant implications for science, technology, and ethics. Totalitarian governments rely on communications technology to spread an official ideology and to monitor subjects, while totalitarian control of the economy creates major hurdles to technological invention and innovation. Scientists face numerous ethical challenges in totalitarian systems, from ideological conditions often imposed on their research (a rejection of *Jewish science* in Germany and the promotion of Trofim Lysenko's genetics of the inheritance of acquired characteristics in the Soviet Union) to the kinds of projects on which they may be required to do research.

Features of Totalitarianism

The two classic scholarly examinations of totalitarianism are Hannah Arendt's *The Origins of Totalitarianism* (1951) and Carl Friedrich and Zbigniew Brzesinski's *Totalitarian Dictatorship and Autocracy* (1956). Friedrich and Brzesinski identify totalitarianism as a unique political order, opposed to democracy yet distinct from authoritarianism and dictatorship, and characterized by six key features. The first is an official ideology. In totalitarian systems, this ideology includes a blueprint for remaking society, either in ethnic or racial terms (as in the case of *fascism*) or in class terms (as in the case of communism) as well as justification for the monopoly of political power.

The second basic feature is a single mass political party, usually with a single leader, with a monopoly of political power. This group is part of the total penetration of society by the rulers. Other rival group identities in society—religious organizations, voluntary associations, other political parties—are either destroyed or brought under the control of the party.

The third characteristic is the existence of a secret police force and rule through the development of terror in the population. Because the leaders of the political system seek to penetrate and remake society, they are ruthless in dealing with political and cultural opponents. Any autonomous organization of activities is seen as a threat and all who are not active in their support of the ruling party are possible targets of harassment by the secret police. Even active, and loyal, party members are not immune, however. The purges of the Communist Party under Stalin, for example, were aimed at party members who were deemed not diligent enough in their identification and condemnation of potential threats to the system.

The fourth feature is its monopoly over the means of communication. Although it is impossible to control all forms of communication, totalitarian regimes seek to limit the autonomous flow of information. Control over information is a crucial component in solidifying the ideology in the minds of the population—facilitating the establishment of legitimacy for the leaders, justifying its monopoly of political power, and creating support for its social blueprint.

The fifth characteristic, highlighted by Friedrich and Brzezinski, is the monopoly over weapons in society. This is not a feature unique to totalitarian systems (many democracies control access to weapons by the general population). It is, however, a necessary feature of totalitarian control.

The final feature is a centrally controlled economy. Control over the economy serves three purposes. First it assures the social blueprint; economic development can be structured in the way most supportive of the plan for remaking society, and the workplace can be used as an arena for socializing the masses in support of the system. Second it assures access by the state to the resources it requires to maintain power at home and expand its influence abroad. Finally, and perhaps most important, a centrally planned economy makes people dependent on the state. Thus, while arguably economically inefficient, a planned economy is politically efficient.

Arendt proposed a similar description of totalitarianism, emphasizing its ability to *atomize* the population (controlling the ability of the population to engage in group activities autonomous from the party or the state) and its effective use of ideology. The development of a mass adherence to official ideology is essential for the formation of legitimacy in totalitarian systems. Control over communications—particularly the educational system and mass media—made the development of such adherence theoretically possible.

Totalitarianism in Practice

In practice totalitarianism has never achieved the complete penetration and control of society. Although people were careful in public, and often went through the motions of participating in state-sponsored mobilization efforts, they led separate public and private lives. Terror crept into the private lives of individuals—one had to be extremely leery of speaking ill of the government even among one's good friends—but people also partook in the activities of normal life: shopping, attending the ballet, walking in the park, and so on.

Because the ideal differed from the reality of totalitarian life, some political scientists and many social historians (see, for example, writings by Sheila Fitzpatrick and Stephen Cohen) criticized the totalitarian model for overemphasizing politics, underemphasizing the role of society, and assuming a system of tight, top down control devoid of political and social conflict. The totalitarian model of politics assumed that everyone was completely controlled and atomized, and that leaders never responded to society. But in the Soviet case, leaders sometimes appealed to constituencies, and policies were, at times, sparked by initiatives from below.

The three examples in the real world that came closest to approaching the totalitarian ideal have been Adolph Hitler's Nazi Germany (1933–1945), Joseph Stalin's Soviet Union (1929–1953), and, more recently, the Taliban-run system in Afghanistan. None of these, however, achieved full realization of the totalitarian ideal. These three cases provide helpful examples of three forms of totalitarianism: fascism, communism, and Islamism. Friedrich and Brzezinski argue that fascist and communist dictatorships were basically alike, though one can identify different points of emphasis between the two forms of government. Fascism is a form of totalitarianism that emphasizes racial and/or ethnic superiority, engages in militarism, and argues for the need for a dominant state to develop the capacity of the superior race and/or ethnic group. According to Barrington Moore (1966), fascism develops as the result of an alliance among the state, the land-owning elite, and the industrial bourgeoisie. Communism emphasizes the remaking of society to eliminate economic exploitation through state control of the means of production. Moore argues—ironically, given Karl Marx's prediction of workers' revolutions in the most economically developed countries—that communism developed where the lack of a middle class and the presence of a large and disgruntled peasantry allowed revolutionary leaders to seize control of the government in the name of destroying the old economic order. In both forms of totalitarianism in practice, increasing control over the economy and society were justified through the claim that one or more groups (for example, capitalists or Jews) were *enemies* of the people.

Islamism is a more recent variant of totalitarianism. Its ideology is anti-western, critical of modernization, and emphasizes the dominance of Islamic law—as interpreted by the leaders—over society.

Science, Technology, and Ethics

The totalitarian goal to penetrate and remake society completely has significant implications for science and technology. The control and monitoring that characterized totalitarianism shaped the practice of science dramatically. In the ideal totalitarian system, scientists are less free than in any other type of system to pursue their research as they see fit. Scientific research and related technological advances become the property of the party-state. This situation poses ethical dilemmas for scientists. On the one hand, the likelihood that the fruits of their labor could be used in unpleasant ways by the state creates a disincentive for scientists. On the other hand, working through the official scientific channels is the only way for such scientists to conduct their research. Thus, although in practice scientists in systems with totalitarian features conducted pioneering research, such scientists were limited both by the imperatives of the totalitarian ideology and by their personal ethical concerns about the consequences of their research.

Technology is a necessary tool in the transformation of tyranny into totalitarianism. Friedrich and Brzezinski emphasize technology in their discussion of totalitarianism, arguing that this type of political system could only have arisen in an era of modern technology. They highlighted the role of technology in allowing control over communications and making possible large scale economic planning, as well as in facilitating the monitoring of everyday life by the secret police. Totalitarian governments direct scientists to develop such technology.

Though technology is a necessary part of a modern totalitarian state, technology was not easily absorbed into the totalitarian system in practice. Not all technological products of scientific research found a receptive audience in the party-state bureaucracy. The economic planning approach that was a feature of the Soviet system, for example, made it difficult to incorporate technology. Many economic planners feared the introduction of new technology because of the uncertainty that accompanied the introduction. As a result, when there was a clear goal to increase production, and when this increase could be achieved through the addition of more inputs into the system (extensive growth), the totalitarian planning system worked fairly well. As the global economy moved in the direction of growth resulting from technology-driven improvements in efficiency (intensive growth), the Soviet planning system lagged behind.

Finally technologically-conditioned improvements in communication posed serious problems for totalitarian systems. While technology made monitoring of large numbers of citizens possible in the middle part of the twentieth century, the growth of fax machines, personal computers with printers, cellular telephones, and Internet connections by the early twenty-first century, provided citizens in dictatorial countries with access to information from outside the country and enabled them to compose and spread antigovernment messages quickly and relatively anonymously. Technology may allow Big Brother more ways to monitor citizens, but it also provides citizens more opportunities to engage in subversive activities.

TOURISM

The ancient Greek philosophers thought that leisure was a necessary component of human flourishing even though freedom from the demands of necessity was possible only for a few people. Modern industrialized countries have achieved economies that for many of their members facilitate leisure, or, as Thorstein Veblen (1857–1929) suggested, the "non-productive consumption of time" (Veblen 1994 [1899], p. 43). In this context tourism is a form of unproductive consumption that is peculiar to the technologically advantaged. Tourism, however, also has become a major stimulus to economic production.

Purpose and Effects

Tourism is travel based on desires to relax, sightsee, appease curiosity, satisfy a sense of adventure or an adventurous self-image, compete with one's peers or colleagues, re-create images of paradise or luxury or the exotic, and escape. Tourism affects the economies and cultures of destination sites in both positive and negative ways. Those locales may organize their production activities around the satisfaction of tourists' demands for leisure, fantasy, adventure, or knowledge, activities that may operate to the detriment of local cultures.

As with any human relations involving production and consumption, even an activity centered on leisure, tourism thus calls for ethical and philosophical reflection. Only recently, however, has the phenomenon of tourism become a subject of ethical consideration, largely through its connection to other concerns, such as environmental degradation (to which "ecotourism" is one response), economic development, and cultural impacts.

Distinctions

The word *tourism* is derived from the Latin *tornus* and before that the Greek *tornos*, referring to a tool for making a circle (the word *turn* comes from the same root). Taking a tour thus implies circumnavigating, and the term *tourism* initially had depreciatory connotations of superficiality. In the early twenty-first century the connotations are more complex.

Tourism must be distinguished from other kinds of and motivations for travel. Economic and political migration, for example, is not new, but its increased extent is considered a significant element of globalization (Held, McGrew, Goldblatt, and Perraton, 1999). Contemporary economic migration includes the journeys made by migrant laborers and travel for business purposes in a postindustrial age of transnational corporations and labor markets, prompted also by international disparities in wealth and movement, especially between less developed countries and Organization for Economic Cooperation and Development (OECD) countries. Political migration includes refugees from crisis or conflict areas. Tourism, in contrast, has no material imperative, although one could argue that advertising and the media create a perceived necessity for tourism.

Flâneurism, a form of consumption activity that is much closer to tourism, is leisurely and detached urban promenading among the crowds, allowing spontaneous perceptual encounters to determine the directions of one's movements and thoughts. Although the expression came from the poet Charles Baudelaire (1821–1867), the philosopher Walter Benjamin (1892–1940) is perhaps the preeminent exponent of flâneurism through his writings on walking in Paris (Benjamin 1999). Voyeurism suggests a disengaged onlooker without a commitment to the local environment and thus overlaps with many common tourist practices. At its most benevolent voyeurism is the observation or immersion experience of other cultures in a way that allows one to extricate oneself when the experience becomes uncomfortable or problematic. The observation or experience, though perhaps immersive, allows a relatively easy exit from the situation, unlike the case for members of the local culture. There is a fine line between "authentic," engaged traveling and voyeurism.

Tourism is first and foremost an industry. It is one of the largest modern industries, accounting for hundreds of billions of dollars per year, and is the most significant industry for many countries. According to the World Tourism Association, which became an executing agency of the United Nations Development Programme in 1976, tourism grew from 456 million international travelers in 1990 to more than 700 million in 2002. Tourism appeared as both a word and a phenomenon in the early 1800s in association with increases in the means of transportation brought about by the construction of roads and highways, advances in carriage technology, and the building of the railroads. The current growth in tourism is due largely to the same processes and technologies that drive and constitute globalization and its consequences, including ease and frequency of transport and the growth of information and communications technologies. Economically advantaged people increasingly seek more far-flung and diverse destinations for vacation and pleasure.

The idealized motivation driving some forms of tourism is, as the Spanish-American philosopher George Santayana (1863–1952) suggested, that "there is wisdom in turning as often as possible from the familiar to the unfamiliar: it keeps the mind nimble, it kills prejudice, it fosters humor" (Santayana 1968, p. 15). Arguably, however, tourism today is much more epistemically ordered even when it takes on authenticity-seeking or adventurous forms.

Varieties of tourism or leisure travel have been distinguished in regard to the authenticity of the experience of other cultures and places (see Boorstin 1961). Dean MacCannell (1999 [1976]) suggests that actual gradations in the search for authenticity resist polar categorizations of tourism as authentic or inauthentic. Rather, destination places, tourist objectives and perceptions, local expectations and dependencies, “staged authenticity” (MacCannell 1999 [1976], title of chapter 5), and the dynamic nature of cultural activities and artifacts render such categories indistinct. The global journeying that through the years has created “backpacker meccas” in places such as Goa (India), Kathmandu (Nepal), and Lamu (Kenya) may seem a more authentic quest for rich cultural experiences in comparison to sheltered resort vacationing (enclave tourism), in which the actual place or culture is insignificant. Authenticity, however, is framed by the tourist’s cultural expectations as much as it is a property of the experience of foreign destinations. The “inauthentic,” moreover, may involve a relatively benign mutual exploitation or exchange between tourists and locals.

Ethical Issues

The paradox of the authenticity-seeking traveler is that the more tourists vacation in a particular place, the more a tourism infrastructure is developed and the more that place comes to resemble the tourist’s home, causing local cultural and environmental deterioration. Pico Iyer (1989) has written about the unusual juxtapositions and hybrids of different cultures one finds across the globe as a result of the forces of globalization and tourism. This paradox creates a dilemma regarding whether to visit a place or to tour at all. The question for anthropologists and environmentalists is whether it is appropriate to visit a fragile culture or a pristine environment when one’s visitation contributes to its alteration. Furthermore, as a tourist destination becomes more developed and attracts increasing numbers of visitors, many tourists may look elsewhere for less-traveled destinations. As a consequence they may perpetuate the same cycle, and some overdeveloped areas ultimately may witness a decline in the visits on which their economies depend.

From the perspective of those who welcome the local tourist industry may provide much-needed income and infrastructure development, but the cycle of unmanaged tourism development ultimately places those economic benefits at risk. Although income is generated locally from the industry, the distribution of benefits is uneven, and there may be severe damage to local cultures, other parts of local economies, and the natural environment. Such considerations have generated antitourism and protourism positions, with the former generally concerned with the environmental and cultural impact and the latter with economic development.

Tourism raises specific and clear ethical and cultural concerns in regard to some of its manifestations, for example, sex tourism and reality tourism, with the latter involving poor or oppressed people inviting visitors to observe and experience their living conditions (an example of voyeurism). Opponents of tourism point to increased child labor, greater crime rates, and increased prostitution.

Tourism may contribute indirectly to resource conflicts and tensions with traditional land-use practices in addition to eroded cultural values and commodification of traditional practices. Economically it can lead to increased prices for basic goods for local people and higher costs for infrastructural development, diverting resources from other critical social sectors. Environmentally tourism may lead to the depletion of natural resources and pollution (air pollution, sewage, solid waste) in addition to problems such as coral reef anchoring, trampling, construction and deforestation, and disruption of ecosystem processes. Other common foci of criticism include the large amounts of fuel burned by airliners transporting tourists to and from their destinations, the construction of golf courses in environmentally fragile areas, and the aesthetic pollution of overdevelopment.

Proponents of tourism point to new infrastructure development for residents, greater civic participation, and reinvigoration of cultural traditions in addition to the mutual understanding and respect that may result from cultural exchange. Tourism may contribute to state revenues and foreign exchange earnings, increase employment opportunities, and help local economies grow. Environmentally tourism may contribute to new investments in conservation efforts, lead to regulatory measures and improved management practices, and provide new forms of employment. It also may indirectly involve the development of better technologies for conservation programs through technology transfer and the growth of science-based programs for environmental management.

The distinction between negative and positive effects depends principally on the specific contexts, rendering the prospects of a global management program extremely challenging. Environmental impacts, however, can have a far-ranging effect beyond the particular tourism context. This contributes another dimension to already complex ethical questions of obligations beyond borders, especially in a globalizing era.

The expansion of ecotourism is a major response to such concerns over environmental and cultural degradation and an attempt to invigorate local economies that otherwise are dependent on environmentally unsustainable practices. In some cases such practices are directly related to the tourism industry (for example, deforestation in the Himalayas for wood-fire cooking); in others the practices may be the sole (and sometimes illegal) source of income (such as rain forest logging).

Ideally, the goals of ecotourism are to combine ecological and cultural awareness with sustainable local economies and resource use and preserve local cultural identities and values. Ecotourism may include what is sometimes referred to as "scientific tourism." This form of tourism may range from volunteer fieldwork in the collection of scientific data to tourism accompanied by an ecologically informed guide. The growth of ecotourism in some areas, however, often represents a superficial assuaging of tourists' environmental concerns and expectations rather than an actual advance in conservation practices. Cheating on the ecotourism designation is common in some areas in the form of advertising regular activities, accommodations, or management practices as "eco-friendly" to attract unsuspecting tourists concerned about ecological impact. This has prompted efforts to certify and monitor ecotourism companies. Nevertheless, genuine ecologically benign tourism, even if it is possible, seeks to attract tourists to fragile places, thus re-creating the paradox mentioned above.

More recently these collective considerations have found expression in international forums. The World Tourism Organization (WTO), which is affiliated with the United Nations, has drafted a "Global Code of Ethics for Tourism" (1999). The code consists of ten general principles intended to guide "stakeholders" and supplement the tourist industry's emphasis on the market and private enterprise aspects of tourism. The WTO seeks to encourage "sustainable tourism," encompassing some of the considerations raised above. The United Nations Environmental Programme also attempts to integrate tourism considerations with international agreements such as the United Nations Convention on Biological Diversity.

The intersection of facilitating technologies, economics, and culture, along with environmental impacts, generates ethical considerations and dilemmas involving tourism. The new directions of tourism remain to be seen as globalization proceeds. Some places focus on the tourist industry to boost economies whose other industries may be stagnating or nonexistent. However, as a result of the fickle nature of tourism and its potential for the destruction of local environmental and cultural resources there is urgent cause for concern over dependency on tourism, particularly in developing countries. Ecotourism may provide only a temporary answer to economic and ecological realities without a more closely regulated and monitored industry or different global economic arrangements. If tourism is inevitable, perhaps the best option is the development of a global regime of "sustainable tourism." The Kingdom of Bhutan may provide an educative example, as it limits the numbers of visitors per year in the name of sustainable environmental and cultural considerations while trying to sustain economic well-being.

These issues perhaps may be overcome through shared, direct experience of places such as the Nepalese Himalayas, the biodiverse rain forests in Costa Rica, and the coral reefs of the South Pacific or of the peoples of New Guinea, Lapland, and central Africa. Perhaps what is needed is an ethics of tourism that is attentive to character, obligations, equity, and rights so that the benefits of tourism may flourish without doing harm. Perhaps there is also a need for a practical ethics of tourism that can admit that sometimes it is better not to be a tourist at all.

TRADEOFFS

Tradeoffs occur under constraints similar to zero-sum games in which one participant's gain (or loss) is balanced by another's loss (or gain). A tradeoff is an exchange that occurs as a compromise, giving up one set of interlocked advantages and disadvantages in order to gain another, more desirable set. The benefits that are foregone in a particular case are often referred to as the opportunity-costs of that decision. Many personal and policy decisions regarding scientific research, technological development, and the use of technological products, processes, or systems depend either consciously or unconsciously on accepting tradeoffs. In many cases so-called ethical criticisms of science and technology are themselves criticized as ignoring the need for tradeoffs. Analysis of the concept of tradeoffs is thus an important feature of any general appreciation of relations between science, technology, and ethics.

Examples in Science and Technology

Human life is saturated with tradeoffs because time is a limiting resource. People can only perform a limited number of activities and thoughts in a given period of time. Usually, the routine of life masks the tradeoffs made and opportunity costs incurred.

ECONOMICS AND SCIENCE. People are perhaps most aware of tradeoffs in financial choices because money is another limiting resource. For example, with the money I have, I can choose between buying a car and taking a vacation. As Kenneth Arrow (1974) noted, much of economics involves saying "this or that, not both" (p. 17).

Budget allocation scenarios present important instances of tradeoffs in science as well. For example, the National Institutes of Health (NIH) experienced annual increases of fifteen percent between 1998 and 2003. Such large growth was justified by the potential health benefits of new advances in biomedical research, but some complained that the physical sciences and engineering suffered as a result of this prioritization. Other tradeoffs occur further downstream in the allocation of these funds through competitive grant processes. At the NIH, for example, decisions must be made about which diseases to prioritize and which researchers and facilities are most qualified to carry out that research. Indeed, this illustrates a more general point that prioritization is one way of dealing with tradeoffs, and the failure or inability to set priorities is a failure or inability to appreciate the reality of tradeoffs.

ENGINEERING. Tradeoffs are essential to both the internal operations of engineering and architecture as well as their social interactions. According to Edward Wenk (1986), "The most demanding skill in engineering design may . . . be the *acute weighing of tradeoffs*" (p. 53). Different materials have different advantages and disadvantages for a given project and competing goals such as beauty, efficiency, responsiveness, and durability must be traded off against one another.

But tradeoffs in the design and implementation of technology are not an insular affair, limited only to considerations of material and design constraints. Another important factor in engineering tradeoffs is the public perception of risk. Engineers must incorporate safety margins and/or redundancy into their designs in order to reach socially acceptable levels of risk. These extra measures impose additional costs and other constraints, which can lead to declines in efficiency or functional performance.

Wenk demonstrated how political and financial aspirations can be traded off against safety in the use of technology. In the 1980s several highway bridges collapsed, but the problem was not poor design or age. Rather, political leaders caved into the pressure from trucking lobbies to permit greater truck weights by relaxing load limits. Citing the costly but failed U.S. federal bailout of railroads and the persistent pursuit of the Strategic Defense Initiative despite signs of systematic problems, he wrote, "the more massive a technology, the greater seems to be the political momentum for implementation and the greater the difficulty in identifying the tradeoffs occasioned by its accomplishment" (p. 38). Wenk also speculated about the influence of political concerns on the ill-fated *Challenger* shuttle. It was launched on the morning of the State of the Union address, which may have affected the managerial decisions about how to treat warnings of a possible failure of the O-rings. These cases point out the ethical responsibility of engineers when political considerations are traded off against safety concerns.

APPLICATIONS. Yet Wenk's most important point is that every choice involving science and technology presents tradeoffs because technological innovation and implementation are not unqualified goods. There are disadvantages to go along with the advantages and costs to go along with the benefits. This symmetrically implies that forgoing or somehow altering the pursuit and application of knowledge presents benefits as well as costs. For example, participants in the lengthy Environmental Impact Statement (EIS) process concerning the construction of a wind farm in Nantucket Sound, Massachusetts, were weighing many tradeoffs, including the one between clean energy and the beauty of a relatively pristine seascape.

The case of chlorofluorocarbons (CFCs) is another example. Industrial and political leaders were at first unaware that the use of CFCs involved tradeoffs between human and environmental health and the conveniences of widespread and cheap refrigeration. The international decision to phase out the use of CFCs was another tradeoff between the costs of such a large-scale economic transition and improved human and environmental health. Companies that produce hazardous wastes face tradeoffs between the costs of containing and storing that waste and the potential liability for damages to human and environmental health. As they attempt to minimize costs, the risks to health usually increase (Sewall 1990). Another example stems from the threat of terrorist attacks and the resulting tradeoffs between national security and scientific freedom of inquiry. In these cases, decisions must be made by public leaders, but many tradeoffs involving the use of technology are made by individuals. For example, those who choose general over commercial aviation accept the tradeoff of increased cost and risk for greater convenience.

RISKS. John Graham and Jonathan Wiener (1995) argued that as technology has come to saturate modern life, government has increasingly adopted the role of reducing risks to environmental and human health. They point out that risk tradeoffs often confound these efforts, as well-intentioned efforts to reduce some risks can turn out to increase others. Efforts to counter a "target risk" can generate "countervailing risks," which are commonly known as side effects (medicine), collateral damage (military tactics), or unintended consequences (public policy). If decision makers are well informed, they may be able to reduce overall risk by choosing "risk-superior" options, but sometimes risk tradeoffs are unavoidable.

Risk tradeoffs occur at both personal and societal levels. For example, a woman dealing with menopause can take hormonal replacement therapies to ward off the risk of osteoporosis and chronic pain, but in so doing she may increase the risk of uterine and breast cancer. Similarly, visiting a hospital can reduce risks from trauma and illness, but it can also lead to other illnesses. On a social level, decision makers must choose when to chlorinate drinking water, which kills harmful microbes but may add a cancer risk. Spraying hot water on the beaches of Prince William Sound, Alaska, after the 1989 *Exxon Valdez* oil spill reduced risks to nearby otters and birds, but may have harmed the longer-term ability of the ecosystem to recover by killing certain marine organisms and microbes. Grahm and Wiener proposed a risk tradeoff analysis framework to help decision makers grasp the entire portfolio of risks that science and technology can present within a given decision.

Tradeoffs as an Explanatory Concept

The notion of tradeoffs is important not only in decision making but as an explanatory term in several scientific disciplines, including economics and evolutionary biology. British economist Lionel Robbins called economics the study of human behavior as a relationship between ends and scarce means that have alternative uses. Indeed, microeconomics rests largely on the math of constrained maximization (for example, Lagrange multipliers). Robbins' definition of economics shows its close connection to ethics and politics as all involve the assessment of social institutions and the consequences of alternative decisions. The ethics of political-economics derives from the fundamental tradeoffs posed by scarcities of land, labor, and capital. Even social programs that do achieve their goals leave society with fewer available resources to further values in other policy areas. Steven Rhoads (1985) stated "spending and regulatory decisions that use scarce resources . . . incur costs in terms of forgone alternatives (that we no longer have the capacity to undertake) elsewhere" (p. 11). But economic activity is not entirely a zero-sum game. For example, comparative advantage can increase overall output and welfare if countries specialize their production processes and engage in trade. Similarly, although many tradeoffs exist between environmental protection and economic growth, there are several cases where environmentally friendly practices are also most cost-effective.

Rhoads (1985) noted that economists and engineers often clash in their understanding of opportunity-costs and tradeoffs. Engineers, he argued, have a narrower conception that revolves around materials selection, whereas economists account for all social costs. The former ask about tradeoffs between using steel and reinforced concrete in building projects, whereas the latter consider ways to solve the problem without building at all. Their differences also point out contrasts in the meaning of efficiency. Engineers push for the implementation of the latest technological innovations, whereas economists account for the tradeoffs involved in replacing older technologies. The former is the path to increasing technological efficiency, whereas the latter implies that economic efficiency takes wider social costs into account.

Although it is true that economic transactions are not always zero-sum games, there can be a tendency by some to underemphasize the importance of tradeoffs in some areas. The broken window fallacy, for example, states that when a child breaks the baker's window, he or she actually spurs economic activity. After all, the baker must buy a new window, which gives money to the window-maker to spend on new shoes, etc. However, "hidden costs" are ignored in this calculus. The money spent by the baker on a new window would have been spent on shoes. Now, for the same cost, instead of a window and shoes the baker only has a window.

The Panglossian attitude of the broken window fallacy has also been attacked in evolutionary biology. Stephen Jay Gould and Richard Lewontin (2001) critiqued the dominant adaptationist program, which atomizes an organism into its traits. It then explains that an organism cannot optimize each trait without imposing expenses on others: "The notion of 'trade-off' is introduced, and organisms are interpreted as best compromises among competing demands" (p. 77). Organisms are presented as the result of an optimization problem, where "each trait plays its part and must be as it is" (p. 77). Gould and Lewontin borrowed the metaphor of spandrels to argue that organisms must be analyzed as integrated wholes with "Baupläne," or phyletic and developmental constraints. These constraints, they contended, are more important in explaining evolutionary change than selective forces. The plurality of tradeoffs between selective pressures, random forces, and various constraints, rather than strictly between selective forces, expands the relevant foci of analysis.

Ethical Analysis

Tradeoffs can be abstracted into a taxonomy of competing goods, including equity, efficiency, freedom, and security (see Okun 1975). Indeed public policy, by virtue of being public, tends to require tradeoffs due to a plurality of views and interests. Science and technology play major roles in several policies that make tradeoffs among social priorities, between costs and risks, between various sectors of the population, and between long- and short-term timescales (Wenk 1986).

The latter tradeoff has become increasingly important as technological capacities have increased our power to create negative consequences deep into the future. This tradeoff is often posed as one between short-term gains and obligations to future generations, although the degree to which this is an ethical concern in any given circumstance is usually contested. Technology-induced displacements of the workforce also seem to create tradeoffs between long-run, aggregate gains and short-term, localized losses.

The development, use, and regulation of technologies pose many other ethical dilemmas in the form of tradeoffs. Some of the most charged issues involve tradeoffs between economic growth and human health and safety. For example, regulations on pollution emissions and synthetic chemicals protect health and safety, especially of workers who come in close contact with those pollutants and chemicals. Similarly, traffic laws and regulations on automobiles ensure some measure of safety. Theoretically, banning pollution, chemicals, automobiles, and other dangerous technologies could save millions of lives annually. Yet even marginally increasing restrictions on certain emissions (let alone banning them) can bring major tradeoffs that pose the difficult question of how much a human life is worth. Rhoads (1985) cited a proposed 1980 benzene emission standard by the U.S. Environmental Protection Agency (EPA) that would have imposed large costs on industry but would not prevent a case of leukemia until 37,000 years had passed. The estimated cost of saving one life was $33 billion. Rhoads argued that decision makers can minimize opportunity-costs by investing money in other areas (for example, traffic safety) where saving lives costs much less.

Cases such as this raise the question of how risks should be measured (for instance, what toxicological dose-response model) and how they are perceived by different elements of society. They also highlight the fact that the tradeoff concept itself depends upon a consequentialist ethic. One must be willing to base a decision on the consequences of alternative course of action to even participate in the logic of tradeoffs. A deontologist who believes it to be immoral to jeopardize human life no matter what the consequences will not accept the tradeoffs mentioned above. They would argue that $33 billion is not too much to pay to save a human life, because protecting human life is considered an inviolable duty.

Another important insight is that individuals may make different decisions about tradeoffs depending on how they encounter information. For example, Norman Augustine (2002) presented his students a hypothetical opportunity of investing in a new product that would create millions of jobs and enhance the quality of life for most people. He received an enthusiastic response, but then he adds that the product would kill a quarter of a million people every year. None of the students remained interested in investing, and most said the product should be banned. He then tells them that he is referring to the automobile. Tradeoff decisions clearly depend on cultural norms, personal experiences, and the socio-psychology of risk perception as much as they do on a rational tabulation of relative costs and benefits (see Slovic 2000).

Whether performed consciously or unconsciously, every time new knowledge is sought and new technologies are applied, a tradeoff has been made. In many cases, the bundle of benefits and costs chosen is obviously more desirable than the forgone alternatives. However, in other instances there may be considerable disagreement on whether and how to proceed. These cases pose challenging questions of who should make such decisions and how they should be made.

Decision makers have several tools for making tradeoff decisions. On the technical end, a tradeoff calibration can be used, which involves filling lookup tables by balancing different objectives. For example, this tool can help an engineer who wishes to increase torque while restricting nitrogen oxide emissions. Economic tools include risk-cost-benefit analyses, revealed preferences, and expressed preferences (for example, contingent valuation and willingness-to-pay surveys). Psychological tradeoff analyses show cross-cultural differences in the interactions between an individual's moral reasoning and the consequences of decisions (see for example Swinyard et al. 1989). More strictly governmental tradeoff analysis techniques include advisory panels and institutions dedicated to assessing decisions and assigning accountability for successes and failures. Decision makers can be guided through the oftentimes high-stakes tradeoffs presented by science and technology by specialized assessment institutions such as the U.S. Office of Technology Assessment (OTA), which existed from 1972 to 1995.

Decision making is inherently forward-looking, so one of the biggest challenges posed by many tradeoffs involving science, technology, and society is uncertainty about likely future outcomes of alternative decisions. Increasing information is often a worthwhile means to reduce uncertainties and increase foresight, but this must also be accompanied by decision-making structures capable of synthesizing that information. Furthermore, uncertainties will remain. For example, regulating toxic chemicals involves tradeoffs between costs and acceptable risks. But the situation is complicated by uncertainties in modeling dose-response functions, ecological interactions, and economic impacts. Eliminating these uncertainties is often impossible, at least on the time-scales required by decision makers.

Therefore, many tradeoff decisions must be made not between two (or more) well-characterized competing bundles of advantages and disadvantages, but rather between two (or more) dimly understood future scenarios. Partially for this reason, Edward Wenk (1986) argued that tradeoffs require anticipatory governments capable of assessing different alternatives and their probabilities. He also insisted that tradeoffs involving science and technology call for participation by an "attentive public" not just political, commercial, and scientific elites. Such assessments raise the fundamental question of which alternative will make us better off. Thus, they are the responsibility of all citizens, not the domain of any particular expertise.

TRANSACTION-GENERATED INFORMATION AND DATA MINING

The term *transactional information* was first employed by David Burnham (1983) to describe a new category of information produced by tracking and recording individual interactions with computer systems. Unlike most human interactions, those processed by computer systems are easily recorded and aggregated to yield knowledge about individual behaviors that would have otherwise been more difficult to acquire and often less complete. Known as transactional-generated information (TGI), it is information acquired from commercial and noncommercial transactions involving individuals in many increasingly computerized day-to-day activities. Examples of commercial transactions include withdrawing money from an ATM machine or credit-card shopping; examples of noncommercial transactions include checking books out of a library or participating in an online educational program. TGI can be contrasted with but does not exclude more traditional information such as a person's age, place of birth, education, work history, and so forth.

The Special Character of TGI

The practice of collecting information about persons is hardly new. Governments have collected census data since the Roman era. But through the twentieth century, the few records that existed about individuals contained information about when and where they were born, married, worked, or owned property. Information about the day-to-day transactions of individuals was rarely, if ever, collected and stored. Even if it had been collected, it would have been difficult to process and store. Armies of clerks would have been needed to sort through this information and huge warehouses or repositories would have been required to store the physical records. Those conditions changed, of course, with the advent of computers and electronic databases.

Additionally much traditional information about persons is gathered in ways that require conscious acts of disclosure on the part of those providing it. When individuals fill out census forms, they are generally aware of providing information about themselves to a government agency. By contrast, with TGI data subjects are not always consciously aware they are providing information about themselves to some data collector. When motorists use the convenience of an Intelligent Highway Vehicle System, such as E-ZPASS, they seldom realize that a transaction occurs each time they pass a toll plaza. Not only is a motorist's pre-paid account with E-ZPASS debited, but the exact time of passing through the toll booth is electronically recorded and stored.

Cookies

Next consider a kind of *on-line* transaction involving typical Internet users, who may have no knowledge that TGI is being collected. Via programs called *cookies*, TGI is routinely gathered about users who visit web sites. Cookies technology enables web site owners to collect certain kinds of data about users who access their sites, including information about the user's Internet Protocol (IP) address and Internet Service Provider (ISP). This information is stored in a text file placed on the hard drive of the user's computer and then retrieved from that computer and resubmitted to the web site the next time the user accesses it. It provides the operator of a web site with information about a user's on-line browsing preferences. Transactions involving the use of cookies to exchange data between users and web sites typically occur without the knowledge and consent of users.

Since their implementation on the web in the 1990s, the use of cookies technology has been controversial. The owners and operators of on-line businesses and Web sites, who defend the use of cookies, claim that they are performing a service for repeat users of a web site by customizing a user's means of information retrieval. For example, they point out that cookies technology enables them to provide a user with a list of preferences for future visits to that Web site. Defenders of cookies also note that users can elect to disable cookies via an option provided on their web browsers.

Privacy advocates, on the other hand, argue that because cookies technology involves the monitoring and recording an individual's activities while visiting a Web site, as well as the subsequent downloading of that information onto a user's PC (without informing the user), the use of cookies clearly cross the privacy line. They also point out that many web sites do not permit users to disable cookies, and they note that users must first be aware of cookies before they can opt out (i.e., reject cookies) on web sites that allow them to do so. Some privacy advocates also worry that information gathered about a user via cookies can eventually be acquired by on-line advertising agencies, which could then target that user for on-line ads.

Merging and Mining TGI

Because TGI exists in the form of electronic records, it can be easily exchanged between databases in a computer network; these records can also be *merged*. *Computerized merging* is the technique of extracting information from records about individuals (or groups of individuals) that reside in two or more databases, which are often unrelated, and then integrating that information into a composite file.

Information gathered about an individual's on-line activities and preferences via Internet cookies can also be merged with information about an individual's transactions in off-line activities in physical space to construct a general profile. In 1999 DoubleClick.com, an on-line advertising firm that used cookies technology to amass information about Internet users, proposed to purchased Abacus, an off-line database company. DoubleClick's pending acquisition of Abacus was criticized by many privacy advocates who feared that the on-line ad company would combine the information it had already acquired about Internet users (via cookies) with the records of some of those same individuals that resided in the Abacus database.

DoubleClick would have been able to merge web profiles with off-line transactional data about consumers. In January 2000, however, DoubleClick was sued by a woman who complained that her right to privacy had been violated by that company. The woman filing the suit claimed that DoubleClick's business practices were deceptive because the company had quietly reversed an earlier policy in which it provided only anonymous data about Internet users (acquired from cookies files) to businesses. Because of public pressure, DoubleClick backed off its proposal to purchase Abacus. However, because of the controversy surrounding the DoubleClick incident, many realized for the first time the kinds of privacy threats that can result from the merging of electronic data. And even though the DoubleClick-Abacus merger did not materialize, the danger of future mergers of this type remain.

In addition to being merged, TGI can also be *mined*. *Data mining* is a computerized technique used to reveal non-obvious patterns in data that otherwise would not be discernible. Data-mining technology also generates new classifications or categories (of individuals), which are not always obvious to the individuals who populate them. Some of these newly discovered/created categories or groups suggest *new facts* about individuals who constitute these groups. For example, a young executive with an impeccable credit history could, as a result of data-mining technology, end up being identified as a member of a (newly generated) category of individuals who are perceived to be high-credit risks because of certain patterns found in aggregated data, despite the fact that the particular person's credit history is unblemished. That is, a data-mining program might associate the young executive with a group of individuals who are likely to start their own businesses in the next three years and then file for bankruptcy within the next five years.

Because of concerns about the ways in which electronic records can be exchanged between two or more databases, various privacy laws have been enacted at the federal and state levels. For example, the Health Insurance Portability and Accountability Act (HIPPA) of 1996, enacted into law on April 14, 2003, provides protection for personal medical records. And the Video Protection Act (also known as the "Bork Bill" because it was passed through the U.S. Congress in the aftermath of Judge Robert Bork's nomination to the U.S. Supreme Court) protects consumers from having records of their video rentals from being collected and exchanged. However, these laws primarily aim at protecting personal information that is: (a) *explicitly* identifiable in electronic records, and (b) considered *intimate* or *confidential*.

Information acquired via data mining fits neither category. First, as noted, it is derived from *implicit* patterns in data, which without data-mining technology, would not be accessible to data collectors. Second the kind of personal information generated in the data-mining process is often considered non-intimate or non-confidential because it is derived from information acquired through transactions in which individuals engage openly and in public places.

The use of courtesy cards in supermarket transactions might initially seem innocuous from the perspective of personal privacy. The items purchased are typically transported in an open shopping cart that is visible to anyone in the store so there is nothing confidential or intimate about the activity. However a record of courtesy card purchases can be used to generate a consumer profile. This profile reveals patterns that identify, among other things, the kinds of items purchased and the time of day/week an individual typically shops. Such information is useful to *information merchants* who use it to target consumers in their advertising and marketing campaigns. Furthermore information in a consumer profile can be used to make judgments about personal lifestyles, health, spending habits, and more. Indeed such a profile may be created even when the aggregated data on which it is based is inaccurate because the courtesy card was loaned to another person.

The new forms of information produced by TGI and data mining thus present special challenges to privacy. First individuals may not be aware of the degrees to which their activities are being tracked by a constellation of computer system interactions and their interactions analyzed by data mining techniques. The lack of knowledge in these regards is itself an ethical issue that deserves to be addressed by general education and disclosure statements associated with the particular computer systems. Second because it is easy for such TGI and data mining products to include inaccuracies that may have substantial if subtle impacts, it may be necessary to consider possibilities for personal review or disclosure when TGI is used to influence decision making.

TREAT, MARY

• • •

Accomplished amateur botanist and entomologist, Mary Treat (1830–1923), born in Trumansville, New York, on September 7, was a popular chronicler of the plant, insect, and bird life that shared her small Vineland, New Jersey, home. Treat, who was considered a peer and valued correspondent by countless scientists (including Asa Gray (1810–1888), Charles Darwin (1809–1882), Gustav Mayr (1830–1908), and Auguste Forel (1848–1941)), was widely acknowledged as an authority on insectivorous plants, harvesting ants, and burrowing spiders. She is credited with discovering two species of spider, as well as rare fern and plant species. The recognition she received for her scientific research distinguishes her in the history of women in the sciences. It is her investigations into the nest-making actions of birds and insects, however, that illuminates her concern with ethics and the effects of human action in the natural world.

Treat's scientific nature essays, first published in *Harper's* and the *Atlantic Monthly,* then collected in *Home Studies in Nature* (1885), reflect the shift in scientific investigation prompted by the publication of Darwin's *Origin of Species* (1859). Treat described a world in which the landscape of morality changed significantly, where humans no longer resided securely at the apex of creation. Treat agreed with Darwin's notion of nature "red in tooth and claw"; she saw instances of struggle, violence, chance, and adaptation all around her. Yet Treat, unlike many other American intellects of the time, refused to see nature exclusively in these terms. Instead, she advocated a sophisticated brand of Darwinian evolution—one that incorporated ideas expressed in Darwin's *Descent of Man* (1871) and *The Expression of Emotions in Man and the Animals* (1872)—to explain how animals and insects construct their domestic spaces in the face of their struggle to survive.

Treat revised the model of nature she inherited from the tradition of women nature writers preceding her—nature is not simply a model for human behavior, nor is it something that exists solely for humans to control. Instead, as she learned from her reading of Darwin, nature is composed of separate but interrelated communities; the moral sense, as Darwin notes, comes into being with the social instincts that animals develop as they learn to live in a community. Treat focused her scientific studies on how birds and insects build their nests and observed that they, like humans, exercise reason in the construction of their homes. These observations led her to question the supposed difference between human and non-human, and she used nest construction to demonstrate kinship through reason. Humans, or at least those whom Treat called "good observers" of nature, cannot deny this kinship with non-human communities and are, as a result, obligated to act in an ethical way toward nature.

Treat did not escape the anthropocentric observer position common to many women writing about nature in the nineteenth century, but like her mid-twentieth century counterpart Rachel Carson, she used what she saw (and how she saw it) to justify her call for the ethical treatment of all inhabitants of nature.

TRUST

Trust of science and technology and of the people who conduct research and invent, design, develop, manufacture, operate, maintain, and repair technology is essential to the development of science and technology. When the trust proves unwarranted, however, the result can be disaster in forms varying from harm to health and safety, to persistent distortions of knowledge, to theft of credit or property that cripples cooperation necessary to support the growth of knowledge and development of technology. A deeper question is what it means for science and technology, and the people responsible for them, to be trust*worthy*.

The Concepts of Trust and Trustworthiness

Although Sissela Bok (1978) discussed trust as a moral resource beginning in the 1970s, the question of the morality of trust relationships—the conditions under which, from a moral point view, one ought to trust—was not explicitly discussed until a decade later by Annette Baier (1986). Two earlier essays were important in laying the foundation for this major turn in the discussion. Ian Hacking (1984) provided a devastating assessment of game theoretic approaches to solving problems of trust, such as the Prisoner's Dilemma. Baier (1985) herself previously had argued for broadening the focus in ethics from obligations and moral rules to the subject of whom one ought, as a moral matter, to trust and when. As Kathryn Addelson (1994) points out, Baier's change of focus establishes a general perspective on ethical legitimacy that is shared by all, rather than privileging the perspective of those who make, instill, and enforce moral rules.

As Baier (1986) argues, trust involves both confidence and reliance. If people lack other options, they may continue to rely on something, such as the water supply, even when they no longer trust it. Similarly, people may have confidence in something, or confidence in their expectations concerning it, without relying on it. To rely only where one can trust is a fortunate circumstance.

Baier's general account of the morality of trust illuminates the strong relation between the trustworthy and the true. A trust relationship, according to Baier, is *decent* insofar as it stands the test of disclosure of the premises of each party's trust. For example, if one party trusts the other to perform reliably only because the truster believes the trusted is too timid or unimaginative to do otherwise, disclosure of these premises will give the trusted party an incentive to prove the truster wrong. Similarly if the trusted party fulfills the truster's expectations not through trustworthiness but only through fear of detection and punishment, disclosure of these premises will lead the truster to expect that the trusted would defect, if able to do so undetected.

Although explicit discussion of moral trustworthiness is relatively recent, both professional ethics and the philosophy of technology have given considerable attention to the concept of (prospective) responsibility. Because being trustworthy is key to acting responsibly in a professional capacity, or to being responsible in the virtue, as contrasted with causal, sense, the literature on responsibility provides at least an implicit discussion of many aspects of trustworthiness.

Niklas Luhmann (1979) has shown how trust simplifies human life by endowing some expectations with assurance. It is prohibitively difficult and time-consuming to consider all possible disappointments, defections, and betrayals by those persons or circumstances on which one relies; all possible consequences of those disappointments; and all actions that might prevent those disappointments or change their effect. Trust reduces that burden. In a later work, Luhmann urged a different distinction between confidence and trust: that *trust* be used only when the truster has considered the alternatives to trusting. Luhmann's discussion of the distinction between trust and confidence highlights the element of risk in trusting. Risk or vulnerability does characterize situations in which trust is necessary, in contrast to those in which one's control of the situation makes trust unnecessary. However the notion of reliance in Baier's definition of trust as confident reliance does capture the sense of vulnerability. One's vulnerability in reliance does not require consideration of the alternatives to such reliance.

The risk taken in trusting does leave the truster liable to disappointment (or worse), whether that trust is of persons, objects, or circumstances (such as, that the temperature will go below freezing overnight). However only if one's trust is in agents capable of recognizing intention, can one be let down. Furthermore, although one may disappoint without intending to, one must at least be aware of behaving in the way that turns out to disappoint in order to be said to have let someone down. So if Alice does not know she is waking Bob each morning by closing the garage door, she cannot be said to have let him down by not waking him today. Because science and technology do not arise except through human intervention, the focus of this entry is on trust in people, individually or acting as a group.

Trustworthy Professionals

For the professionals behind science and technology to behave in a responsible or trustworthy manner requires both technical competence and moral concern—specifically a concern to achieve a good outcome in the matter covered, which is sometimes called their fiduciary responsibility, the responsibility of a person in a position of trust. The moral and technical components of professional responsibility led sociologist Bernard Barber (1983) to speak of these as two *senses* of trust. However if the public is to trust the members of the science and engineering professions, it is not in two senses. Rather the public trusts the professional to achieve some outcome for which both competence and concern are required. For researchers, the outcome typically centers on the accurate report of the methods and results of research, a report that fairly acknowledges any contributions of others. For engineers, it typically centers on the provision of a technology that performs its function and does not pose unnecessary threats to safety.

For engineers the competence and concern are engineering competence and concern for such social goods as public safety, confidentiality of information, fairness in competition, the public understanding of science and technology, protection of the environment, and the quality and performance of the technology in question. Engineering codes of ethics enjoin engineers not to take on work beyond their competence, so at least for engineers technically incompetent performance is also recognized to be a moral failing. In contrast, researcher investigators generally do not regard undertaking research beyond one's competence as a *moral* failing, although certain incompetencies, such as those that result in harm to experimental subjects or to public health, might be.

Because the exercise of professional responsibility characteristically draws on a body of specialized knowledge that is brought to bear on the promotion or preservation of another's welfare, to trust a person to fulfill a professional responsibility is to trust that professional to perform in a way that someone outside of the profession cannot entirely specify, predict, or often even recognize. The point is not captured in the frequent suggestion that trust is necessary because the trusting party cannot control or monitor the trusted party's performance. It would do the layperson little good to have full knowledge of the plans for a medical device or an experiment, or even the ability to guide the actions of the science and engineering professionals. Although laypeople might be able to recognize some acts of gross negligence, they would not know the implications of most of what they saw or how to improve the professional's performance. For this reason, from the point of view of the public, there are no good alternatives to having trustworthy professionals. In her 2001 Gifford Lectures, Onora O'Neill (2002) makes the same point that nothing can guarantee trustworthiness and emphasizes the burden that what she calls the *culture of suspicion* places on officials and professionals, such as medical researchers.

The question of whether scientists and engineers are responsible for the ultimate uses of the knowledge and technology they create is sometimes called the *end use question*. Caroline Whitbeck (1998) has argued that for scientists and engineers to be entrusted to prevent evil end uses of their products and discoveries those uses must be intended as well as foreseeable, because, for example, it would be impossible to forego the creation of all the many useful tools from hammers to pokers, to kitchen knives to hatchets that one can foresee can also be used as weapons.

It is arguably unreasonable to say that scientists and engineers are untrustworthy (more specifically, negligent), if they fail to consider *unforeseeable* uses and consequences. Indeed National Academy of Engineering President William Wulf (2004) draws attention to technological systems, such as computer systems, that are so complex that failures in them are inherently unpredictable, so it would not be possible for engineers to predict them. Criteria for trustworthy behavior or policies regarding such systems have yet to be settled.

The application of standards of professional responsibility in science and engineering is complicated by the fact that not all scientific and engineering professions have the same developed understanding of themselves as professions. Although U.S. engineering societies formulated ethical codes and guidelines from the early decades of the 1900s, attention to the professional responsibilities of research investigators has only received broad attention since the mid-1980s. However trust and trustworthiness became a central theme in those discussions in the 1990s (Whitbeck 2004). An international perspective provides even greater variation although the so-called Washington Accord, an agreement that recognizes equivalency of accredited engineering education programs in participating countries, is leading to more uniformity.

Trustworthy Policies

Some questions about the ethical implications of science and technology are policy questions, sometimes called *macro issues*. Although people can and do praise and blame particular individuals for formulating, adopting, implementing, or carrying out policies regarding science and technology, in a democracy these are societal decisions. Policy decisions run the gamut from decisions about what research and development should be given public support or even legally permitted, to what can be used as research material (for example, embryonic stem cells), to how and when to prevent or clean up toxic and nuclear contamination, to whether and how to control the social consequences of new technologies, such as privacy invasions on the Internet.

Typically such policy questions must be decided under conditions of significant uncertainty. Often the nature of the possible outcomes as well as the likelihood of various outcomes are unknown. Such uncertainties lead to misgivings about the pace of innovation and discovery. Technology is said to create new options, but technological advance also forecloses options. For example, after the introduction of the automobile, one could no longer choose to keep a horse and buggy in the city. Furthermore its consequences may contradict expectations. For example, historian Ruth Cowan (1983) found that household appliances did not reduce housework but raised the standards for that work. The relationship between science and technology and the societies in which they develop is extremely complex. Therefore the extent to which the frequent criticism of modern life in technologically developed societies is most properly directed at science and technology (or at least the pace of their development); at social factors, such as market forces affecting their development; or at human tendencies to use and abuse power in general is likely to continue to be disputed.

TURING, ALAN

Alan Mathison Turing (1912–1954), the founder of modern computer science and an important World War II cryptanalyst, was born in London on June 23. He died near Manchester, England, on June 7. His short life illustrates the ethical conflicts and ambiguities of scientific and technological aspirations.

Basic Creativity

Turing's early life was characterized by an intense enthusiasm for science that was only weakly supported by his upper-middle-class family. In 1931 he became an undergraduate at Cambridge University and read mathematics, demonstrating a rapidly emerging originality. At age twenty-four he settled an important problem in the foundations of mathematics, using a method that had much wider implications. Turing developed a precise way to characterize the concept of the "effectively calculable." This consisted of the "Turing machine," as the logician Alonzo Church immediately dubbed Turing's construction when reviewing it in 1937.

A Turing machine is an imaginary device with a finite number of possible configurations, a finite table of instructions for moving from one configuration to another, and the capacity to read, erase, and write a set of finitely many different symbols on a tape. With this structure Turing captured the idea of a finite mechanism, which he compared with the finite capacity of the human mind. By allowing unlimited space and time for working out the machine's operations, Turing was able to argue that such a device could encompass everything that could be achieved by a human calculator following a definite rule. Church endorsed Turing's argument that the concept of "effectively calculable" had been given a natural and convincing definition in terms of being computable by a Turing machine, a proposition now known as the Church-Turing thesis.

More recently there has been discussion of whether there could be, in the real universe or an imaginary one machines capable of operations beyond the scope of a Turing machine, and this debate has generated controversy about the correct interpretation of the Church-Turing thesis (Floridi 2003). At the time, however, Church simply characterized "computable" by reference to what could be done by any kind of machine of a finite size, and Turing similarly referred to that term as being synonymous with *mechanical*.

What is not in dispute is the fact that the Turing machine is still definitive as the foundation for computer science. By attacking an abstruse problem in the most rarefied and philosophical aspects of mathematics Turing arrived at the principle behind the dominant technology of the late twentieth century. Indeed, it was Turing who, seeing the practical potential of his ideas in 1945, was a leading designer and promoter of the electronic computer and its software.

However, this was possible only because of world events between 1938 and 1945 that gave Turing unique insight into practical computation and the promise of digital electronic technology. During the World War II Turing was the chief scientific figure in the successful British effort to decipher coded German communications, a project that became a joint Anglo-American operation after 1941. Turing's ingenious logical methods and theory of information measuring were used throughout the communications war, especially in the section he personally headed, which was responsible for reading U-boat signals.

By 1945 Turing thus possessed unrivaled theoretical and practical experience in the emergent field of information processing. He was disappointed by the practical progress of his plans at the National Physical Laboratory, the British government establishment to which he was appointed. He soon left to take up another, also disappointing, position at Manchester University. However, those short-term setbacks illustrated the fact that Turing's interest was never in the economic potential of computers but only in the long-term scientific question of what he called intelligent machinery, now usually referred to as artificial intelligence.

Alan Turing, 1912–1954. The British mathematician was noted for his contributions to mathematical logic and to the early theory, construction, and use of computers. *(Photo Researchers, Inc.)*

Is the computer in principle capable of rivaling human thought? That question was hinted at even in Turing's prewar references to human memory and states of mind but became much more prominent after 1945. In that period Turing went much further than he had in 1936, arguing that the computer could emulate all aspects of human thought, not merely those corresponding to a human being following a definite method. At that time he also spoke frequently about the physical basis of mental operations and informally described his work as "building a brain."

Contested Issues

A crucial element in Turing's argument is that the computer is a practical form of a universal machine that is capable of performing any algorithm. According to this argument, if the function of the brain can be described as any sort of definite process, in principle a computer can simulate it. It is not suggested that the architecture of the brain should resemble that of a digital computer. Another vital part of Turing's argument is that programs that modify themselves can be considered as learning from experience. He expected them to show the features of surprise and originality that characterize the apparently "nonmechanical" aspects of human thought. Turing's famous 1950 paper (reprinted in Boden 1990) introduced the "imitation game," now called the Turing test, in an attempt to make an objective comparison between computational and human processes.

Interest in these issues has never flagged. The arguments of Roger Penrose (1989) have supplied important new ingredients. It is noteworthy that the interpretation of Gödel's theorem and the quantum-mechanical nature of matter, which are central to Penrose's arguments, are also issues that Turing found important and difficult to address.

The Turing test for intelligence can be accused of having been set up to evade questions of consciousness and responsibility: It is the problem of mind made into a game perhaps in the way codebreaking made it possible to think of World War II as a fascinating and exciting but bloodless game. In real life Turing struck everyone as a person of great integrity, not as a superficial or insensitive person. However, he did not offer an ethical view in his writing on mind and machines. It was the same with the war in which he played so important a role: Turing never spoke about motivation or political allegiance, though his actions showed a strong commitment to the defeat of Nazi Germany. His moral speech was generally directed against anything "phony." In this he was like G. H. Hardy, the Cambridge champion of pure mathematics, but whereas Hardy hated war and rejoiced if his work was "useless" for it, Turing applied mathematics to more effect in war than perhaps anyone else ever had.

After 1950 Turing devoted himself mainly to a mathematical theory of biological growth and form, a quest roughly parallel with the elucidation of DNA. This time he stated a motivation: to defeat the religious "argument from design" and vindicate the power of scientific explanation. However, in 1952 Turing was arrested as a homosexual, and after the ensuing trial he was sentenced to receive injections of estrogen, which was the advanced "scientific" treatment of that period. Turing rose to the crisis with a staunch defense of his personal liberty and equality that has become a standard of European human rights but in his time was an isolated position. He was even more isolated because of his unique access to sensitive Anglo-American military secrets. At the height of Cold War paranoia in June 1954 Turing found his life impossible. He died by taking cyanide.

That period has been dramatized for the stage and television (Whitemore 1986) in scenes in which a fictional Turing gives speeches to an audience, but the real person left his life without a word about the major ethical conflicts he faced. Although Turing was a farsighted and original thinker on fundamental scientific questions and an extraordinary personality, in his silence and unwillingness to pontificate he bore witness to a particular view of scientific practice.

TURING TESTS

Turing tests are procedures to test the functional equivalence of people and computers. They generalize the thought experiment proposed by the British mathematician Alan M. Turing (1912–1954) in his pioneering 1950 paper, "Computer Machines and Intelligence," to answer the question, Can machines think?:

> [T]he "imitation game" . . . is played with three people, a man (A), a woman (B), and an interrogator (C) who may be of either sex. The interrogator stays in a room apart from the other two. The object of the game for the interrogator is to determine which of the other two is the man and which is the woman.
>
> In order that tones of voice may not help the interrogator the answers should be written, or better still, typewritten. The ideal arrangement is to have a teleprinter communicating between the two rooms.
>
> We now ask the question, "What will happen when a machine takes the part of A in this game?" Will the interrogator decide wrongly as often when the game is played like this as he does when the game is played between a man and a woman? These questions replace our original, "Can machines think?" (Turing 1950, pp. 433–434)

Turing's proposed test has been very influential in the philosophy of mind and cognitive science. Variations apply as well to some issues in the ethics of technology. Consider four cases.

A Moral Problem

First, Turing's original test had a moralizing aspect. A tricky game is needed to arrive at a fair test of human versus machine ability because humans are prejudiced against machine intelligence. Turing's blind test combats this prejudice. Note that in Turing's imitation game, computers serve two roles: as potential artificially intelligent interlocutor and as filtering media. This second role has become more significant with the spread of networked computer-mediated communication. As Turing noted, when people communicate only by typing, many cues drop out, and it is not immediately obvious who is male or female. Indeed, in a long-running Internet implementation based on Turing's original male–female game gender turns out to be very difficult to detect (Berman and Bruckman 2001). The spread of the Internet has made this filtering and uncertainty, which might be termed a "Turing effect" of computer-mediated communication, practically important. Its equalizing and liberating aspect is summed up by Peter Steiner's 1993 *New Yorker* cartoon caption: "On the Internet, nobody knows you're a dog." So too do age and rank in organizations drop away in chat rooms and e-mail, creating one of the moral risks of Internet anonymity: adults posing as children and vice versa. Indeed, the recent winners of the annual Loebner metals for best Turing test performance have been chatbots (Loebner Prize Internet site).

Machines with Moral Standing?

Second, and more speculatively, were a computer program to pass Turing's original test for intelligence, this success might have moral implications. For Roger Penrose, ownership of a device that passed the test "would involve us in *moral responsibilities* [because] to operate [such a] computer to satisfy our needs without regard to its sensibilities would be reprehensible." This could be morally equivalent to slavery. "Turning off the computer, or even perhaps selling it, when it might have become attached to us, would present us with moral difficulties" (Penrose 1989, p. 8). Of course, this argument assumes human-level intelligence sufficient for moral standing. A broader account of moral standing leads to an extension of Turing's test.

Third, there is the direct ethical extension of the Turing test. Instead of testing for intelligence, one could test for moral standing itself. Arguably, a computer program that could discuss ethically complex issues indistinguishably from a person should be granted moral standing (Allen, Varner, and Zinser 2000). Variations on this theme of testing for moral personhood via indistinguishability is common in science fiction. For example, in Ridley Scott's 1982 film *Blade Runner,* humans and computer-based "replicants" are indistinguishable by any nonphysical (invasive) Turing test.

Problems with Turing Tests

These Turing test applications disclose some of its problems: (a) The original version tests for communicative ability, but ethics (and perhaps intelligence) arguably requires the ability to *act* as well as to communicate. (b) Turing tests make playing a game (the imitation game) the criteria for intelligence or ethics, respectively. But the ability to deceive is neither necessary (think of naive but intelligent agents) nor sufficient (think of programmed con artists) for moral considerability. (c) More generally, experience with computers because Turing makes it obvious that people tend to overestimate the abilities of computer programs. Notwithstanding such problems, the Turing test remains ethically salient, invoking core moral ideals of fairness and the equivalence of the indistinguishable to challenge prejudice about the unique status of human abilities.

Human versus Machine: Chess

Fourth and again quite practically, there are indirect ethical questions about the human values challenged by machine performance of activities once thought to be open only to humans. The most noted example is the game of chess and the victories of IBM's Deep Blue computer system over grandmaster Gary Kasparov in 1996 and 1997. This can be considered, loosely, a real-world Turing test, whereby master level chess ceased to be a realm in which humans could be distinguishable from machines.

Predictably Deep Blue's success led to a strategic retreat, distinguishing easily (we say now!) mechanizable formal games such as chess from "really difficult" tasks embedded in thick human contexts. Subsequently the Internet search engine Google introduced automated news editing, and reviewers claimed that its editing service was indistinguishable from that of normal human editors. It remains open whether people will view these tests as raising the value of what machines can now do or lowering it. The initial reaction to Deep Blue's victory suggests the latter.

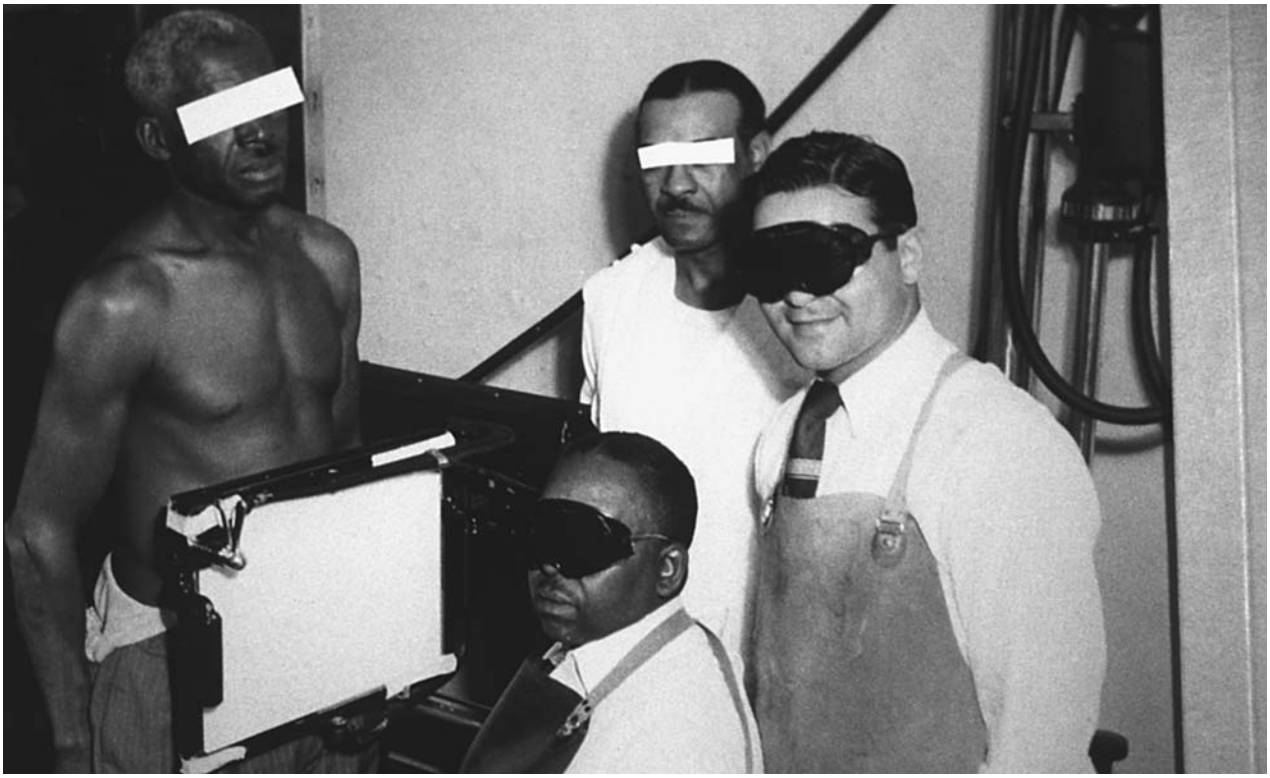
TUSKEGEE EXPERIMENT

From 1932 to 1972 the U.S. Public Health Service (PHS) tracked the nonmedicated course of syphilis, a disease that is caused by the bacterium *Treponema palladium*, among 399 patients and 201 controls at Tuskegee Institute (now Tuskegee University). In the region around Tuskegee in Macon County, Alabama, the PHS, in conjunction with the county health department and the Rosenwald Foundation, initially began a survey and small treatment program for African-Americans with syphilis.

The study goals and research methods soon shifted in response to financial limitations, and the project became the longest nontherapeutic observational study on human beings in medical history, manifesting major violations of basic human rights and ethical precepts. The legacy of government-sanctioned refusal to treat syphilis continues to influence the reluctance of African-Americans and other ethnic minorities to participate in government-funded clinical trials, contribute to organ and tissue donation campaigns, support biomedical research initiatives, and be involved in routine preventive medical care programs.

Throughout forty years of untreated observations infected poor rural African-American men intentionally were denied effective therapy as their disease progressed. Indeed, the premise of the study entailed nontreatment until the participating men died and could be autopsied to document the effects of syphilis on their tissues and organs. U.S. government health professionals withheld the standard treatment for syphilis in the early years of the project, injections of arsenic-based salvarsan and



Doctors taking an x-ray of a Tuskegee subject. *(© Corbis Sygma.)*

topical applications of mercury or bismuth ointments; study participants never received clear advice about their disease state. When penicillin became the therapeutic agent of choice, study participants continued to be denied access to this known cure and their unremediated infections progressed.

Ongoing participation in the study by the men and their families was secured through the deception that they were receiving valuable medical care. Although the PHS provided the bulk of the medical personnel for this study, participant's primary contact throughout the years was with the Tuskegee-trained, PHS employed African-American nurse.

Permission for the study was obtained from key officials, including the U.S. surgeon general, the president of Tuskegee Institute, the medical director of Tuskegee Institute's John A. Andrew Hospital, and public health officials of Macon County. However, at no point were the basic human rights of the study participants protected. There was no voluntary, informed consent of the men under study and no opportunity to end the experiment at will, and the participants continued to be deceived throughout the study. The project, often called America's Nuremberg, reflected the convergence of scientific insensitivity and arrogance, racial injustice and dehumanization, and socioeconomic class–based duplicity in the victimization of the study participants.

Target participants in the study were syphilitic African-American men in the later stages of the disease. In these less contagious stages untreated syphilis still causes serious cardiovascular abnormalities, neurological disorders, blindness, and death in infected individuals. Lack of treatment through participation in the study caused 28 to 100 men to die, and it has been estimated that the withholding of medical care adversely affected 22 wives, 17 children, and 2 grandchildren who subsequently contracted syphilis. The impact of intentional nontreatment of the men who were studied on rates of offspring miscarriages, stillbirths, infant mortality, and infants born with serious syphilis-related mental and physical problems remains unknown. Additionally, the degree of infertility among women sexually affiliated with the study's untreated syphilitic men has not been quantified.

The study was continued at a time when Jim Crow racism and segregation dominated interethnic interactions in the American South and when patients with sexually transmitted diseases faced social and medical discrimination. In the United States syphilis was both a medical problem and a metaphor for immorality and indecency. The PHS study focused on a nonrepresentative cohort of poor, uneducated African-American men residing in a remote location. Their selection was compatible with the emergence of U.S. eugenic programs.

Syphilis historically had been a significant social scourge in much of the Western world; the development of effective treatments for treponemal disease increased public confidence in the capacity of science to develop innovative technological solutions for persistent social problems and suggested that this dreaded sexually transmitted disease could become rare. Tracking its natural history in an expendable group was for some people a "tolerable" breach of ethics.

The government study was exposed publicly in 1972. In 1997 U.S. President Bill Clinton apologized on behalf of the nation to the few surviving victims. Ten million dollars in lawsuit-generated reparations was distributed among six hundred study participants and their descendants in partial compensation for their suffering.

TWO CULTURES

The term *two cultures* refers to a failure of scientists and humanists to comprehend the content, nature, and implications of each other's intellectual activities. An issue that goes back at least to the rise of modern science as a distinct practice and the romantic criticism of some of the results of the scientific worldview, it received international attention when Charles Percy Snow (1905–1980) considered the breakdown in a 1959 lecture, "The Two Cultures and the Scientific Revolution."

Snow, who had experience as a novelist and a scientist, coined the phrase to deplore a widening *gulf of mutual incomprehension* between *literary intellectuals* and natural scientists. The division between cultures represented a dilemma over the role of science and technology in human affairs and led to the failure to address the three *menaces* of nuclear weapons, overpopulation, and the gap between rich and poor. Although he recommended broadening education for both groups, Snow ultimately implied that solving these problems simply required more science and technology. Accordingly Snow accused literary intellectuals of being anti-scientific: While scientists held *the future in their bones,* the literati (whose ideas, Snow believed, unduly influenced western policy makers) were *natural Luddites.*

Critics, notably Frank R. Leavis, criticized Snow for being anti-cultural: In reducing humanistic knowledge to the equivalent of factual information, Snow undermined the capacity for *reflexive* ethical inquiry. In "A Second Look" (1964), Snow acknowledged that his phrase ignored the emergence of a *third culture* of social scientists that studied *the human effects of the scientific revolution.* Snow's phrase, imprecise in excluding *third* groups and in reducing *culture* to a set of conditioned responses, nevertheless calls attention to the problem of specialization and the disagreements about the proper function of science and technology that have persisted to this day.

Exchanges such as the *science wars* demonstrate that in many respects intellectual chasms have only continued to widen. Moreover, public policy debates over the relations among science funding, technology development, and the common good are often indicative of clashing worldviews reminiscent of Snow's two cultures. Within academe, most often in engineering and science curricula, occasional multidisciplinary and interdisciplinary programs do allow students to analyze and even synthesize humanistic and scientific paradigms; these offset to some extent the trends of increased specialization and balkanization. Public science agencies have likewise paid increasing attention to the ethical and societal implications of their research and development activities.

Efforts to integrate the two cultures can potentially balance technological goals with humanistic ones, but they can also be superficial and even counter-productive if they treat humanistic contributions as afterthoughts. Moreover the problem is not simply one of social groups; engineers, for example, tend to be the main advocates of appropriate technology. The gap, however, will continue to widen as specialized knowledge continues to be valued over broader, more integral understanding. A modern educational grounding in the fundamental concepts and practices of technical and humanistic traditions would be ideal. At the very least, interdisciplinary efforts that critically engage values and assumptions on both sides are indispensable if there is to be communication, understanding, and collaboration across the various intellectual divides.

U

UNCERTAINTY

The privative concept of uncertainty is more important in science, technology, and ethics than its positive root, certainty. (There is no entry in the encyclopedia on certainty.) This is the case for two reasons: Uncertainty is more common than certainty, and the implications of uncertainty for human action are more problematic than certainty. Uncertainty in science or engineering appears to call for an ethical assessment; uncertainty in ethics is a cause for moral concern. Nevertheless before discussing uncertainty, it is useful to begin with some considerations of certainty, the positive notion from which it is derived.

Certainty and Uncertainty in History

Concern for certainty as a distinct issue emerges at the same time as modern natural science. In premodern philosophy and science, it is difficult to find any term or concept that is strictly analogous. The Latin *certus,* the etymological root of certainty, is from the verb *cernere,* meaning to decide or determine; the Greek cognate *krinein* means to separate, pick out, decide, or judge. This sense remains in English when speaking of *a certain X,* indicating one item picked out from a group.

The concept of certainty in something approaching the modern sense is first given extended analysis in relation to religious faith. Faith, according to Augustine, is more certain than other forms of knowledge. Thomas Aquinas replies (*Quaestiones disputatae de veritate,* q. 14) that faith is psychologically but not epistemologically more certain than knowledge. Falling between knowledge and opinion in its degree of certainty, faith is defined as "an act of the intellect assenting to divine truth at the command of the will moved by the grace of God" (*Summa theologiae* II-II, q. 1). Moreover the certainty of faith provides a basis for moral judgment that is more secure than any provided by natural knowledge. Through faith, ethics takes on obligations of a stronger character than would otherwise be possible.

From theology, certainty becomes an issue for science when philosophers such as Francis Bacon and René Descartes argue for seeking cognitive certainty not through faith but through new methodologies. As interpreted by John Dewey in *The Quest for Certainty* (1929), "The quest for certainty is a quest for peace which is assured, an object which is unqualified by risk and the shadow of fear that action casts" (Dewey, p. 7). But the effort to secure such certainty and security that was originally undertaken through religious acceptance or propitiation of the gods is, in the early twenty-first century, commonly sought by means of technology and science. Extending Dewey, it is noteworthy that significant worries about lacks of certainty only became prominent as the new methods began to succeed so as to raise expectations of still further achievement. Thus has the pursuit of certainty through science and technology acquired a sense of ethical obligation.

The quest for certainty implies the presence of uncertainty, so that although this could not have been said prior to the modern period, it is now common to describe all human action as taken in the context of uncertainty. Insofar as this is the case, uncertainty is a locus of ethical discourse and conflict. Yet there are two forms of uncertainty in the modern sense that are most basic. Although often thought of as incomplete knowledge and applied to propositions, uncertainty can also be a psychological state. This distinction is important because perceived uncertainties may or may not reflect the actual state of incompleteness in knowledge. Perceptions of uncertainty may themselves be uncertain.

Uncertainty in Science

Characterizing and quantifying uncertainty is a core activity of science. Uncertainty emerges from research methodologies themselves, from the inherent characteristics of the processes and phenomena being studied, from incomplete or imperfect understanding, and from the contexts within which human beings seek to understand their surroundings. These sources of uncertainty may be understood, but they can never be eliminated. Uncertainty is always present to some degree in scientific knowledge, and in our formal knowledge of the world. This phenomenon is most famously embodied in Heisenberg's Uncertainty Principle, which states that the location and momentum of subatomic particles—the fundamental components of existence—can never simultaneously be known with complete accuracy.

Uncertainty is conceptually and practically distinct from fallibilism, or the notion that all scientific knowledge may turn out to be false. While both uncertainty and fallibility are attributes of knowledge, uncertainty refers to the accuracy of knowledge; fallibility to the provisional nature of knowledge. As Heisenberg's Uncertainty Principle illustrates, even if some knowledge (in this case, the uncertainty principle itself) were not provisional, uncertainty would still exist.

If, by contrast, the world were largely deterministic—that is, if its behavior could be explained through comprehensible and invariant cause and effect relations—then uncertainty could be eliminated, at least in theory. In practice, determinism can be approximated in some important human activities. Engineered systems, for example, can be designed as closed systems whose functional behavior is dictated by well-tested, scientific laws (laws of gravity, thermodynamics, and more), tested in laboratories, and supported by experience. Thus, for example, a bridge, or electronic circuit, or nuclear reactor, may operate with high reliability for decades. Eventually, however, the apparently closed system is breached—by corrosion, contamination, earthquake, or terrorism, among others—and the behavior of the system can no longer be thought of as deterministic or certain. The embeddedness of all engineered systems in larger social and natural systems dictates that uncertainty will eventually be introduced into engineering.

Uncertainties can be known with accuracy in closed systems that display random, or aleatory, behavior. Once the laws governing such system behavior are well elucidated, aleatory uncertainties cannot be further reduced. The obvious example is a game of dice or cards, where probabilities of particular outcomes can be determined from relatively simple statistical methods due to the known behavior of six-sided dice or fifty-two-card decks. Random behavior, and thus aleatory uncertainty, also exists in nature (for example, radioactive decay, Brownian motion), and can be approximated by some living systems (such as growth of bacteria in a medium) over limited periods of time, and often described by simple mathematical relations. Aleatory uncertainty is a property of random behavior in closed systems; it is inherent in the system itself.

For open systems whose governing laws cannot be fully elucidated, which includes all social and many technological and natural systems, uncertainty is said to be epistemic—a consequence of incomplete knowledge about cause-and-effect relations. In such cases—that is, most of the real world—uncertainty is a characteristic of both the system itself, and the psychological state of those who are assessing the uncertainty. Most problems at the interface of science, uncertainty, and ethics, are problems of epistemic uncertainty.

Epistemic uncertainties are most typically measured and expressed in probabilistic terms. Probabilities may be determined through frequentist approaches based on statistical analysis of past events or phenomena, or through subjectivist approaches, such as eliciting expert opinions, or surveying the scientific literature on a given subject. It is important to keep in mind that probability distributions derived from subjectivist approaches are distributions of beliefs about events, not of actual event occurrences.

Epistemic uncertainties also may be expressed in qualitative terms (such as *likely*, *unlikely*, and *doubtful*), or nonprobabilistically as ranges in values (for example, as error bars on a graph). Quantitative, nonprobabilistic uncertainties can also be derived from a comparison of the differences among outputs from different mathematical models ("model uncertainty").

Uncertainty in some complex systems or problems can be successfully addressed with frequentist approaches, because observational experience is sufficient to allow rigorous statistical treatment. Insurance companies, for example, set premiums using population-based data on life expectancy, morbidity, and frequency of auto accidents, among others. Engineers use data from tests and historical performance to estimate probabilities of failures in technological systems. Weather forecasts take advantage of a long history of careful observation of meteorological events. In such cases, uncertainty estimates can be refined and sometimes reduced on the basis of ongoing experience. It is important to recognize, however, that frequentist estimates of uncertainty are not necessarily accurate indicators of future probabilities, because in open systems, past behavior, however well documented, does not necessarily foretell future behavior. For example, 100-year flood levels, which are based on historical records and used in the United States for planning and insurance purposes, derive from the false assumption that climate behavior does not vary on time scales of more than a century (Pielke 1999).

Contextual Origins of Uncertainty

Uncertainty is a crucial concept in human affairs because knowledge of the future is always imperfect, and decisions are therefore always made in the face of uncertainty about their outcomes. From this perspective, the word uncertainty refers most generally to the disparity between what is known and what *actually is* or *will be*. Uncertainty, that is, reflects an incomplete and imperfect characterization of current conditions relevant to a decision, and the incomplete and imperfect knowledge of the future consequences of the decision. Logically, then, one way to improve the success of a decision should be to characterize, and if possible reduce, the uncertainty relevant to that decision, and considerable resources in science are devoted to this task. But significant obstacles stand in the way of this goal.

Many, perhaps most, of the important decisions faced by society have one or more of the following attributes: (1) the problem cannot be characterized in terms of easily measured outcomes in a well-defined population; (2) sufficient or relevant historical data are not available to allow frequentist approaches; (3) the dynamics of system behavior are incompletely and imperfectly understood; (4) the system is open; (5) numerous disciplines can contribute relevant understanding; and (6) different interests or values define the problem in different ways. For these reasons, most uncertainties in human affairs are epistemic, and most must be assessed through subjectivist methods. In all such cases, estimates of uncertainty are themselves both uncertain and strongly conditioned by the social context within which they are generated and used.

Less uncertainty can be an attribute of less knowledge. Continual research into and experience with complex, open systems should be expected to reveal new questions and new intricacies that may add to uncertainty over time. New knowledge does not necessarily translate into a greater ability to make well-constrained statements about cause-and-effect relations relevant to human decisions. The archetypal example of this phenomenon is the climate change controversy, where ongoing research into the operations of the earth system and its interactions with human activities is continually introducing new variables and parameters, new appreciation of existing complexities, and new areas of scientific disagreement. While the observation of global warming is robust, and the rising impact of climate on society well documented, continued investigation into the causal relations between these two observations yields an ever expanding array of possible causal agents, and growing intricacy in the relations among agents.

A conventional view of this problem describes a *cascade of uncertainty*, where the more modest uncertainties embodied in the understanding of relatively simple systems or phenomena are introduced into and magnified at the next level of complexity, which in turn introduces its own, perhaps greater, uncertainties (Schneider and Kuntz-Duriseti 2002). The importance of this notion lies especially in the fact that simpler systems are generally farther away from real world problems. Thus it is hard enough to understand and reduce the uncertainties surrounding greenhouse gas behavior in the atmosphere, but if the concern is the impacts of those gases on society via changes in regional climate, then uncertainties cascade beyond comprehension or control.

This view of the problem locates uncertainty in the complexity of natural and social systems being studied, but uncertainty also arises from the conduct of these studies. Science is not a unitary activity; multiple disciplinary approaches often yield multiple perspectives that do not fit together to yield a seamless picture of nature, but rather create multiple and sometimes even conflicting pictures (Dupré 1993). For example, plant geneticists and those in related fields commonly evince greater certainty than ecologists that genetically modified crops will be beneficial to humanity and the environment. These differences derive in part from different ways of understanding nature. Plant geneticists, employing reductionist approaches to crop engineering, are thus confident about their ability to control crop behavior. Ecologists, in contrast, study complex systems where small variations in conditions are often seen to have large and unpredictable impacts.

Lying beneath these epistemological differences are likely to be ethical tensions between one worldview where control of nature yields human benefit and another where pretensions to control can be futile and dangerous. For complex issues where relevant knowledge comes from multiple disciplines, estimates of

uncertainty may thus partly be a reflection of competing disciplinary perspectives, and the ethical commitments entailed in those perspectives. These relations are likely to be reinforced by behavioral attributes of scientists. In particular, experts typically underestimate uncertainty in their own area of expertise (Kahneman et al. 1982) while locating the sources of uncertainty in disciplines other than their own (Pinch 1981).

Uncertainty estimates may strongly reflect institutional and political context. Consider, for example, that the U.S. National Aeronautics and Space Administration (NASA) initially estimated the reliability of its space shuttle fleet at 0.9997, or one failure every 3,333 launches (Pielke 1993). Since then two shuttles out of 112 total launches have self-destructed during flight, yielding a historical reliability of 0.98—thirty times less than the initial estimate. High certainty about shuttle reliability could exist when experience with shuttle flights was small, and knowledge was limited. Yet high certainty was also consistent with the political interests of NASA, and with the institutional incentives in the agency, which rewarded launching shuttles, not grounding them. Another illustration comes from medical science, where a number of studies have shown that clinical trials directly or indirectly supported by pharmaceutical companies often yield more favorable assessments of new therapies—greater certainty about positive results—than trials that are not tied to the private sector in any way (Angell 2000). The point here is not that scientists are engaging in fraudulent research in an effort to bolster desired conclusions, but experimental design and interpretation of data are partly matters of judgment, and judgment may be influenced by the incentives, priorities, and culture of one's work environment.

Additional examples from such areas as climate change science (van der Sluijs et al. 1998), earthquake prediction (Nigg 2000), oil and gas reserve estimates (Gautier 2000), and nuclear waste disposal (Metlay 2000) show that uncertainty estimates are strongly dependent on institutional and political context, and that opening up the research process to additional scientific and institutional perspectives often leads to significant changes in perceived uncertainty.

Uncertainty and Values

Important decisions in human affairs create winners and losers relative to the status quo ante, and thus implicate competing interests and values. In areas of decision making that include a significant scientific component, such as the environment, public health, and technological risk, uncertainty provides the space for disputes between competing interests and values to play out, because those who hold contesting positions can make conflicting or disparate science-based claims about the consequences of particular courses of action. Thus, for example, supporters of genetically modified foods can point to the potential for gains in crop productivity, and opponents can point to the threat of diminished crop genetic diversity. This is a self-reinforcing process: As value disputes grow more heated, they bring out the latent uncertainties associated with a problem or decision by expanding the realm of phenomena, disciplinary perspectives, and institutional and political players relevant to the problem. These relations are schematically illustrated in Figure 1.

So long as uncertainty is understood simply in terms of the incomplete but ever-improving knowledge of the world, reduction of uncertainty will be prescribed as a path toward resolving political disputes. But when uncertainty is also recognized as an outgrowth of the contexts within which scientific inquiry is structured and carried out, the path begins to look Sisyphean. Indeed the contextual diversity of science is the manifestation of, not the solution to, the conflicting values that underlie political debate. These observations suggest that the taming of uncertainty must depend not on the capacity of science to characterize and reduce uncertainty, but on the capacity of political processes to successfully resolve value disputes that underlie the choices that humans face.

UNINTENDED CONSEQUENCES

Human activities often produce consequences very different from those intended. Indeed this is a theme of classical tragedy and much premodern argument about the indeterminacy of human affairs. Sociologist Robert K. Merton was one of the first to subject "The Unanticipated Consequences of Purposeful Action" (1936) to systematic analysis, noting the influences of the need to act in spite of uncertainties, the allocation of scarce resources such as time and energy, and how personal interests shape perspectives and decisions. Advances in science and technology seem particularly likely to change the world in unanticipated ways. Innovations are by definition something new and are likely to involve unknowns. Innovations may be used in unplanned ways that trigger surprising results. The more complex a system, the harder it is to anticipate its effects. Unintended consequences can shift the cost-benefit analysis of a new technology, theory, or policy; distribute costs and benefits inequitably; or lead to other direct or indirect social problems. Such consequences raise questions of responsibility and liability; decision making under uncertainty; equity and justice; and the role of individual citizens, corporations, universities, and governments in managing science and technology.

Types of Unintended Consequences

Unintended consequences occur in many forms, although the categories are neither entirely discrete nor universally recognized. *Accidents* are usually immediate and obvious, and result from problems such as mechanical failure or human error, such as the disastrous 1986 explosions, fires, and releases of radiation at the nuclear rector in Chernobyl, Russia.

Side effects are additional, unanticipated effects that occur along with intended effects, such as gastrointestinal irritation resulting from aspirin taken to relieve pain. *Double effects*, meaning simply two effects, often refer to simultaneous positive and negative effects, as in the aspirin example. Many medical side effects are well documented, such as the devastating effects of diethylstilbestrol (DES) and thalidomide and the ability of bacteria to develop resistance to antibiotics (Dutton et al. 1988).

Surprises could apply to any unintended consequence, but the term is more specifically used, along with *false alarms*, to describe errors in prediction. A false alarm is when a predicted event fails to occur, such as the millennium computer bug, whereas a surprise is an unexpected event, such as the 2004 Indian Ocean tsunami (Stewart 2000).

Henry N. Pollack (2003) refers to *inadvertent experiments,* in which human actions unwittingly allow and sometimes force society to consider the effects of its actions. He cites the hole in the ozone layer and climate change as classic examples. Historians of science and technology also have noted the occasional benefits of *serendipity* in both discovery and invention.

More provocatively science and technology sometimes have the reverse of their intended effects. In the 1970s Ivan Illich (1973) among others argued that scientific and technological development, after crossing a certain threshold, may exhibit a counterproductivity, producing new problems even as it solves old ones. Extending this notion into political theory, Ulrich Beck (1986) argues that unintended consequences in the form of *boomerang effects* are transforming politics into a concern for the just distribution not of goods but of risks.

With a more individualist focus, Edward Tenner identifies *revenge effects* as the "ironic unintended consequences of mechanical, chemical, biological, and medical ingenuity" or, more anthropomorphically, as "the tendency of the world around us to get even, to twist our cleverness against us" (Tenner 1997, p. 6). He further divides revenge effects into *rearranging effects,* that shift the locus or nature of a problem, such as urban air-conditioning making the outside air hotter; *repeating effects,* that have people "doing the thing more often rather than gaining time to do other things"; *recomplicating effects* such as the annoying loops of voice mail systems; *regenerating effects,* in which a proposed solution such as pest control makes a situation worse; and *recongesting effects,* such as the human ability to clog space with debris from space explorations (Tenner 1997, p. 10).

Direct effects are those that occur fairly quickly, with no intervening factors. *Indirect effects* are likely to take longer to develop and may involve interactions with other factors; *latent side effects* also refer to impacts that occur later in time. *Secondary effects* are the next level of impacts resulting from direct effects; they generally impact people or places other than those a product or activity is intended to affect; these may also be called *ripple effects*. The secondary effects of smoking on nonsmokers have been well documented. *N-order effects* are even more removed from the direct effects. *Cumulative effects* are additive. Combinations of substances, particularly pesticides or medicines, are sometimes called *cocktail effects*, especially in the United Kingdom. *Interaction effects* are those resulting from a combination of two or more factors that act on or influence each other to produce a result different from either acting alone.

The military uses the term *collateral damage* to describe injuries to people and property other than intended targets, such as the destruction of the Chinese Embassy during the 1999 North Atlantic Treaty Organization (NATO) bombing campaign in Yugoslavia. Civilian casualties are often framed as collateral damage because ethical principles of noncombatant immunity proscribe the deliberate injury of civilians.

Economists often refer to unintended consequences as *externalities,* "An action by either a producer or a consumer that affects other producers or consumers, yet is not accounted for in the market price" (Pindyck and Rubinfeld 1998, p. 696). Pollution is usually considered an externality, as its effects on human health, safety, and quality of life are often not factored into industrial costs. Externalities may require management such as government imposed regulations, subsidies, or market-based mechanisms to prevent economic inefficiencies. Externalities such as pollution or hazardous wastes often impose unequal burdens on the poor or powerless, raising questions about equity and environmental justice.

Unintended consequences are different from *unanticipated consequences,* in which effects may be suspected or known to be likely but are not part of the intended outcome. Some anticipated consequences may be ignored if they interfere with the interests of decision makers or seem relatively minor; cumulative or interactive effects may make them more serious. Knowledge about effects, or effects that should have been anticipated, may be important in deciding who, if anyone, should be held legally, politically, or morally responsible for unintended outcomes.

Causes and Effects

Unintended consequences of science and technology can have many causes. Design flaws may lead to project failure. Materials may not meet expectations. Assumptions may prove incorrect.

Human factors frequently trigger unintended consequences. Human errors, sometimes interacting with technical failures and environmental stresses, often cause accidents, such as the 1984 release of poisonous gas from Union Carbide's pesticide plant in Bhopal, India (Jasanoff 1994). People often use science and technology in unexpected ways. What appears to be operator error may be the result of an overly complex or inherently unsafe technology. Additionally safety measures such as seat belts sometimes may actually increase hazards as people compensate by taking more risks, illustrating a phenomenon known as *risk homeostasis*.

Unintended consequences may have social, economic, or behavioral as well as physical causes and impacts, especially when transferred from one culture to another. Anthropologists, for instance, have well documented the often unintentionally destructive outcomes of technology transfer across cultures (Spicer 1952). The movie *The Gods Must Be Crazy* (1981) depicts a comic version of this phenomenon. Effects may be catastrophic, even when the transfer is only from laboratory to market place.

Richard A. Posner (2004), for instance, distinguishes four types of catastrophe, all but one resulting from the unintended consequences of science and technology. The exception is a natural catastrophe. The other categories are accidents from the products of science and technology, such as particle accelerators or nanotechnology; unintended side effects of human uses of technology, such as global climate change; and the deliberate triggering of destruction made possible by dangerous innovations in science and technology, which can be considered technological terrorism. Posner also notes "the tendency of technological advance to outpace the social control of technology" (Posner 2004, p. 20), an instance of cultural lag.
