In animal experiments, the health status of exposed animals is compared to that of an unexposed control group. Because of the high degree of biochemical and physiological similarity between humans and the common experimental animals, animal experimentation has predictive power, but unfortunately the predictions are far from perfect. There are substances to which humans are much more, or much less, sensitive than the common laboratory animals.

Because of the uncertainty inherent in both epidemiology and animal experiments, it is in practice virtually impossible to determine with certainty absolutely safe nonzero levels of toxic exposure. Furthermore, for genotoxic carcinogens, it is generally believed that although the risk diminishes with the exposure, it is not completely eliminated until the exposure has been reduced to zero. Accordingly, the ACGIH has stated that the TLVs "represent conditions under which ACGIH believes that nearly all workers may be repeatedly exposed without adverse health effects. They are not fine lines between safe and dangerous exposures, nor are they a relative index of toxicology" (ACGIH website). Other setters of exposure limits have made similar statements.

To set occupational exposure limits is no easy task. Workers exposed to potentially dangerous substances expect exposure limits to fully protect their health. Employers expect the exposure limits to impose only such costs as are necessary to protect employee health. It is in practice impossible to set OELs that fully satisfy both demands. The task of standard setters is to find a reasonable compromise. To achieve this is a science-based enterprise in the sense of making use of scientific information, but not in the sense of being based exclusively on science. It is in fact both science-based and value-based.

As already indicated, the determination of exposure limits involves not just empirical data but also scientific theories about how this data should be interpreted and ethical views about how it should be applied. In some cases the application of very safe exposure limits can put an industrial operation out of business, so that workers are fully protected but only at the cost of losing their jobs. In other cases, not to apply strong exposure limits can have deadly consequences. The adjudication of exposure limits in the workplace, as outside the workplace, is an issues that involves scientific and ethical education on the part of workers, employers, politicians, and citizens.

FACT/VALUE DICHOTOMY

Representatives of modern science and its social institutions have repeatedly claimed that science is *value free,* and this claim has contributed to marginalizing serious discussion of the relations among science, technology, and values. Lying behind this claim is the philosophical view that there is not just a distinction but a sharp separation, an unbridgeable gap or *dichotomy,* between *fact* and *value.* The supposed fact/value dichotomy arose at the beginning of the seventeenth century, accompanying the early works of modern science, underpinning an interpretation of their character and epistemic status and became part of the mainstream tradition of modern science (Proctor 1991). Prior to that, it was not a major issue in philosophical thinking about science.

Science and Technology as Value Free

The claim that science is value free is that science deals exclusively with facts and—*at its core*—admits of no proper place for ethical (and social) values. This is not to deny that important relations between science and values exist—for example, that scientific knowledge is a value (even a universal one), that the conduct of scientific research requires the commitment of scientists to certain virtues—such as honesty and courage to follow the evidence where it leads (Merton 1973), and that experimental activities are subject to ethical restraint. Rather, elaborating what it is to keep values out of the core of science, it is to affirm four theses: (1) Scientific knowledge is *impartial:* Ethical values should not be among the *criteria* for accepting or rejecting scientific theories and appraising scientific knowledge. (2) Ethical values have no fundamental role in the *practices* of gaining and appraising scientific knowledge, because the broad characteristics of scientific methodology should be responsive only to the interest of gaining understanding of phenomena. (3) Similarly, research priorities should not be shaped systematically by particular values. The point of both (2) and (3) is that scientific practices are *autonomous.* (4) Scientific theories are *neutral:* Value judgments are not among the logical implications of scientific theories (*cognitive neutrality*); and, on application (e.g., in technology), in principle these theories can evenhandedly inform interests fostered by a wide range of value outlooks (*applied neutrality*) (Lacey 1999). The theses of impartiality and applied neutrality have counterparts regarding the claim that technology is value free. This claim involves the theses: (1) The characteristic criterion of appraisal for technological objects is *efficacy,* the factual issue of whether they work or not. (2) Technology progressively makes it possible to effectively achieve more ends, but it does not privilege any particular ends; its products are available to be used to serve the interests of a wide range of value outlooks (Tiles and Oberdiek 1995).

Sources of the Fact/Value Dichotomy

Materialist metaphysics constitutes one source of the fact/value dichotomy. In the words of Alexandre Koyré (1957), one of the most authoritative historians of early modern science, it—by rationalizing the mathematical and experimental character of science—led to the "discarding by scientific thought of all considerations based upon value-concepts, such as perfection, harmony, meaning and aim, and finally the utter devalorization of being, the divorce of the world of value from the world of facts" (p. 4).

According to materialist metaphysics, the "world of facts" is identical to the "world as it really is in itself." This world consists of the totality of the underlying (normally unobservable) structure and its components, processes, interactions, and mathematically expressed laws, whose generative powers explain phenomena, in a way that dissociates them from any relation to human experience, social and ecological organization, or values—the totality of *bare facts*, purely material facts. On this view, because its aim is to gain understanding of the world, science will attend to grasping the bare facts. Thus, scientific theories should deploy only categories that are devoid of evaluative connotations or implications, such as the quantitative ones (force, mass, velocity, etc.) characteristically used in physical theories. No value judgments follow, for example, from Isaac Newton's law of gravitation, and it makes no sense to ask whether it is good or bad, or whether one ought to act in accordance with it or not. Newton's law expresses a bare fact; faithful to the way the world is, it makes an *objective* statement.

Representatives of modern science often argue that value judgments, by contrast, do not make true or false statements about objects of the world. Rather they serve as expressions of *subjective* preferences, desires, or utilities (perhaps grounded in emotions). In this way, the fact/value dichotomy is reinforced by the objective/subjective dichotomy. Science deals with facts; it is objective. Ethics deals with preferences; it is subjective. The efficacy of technological objects, attested to by confirmed scientific theories, stands on the side of facts. Legitimating their uses, however, involves ethical judgments, which cannot be derived from the bare facts that account for the technology's efficacy and the material possibilities that it makes available.

Epistemology is a further source of the fact/value and objective/subjective dichotomies. Scientific epistemologies identify facts—*confirmed facts*—with what is well supported by empirical data, and the results of established scientific theories. Those that inform technological practices are exemplary instances. Confirmed facts derive from *intersubjectivity*, that is, replicability and agreement, which cuts across value outlooks and cultural norms. Value judgments are not considered intersubjective. Whereas from the metaphysical source, objectivity derives from faithfully representing objects of the world in statements that express bare facts; from the [other] from the epistemological, it derives from the intersubjectivity of confirmed facts. In practice the two notions of fact tend to fuse together and, from both sources, value judgments appear to be subjective, unlike scientific results that are objective. Hilary Putnam (2002) reviews and criticizes much of the vast philosophical literature on the subjectivity of value judgments.

Finally, *logic* constitutes a third source of the fact/value dichotomy, and for many philosophers it is the principal one. David Hume, in *A Treatise of Human Nature* (1739–1740), is argued to have demonstrated an unbridgeable logical gap between fact and value, because factual statements cannot logically entail value judgments; *ought* is not logically entailed by *is*. The mark of a fact in Hume's argument is a linguistic one: the role of *is* and grammatically related verbs, and the absence of such terms as *good* and *ought*. Less discussed is the complementary thesis, defended by Francis Bacon in *The New Organon* (1620), with his famous injunction to avoid "sciences as one would," to avoid inferring *is* from *ought*, or *good*, or from what serves one's interests; for example, it may serve the interest of legitimating the use of a particular technology that it not occasion serious risks to human health, but that interest is irrelevant to determining what the facts are about the risks.

The Entanglement of Fact and Value

Many criticisms have been made of the fact/value dichotomy, including those of pragmatists and critical theorists. But they all come down to one basic argument, that rather than dichotomy there is some kind of *entanglement* (Putnam 2002) between facts and values. Some (not all) aspects of the entanglement, most of which were discussed by Dewey (1939), are identified below.

NO UNBRIDGEABLE GAP. Many significant factual statements are articulated in scientific theories (such as Newton's law of gravitation). Whether or not a theory is rationally accepted, and thus whether or not statements articulated in it represent confirmed facts, depends on the satisfaction of criteria that require that certain relations obtain between the theory and relevant *observed facts*. Exactly what these relations should be (inductive, abductive) remains disputed; nevertheless, it is clear that the theories are not logically entailed by the observed facts. the criteria that must be satisfied are those for *evaluating* the scientific knowledge and the understanding of phenomena represented in theories.

These criteria have been called *cognitive values* (McMullin 2000); they are a species of values in general, and include empirical adequacy, explanatory power, and consilience. Cognitive values are held to be distinct from ethical, social, and other kinds of values (Lacey 2004), although this is disputed (Longino 1990). Cognitive value judgments concern how adequately cognitive values are manifested in a theory in the light of available observed facts. Soundly accepting that a statement represents a confirmed fact amounts to making the cognitive value judgment that the cognitive values are manifested in the theory to a high enough degree. Far from there being an unbridgeable gap between fact and value, confirmed facts are partly constituted by cognitive value judgments.

FACTS AS PRESUPPOSITIONS AND SUPPORT FOR VALUES. Hume's argument by itself does not rule out that factual statements may provide support for value judgments; otherwise, it would also rule out that observed facts can provide evidential support for facts confirmed within scientific theories, for the fundamental hypotheses of scientific theories are not logically entailed by facts. Logical entailment need not be a particularly important relation in analyzing how facts may support other facts or other kinds of judgments. Consider, for example, the statement: "Recently enacted legislation is the principal cause of the current increase in hunger and child mortality rates." This is a factual statement, because it has the relevant linguistic marks, and empirical inquiry may confirm it to be true or false. At the same time, accepting that it is well confirmed would support holding the value judgment that the legislation should be changed, because, unless there are other factors to consider, it would make no sense to deny that the legislation should be changed, if it is accepted that the factual statement about the causes of hunger has been confirmed. Linked to this, the ethical value of the legislation *presupposes* that it does not have ethically undesirable causal consequences such as increased hunger (Lacey 2004; for a variant of this argument, see Bhaskar 1986).

SOME SENTENCES MAKE BOTH FACTUAL STATEMENTS AND VALUE JUDGMENTS. Declaring that legislation is the cause of hunger may be intended as the statement of a confirmed fact. Alternatively it may serve to express a value judgment, that is, ethical disapproval of the legislation. The logical and linguistic form of the declaration permits it to be used in either role, showing that there is an overlap of the predicates used in factual and ethical discourse. What have been called *thick ethical terms*, terms such as *honest* and *unjust* (also *hunger* and *high child mortality*)—in contrast to *thin ethical terms*, such as *good* and *ought*—may be used simultaneously to serve factual and evaluative ends (Putnam 2002).

Declaring that legislation causes hunger is simultaneously to describe it and normally to criticize it ethically. Using thick ethical terms in factual discourse is no barrier to arriving at results that are well confirmed in the light of the cognitive values and available empirical data; and when such results are obtained, the ethical appraisal is strengthened. Theories that contain such results are not cognitively neutral; they lend support to particular ethical appraisals. Of course, the ethical values of the investigators may explain why they engaged in the relevant research and used the thick ethical terms as their key descriptive categories. Ethical values may influence what facts a person comes to confirm; but they have nothing to do with their appraisal as facts.

SCIENTIFIC APPRAISAL MAY INEXTRICABLY INVOLVE EMPIRICAL CONSIDERATIONS AND VALUE JUDGMENTS. Empirical appraisal never provides certainty; in principle, even the best confirmed statements might be disconfirmed by further investigation. Thus, when a hypothesis is applied, the appraisal made is that it is sufficiently well confirmed by available empirical evidence so that, in considerations about the legitimacy of its application, it is not necessary to take into account that it might be disconfirmed by further investigation, and that, if it were, it might occasion negatively valued outcomes. In the light of this, the standards of confirmation that need to be satisfied depend upon how valuatively significant are these outcomes (Rudner 1953).

MODERN SCIENCE HAS FOSTERED THE VALUE OF EXPANDING HUMAN CAPACITIES TO EXERCISE CONTROL OVER NATURE. Because there are confirmed facts—that is, facts that reliably inform human action—that deploy thick ethical terms, not all confirmed facts are bare facts. This challenges the metaphysical view that the world "as it really is" is identical to the totality of bare facts; and, indeed, it is neither a bare fact, nor a confirmed fact, that the world "really" is that way. Scientists may make the choice to attend only to bare facts. Although this is not the only way to gain factual knowledge, it has generated an enormous amount of knowledge of inestimable social and technological importance. Moreover, because its categories are (by design) chosen to describe facts without the use of thick ethical terms, this knowledge has no ethical judgments at all among its implications. Approaching scientific research, attending only to bare facts, produces results that are cognitively neutral.

At the same time, the contribution of scientific knowledge to enhancing human capacities to exercise control over nature has been highly valued throughout the modern scientific tradition. It has been argued (Lacey 1999) that the approach to scientific research that attends principally to bare facts gained virtual hegemony because of its dialectical links with according high ethical value to enhancing human capacities for control, as well as the exercise of these capacities in ever more domains of life. Bare facts are especially pertinent for informing projects of technological control. Furthermore, sometimes the results of modern science (for example, the developments that have produced transgenic crops) have little application where competing values are held (such as the values of simultaneously gaining high productivity, ecological sustainability, protection of biodiversity, and empowerment of local producers [Altieri 2001]). Thus, while the results gained in this approach of modern science are cognitively neutral, they do not, on the whole, display applied neutrality. (For a variant of this point, see Kitcher 2001.) Humans have considerable knowledge of bare facts (in part) because the values about control are widely held in society and shape scientific institutions. It is not the nature of the world that leads humans to search out such facts but, contrary to the claim of autonomy, a choice highly conditioned by social and ethical values, one that Robert N. Proctor (1991) refers to as "political."

Assessment

Not all the components of the claim that science is value free can be sustained. While there are important results that are cognitively neutral, that is, results that do not logically entail value judgments, in general results do not fit applied neutrality; that is, they are not evenhandedly applicable for a wide variety of value outlooks. Moreover, because applied neutrality does not hold in general, the claim that technology is value free cannot be sustained. There is no objection, then, to engaging in research for the sake of obtaining results that could inform one's ethically favored projects. What confirmed facts are actually obtained reflect these values. That they are confirmed facts does not. The ideal of impartiality remains intact. Ethical values are not among the cognitive values, so that ethically laden commitments (ideological, religious, political, entrepreneurial) are irrelevant to appraising knowledge claims. Science does not need the strong separation of facts and values in order to protect the ideal of impartiality. It needs only a nuanced account of their entanglement.

FAMILY

The family is one of a number of basic social institutions that have been subjected to scientific study and affected by changes in science and technology. Because of the fundamental role the family plays in socialization, including the inculcation of moral behavior and ethical attitudes, it merits consideration in relation to science, technology, and ethics.

Throughout human history there has been a strong relationship between the family and technology. That relationship can be understood by tracing the successive technological revolutions that began with hunting and gathering societies and the discovery and use of tools and progressed through a series of technological societies, such as horticultural, agricultural, industrial, and postindustrial societies (Ribeiro 1968). Each successive step has altered ways of thinking and doing things by human beings, and this progression has been made possible primarily by new means of environmental adaptation. In the past families provided the organizational structure needed to develop tools and techniques to meet basic human needs, and this has continued in many ways into the present.

Defining the Family

A family may be defined as a group of people linked by descent. However, because descent can be understood in biological or nonbiological terms and is subject to narrow or broad interpretations, the scientific study of the family has led to the recognition of a number of basic distinctions. Indeed, the family has taken different forms throughout history and across cultures, related to diverse functions. In hunting and gathering and horticultural societies the kin group performed all religious, economic, and political functions. Kinship groups were broad enough to include relationships with almost everyone with whom a person interacted (Radcliff-Brown 1930). The kin group remained the major socializing agent, and the production and consumption of material goods continued to be centered in the family.

With the advent of agrarian families inheritance of property, primarily along male lines, became a central concern. The evidence from several studies (Gough 1971) indicates that because of land ownership and a more settled way of life the power of males increased (compared with the situation in hunting societies) at the expense of females. In agrarian families parents had considerable control over their children. However, agrarian families still were concerned about alliances with immediate and distant relatives. Those alliances are known as the extended family.

Industrialization brought the rise of the conjugal family unit. The nuclear family was becoming less embedded in the extended family, bringing a host of changes (Goode 1963). The major changes, according to William J. Goode, included social mobility, specialization, and geographic mobility. The family was no longer economically a producing unit, but its function as a consuming unit was heightened. In addition, many functions were outsourced from the family unit, resulting in greater dependence on the larger society.

The relationship between families and society thus has undergone major changes throughout history. In hunting societies institutions such as the economy and religion were embedded in kin groups. In agricultural society various institutions still were embedded in the extended family, although some institutional differentiation started to appear. In industrial society, disembedding reached a peak and the nuclear family became one of the many institutions that served individuals.

These distinctions are especially important in understanding interactions among families, science, and technology in relation to three social functions: producing and consuming material goods, information technology, and human reproduction.

Producing and Consuming Material Goods

The earliest families used hunting and gathering as their modes of production. Family members were producers of food for sustenance, and most tools were associated with the basic activities of survival: spear and bow and arrow for hunting, stone ax for skinning animals to make clothing, and basketry for food gathering. Hunting tools were made from stone, bone, and wood. Hunting and gathering societies were small and migrated frequently. In the family gender roles were defined clearly: Men had a monopoly on hunting, and women gathered food and raised children. In addition, men, being physically stronger, were expected to defend the tribe, thus accumulating more decision-making power. Once those gender roles became traditional, they were considered not only practical but "natural." Some scholars believe that this is where sexism or gender superiority began, although not in as pronounced a form as was to occur later.

Families continued to be producers of food in horticultural societies. Horticultural societies, a precursor of agricultural societies, were based on hoe agriculture: small-scale farming using a hoe and a digging stick.

Some copper tools and sickles made from clay fired at a high temperature also were used. Horticulture allowed populations to settle and provided some permanence in people's lives, something that had not been possible in foraging societies.

Simple horticultural societies gave way to agrarian societies around 3000 B.C.E. The family remained the primary producer, but agriculture provided the means to move from an existence that was dependent on what was given by nature to one of active participation, utilizing the environment to enhance the potential for a better life. One of the most important innovations in that period was the introduction of plow cultivation, which Gudmund Hatt (1961, p. 218) has called "the prerequisite of civilization." Animals were used to pull a plow. With the introduction of iron, superior plows, weapons, and tools were produced. Male dominance increased because agrarian tasks required greater strength and more intensive labor. Women's status declined further because of economic dependence, which was a result of a lack of direct contribution to the economic activities required in large-scale agriculture.

Families in industrial societies lost many of their production functions and became little more than a source of labor. Gerhard Lenski and Jean Lenski (1987) divided the Industrial Revolution into four phases on the basis of technological innovation. The first phase (1760–1850) began in England with major developments in the textile, iron, and coal industries. The second phase (1850–1900) saw expansion throughout most of Europe and North America. The steam engine was adapted for transportation by railroads and steamships. Agricultural production increased with the use of new kinds of machines and chemical fertilizers. Family ownership of companies began to give way to corporations, and the number of industrial workers increased substantially.

The third phase (1900–1940) was characterized by major advances in energy technology. The use of automobiles increased in most industrialized countries, and with it the demand for petroleum. Most homes were electrified and were connected to others by telephones. The fourth phase (1940–1970) saw major changes in the aviation industry spurred by World War II. The war economy also saw the expansion or development of nuclear power, plastics, and aluminum. Entertainment industries such as television, radio, and films experienced tremendous growth. The industrial sector became automated, and the nature of labor changed considerably. The most important innovation in this phase was the development of electronic computers.

All this technological innovation had a substantial impact on the structure and functions of the family. Home and work were separated. Family members—mostly men—had to work outside the home to purchase goods and services. In the early phase of industrialization the status of women reached its lowest point because women had no role in the economy outside the family. However, that changed after World War II as women entered the workplace in increasing numbers. By contrast, children had to wait longer to enter into the labor market because industrial economies required specialized skills. Hence, their economic dependence on parents increased compared with that of their counterparts in agricultural economies.

Information Technology and the Family

The concept of a "postindustrial society," as developed by Daniel Bell (1973), refers to a new mode of technological and economic production that is based increasingly on information and services. Information technology (IT) has revolutionized almost all aspects of human life.

Although its effects on families vary, family members tend to use IT as often in managing home life as in regulating work-home relationships. Pagers, faxes, cell phones, telephone answering systems, and computers are used to keep track of children, spouses, and other family members. Paging children to find out if they have arrived home safely from school demonstrates parental responsibility. E-mail and cell phones keep family members in constant contact. In addition, family members use answering machines, cell phones, and palm pilots to coordinate complex household schedules. However, not every effect of the use of IT has been positive. The colonization of home time by work is one obvious negative. The technical ability to work from home has blurred the distinction between workplace and family life.

Human Reproduction

Technology also has altered human reproduction, initially by means of birth control. Artificial contraception has disembedded conception from sexual intercourse and made fertility dependent on personal decisions. At the same time, with the growth of genetic research infertile couples now have many options for having a child through assisted reproductive technologies (ARTs). Among the many types of ARTs, artificial insemination is the most common.

The other commonly used procedure is known as in vitro fertilization (IVF), in which a woman's eggs are removed surgically and placed in a petri dish with sperm from her husband or a donor. One or more fertilized eggs then can be implanted directly into the woman's uterus. Sometimes extra fertilized eggs are frozen for possible later use. Surrogate pregnancy is available for women who cannot bear children.

Ethical Considerations

Science and technology not only have altered family life, they have generated fundamental ethical questions. The most controversial are associated with reproductive technology.

Are new technologies redefining previously held notions of family, parent, mother, and father? In embryo transplantation a fertilized egg from a female donor is implanted into an infertile woman. The developing embryos may be tested for genetic abnormalities before implantation. Critics (Benokraitis 2002) have raised concerns about parental rights to reject imperfect fetuses and create "designer babies." In 1999 a wealthy couple placed an ad in the newspapers of universities such as Harvard, Princeton, and Stanford, offering $50,000 for the eggs of a woman who was intelligent (SAT score 1,400 and higher), athletic, and tall. More than 200 college women responded to the advertisement (Weiss 2000). The implications are that rich people can "manufacture" babies and women who are in debt may offer their bodies.

A surrogate mother may decide to keep the baby. In 1987, in the celebrated "Baby M" case, Mary Beth Whitehead was artificially inseminated with the sperm of William Stern. Although Whitehead signed a surrogate contract with Stern, she changed her mind and turned down the $10,000 she had contracted to receive. She lost the case, but the court granted her visitation rights. Many critics who object to surrogacy argue that it exploits poor women because rich couples can afford to "rent a womb" (Benokraitis 2002).

Barbara Rothman raises a larger question in regard to motherhood: Should it always be defined in biological terms? Her answer is no. For Rothman, "Every woman is the mother of the child she bears, regardless of the source of the sperm and regardless of the source of the egg. The law must come to such an explicit recognition of the maternity relationship" (Rothman 1994, p. 201). In another situation surrogacy raised a complicated question of kinship. In 1991 Annette Schwartz served as a surrogate for her daughter, Christa, and gave birth to twins who became Christa's legal children. What kinship term should be applied to the relationship between the twins and Schwartz (Benokraitis 2002)?

Questions also arise about the impact of IT on the family. Information technology has had many unintended consequences. The issues of privacy and security breaches have become a major problem in most advanced countries. For instance, users of cellular phones can have their location tracked and hackers can get into family computers and remove private information. Parents can use IT to keep track of their children.

Does IT create stronger social relationships or distract people because it does not promote face-to-face relationships? Harold Rheingold (1993) and Sherry Turkle (1995) argue that computers and telephones provide emotional support and a sense of belonging. However, skeptics such as Mark Slouka (1995) and Clifford Stoll (1995) think that online relationships are narrow and lacking in quality. Those relationships are also manipulative because making affiliations in an electronic medium teeming with strangers is dangerous for young people. Moreover, "In the office, in their cars, and in their houses, the demands of work come pouring in. Work is so pervasive that conventional boundaries between work and home have all but collapsed" (Rheingold 2002, p. 191).

The fact that the use of technology is never neutral is demonstrated clearly by its impact on the family. Technology has been considered the hallmark of civilization; it has enabled humans to overcome the inertia and entropy of a harsh physical environment. However, dependence on technology has created cultural disorder as well, calling forth ethical reflection and responses.

FASCISM

Fascism played a major role in twentieth-century European and world history, especially in its attempt to develop a particular nonliberal and nonhumanistic modern perspective on science and technology. Fascism, in power, was a form of rule where key societal resources were monopolized by the state in an effort to penetrate and control many aspects of public and private life, through the state's use of propaganda, terror, and technology.

Fascism also remains a highly complex and illusive political phenomenon. Classical fascism (the small *f* for comparative purposes) can be described in terms of a number of loosely-related early-twentieth-century political parties, movements, and regimes, especially in Germany (Adolph Hitler's National Socialism), Italy (Benito Mussolini's *Fascism* proper, from which the generic term fascism is derived), and Spain (Francisco Franco's more radical wing of Falangism).

All fascisms oppose communism, the values of liberal democracy, rationalism, and scientific positivism, with assertions of bellicose nationalism, and each variety of fascism has sought in its own manner and cultural context to adopt advanced military, penal (including in the Nazi variant genocidal), and communication (propaganda) technologies, while criticizing the universalism and humanism of liberal science and technology. Some suggest that a *palingenetic* and inherently revolutionary mythology of rebirth ultimately binds all authentic forms of generic fascism together and separates them from authoritarian and reactionary military dictatorships, and totalitarian regimes such as that of Stalin (Griffin 1993).

In spite of fascisms' ritualistic invocation of an idealized past—the Nazi Aryan myth; the Italian myth of Rome, the preoccupation with the glorious age of Elizabeth I among interwar British fascists—fascism actually emerged from a background steeped in pseudoscience and social Darwinism, and the high-tech myths of futurism, and as such can be seen as an authentically *modern* movement, especially in terms of its attitudes toward, and application of, science and technology.

Fascism has also persisted since the collapse and defeat of the Mussolini and Hitler regimes, in various manifestations of *neo-* or *post-* fascism, operating as a sometimes influential, but often marginalized, opposition movement within liberal democracy. Latter day fascists often deny their fascist roots, or operate clandestinely, because of the negative and reviled nature of fascism because of its well known and understood connection with the systematic process of Nazi war and genocide. Others have been partially absorbed into liberal democracy and deradiclalized.

Fascism in Italy (1922–1943)

In 1932 the fascist dictator Mussolini, with the considerable help of the neo-Hegelian philosopher Giovanni Gentile (1875–1944), contributed an entry to the *Encyclopedia Italiana* on the definition of fascism. Italian conceptions of the work of Georg Hegel derived largely from Benedetto Croce (1866–1952), a philosopher of international repute. Mussolini asked Croce to write this doctrine of fascism for him, but Croce refused. But in Gentile's writings, Mussolini discovered a serviceable philosophical peg of neo-Hegelian idealism on which to hang his brutal, vitalistic doctrines.

The famous entry contains elements of Gentile's personal criticisms of liberal and post-enlightenment science and technology, depicting the state as the source of all ethics, individual as well as collective. A key passage reads:

> The State, as conceived and realized by Fascism, is a spiritual and ethical entity. . . . which in its origin and growth is a manifestation of the spirit. The State . . . safeguards and transmits the spirit of the people, elaborated down the ages in its language, its customs, its faith. The State is not only the present; it is also the past and above all the future. . . . the State stands for the immanent conscience of the nation. The forms in which it finds expression change, but the need for it remains. . . . it transmits to future generations the conquests of the mind in the fields of science, art, law, human solidarity; it leads men up from primitive tribal life to that highest manifestation of human power, imperial rule. . . . Whenever respect for the State declines and the disintegrating and centrifugal tendencies of individuals and groups prevail, nations are headed for decay. (Mussolini 1932, p.26)

Aside from this perverted Hegelian notion that the state equals life itself, the entry usefully emphasizes other core themes of Italian Fascism: a firm belief in the concrete reality of life, anti-individualism, antiliberalism and liberal democratic sentiments, antisocialism, the call for *action* and revolution, a denial that happiness is achieved through comfort and *well-being,* the belief that fascism is ultimately a *spiritual force,* and the idea that fascist ideology was a far stronger ethical basis for existence than any mere rule of law (on this last point see the writings of Carl Schmitt).

A major strand of Italian fascist technologism emerged from the prewar futurist movement in art, founded in 1909 by the poet Filippo Marinetti. Futurism arose as part of the general modernist artistic ferment that characterized the intellectual life of Europe, and particularly France and Italy, in the period before 1914. The futurists' goal was to celebrate modern technology and to free Italian art from the psychology of the past. In 1910 Umberto Boccioni published the *Manifesto of the Futurist Painters*. The cult of the machine age was central to futurism and from the beginning futurist ideology was saturated with violence and aggression. The infatuation with speed, change, and modernity soon became intertwined with ultranationalism and in 1915 Marinetti published *War—the Sole Hygiene of the World,* placing science and technology at the service of war and brutal imperialism. What had started as the rejection of stagnation in art became an all-encompassing, authoritarian political message, in which all *decadent* (code for liberal and leftist) manifestations of the old Italy were to be overthrown. Under Mussolini's regime, futurism lost its radical edge and was largely confined to producing extravagant plans for buildings in the futurist style, very few of which were actually built.

But the tenor and relentless propaganda of the regime remained focused on placing the latest science, technology, and management techniques at the disposal of the Italian people—hence grand public buildings such as the Milan and Florence railway stations, the Autostrada, and electrification of the main railways network. There was also a ceaseless drive to embrace the dynamism of the second industrial revolution embodied in the Fascists' Third Rome, the exploitation of hydroelectric power, the propaganda surrounding the launch of any new Fiat vehicle, and Italo Balbo's daring flying antics in the United States. Fascist propagandists also strove tirelessly to emphasize the link between technology, science, modernization, and the regime. In addition, attempts were made to create new institutions for managing the modernization process, institutions of an authoritarian, technocratic character such as the Confederazione Generale dell'Industria Italiana and the Gruppi di Competenza. In addition, genuinely innovative institutions were created to manage the modernization process: Confederazione Generale dell'Industria Italiana, Gruppi di Competenza, Consigli Tecnici, and Istituto per la Ricostruzione Industriale. The highly technocratic Guiseppi Bottai, Minister of Corporations and also editor of *Critica Fascista,* used every opportunity to emphasize the technocratic and scientific core of the "New Italy" and its third way "Corporate State"—a process that rapidly ran out of steam when he ceased to be Minister in 1932. (For the best account of fascist modernism, see Griffin 1994.)

Germany (1933–1945)

Fascism in Germany was, in almost every aspect, the most radical and extreme manifestation of fascist ideology, putting science and technology to the most unethical of uses, including mass genocide achieved through Ford-style, efficient factory methods The German regime eventually waged a brutal, and for the period, high-tech war through the development of weapons of mass destruction and rocket-propelled delivery systems. From the road construction of the Todt Organization to the development of the V3 rocket bomb, there is no

Benito Mussolini addressing troops. The Fascist dictator was head of the Italian government from 1922 to 1943 and led Italy into three successive wars, the last of which overturned his regime. *(© Bettmann/Corbis.)*

question that Nazi Germany promoted a culture of advanced technology (Griffin 1994). As Roger Griffin cogently puts it, "the Third Reich was saturated with technocratic values.... The V3 rocket bomb could hardly have been developed by an anti-technological culture" (Griffin 1994, p.10).

Part of the reason for this was that Nazism emerged from a cultural climate imbued with the idea that the West was degenerating, a fear dating back to Edward Gibbon's *Decline and Fall of the Roman Empire* (1776–1787), and an associated sense of the urgency of the task of regeneration and rebirth. The rise of Nazism also coincided with the period of the most influential writings of Martin Heidegger (1889–1976) and Schmitt (1888–1985). Heidegger favored a form of antimodern rule that would restore *Being* to its proper role in Western affairs. Mistaking the Nazis as the political basis for a rebirth of technology and humanity, he threw in his lot with Hitler's regime, and never repudiated Nazism, continuing to speak of its *inner truth and greatness*.

It was Friedrich Nietzsche who famously fathered a distinctly Germanic critique of decadent European society. He affirmed that a regenerative instinct for the *Will to Power* realized through the *blond beast* could destroy weak institutions and beliefs, blazing a trail for *the vital, the powerful, and the creative*. German interwar thinkers and public intellectuals adopted Nietzsche's Zarathustra in a bastardized and popularized form, as a symbol for a rejuvenating *Kultur* capable of overcoming the effects of decadent commercial and wasteful technological civilization. Nietzsche's writings influenced many of the leading German cultural pessimists, especially Ernst Junger (1895–1998) and Oswald Spengler (1880–1936) who, in turn, influenced Heidegger.

As Michael Zimmerman has argued, "Jünger claimed that the soft, decadent, and unmanly European bourgeoisie was being displaced by *der Arbeiter* (the Worker), a new type of humanity combining the steely hardness of modern technology with the iron will of a proto-Nietzschean blond beast. Jünger foresaw a powerful new upsurge of Will in the face of Western decrepitude" (p. 14). Adopting Junger's rhetoric of struggle and hardness, Heidegger appeared to the less sophisticated minds to be exhorting all Germans to submit to a technological Will to Power in order to overcome decline and despair (*uberwinden*).

But in fact he criticized the technological Will to Power and argued for its transcendence through Volk politics and *Gelassenheit* (detachment)—a highly misplaced hope in the case of the Nazis. Heidegger's ontological language was pitched at such a high level of linguistic and philosophical abstraction that it was impenetrable to most intellectuals, and his solution was an equally obscure and backward-looking spiritual renewal far too abstract for his Nazi masters to grasp. He was naturally predisposed toward Nazi ultranationalism through the special destiny he assigned to the German people because of their language, which he saw as the natural heir to classical Greek—a pure philosophical language, a quality that had disappeared from all other Western European languages. In addition, Heidegger's key concept of *Dasein* (a combination of the words *being* [*sein*] and *here* [*da*]) was based on the belief that the real is also rational, and, after 1933, the here was nazism and the obvious concrete power of National Socialism was, for him, an *uncovering* of authentic Being.

Heidegger's initial enthusiasm for nazism was soon reduced by the complete lack of interest the Nazis showed in his philosophy. As rector of Freiburg University in 1933, Heidegger delivered a famous address in which he announced that he had the correct philosophical understanding of National Socialism, but the Nazis did not understand him. His exclusive form of philosophical National Socialism was not based on any concept of race or imperial conquest and was, therefore, completely irrelevant to his political bosses.

Schmitt, a pupil of Max Weber, was a leading German thinker on constitutional law who wrote several seminal studies during the Weimar period and became known as *the enemy of liberalism*. Like Heidegger he entered the Nazi university establishment after 1933. Schmitt rejected *cosmopolitan* ideals and the intrinsic goodness of humankind and argued that the law was ultimately subservient to politics. Liberalism, meanwhile, offered a false universalism, which obscured the existentially paramount nature of politics and replaced it with the struggle for abstract notions of *rights*. Political *reality* ultimately transcended all legal norms for Schmitt, who supported the existential over the theoretical. Thus war lacks any normative justification, its reason lying not in ideals of justice, democracy, or economic prosperity, but in preserving the very existence of the sovereign and sacred polity when it is threatened—in this case a Germany threatened by decadent liberals, Jews, and communists.

Despite his openly Nazi ideals, Schmitt's work proved influential on later authoritarian conservatism outside Germany; Raymond Aron referred to him as a great social philosopher in the tradition of Weber. His writings continue to influence the left, as demonstrated by the content of the journal *Telos*, and to fascinate poststructuralists, including Chantal Mouffe (1999) and Jacques Derrida.

Spanish Falangists (1936–1975)

The Falange was a quasi-fascist political organization, which constituted the single official party in Spain between 1939 and 1975, making it the longest-lasting fascist-style regime. This minor party was founded in 1933 by Jose Antonio Primo de Rivera, and, with other parties, became the Spanish Phalanx of the Assemblies of National-Unionist Offensive.

During the Spanish Civil War, the Falangists fought on the *nationalist* side against the left-led Republicans. When Franco seized personal power, he united the Falange with the Carlist monarchists, forming the Movimiento Nacional—thus purging the Falange of its more radical and modernizing fascistic elements. After the war, moderate Falangist ministers had an important role in Francoism, but Franco turned increasingly to younger politicians thus allowing Spain be dominated by the technocratic wing of Falangism, whose policies arguably promoted a return to democracy.

Non-European Fascisms

Minor potential examples of generic fascism and neofascism have existed elsewhere in Europe and around the world both before and since 1945. But the only other continent that has witnessed significant concentrations of quasi-fascist parties, movement, and regimes is Latin America, principally Paraguay, Argentina, and Chile.

Between 1954 and 1989, Alfredo Stroessner's authoritarian Colorado Party made Paraguay a safe haven for Nazi war criminals such as Josef Mengele. However the most significant neofascist regime existed in Argentina under Juan Perón (president from

1946–1955 and 1973–1974) who fostered a powerful populist, authoritarian personality cult initially with the assistance of his beautiful but ill-fated wife Eva.

Islamic Fascism

Some claim that Islamic Fascism exists and is also a phenomenon of modernism (see Wistrich 2001). In this thesis it is basically a twentieth-century totalitarian movement—like fascism and communism. Islam existed before Islamic Fascism, and will exist after it.

Islamic Fascism is designed—like fascism and communism—to appeal to idealistic young people with a utopian future where the world will be *cleansed*. It really started with the Iranian revolution in 1979, and was formerly called *Islamic fundamentalism*. Other names for it include *Islamofascism* or *Islamism*. And—like fascism and communism—its only solution, according to its adherents, is the total and utter destruction of western liberal and Christian culture and philosophy. This may, of course, require a long cold war, lasting for perhaps the next two or three decades, punctuated by perhaps one or two more hot wars, but Islam will prevail.

Broader Issues for Science, Technology, and Ethics

Among other things, the rapid rise of fascism illustrates the severe problem of cultural disorder created by radical and rapid scientific and technological change in the early-twentieth century and the associated difficulty of moving from essentially premodern traditional societies to modern rationalistic, scientific, and technological societies with mass democratic systems.

By nature fascism is clearly opposed to those aspects of modernity linked with decadence, particularly cultural-pluralism, liberalism, and materialism. There are obvious examples of premodern thought within fascism—for instance the Blood and Soil movement, ideals in both Germany and Italy of regeneration of the peasantry and the restoration of the ancient bond between Germans and Italians and the land. Yet fascism is by no means entirely antimodern, as Gentile suggested:

> . . . as a descendant of early twentieth-century modernist nationalism, fascism does not identify with anti-modernism, but in its own way . . . it had a certain passion for modernity not inconsistent with its harking back to the traditions of the past . . . The fascists saw themselves as the modern "Romans" . . . compatible with the myth of the future and with fascism's ambition of revising modernity in order to leave its mark on the new civilization in the age of the masses. (Gentile 1993, p. 24–25)

At one level fascism clearly represented a rejection of liberal scientific positivism. But equally, as Roger Griffin (1994) argues, it contained a readiness to employ the latest scientific and technological techniques to destroy liberalism and communism and achieve its irrationalist and dystopian ends.

Many varieties of fascism also tried to replace orthodox religion with a perverted secularized and spiritualized modernism, based in part on developing and deploying the dazzling potential gains of modern science and technology and offering the chimera of an economics of plenty—a technological heaven on earth. Indeed Gentile has depicted Italian Fascism as the first and most highly developed form of modern mass political religion—offering a new ideology to fill the void left by the decline of traditional religion in Italy. Earlier cults and myths of Italian ultranationalism forged the basis of a civic religion that was then colonized and adapted by the Fascist party. As such, Italian Fascism was a vital catalyst for contemporary Italian mass politics (Gentile 1996).

Fascism clearly demonstrates the considerable negative as well as liberating functions of modern science and technology, with the state entirely taking over its promotion, direction, and end use for the deeply unethical purposes of brutal imperialist wars and, in the case of Nazi Germany, systematic mass genocide. It is, perhaps, useful to speculate on what latter-day Nazis would do with current cloning techniques and biotechnology, or with the latest weapons of mass destruction—chemical, biological and nuclear based. And with regard to the miracles of modern mass communications: the frightening image of tall men in stylish black Nazi uniforms waiting at Heathrow, or JFK, talking animatedly into their exclusive SS-issue mobile phones and opening their sleek black SS laptops in a wireless-zone, to contact the web and read their encrypted emails, comes all too readily to mind.

FAUST

The story of Faust has been widely used in literature and popular discussions to reflect on the ethics of science and technology. The Faust myth first appeared in 1587 when it was published by an unknown German Protestant in a popular chapbook. In 1592, the book was translated into English under the title *The Historie of the Damnable Life and Deserved Death of Doctor John Faustus*. There have been several famous interpretations of the myth since the original publication, including works by Christopher Marlowe (1564–1593), Gotthold Ephraim Lessing (1729–1781), Johann Wolfgang von Goethe (1749–1832), and Thomas Mann (1875–1955). All of the interpretations are united by the central theme of one man's insatiable quest for knowledge and its implications for his world and his own soul.

Historical Roots

Dr. Johann Georg Faust (c. 1480–1540) is the historic figure on which the myth has been built. An astrologer and alchemist, Dr. Faust was born in Knittlingen, Württemberg (southwest Germany); studied at Wittenberg, Erfurt, and Ingolstadt universities; and later became a lecturer. Often accused of practicing black magic, Dr. Faust was repeatedly banished from villages. An elusive and mysterious figure, he reportedly admitted of pledging himself to the devil with his own blood. Dr. Faust was put to death in Staufen, Breisgau.

The original German publication was titled *Historia von D. Johann Fausten dem weitbeschreyten Zauberer und Schwartzkünstler* (History of Dr. Johan Faust, the notorious black-magician and necromancer). In this book, details of Faust's life are connected with speculative ideas about black magic and pacts with the devil. The first part of the book describes Faust's childhood and his studies in Wittenberg, which ends in a pact with the devil, because he wanted "*alle Gründ am Himmel und Erden erforschen*" (to probe all causes in heaven and on earth) and "*die Elementa speculieren*" (to speculate on the elements). This cannot be achieved through mere scholarship, but only with the aid of demonic powers. The second part describes Faust's travels—thanks to the power of the devil—through Earth, Heaven, and Hell. It also relates how he finally beholds paradise. The third part is composed of various tales, magic, and conjuring tricks. In the last part, an old man tries in vain to convert Faust's soul, but Faust renews his pact with the devil. In front of his students, Faust conjures Helena, the beautiful daughter of Zeus. He marries her, and they have a son, Faustus Justus. The book concludes with Faust's agonizing death and his descent into Hell in accordance with the rules of his satanic pact. Helena and their son disappear after his death.

This original tale is a moral and theological warning to live a God-fearing, modest life. Importantly, Faust's pact with the devil was not made out of a desire for material wealth, as was the case in most of the similar myths from that time, but rather from a desire for knowledge. Faust thus personifies the scientific, inquisitive intellect that is opposed to both the Catholic tradition founded upon papal authority and the humility and consciousness of sin found in the followers of Martin Luther (1483–1546).

From Marlow to Goethe

Marlowe was captivated by the English translation of Faust's story and used it as the basis for his play, *The Tragical History of Doctor Faustus*. Two versions of his play exist, one dated to 1604 and the other to 1616. It is believed to be the first dramatic interpretation of the Faust tale, and it follows the original story closely in terms of the proportions of comedy and tragedy. Marlowe's Faust is a complex character and a renaissance person who is driven by an overwhelming intellectual curiosity. Always striving for power and seeking beauty, Faust signs a pact with Mephistopheles (the devil) because the sciences of his time could bring him neither godlike knowledge nor superhuman talents and power. The punishment for this hubristic bargain is eternal damnation.

Marlowe's play became one of the most successful dramas of the Elizabethan epoch. An adaptation for the puppet theater was brought to Germany by traveling artists and became an indirect inspiration for Goethe's drama *Faust*, because he watched the puppet play as a boy. A German translation of Marlowe's drama was published in Germany at the beginning of the nineteenth century. Upon reading it, Goethe reportedly remarked, "How greatly it is all planned!"

Goethe's *Faust* is possibly the most important drama in the German language, and many quotes have been adapted into colloquial usage and proverbial sayings. Goethe's tragedy has two parts, the first was published in 1808 and the second in 1832. Goethe's Faust character is distinguished from earlier variants by his rich inner complexity. The drama raises questions across the spectrum of human knowledge from philosophy and theology to anthropology and history to ethics and aesthetics.

The play opens with a wager between God and Mephistopheles. God gives permission to the devil to lure the soul of Faust, a scholar and alchemist, and maintains that Faust would be saved despite his reliance on reason and sorcery rather than faith. Later, Faust complains that "*Wir nichts wissen können!*" (we cannot know anything!). All science stays in the dark, because it lacks a secure and certain foundation. This is why Faust devotes himself to magic: "*Daß ich erkenne was die Welt / Im Innersten zusammenhält*" (That I may know what the world / holds at its very core.)

Faust is not interested merely in power, pleasure, and knowledge, but longs to take part in the divine secrets of life. He conjures up an Earth-Spirit, but it refuses to help him slake his insatiable thirst for knowledge. Faust becomes depressed and wants to kill himself. But it is Easter and the church bells tell of the resurrection. He is overcome by childhood memories: "*Die Botschaft hör' ich wohl, / allein mir fehlt der Glaube*" (I hear the message clearly, / but I alone lack the faith). He does not commit suicide, but his inner tensions heighten. He is both sick of life and unbearably hungry to know and experience its deepest offerings. He hunts ravenously for knowledge but he also yearns to satisfy his bodily desires for action. In this situation, Mephistopheles makes an appearance and offers to fulfill Faust's every desire—for the price of his soul.

In both parts of the drama, innocent people become victims of Faust's pact with the devil. In the first part, the victims are the girl Margarete (nicknamed Gretchen), her mother, and her brother. With the help of Mephistopheles, Faust seduces Margarete, but the narcotic he gives to her mother has a lethal effect. Margarete's brother attempts to take revenge for his mother and the lost honor of his sister in a duel with Faust, but he falls by Mephistopheles's intervention. Gretchen gives birth to Faust's child, kills it, and ends up in jail.

In the second part, Faust's megalomaniac enterprise demands human sacrifices. He wishes to wrest land from the sea in Greece, so he begins the engineering construction on a system of dykes—thus becoming an archetype not just of one pursuing scientific knowledge, but also of someone intent on technological power. The henchmen of Mephistopheles burn down the home of an old couple who had cared for him as a young man, which was the only thing that the enormously wealthy yet discontented Faust did not own. The fire kills the old couple. Faust as an engineer does not foresee the unintentional consequences of his work but finally accepts them approvingly.

Goethe's *Faust* is a tale of reckless striving for boundless love, knowledge, and power. In the end, this culminates in the blind and maniacal pursuit of an engineering project that breeds outrage, destruction, and doom. Nonetheless, Faust's soul ascends to heaven with the angels singing: "Whoever strives in ceaseless toil / Him we may grant redemption." And it seems that the moral is that as long as we struggle toward greatness, God will grant salvation, even if we stray into excesses and sin.

FEDERATION OF AMERICAN SCIENTISTS

Founded in 1945 by scientists involved in the Manhattan Project to create the atom bomb, the Federation of American Scientists (FAS) is a nonprofit organization of more than 2,000 scientists, engineers, and other citizens dedicated to the responsible use of science and technology. Originally known as the Federation of Atomic Scientists, FAS continues to focus much of its efforts on nuclear arms control and security, but it also addresses issues involving information technologies, science policy, and the environment. To achieve its goals of informed debate and the application of science and engineering to national problems, FAS utilizes several strategies including research, advocacy, outreach, and grassroots organizing.

Membership and Finances

The composition of FAS, originally dominated by physicists, has slowly diversified. A 2002 in-house survey found that nearly thirty percent of the respondents identified themselves as physicists. The next largest fields represented were medicine (18%), biology (15%), engineering (15%), and chemistry (13%). Members receive *Secrecy News*, an informal electronic publication on government secrecy, security, and intelligence policies.

The FAS budget for fiscal year 2004 was $3 million, 70 percent of which directly funded projects, while the remaining 30 percent covered overhead expenses. Approximately two-thirds of the budget was derived from private foundation contributions and one-third from government grants. Membership dues in 2004 amounted to $125,000.

Origins and History

After World War II a minority of U.S. scientists (roughly 3,000) formed the loose "scientists' movement" that sought not just to create new technologies that had an impact on social and political change, but "tried to direct that change toward a particular end" (Smith 1965, p. 528). FAS was the most important element of this movement in the early post-war years. Roughly ninety percent of the Manhattan Project scientists supported the FAS mission. Ernest O. Lawrence, however, discouraged participation by scientists in organizations devoted to non-scientific ends. FAS, originally dubbed the "scientists lobby," emerged in the same spirit as the *Bulletin of the Atomic Scientists* (also founded in 1945 by members of the Manhattan Project) and the 1955 Russell-Einstein Manifesto, which led to the first Pugwash Conference on Science in World Affairs. In all these cases, scientists gathered to appraise the perils of science and technology, prevent their misuse, and advance solutions in the name of peace and prosperity.

Three topics dominated the early FAS agenda: the need for domestic and international control of atomic energy, the need to educate the public on the promises and perils of atomic energy, and the harmful effects of secrecy on international trust and scientific growth. One of the biggest battles waged by the early FAS members and other concerned scientists was over civilian versus military control of nuclear energy. Many scientists distrusted the military, and envisioned limitless, clean energy if only the proper civilian controls could be established.

FAS did play at least a minor role in the international monitoring and control of atomic energy and weapons. Although it is difficult to assess FAS impact on the process, the formation of the U.S. Atomic Energy Commission in 1946, a civilian entity that regulated nuclear energy and controlled national research, was a major success in the battle for civilian control of atomic energy (Hewlett and Anderson 1972). In general, however, FAS members always faced limits on what their technical data and scientific knowledge could contribute to international and domestic nuclear politics.

A period of disenchantment and diminished influence ensued after the early post-war years. Members defended the integrity of science and civil liberties of scientists vigorously, while their demands for a positive role in policy making waned. Although not a member of FAS, the judgment of J. Robert Oppenheimer as a security risk in 1953 further weakened the political clout of scientists by attacking their image of trustworthiness and independence. After the McCarthy era, members adopted more modest expectations about the contributions of scientists to public life. The increased incorporation of scientists into government also forced FAS to adjust its role.

By 1969, FAS had reached its lowest ebb, with an annual budget of roughly $7,000 and a mostly volunteer staff. The greatly defunct organization was rejuvenated with the appointment of Jeremy J. Stone as president in 1970. For the next five years, FAS was heavily influenced by Stone, because he was the only staff member. He began revitalizing and promoting FAS with his monthly newsletters. Membership grew rapidly over the next two decades (including a 450 percent increase between 1970 and 1974) and by the 1990s FAS was able to support a staff of roughly a dozen (Stone 1999). From its inception, FAS had been composed of local associations or chapters, which occasionally met but primarily worked independently of one another. In the 1950s, there were approximately thirty chapters, but by 1970 only two remained—one of which, the Boston chapter, called itself the Union of Concerned Scientists (Stone 1999). Stone disbanded the chapter system in 1970 and the two remaining chapters became independent organizations. In 1974, FAS established a permanent headquarters in Washington, DC, something it had not had since the late 1940s.

By the mid 1980s, FAS relied more heavily on journalists, professional staff, and policy analysts than famous scientists. FAS has maintained a sizable influence despite the increasingly crowded security-oriented public interest community and science lobby movement. Its mission has also steadily expanded to include other areas of science and technology. In 2000 Henry Kelly became the new president and further bolstered FAS under the overarching goals of strengthening science in policy and using science to benefit society.

Assessment

In its early years (1945–1948), FAS played an important role in efforts to maintain civilian control of atomic energy. Alice Kimball Smith (1965) argues that "By guarding the rights of a particular profession in a dangerous period in the 1950s the FAS contributed to the general cause of civil liberties" (p. 531). It has also served as an effective watchdog over the relations of science and public policy. This has afforded some protection for scientists and science against attacks and, by providing a forum for self-criticism, has prevented scientists from being dangerously seduced by their own successes (Smith 1965). Its website is a comprehensive source of information pertaining to global military technologies, intelligence, terrorism, and other areas of science and society. It is a valuable educational and research tool that enhances military and government transparency.

FAS publishes an "Occasional Paper Series" to inform and stimulate debate on current science and security policy issues. The second paper in the series (Kelly et al. 2004) takes up the state of science policy advice in the United States, and argues that the infrastructure for providing science and technology advice to Congress and the President is in a state of crisis. It asserts that sound policy needs sound science advice. However, this claim raises the question of where scientists stop acting as advisers (that is, providing balanced, "objective" information) and start acting as advocates (promoting a course of action that serve the scientific community but may not align with common interests).

Since its inception, this has been the central question about FAS and other professional science and engineering organizations concerned to play an active role in shaping how science is used in politics and how policies affect the practice of science. Should scientists have a privileged voice in public decision making? What is their proper role in the value-laden, political questions raised by science and technology? These are the more subtle questions about the dual role of scientist and citizen underlying the FAS mission to focus the energies of scientists and engineers on issues of critical national importance.

FEMINIST ETHICS

Feminist ethics has developed in response to feminist attention to androcentric and sexist limitations of traditional Western ethics.

Broadly speaking, the perspectives advanced by feminist ethics may have implications for the understanding of professional ethics in science and engineering, and in such science and technology related areas of applied ethics as biomedical, environmental, or computer ethics. In the sciences and technologies themselves, feminist ethics may have more direct impact on the theoretical structures of some disciplines (such as anthropology and psychology) than others (such as physics and chemistry).

Feminist critiques have focused on three interrelated concerns. First, that women's moral capacities frequently have been seen as less developed than those of men. Second, that accounts of moral capacities have privileged traits historically identified as masculine, such as reason, autonomy, and independence, over traits identified as feminine, such as caring, community, and interconnection, and that moral theories have similarly emphasized reason, principles, and impartiality over emotion, situatedness, and relationships—again reinforcing the primacy of the culturally masculine. Third, that the majority of moral theorizing has focused on the public realm, with primary attention to men's interests, and has neglected moral concerns arising in the private realm, as well as often overlooking women's rights and interests in the public realm.

The Virtues of Women

Attending to the gendering of ethics has a long history. The tenet that women's virtues differed from those of men was canonized in Aristotelian philosophy. Based on the commonly held belief in women's relative physical weakness and rational inadequacies in comparison to men, Aristotle (384–322 B.C.E.) argued in *The Nichomachean Ethics* that the virtues of women would be different than those of free men. Whereas free men were charged with developing such virtues as courage, temperance, honesty, and justice, women's virtues were viewed as those that would best suit their domestic role and rational capacities, namely, industry and self-command.

The question of women's specific virtues or moral abilities was an often-debated tenet in the history of philosophy. Whereas many non-feminist philosophers continued to insist upon women's inferior moral abilities, many philosophers whose works can be seen as concerned with women's rights questioned both the alleged difference in moral virtues and the imputed inferiority. Mary Wollstonecraft (1759–1797) and John Stuart Mill (1806–1873), for example, argued that there were no fundamental differences between women's and men's morality. But many others argued that although there was a difference in the virtues of women and men, this difference did not imply that women's moral capacities were inferior to those of men. A few such theorists, however, such as Elizabeth Cady Stanton (1815–1902) reversed the traditional position by arguing that women's morality was both different than and superior to that of men.

Few contemporary philosophers hold the type of gender essentialism that was historically the basis for viewing morality as gendered; however, an attention to gendered differences in moral reasoning and habits once again became popular with the work of psychologist Carol Gilligan. In her widely read *In a Different Voice: Psychological Theory and Women's Development* (1982), Gilligan critiqued the developmental psychologist Lawrence Kohlberg's widely-used model of moral development as privileging masculine approaches to moral reasoning, and, in particular, the privileging of universal principles such as justice, and ignoring more typically feminine concerns with relationships, caring, and responsibilities that are richly situated and not amenable to formulation through universal rules. Gilligan argued that the empirical finding that women typically did not develop to the higher stages of Kohlberg's scale of moral development (often only achieving the third stage of his six-stage process, whereas men often reached stages four and five) was a reflection not of women's moral inadequacy but of a biased methodology.

Some have interpreted Gilligan's work as supporting the view that women's morality is different in kind than that of men, but the most significant impact of her work has been to turn scholarly attention to an analysis of moral frameworks that include attention to care, community, and relationships: analyses previously inhibited by accounts of moral capacities that privileged traits historically identified as masculine.

An Ethics of Care

Gilligan's emphasis on an ethics rooted in relationships was the catalyst for a profound rethinking of ethics within feminist philosophy. The ethics of care is seen by many as either an alternative to or a complement to principle-based universalistic ethical theories. Unlike universal rules, which require that behavior be impartial and the same for everyone in like circumstances, an ethics of care is a richly situated ethics that sees each caring relationship as unique. Rather than the rational and emotional detachment predicated by deontological or utilitarian moral theories, care ethicists argue that ethical practice includes the emotions as well as reason.

A feminist ethics of care has been developed by a number of theorists, including Virginia Held, Eva Feder Kittay, Nel Noddings, Sara Ruddick, and Joan Tronto. Care ethicists do not all share the same definition of care, but there are areas of agreement among them. A caring relationship is seen as one in which an individual is both attentive to the specific needs and interests of another, as well as acts to advance them. Hence care involves both knowledge and motivation. It is also seen as an interactive relationship in which the one caring must be attentive to the responses of the one cared for, and modifies his or her efforts to care based on how the other responds to the caring actions. Care ethicists have noted that many human relationships are not between equals but rather between individuals in very different positions—parent/child, doctor/patient, teacher/student. Based on this, care ethicists have argued that moral theories would be best constructed not from contract models that often assume relatively equally positioned individuals, but rather from models that recognize the range of relationships possible between what Noddings calls the "one-caring" and the "cared-for" (1984).

One relationship feminist care ethicists often turn to is that of parenting and, more specifically, mothering. Ruddick focused on "maternal practice" as a form of thinking that although traditionally overlooked by moral theorists provides an excellent model of relationships that strive to foster the goals of preservation, growth, and social acceptability (1989). Ruddick argues that the virtue of "attentive love" involves both reason and emotion and is key to good maternal practice. Ruddick does not limit what she calls maternal practice to women or even to parents, but rather argues that maternal practice should extend to the public world and argues that the skills of maternal thinking will enable society to move towards a politics of peaceful cooperation.

Kittay extends such insights to consider the situation of long-term care, including care of those who are too young, or too ill or impaired to take care of themselves (1999). She argues for the need for what she calls a globally pertinent ethics of long-term care. Kittay, like other care theorists, argues that much of traditional ethical theorizing, as well as liberal political theory with its distinction between public and private, gains legitimacy only through a deep denial of the inevitability of human dependency. Society's conception of justice and much of social policy is structured around the myth of the able-bodied, independent individual. Acknowledging the centrality and ever-changing nature of dependency to human life then demands a reassessment of issues of equity and justice that takes both dependency and the complex natures of care relationships seriously.

Critics of feminist ethics of care worry that care relationships have been "gendered" feminine in such a way that the traits privileged in caring relationships are and will continue to be seen as less valued than the traits of independent agents, and will result in women continuing to be seen as "naturally" more fit for such labors and thereby trapped in low-paid service occupations. Clearly a transformation of ethics that takes seriously the centrality of relationships must go hand-in-hand with social reorganization that recognizes and supports the value of caring labor.

Attention to Women's Concerns

Held has argued that dominant moral theories and the specific issues that have been at the heart of contemporary western ethical analyses have privileged men's experiences and have focused far more on the public realm than the private. Through their attention to the concerns of women, feminist ethicists have introduced new issues to ethics and social theory such as affirmative action, sexual harassment, and comparable worth, and have brought new insights to more traditional issues—for example, discussions of reproductive rights and technologies, and the institutions of marriage, sexuality, and love, as well as caring labor.

Feminist philosophers have also argued that attention to gender cannot be done in isolation from other axes of oppression such as sexuality, race, ability, or class. The work of feminist philosophers such as Linda Martín Alcoff, Claudia Card, Nancy Fraser, Marilyn Frye, Sarah Lucia Hoagland, Eva Feder Kittay, María Lugones, Anita Silvers, Elizabeth Spelman, Iris Marion Young, and Naomi Zack reveal the importance of analyses that identify the structure and consequences of the interaction between different forms of discrimination or subordination.

Sensitivity to women's concerns has had special influence in science and engineering education, where women have historically been underrepresented. It has led to reforms in the educational practices and in the structures of professional practice. In the area of professional ethics, for instance, feminist ethicists have argued for more emphasis on trust behavior development over moral rule following and have emphasized care and communities over rights and individuals. In some special areas of applied ethics related to science and technology, feminist ethics has even produced distinctive perspectives—as in the contribution of ecofeminism to environmental ethics and cyberfeminism to computer ethics.

FEMINIST PERSPECTIVES

The term *feminism* encompasses various social movements, from the late-nineteenth-century women's rights movement to the mid-twentieth-century women's movement in Europe and the United States, as well as referring to theories that identify and critique injustices against women such as Mary Wollstonecraft's *A Vindication of the Rights of Woman* (1792) or Harriet Taylor Mill's *Enfranchisement of Women* (1868). A core connotation of "feminism" is thus a commitment to revealing and eliminating sexist oppression.

In the early twenty-first century, the label "feminist ethics" is used to signify a method or focus of attention for ethical theory and practice. Many scholars have marked the genesis of contemporary feminist philosophy and ethics with Simone de Beauvoir's *The Second Sex*

(1993 [1953]), which provides one of the first sustained analyses of the lived experience of "becoming woman." Beauvoir opened her classic text with a critique of theories contending that there are basic biological differences between women and men that explain women's secondary status in society. She concluded that "one is not born a woman: one becomes one" (p. 249), that is, that women and femininity are "produced" through complex disciplinary practices such as marriage, motherhood, and sexuality. In this way, Beauvoir's work foreshadowed contemporary work in the area of feminist science and technology studies.

Women in Science

Feminist investigations of science and technology emerged in the 1970s, but their origins can be traced to concerns over the low numbers of women in science. Feminists argued that it is a moral imperative to determine the causes of women's underrepresentation in the sciences and to remove those that unjustly block their participation. Because feminists soon realized that sexism also intersects with other axes of oppression, this move to understand the causes of women's underrepresentation in the sciences was followed by efforts to include similar studies of the impact of racism, and more recently of abilism (discrimination against persons with disabilities).

While the numbers of women have been improving in the biological and life sciences since the 1970s, the numbers of women receiving degrees in engineering, physics, and computer science continue to raise concerns. A study conducted by the U.S. National Science Foundation (NSF) found that while women received 57 percent of the doctoral degrees awarded in non-science and engineering fields in the United States in 2001, only 19 percent of the doctoral degrees in computer sciences and 17 percent of the doctoral degrees in engineering were earned by women (NSF 2004). The American Institute of Physics also reported that only 12 percent of the doctoral degrees in physics in 1997 were awarded to women. In addition both studies found that women scientists who worked in the academy were more likely to hold positions at the lower ranks in less prestigious institutions.

Given that overt barriers to women training in science had virtually disappeared by the 1950s, yet the number of women in science remained low, feminists began to explore features of science itself that might account for this disparity. Some of the more liberal approaches argued that the sole cause of the problem was that girls and women were not being encouraged to enter science. This approach led to proposals for science education reform designed to improve the education of girls and young women in science and mathematics. The American Association for the Advancement of Science's *Science for all Americans* (1989) and the National Research Council's *National Science Education Standards* (1996) are two examples.

Many feminist scholars nevertheless argued that solving the problem of science for women would take steps more far-reaching than simply reforming the education system. They began to examine the ways in which sexist and androcentric biases had marked the very topics that were of interest to scientists and had permeated research design as well as the interpretation of research findings. From this perspective, feminists began to propose a transformation of the themes and practices of science itself.

Gender Bias in Science

As feminists began to attend to the role of gender in science they identified a number of examples, particularly in the biological and medical sciences, of scientific practice that was either androcentric, that is, focused on male interests or male lives, or sexist, that is, manifested a bias that women and/or their roles are inferior to those of males.

One classic example of gender bias in science emerged out of feminist investigations of theories of human evolution. Feminists argued that theories of evolution, in providing accounts of the origin of the family and of the sexes and their roles, turned on widely accepted biases about sexual difference. "Man, the hunter" theories of human evolution were analyzed and critiqued not only for focusing primarily on the activities of males but also for the assumption that only male activities were significant to evolution. Hunting behavior alone was posited as the rudimentary beginnings of social and political organization, and only males were presumed to be hunters. Language, intellect, interests, emotions, tool use, and basic social life were portrayed as evolutionary products of the success of the hunting adaptation of males. In this evolutionary account, females were portrayed as following natural dictates in caring for hearth and home, and only male activities were depicted as skilled or socially oriented.

Feminist primatologists, among them Linda Marie Fedigan (1982), Sarah Blaffer Hrdy (1981), Nancy Tanner (1976), and Adrienne Zihlman (1978), not only exposed the gender bias of "man, the hunter" theories, their research led to an alternative account of evolution now accepted as more accurate. By questioning the assumption that women's actions were instinctual and thus of little evolutionary importance, these scientists began to examine the impact of women's activities, in particular the evolutionary significance of food gathering. From this focus, an alternative account of evolution emerged that posited food-gathering activities, now of both women and men, as responsible for increased cooperation among individuals, which resulted in enhanced social skills as well as the development of both language and tools (Haraway 1989).

Examples of androcentrism or sexism in science are numerous and frequently shown to result in poor science and, in many cases, ethically problematic beliefs or practices. The following list provides just a few examples identified by feminists: the exclusion of women in clinical drug trials, attributions of gendered cognitive differences in which female differences are posited to be deviations from the norm, the imposition on women of a male model of the sexual response cycle on women, and the lack of attention to male contraceptive technologies.

Objectivity and Situated Knowledges

Feminist perspectives on gender bias in science and technology led to an appreciation of the link between ethics and epistemology. Feminists such as Donna Haraway, Sandra Harding, and Helen E. Longino argued that nonfeminist accounts of scientific objectivity were inadequate because they provided no method for identifying values and interests that are unquestioningly embraced by the scientific community and that impact theoretical assumptions or the design of research projects. Careful analysis of the history of science documented systematic assumptions about women's biological, intellectual, and moral inferiority that were not the idiosyncratically held opinions of individual scientists but widely held beliefs imbedded in social, political, and economic institutions, as well as scientific theories and practices (Schiebinger 1989, Tuana 1993). Given this, no account or practice of scientific objectivity that does not control for community-wide biases and values could be sufficient.

Feminist science and technology theorists thus argue for a "strengthened objectivity" by developing methods for uncovering the values and interests that constitute scientific projects, particularly those common to communities of scientists, and developing a method for accessing the impact of those values and interests (Harding 1991). In developing such an account, feminists gave up the dream of a "view from nowhere" account of objectivity with its axiom that all knowledge, and in particular scientific knowledge, can be obtained only using methods that completely strip away all subjective components such as values and interests. Feminists, rather, argue that all knowledge is situated, that is, emerges from particular social, economic, or political locations. Strengthened objectivity requires attention to particularity and to partiality, with the goal not to strip all bias from knowledge, but to assess the impacts of "beginning knowledge from different locations." On this account human knowledge is inherently social and engaged. The goal, then, of any quest for objectivity is to examine how values and interests can either limit or enlarge one's knowledge practices.

As just one of many examples analyzed by feminists, consider the emphasis on recombinant DNA technologies that has been proposed since the late twentieth century as a unifying principle for molecular biology (Lodish et al. 2003). Feminists have argued that rather than the lauded neutrality and objectivity, this position reflects numerous values and interests. Recombinant DNA technologies emphasize the centrality of DNA as a "master molecule" that controls life, and ignore or view as less important the organism's environment or the organism's history. In this way, such an allegedly "neutral" technology actively frames a sharp division between genetic and nongenetic factors, trivializes the role of environments, and reinforces biological determinism. Feminists have argued that efforts to cement molecular genetics as the foundation of the science of biology leads to a perception of life, including behavior and social structures, as "gene products."

This situated knowledge practice of contemporary molecular biology is clearly linked to the emergence of "big science" and its support by venture capital. Funding for the Human Genome Project has emphasized a hierarchical, centralized organization of scientific research. And venture capital, following the promise of marketable discoveries in biomedical research, has similarly fueled the growth of such science.

Insofar as molecular genetics becomes the focus of biology, it embeds ideologies concerning the functions and significances of genes and environments that carry with them a renewed emphasis on genetic factors in disease. For example, although the vast majority of all cancers, including breast cancer, are attributable to environmental factors, there is an increasing emphasis in scientific research and medical practice on genetic factors, a move that has been sharply criticized by feminists (Eisenstein 2001). Another concern of feminists and race theorists is that this "geneticization" of human health has also led to a renewed interest in biological difference between groups, which is reinscribing a biological basis to racial classifications (Haraway 1997).

These shifts in research focus can have dramatic effects on resource allocations. Occupational hazards and environmental carcinogens have been clearly implicated in cancer rates, and the effects of environmental racism on the health of minorities have been well documented. Yet funding for research into or cleanup of modifiable environmental factors is shifting to research on genetic inheritance.

Given feminist perspectives on the interaction between biology and environment in the constitution of sex (as well as gender) and sexual identity, this reemergence of biological determinism is in conflict with feminist values and interests. Strengthened objectivity calls attention to the different values and interests guiding research and asks for examination of their roles in contributing to more effective and liberatory practices of science and technology as well as an investigation of how practices of science and technology affect values and interests.

Feminist Technology Studies

Such attention to the values and interests guiding scientific practice also influenced feminists working in the field of technology studies. Feminists came to understand that historians of technology had been accepting gender stereotypes such as "man, the producer" and "woman, the consumer," which had biased the field. In the words of Judith A. McGaw (1989), theorists working in technology studies had "looked *through* masculine ideology at the past rather than looking *at* masculine ideology in the past" (p. 177). Following Harding's call for a strengthened objectivity, feminist investigations of the history of technology recovered the histories of women who both produced and employed a technology, that is, women architects, engineers, and inventors, as well as women workers and their experiences of technological change.

But an attention to sexist or androcentric ideology revealed other types of biases in the field. Technology studies often focused on only certain types of inventions and specific kinds of work as worthy of study. The work of women in textiles and food production, for example, was either ignored or labeled "consumption." Ruth Schwartz Cowan (1983) argued that technology studies had overlooked the fact that female experiences of technology and technological change were often markedly different than male experiences. Studies such as those of McGaw, for example, demonstrated that the mechanization of industrialization often differentially affected men and women, keeping women in the lowest paying jobs where their skills were denied and they had no opportunity for advancement. Feminists also argued that attention to women's most common relationships to technology, namely through use, maintenance, and redesign, revealed an overemphasis in technology studies on the design of technology rather than its use. In critiquing the dichotomy commonly embraced in technology studies between production and consumption, feminists revealed how gender formation and technological development are co-constitutive, meaning that gendered norms are encoded into technological design and use, and that gender roles themselves emerge out of interactions with technologies (See, for example, Wajcman 1991 and 2004, and Rothschild 1983).

Medical Technologies

There is no more obvious arena for mapping the interactive emergence of gender and technology than in the science of medicine. Indeed this interaction can be found at its most literal instantiation, along with all the attendant ethical dilemmas, in the case of the intersexual child (that is, a child born with genitalia and/or secondary sexual characteristics of indeterminate sex, or which combine features of both sexes). In *Sexing the Body* (2000), Anne Fausto-Sterling argues that the U.S. and European medical practice of "fixing" intersexual individuals by assigning a specific sex and offering surgical and other medical

Such practices rest, of course, upon a series of technological advances including advances in plastic surgery originally developed to return to "normal" those bodies that had been deformed by war, accident, birth defects, or illness. But because they also rest upon a series of values, these practices provide a window into the ways in which beliefs about sex and gender affect medicine and also raise a complex series of ethical concerns. Whereas many in the medical community view infant genital surgery as being designed to fix or "cure" an abnormality, which they believe would then allow the individual to lead a "normal" and healthy life, many feminists and Lesbian, Gay, Bisexual, Transexual scholars have argued that such surgery is performed to achieve a social result, namely to make sure all bodies conform to a two-sex system. They also contest the belief that such surgery is necessary for either physiological or psychological health, citing the many cases of intersexuals whose lives were not negatively impacted by this physiological difference. While the medical community views early genital surgery as a medical imperative, critics note that such surgery is frequently a "failure," often requiring numerous additional surgeries, extensive scarring, and a decrease or elimination of sexual pleasure (Fausto-Sterling 2000). Ethical issues abound in this area of medical practice from questions of autonomy (Who decides what is best for an intersexual child?), to issues concerning sexual identity and current societal regulations concerning same-sex relations (Does an intersexual individual who has both a vagina and a penis "count" as a woman or a man in the prevailing two-sex legal economy?).

Ethical issues also permeate the new reproductive technologies, another focus of feminist analysis. Feminists have addressed the risks of various types of reproductive technologies as well as the fact that such technologies are available only to certain women, identifying the way that class issues as well as sexuality and marital status have been limiting factors in the availability of such technologies. Issues of "normalcy" are also central to feminist analyses of reproductive technologies. Many feminists have, for example, critiqued the ways in which prenatal testing intersects with societal biases concerning disability, noting that whereas prenatal testing and selective abortion for the purposes of sex selection are decried in many countries, this practice is widely accepted for fetuses with disabilities such as Down syndrome. Feminists have also investigated how new reproductive technologies are reshaping what is seen as "natural" and affecting the ways women and men experience their bodies. As women and men "bank" their eggs and sperm, as postmenopausal women become pregnant through technological interventions, as lesbian couples give birth to their own biological children, the nature/culture divide shifts and alters.

Global Issues

Feminist investigations of the impact of Western science on women in non-Western societies reveal the Eurocentric and undemocratic nature of Western science. Western scientific "voyages of discovery" were often part of colonialist efforts to mine other cultures for resources, both human and material, and maintain the forms of social control necessary to do so. Feminist and postcolonial science studies have documented how European expansion has contributed to the destruction or devaluation of the scientific practices of the colonized cultures, leading to the false belief in the superiority of Western science, indeed to the false but pervasive belief that Western science is "generic" and not itself "local," that is, not situated in particular economic and social practices (See, for example, Adas 1989).

Feminist scholars have also mapped the continuing de-development of other cultures and their scientific and technological practices through so-called development policies such as the "green revolution" and the more recent impact of biotechnology in agriculture. Feminists have examined who benefits and who is made worse through such practices, paying close attention to the profit margins of those chemicals companies, such as Novartis, AgrEvo, and Dupont, that sell the fertilizers, pesticides, and genetically engineered seeds of this revolution. Although economic impact is a key factor in such analyses, feminists pay close attention to the impact on diversity—both human diversity as well as biodiversity. Vandana Shiva (1997) has argued that the marginalization of women and the destruction of biodiversity through monocultures go hand in hand because women provide the majority of the agricultural labor in many Third World countries. Shiva examines how the biodiversity-based technologies of Third World societies have been viewed as backward and have been systematically displaced by monocultures biased toward commercial interests.

Feminists and postcolonialist science and technology theorists have argued for a democratized science/technology practice that acknowledges the importance of biological as well as cultural diversity as a way to undo the harms of colonialist science practices, including many of the current capitalist-generated practices. While this vision of science and technology emerged from feminist-inspired investigations, it is a moral vision of the intricate interactions between humans and the more than human world, between natures and cultures, and between organisms and environments that should inspire everyone.

FETAL RESEARCH

Fetal research encompasses a broad array of research activities and potential clinical applications. It is ethically controversial because, although it may yield beneficial results, it involves the human organism at a stage of development where its moral status is contested and informed consent is not possible.

Distinctions and Benefits

One key distinction centers on the stage of development of the human organism when the research is conducted, from pre-implantation to late fetal stages. The general sources of fetal material include tissue from dead fetuses; pre-viable or nonviable fetuses in utero prior to an elective abortion; nonviable living fetuses ex utero; or embryos, either in vitro or pre-implantation. Another distinction is that between *investigational* research that cannot benefit the subject fetus and *therapeutic* research that might benefit the fetus subject or is likely to benefit future fetuses. *Clinical* applications including transplantation using fetal material such as tissues, cells, or organs represent another form of fetal research. Moreover, among the many non-clinical uses of human embryos are the development of contraceptives and abortifacients and the study of abnormal cell growth and chromosomal abnormalities.

Moral Issues

One of the most controversial types of fetal research involves embryonic stem cells. Stem cells are primitive cells that have the capacity to divide for indefinite periods in culture and give rise to specialized cells. Most attention is focused on pluripotent cells, those capable of giving rise to most tissues of an organism but not all types necessary for fetal development. The source of these cells can be adult humans, modified stem cells from other species, or most promising (and controversial), cells from aborted fetuses or human embryos (either "spare" embryos from in vitro fertilization or embryos created specifically for research purposes). Some of the potential benefits of stem cell research being discussed are growing new organs, reversing paralysis and other neural/spinal damage, reversing the effects of neuro-degenerating diseases such as Alzheimer's, repairing heart damage, and treating diabetes, cancer, and other diseases.

Potential benefits of other types of fetal research include both knowledge and therapeutic applications. Among the many non-clinical uses of fetal and embryo research are: (1) investigation of abnormal cell growth including various cancers; (2) studying the development of chromosomal abnormalities and other birth defects; (3) understanding implantation problems and miscarriages; and (4) increased knowledge of cancer and aids.

Historical Background

Fetal research first appeared on the national policy agenda in the early 1970s after widely publicized exposés on several gruesome experiments conducted on still-living fetuses. In response, the U.S. Congress passed the 1974 National Research Act (Public Law 93–345) establishing the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research, whose first charge was to investigate the scientific, legal, and ethical aspects of fetal research. In 1976, regulations for the federal funding of such research were promulgated (45 CFR 46.201–211). Under the regulations, certain types of fetal research are fundable, with constraints based on parental consent and the principle of minimizing risk to the pregnant woman and the fetus.

In 1985, Congress passed a law (42 U.S.C. 289) forbidding federal conduct or funding of research on viable ex utero fetuses with an exception for therapeutic research or research that poses no added risk of suffering, injury, or death to the fetus and leads to important knowledge unobtainable by other means. Federal regulations on fetal research, then, appear to be quite clear in allowing funding within boundaries. However, in two key areas—embryo research and fetal tissue transplantation research—there in effect was a moratorium on federal funding between 1980 and 1995, which, according to the Institute of Medicine, severely hampered knowledge in medically assisted reproduction because the reliance on private funding shifted emphasis from essential basic research to rapid and often risky clinical applications. In addition, many states have laws regulating or even prohibiting certain types of fetal research, often either part of or attached to abortion statutes (for details see NCSL 2003).

At the center of the controversy over fetal research is disagreement over the moral and legal status of the fetus. Questions also center on who may consent for the use of fetal materials, under what circumstances the abortion procedure can be modified to meet the needs of the research, and what type of compensation, if any, for fetal tissues should be allowed. As a result of these issues, fetal research has been elevated to the public agenda and has become a highly volatile moral and political issue (Vawter, Kearney, and Gervais 1990).

Ongoing Debate

There is an ongoing debate over whether the use of fetal tissue from elective abortion encourages or legitimizes abortion. On the one hand, opponents argue that research using aborted fetuses gives abortion greater legitimacy and contend that use of embryos and fetuses for research exploits them and reduces them to biological commodities (Brown 2003). Moreover, because the fetus is unable to consent, there is concern over what type of consent and by whom is sufficient, and how to balance research needs with interests of the pregnant woman. On the other hand, supporters argue that research using human fetal and embryonic materials is critical for progress in many areas of medicine (Fletcher 1993).

As already suggested, perhaps the most controversial area of fetal research involves the use of fetal cells for transplantation to adult patients to treat a wide range of disorders (Stein and Glasier 1995). Such tissue can come from spontaneous abortions, induced abortions on unintended pregnancies, induced abortions on fetuses conceived specifically this purpose, or from embryos produced in vitro. A dependence on spontaneously aborted fetuses for research is impractical because of the limited number available and the inability to control the timing. The major supply of fetal tissue, therefore, is likely to come from induced abortions, but this raises vehement objections on moral grounds by groups opposed to abortion (Brown 2003).

Privatization and Related Issues

In light of the extent to which stem cell research might revolutionize health care, there is a huge commercial stake in fetal/embryo research. Already, marketing and advertising has started in the area of umbilical cord stem cell preservation and this is certain to be followed by broader efforts to market the fruits of this research. Moreover, once the benefits start to materialize, demand for cell lines will intensify, thus putting pressures on potential suppliers. Both of the two options, production of designated research embryos or increasing the supply of spare embryos, bring risks to women and raise questions concerning the consent process and proprietary rights over what promise to be very lucrative human materials.

There is also concern that increased pressures for these scarce resources could lead to exploitation of poor women paid to conceive solely to provide fetal material or an international market for multi-national drug companies.

Moreover, the continually expanding field of potential uses of fetal tissues, complicated by the difficulty of ensuring cooperation from abortion clinics and obstetricians in making fetal tissue available, has raised concerns for maintaining an adequate supply of fetal tissue. The availability of RU-486 and other abortifacients might actually diminish the supply of usable fetal tissue at a time when demand is increasing.

Assessment

Clearly some important areas of fetal research have been explicitly constrained on moral rather than scientific grounds. The presence of abortion politics continues to exert strong influence on research funded by the government across a wide range of substantive areas. In the process, some argue that long-term scientific goals are being compromised by immediate, pragmatic political objectives. The spirited debate over stem cell research in the 2004 election and the decision of California voters to invest $3 billion demonstrates that these issues will not dissipate. Given the sensitivity of human embryo and fetal research and its interdependence with abortion, this should not be surprising. Fetal research raises moral red flags for many persons and thus will remain a political as well as moral issue.

FIRE

From the prehistorical era, fire has generated the energy that allowed human beings to warm themselves and their surroundings, illuminate the darkness, prepare food, and create artifacts with both utilitarian and aesthetic value. More recently, fire has powered transportation and manufacturing and served as an object of and means for research.

These dual aspects of fire are represented in its deeply symbolic character. From the earliest periods fire has served as a symbol for moral and intellectual achievement. Many religions use fire in ceremonies, as in candles and funeral pyres. Fire is also common in celebrations, such as birthday candles and fireworks.

Although fire is indispensable to human beings and civilization, it also can kill and destroy or be used as a means for intentional destruction and warfare. The great library at Alexandria was destroyed by fire in 47 B.C.E. and the Chicago fire of October 1871 forced the city to rebuild itself. The World War II firebombings of Dresden and Tokyo were more destructive than the atomic bombings of Hiroshima and Nagasaki.

The Science of Fire

Chemically, fire is an exothermic reaction involving the rapid oxidation of fuel. For example, the burning of red oak could be approximated as follows:

$$CH_{1.7}O_{0.72}N_{0.001} + 1.065O_2 \rightarrow CO_2 + 0.85H_2O + 0.0005N_2$$

This reaction liberates approximately 12.7 megajoules of energy for each kilogram of red oak burned. (One joule of energy is equal to one watt of power generated for one second; a megajoule represents one million joules.) This liberated energy raises the temperature of the reaction products and emits thermal radiation. Most fires occur in a normal air atmosphere, which is approximately 21 percent oxygen and 78 percent nitrogen. Thus, the burning of red oak in air is written more correctly as follows:

$$CH_{1.7}O_{0.72}N_{0.001} + 1.065(O_2 + 3.76N_2) \rightarrow CO_2 + 0.85H_2O + 4.0049N_2$$

Because the nitrogen in the air plays no role in the reaction, the temperatures of flames in air are lower than the temperatures in pure oxygen; some of the energy that is liberated by the fire heats the ambient nitrogen.

Fires can be characterized as two different types of flaming: premixed and diffusion. Premixed flaming occurs when fuel and air are mixed before combustion; a diffusion flame exists when burning occurs as fuel and air are being mixed. Both types can be illustrated with a standard laboratory Bunsen burner. Typically, when a Bunsen burner is used, a blue flame is desired. That flame is premixed because air is entrained into the fuel stream through openings in the burner before the flame zone is established. However, if the openings where air is entrained into the burner are closed, the flame loses its regular shape and changes color from blue to yellow. This is a diffusion flame, where the gas feeding the burner must mix with the surrounding air in the area of flaming.

In general, all fires involve the combustion of gaseous fuel. If the fuel is a gas, such as the fuel that feeds a Bunsen burner, it only needs to mix with air for burning to occur. If the fuel is a liquid, it must be heated sufficiently to release vapors. The temperature at which a liquid fuel releases sufficient vapors for combustion to occur is called its *flashpoint*, and it occurs at a temperature lower than the boiling point of the liquid.

Solid fuels similarly must be heated to a temperature at which sufficient vapors are released to support combustion; however, solid fuels do not necessarily vaporize as liquids do. Some solid fuels melt and then subsequently vaporize before combustion. Others, such as wood, do not melt before releasing combustible vapors. Upon heating, these solids decompose into simpler compounds that are distinct from the original material in a process called *pyrolization*. The temperature at which a solid fuel releases sufficient vapors for combustion is called its *ignition temperature*.

Ignition of a fire requires the introduction of energy. For a gaseous fuel or a liquid fuel that is at a temperature above its flashpoint, a spark or small flame may be sufficient to provide that energy. For solid fuels or liquid fuels that are at a temperature below their flashpoint, the fuel first must be heated to a temperature at or above its flashpoint or ignition temperature.

Once a fuel is ignited, the heat liberated form the fire can transfer back to the fuel, causing the fire to sustain itself or grow. However, if the energy feedback to the fuel is not sufficient, the fire will decay and eventually go out. This can be illustrated by looking at logs in a fireplace. If there is only one wood log in a fireplace, so much of the energy liberated by burning the log is lost to the environment that the fire will go out. However, if more logs are added, some of the energy that would have been lost is transferred to the other logs, and the fire will be sustained.

Fire and Technology

Humans are the only creatures that have the ability to control and harness fire. Fire has been indispensable to technological progress. It is no accident that Prometheus is said to have stolen fire from the gods to make it possible for human beings to live. Early humanity learned how to start fires that could serve very simple uses. As humanity evolved, the heat generated by fire was used for more complex tasks, such as hardening clay and molding metals. Later, the energy liberated by fires created steam to power moving equipment.

As the understanding of fire increased, so did the efficiency with which it was used to generate energy.

Instead of using fires to heat water to create steam, fires could be ignited under controlled conditions in cylinders, allowing the potential energy in the fuel to be converted more directly to kinetic energy. It is through these types of processes that fire can be used to power generators that create electricity or to create mechanical energy to power airplanes and boats directly.

However, just as fire can serve benign purposes, it can be used in more destructive tasks. Fire applied to people or their environments either intentionally or unintentionally can cause death, injury, and the loss of property. Entire cities have been lost to fire; although the rate of death, injury, and destruction caused by fire has decreased steadily, fire continues to take a serious toll. It is likely this dichotomy of purpose that prompted fire as a symbol of attractive self-destruction, as when the moth flies into the flame.

The Ethics of Fire

The technological advances that have been made possible by the ability to harness fire also have created risks to society. As the Industrial Revolution created an environment in which manufacturing facilities were placed closely together, the flammability of the items inside those facilities, coupled with the closeness of buildings, allowed for fires that could destroy entire cities. This caused society to look for ways to protect people and the community from the hazards of fire.

As a result of fires that caused the loss of whole cities, people began to look for means of limiting the effects of a fire to a single building. This was accomplished by controlling the materials from which buildings were constructed, the spacing of buildings, and the types of openings, such as windows, installed in buildings.

As people learned ways to limit the impact of a fire to a single building, the goal of fire safety changed to limiting that impact to a single portion of a building. As methods of protection against fire improved, the maximum tolerable effects of fire became smaller.

Society has devised a number of ways to prevent fire that can be divided into two broad areas: prevention of fire ignition and management of fire impact. By controlling the methods of creating and distributing energy, it is possible to make it less likely that a fire will be ignited. Examples of means to prevent fire ignition include the electrical protections that typically are required in a home or business: the use of minimum wire sizes, electrical insulation on wires, and the use of fuses or circuit breakers.

Management of fire impact can involve means of managing a fire once it begins or ways to manage the things that are intended to be protected from fire. Fires can be managed by controlling the fire combustion process, suppressing fires, and controlling fires by means of the types of construction used. Examples of these means include controlling the type of fuel present, the use of fire suppression systems such as automatic sprinkler systems, and the use of building materials that resist the spread of fires, such as fire walls and doors.

In light of the fact that almost all human pursuits create fire risk, society has an obligation to ensure that the risks that are created are controlled. Developing better means of fire protection requires the development of a better understanding of fire and of the way fire affects buildings, people, and property. To this end there is a branch of science that is dedicated to the study of fire. Fire science involves scientific study of how fires start, how they grow, how they can be extinguished or suppressed, and the amount of heat and chemical compounds that are created when fires occur. Fire scientists also create models, or methods of simulating, fires. Fire models range in complexity from sophisticated computer programs to relatively simple equations that can be solved with a calculator.

Similarly, there is a branch of engineering that is dedicated to the application of scientific principles to protect people, property, and the environment. Fire protection engineers apply the scientific understanding of fire to reduce the risks of fire to reduce the likelihood of unwanted fires and manage the impact to society when unwanted fires occur.

FOOD AND DRUG ADMINISTRATION

SEE *Food and Drug Agencies*.

FOOD AND DRUG AGENCIES

Because foods and drugs are intimately involved with the quality of life, their purity and safety have been of deep concern to many citizens and the governmental agencies dedicated to human welfare. Throughout the world the purpose of food and drug agencies is to certify that foods are safe and drugs effective. Consequently these agencies have as one of their chief goals the prevention of adulteration—debasing foods or drugs by diluting them with less valuable ingredients or adding substances to make the food or drug appear to be what it is not. Adulteration has ethical consequences; for example, the dilution of a cancer drug may hasten rather than hinder death. Corrupt companies can use scientific knowledge and chemical techniques to thwart detection of their adulterated products, forcing food and drug agencies to develop advanced techniques to ferret out fraudulent drugs and thereby protect the public from harm. Science and technology are thus inextricably involved in the ethics of food and drug agencies and industries.

Early History

During the Latin Middle Ages writers of herbals and medical treatises expressed ethical qualms about adulteration and proposed remedies. These writers found that scarcity of supply played a role in fraudulent practices. In 1202 King John instituted the first English food law, which prohibited the admixture of inferior ingredients in publicly sold bread. In Germany and France rulers passed statutes that fined brewers for doctoring beer and wine. Arabs of medieval Islam appointed police officers to test the genuineness of foods and drugs in markets. Medicinal compounds had to be prepared before a supervisor, who was the guarantor of the drug's purity.

With the European voyages of discovery in the fifteenth and sixteenth centuries, new foods and herbal drugs became part of an expanding global marketplace. To preserve foods on long journeys, producers and transporters used chemicals to retard spoilage and color foods. These practices led to abuses, and some European governments passed laws to prevent and punish harmful or deceptive practices. In the seventeenth century Robert Boyle, a British physicist and chemist, invented a device for determining specific gravities, which gave pharmacists a new way to detect drug adulteration. With the increasing sophistication of scientific knowledge in the eighteenth century, technical books by Adolph Gottlob Richter, Jean-Baptiste-Augustin Vanden Sande, and others appeared on adulteration and its detection and eradication. Although these authors used the new knowledge of chemistry and highly developed apparatus of the Scientific Revolution, they also analyzed the ethics underlying nefarious practices by merchants, pharmacists, and physicians. They suggested such remedies as better education and more effective laws to correct the injuries being done to customers and patients.

Food and Drug Agencies

As the first country to combat food and drug fraud through a comprehensive set of laws, Great Britain became the model for many other nations. Beginning in the eighteenth and early nineteenth centuries with laws on the adulteration of tea, wine, and beer, the British were able to protect the integrity of these and other important commodities and, through revenue officers, enhance state income. New technologies such as the microscope helped scientists detect the adulteration of coffee with chicory, but scandals associated with injurious foods and drugs forced legislators, in a series of new laws, to shift from noninjurious adulteration to the illegal addition of substances to foods and drugs that caused physical harm.

In colonial America the earliest food adulteration laws closely followed British examples, but in the late eighteenth century the first U.S. food law clearly targeted those persons, corrupted by greed, who sold unwholesome food in Massachusetts. Once convicted, such persons could be fined, imprisoned, or pilloried. The first U.S. federal drug law was passed in 1848, and it prohibited the importation of adulterated drugs. In 1862 President Abraham Lincoln signed legislation creating the U.S. Department of Agriculture (USDA), which included a Division of Chemistry (renamed the Bureau of Chemistry in 1901). This agency, which was a precursor of the Food and Drug Administration (FDA), employed chemists to identify adulterants in foods. During the rapid growth in population and industry after the Civil War (1861–1865), interstate traffic in foods and drugs also increased, as did tragedies associated with the addition of harmful dyes and preservatives to food and drink. An outraged public clamored for remedies, and between 1880 and 1906 more than a hundred bills were introduced in the U.S. Congress, but not one passed both houses.

The person largely responsible for breaking this deadlock was Harvey Wiley (1844–1930), chief chemist at the USDA from 1883 to 1912 and the "Father of the Pure Food and Drug Law." Convinced that many food and drug businesses were placing profits ahead of public health, Wiley hired idealistic young chemists, who were nicknamed the "Poison Squad," to study how chemical additives in foods affected health. Reports of their results aroused public concern, but "Wiley's Law" would never have been realized were it not for Upton Sinclair (1878–1968), whose novel *The Jungle* (1906) dramatized the repulsive practices in the Chicago meatpacking industry. The Pure Food and Drug Act of 1906 prohibited the "manufacture, sale, or transportation of adulterated or misbranded or poisonous or deleterious foods, drugs, medicines, and liquors." The Bureau of Chemistry administered the law, and Wiley and his successors developed an organization that won many victories for pure foods and drugs in the courts.

During the three decades after passage of the new law, weaknesses in its provisions appeared, because unscrupulous manufacturers were able to use advances in scientific knowledge and techniques to circumvent the statute. Muckraking journalists charged the food, drug, and cosmetics manufacturers with using 100 million Americans as "guinea pigs," and they provided examples of cosmetics that blinded women and drugs that caused children to suffer agonizing deaths (Kallet and Schlink 1933). Although administrative modifications were made (the Agricultural Appropriation Act of 1930 changed the agency name to the Food and Drug Administration), it was not until 1938 that Congress passed the Federal Food, Drug, and Cosmetic Act, which required manufacturers to provide scientific proof, through tests on animals and humans, that all their products were safe *before* they were put onto the market.

To isolate the FDA from advocacy groups, it was transferred from the USDA to the Federal Security Agency in 1940. World War II expanded the FDA workload, and during and after the war the number, variety, and power of new drugs increased dramatically. Food and drug companies grew in size and influence, which precipitated both abuses and legislative remedies. During the 1950s and 1960s, the 1938 act was periodically amended, and after the FDA became part of the Department of Health, Education, and Welfare in 1953, it used these new laws to give control of new drugs to doctors and FDA officials. The Delaney Clause (1958), which prohibited the use of substances in food if they caused cancer in laboratory animals, led to the controversial ban on saccharin, an artificial sweetener and weak carcinogen (this clause was replaced, in 1996, with the less stringent standard that "no harm will result from pesticide residues on raw and processed foods").

In the late 1950s, because of the widespread use of the sedative thalidomide by pregnant women in Europe, thousands of deformed infants were born, which eventually led to stronger drug laws in many countries. This drug was not widely available in America because of the valiant efforts of Frances Kelsey, an FDA examiner, whose suspicions about thalidomide led to her repeated rejections of applications to market it in the United States. Congress responded to the thalidomide tragedy by passing the Kefauver-Harris Amendment in 1962. This law changed the ways in which drugs were created, rested, developed, prescribed, and sold. The burden was now on the companies sponsoring a new drug to show that it was safe and effective. The FDA also issued new regulations that made the drug review process extremely stringiest, leading to criticisms that drug approval became glacially slow, because FDA officials, fearful of another thalidomide-like calamity, required study after study.

Criticizing the FDA—and Ethics

During the last four decades of the twentieth century the FDA came under attack by industry executives, congressional subcommittees, and public action groups. These FDA critics proposed that 200 million Americans were now being used as guinea pigs, because they were ingesting drugs and food additives that were even more deadly than those of the 1930s (Fuller 1972). Congress responded with a series of laws that, for example, strengthened FDA authority to regulate medical devices and commercial baby foods. These changes did not prevent the generic drug scandals of the 1980s, and in the 1990s the FDA continued to be an agency struggling to regain its credibility as the guardian of national health.

As with similar agencies in other countries, the FDA is charged with protecting public health, and in doing so it is often entangled in controversial ethical issues made more complex by advances in science and technology. For example, the FDA is responsible for regulating investigational new drugs (INDs). These drugs, not yet approved for sale, must be scientifically tested on animals, because an adverse effect on an animal often correlates with a similar effect on humans. Animal rights advocates have objected to this phase of IND development as unethical, whereas other groups have objected to the next three phases of IND testing, because humans are involved. In Phase I, small groups of healthy volunteers are given the IND to help researchers study its effectiveness, dosage, and metabolism. In Phase II, one to 200 patients with the drug-targeted disease are monitored for drug safety, efficacy, and side effects. In Phase III, even larger numbers of patients take the drug to refine optimum dosages, and placebos are given to some patients to make sure that IND effects are not due to chance or a developer's optimism.

Critics have raised doubts about FDA procedures on INDs. For example, in the 1970s, the General Accounting Office (GAO) studied ten of the more than 6,000 drugs then classified as INDs, concluding that in eight cases the FDA failed to halt human tests after learning that the new drugs were unsafe. Furthermore, the GAO found that drug companies delayed reporting adverse drug effects to the FDA. Other critics have attacked the FDA for approving too many drugs too quickly, thereby increasing risks, whereas still others blamed the FDA for approving drugs too slowly, thus depriving people of beneficial treatments.

Because of physicians' professional involvement with nutrition, prescription and nonprescription drugs, and medical technologies, they have a vested interest in food and drug companies as well as the FDA. This interest can raise ethical conflicts. According to some studies, physicians are protective of their independence and the integrity of the doctor–patient relationship, and many doctors are wary of governmental intrusions into how they practice medicine. Some critics have nevertheless pointed out the dangers of the close relationship that has developed between many doctors and drug companies.

Congressional subcommittees have questioned the ethics and legality of certain drug company activities. For example, in 1988 generic drugs became the focus of interest when investigators discovered that three generic drug companies were receiving accelerated approval of their drug applications in exchange for payoffs to FDA employees. By the time this scandal was over, federal courts had convicted ten companies and forty-two people of corruption. This scandal also revealed a potentially corrupting collusion between FDA workers and pharmaceutical companies, because FDA employees often leave their government jobs for highly paid positions at the companies they have formerly regulated.

Other controversies associated with science, technology, and ethics have involved artificial hearts, genetically engineered foods, and pediatric drugs. In these and other cases some ethicists claim that the law of the marketplace has contaminated the ethic that has generally guided scientists. For instance, they believe that profits rather than a genuine concern for humans and the environment have guided research on genetically modified plants and animals. Because many newborns have died after receiving drugs unsuited to their undeveloped organs, ethicists have pleaded with pharmaceutical companies and the FDA to do more research on proper drug doses for infants and children. Other ethicists have been troubled by the predominant use of white males in many drug studies, to the exclusion of women and minorities, whose genetic make-up and susceptibility to certain diseases are different from white males.

Assessment of FDA Influence and Future Prospects

Food and drug industries are among the largest and most lucrative in the world, and the governmental agencies that have evolved to regulate them have also become massive and complex. Because of the accelerating growth of science and technology, some predict that these industries and agencies will continue to expand, but others have warned that pharmaceutical companies are not creating new drugs at a rate necessary to maintain their viability in the marketplace. Although global funding for drug research doubled in the last decade of the twentieth century, the number of new drugs declined by 50 percent. The reasons for this decline are controversial. Some blame an industrial emphasis on "blockbuster drugs" that generate huge profits. But others blame the gargantuan costs required to develop new drugs. At the end of the twentieth century it typically took fifteen years and $900 million to develop a new drug, but only a very small percentage of these drugs actually become commercial successes. Still other critics have proposed replacing governmental food and drug agencies with free-market certification agencies, arguing that economic incentives are more conductive to effective results than bureaucratic incentives. Furthermore, simple drug solutions to such complex diseases as cancer and Alzheimer's have proven to be illusory.

Optimists believe that new technologies will be able to lessen these skyrocketing costs. For example, some have predicted that the sequencing of the human genome will revolutionize drug creation, but so far the mass of new data has confused rather than clarified future prospects. Scientists have used rational drug design, combinatorial chemistry, and high-throughput screening to accelerate the development of new drugs, but pessimists point out that, although the quantity of potential new drugs has increased, their quality has not. These critics also emphasize a fundamental ethical conflict between commercial interests and human needs for life-enhancing foods and lifesaving drugs.

As the need for safe, high-quality foods and drugs has grown, possible solutions to the problems posed by pessimists have been offered. Some believe that the reason so many useless drugs are generated is poor understanding of basic life processes. These analysts hope that, with more research in molecular and cell biology, the information needed to create precisely targeted drugs will become available. Others believe that computers will be able to predict how certain "new molecular entities" will bond to target compounds in human cells, thus fulfilling Paul Ehrlich's dream of "magic bullets." Still others believe that the solutions will be found in the plants populating the rain forests of the world. For a growing number of scientists, the future of healthful foods and safe and effective drugs lies in combining all of these solutions together, but with a realization that new foods and drugs must be created, developed, and marketed in ways that are compatible with the most profound ethical ideals of the human family.

FOOD SCIENCE AND TECHNOLOGY

Among the concerns of food science and technology are postharvest changes in substances that nourish human beings. Food science examines everything that can happen to food between harvest and consumption. Food technology is used to develop and manage the processes by which food is transformed from raw harvest to edible goods purchased by individual consumers. Almost all foods are modified before consumption. Only some fruits, nuts, vegetables, meats, milk, and eggs may be eaten raw. About three-quarters of all the calories consumed by humans worldwide are derived from rice, wheat, and corn (maize)—truly the staff of life in almost all societies—all of which must be processed to make their delivery of nutrients feasible.

Food science and technology draw on chemistry, microbiology, engineering, physiology, toxicology, nutrition, dietetics, economics, marketing, and law; therefore, food science and food technology are inherently interdisciplinary subjects rather than narrow disciplines. Because of the importance of food, this topic also raises a host of ethical issues, including professional responsibility, equity of availability, determination of levels of safety in regard to public health, risk to workers' rights, and informed consent among consumers.

Background

Along with the making of shelter and clothing, the securing and preparing of food constitute one of the oldest technical activities, being coeval with the emergence of *Homo sapiens*. Because of its importance, from the beginning of human society food appears to have been associated with a number of ethical judgments in the form of rituals and taboos. Gender differences in regard to food procurement evolved for natural reasons: Males were the hunters, and females were the gatherers and subsequently the crop cultivators. Anthropologists also focus on cultural aspects such as food as a means of asserting identity or group membership; the reciprocal effects of class or caste systems on foodways; communal eating and food as a means of bonding and hospitality; ritual aspects of food, for example, at funerals and weddings; and food taboos and food eaten for religious reasons—these so-called ceremonial foods include bread, wine, and oil, the first manufactured foodstuffs.

Two major changes allowed human populations to shift from nomadic hunting and gathering, which they had engaged in for hundreds of thousands of years, to living in settled communities. The first was the domestication of animals, probably beginning with that of the Asiatic wolf as an aid in hunting, around 13,000 years ago after the end of the last ice age. More significant was the keeping of lactating animals such as goats and sheep to guarantee a regular supply of milk, meat, and nonfood products. By approximately 10,000 years ago sheep had been domesticated in the area that is now Iraq, as were goats. Pigs were domesticated a thousand years later, and it took another thousand years before the wild aurochs had been transformed into cattle in the Balkan area.

The second achievement was the recognition of the relationship between plants and their seeds. This allowed a previously nomadic clan to settle in an appropriate landscape. With the receding ice, fields of wild grain or grasses with edible seeds appeared, and eventually women began to plant seeds in cleared areas.

Those two achievements were the key elements in what has come to be known as the Agricultural or Neolithic Revolution, which occurred during the New Stone Age, a period that began 11,000 years ago in southern Asia and 9,000 years ago in the Tigris and Euphrates river valleys, from where the new techniques began to spread. The agricultural revolution provided more and better food, promoting improved human fertility and longevity, and therefore increased human population numbers.

Differentiating between life-sustaining and harmful foods is probably an instinctive human behavior. People are drawn to carbohydrate-rich foods, which are generally sweet, and usually are repelled by alkaloidal products, which contain bitter toxic chemicals. An important discovery was that heat, such as that provided in cooking by fire or hot water, can alter the characteristics of food. The transformation of food materials by heat to make them consistently and predictably edible, flavorful, and spoilage-resistant developed into a practice that preceded techniques for deliberately changing inorganic materials, as in the making of pottery from clay some 30,000 years ago and then the use of metallurgy about 6,000 years ago, both of which contributed to cookery.

According to Harold McGee (1990), chemistry began with the "food chemistry" of ancestral cooks. The molecules those cooks transformed and manipulated were food molecules. Each time contemporary people prepare food for eating, whether in a large food-processing plant or in a kitchen, they replicate the origins of an art practiced since the harnessing of fire 125,000 years ago.

It was not until the Enlightenment and well into the Industrial Revolution that food became a focus of scientific study. It was the modern period as well that witnessed the related developments in public health, medical nutrition, and mechanization in food processing, especially for mass production. The adaptation of mass production technologies to agricultural production and food processing radically transformed human-food relations. Those processes made it possible for smaller numbers of food workers to support larger numbers of food consumers, thus promoting urbanization on an unprecedented scale. That urbanization led to new technologies of preservation, transportation, and marketing; inspired scientific studies of nutrition (because in many instances the new technologies altered the balances in traditional diets); and raised ethical issues about the treatment of food processing workers as well as equity in access and distribution (which previously had been subject to the negotiations characteristic of traditional cultures).

Nevertheless, the basic objectives of assuring a satisfactory supply of food did not change. Those objectives only become more visible, controllable, and subject to management. Indeed, only new insights and improved techniques can assure a continuing stream of food products for the growing human population.

The Perennial Vital Objectives

All functioning modern societies attempt to provide people with foods that are readily available, abundant, affordable, appealing, appetizing, nutritious, and safe. Agriculture (including fisheries), along with food science and food technology, is essential in meeting those goals. Since prehistoric times the objectives related to feeding a clan or a larger community have been optimization of harvest yields, prevention of losses, achievement of edibility, and protection of food integrity factors such as flavor, texture, color, and nutrition.

The food system—the path from soil to mouth or from farm to fork—is a precarious one. Numerous technologies are involved in the modern effort to bring food to consumers. Much can go wrong, and much depends on climate and other natural forces. However, human ingenuity, a multitude of tools, and technological interventions are the critical factors in seizing life-sustaining products from nature. Then all foods must be protected during the transfer from their production habitats to their final destination. The notion of a carefree dependence on the abundance of nature is far removed from reality.

Each food product on the shelves of grocery stores can be traced through its passage from harvest (including slaughtering and fishing) to channels of transportation and then to storage, packaging, and distribution until it is purchased for preparation in a consumer's kitchen or an efficient mass-feeding facility. About half of all dollars spent on food consumption in the United States at the beginning of the twenty-first century was expended in eating away from home.

Other animals compete with humans for the products of nature. The biblical scourges of locusts are a familiar example, but it is mainly invisible competitors that take the most. Bacteria, molds, yeasts, and even viruses consistently make foods unavailable, inedible, or the cause of disease. Only a few microorganisms have been put to positive use, mainly in fermentation. Because eradication is impossible, pest control is a major activity and expenditure for farmers and food processors and even for the food service industry and some householders. This war against microscopic competitors is waged most effectively with chemical weapons and must be affordable and properly done.

Current agricultural pesticides are largely products of the 1950s. As with all technological interventions, it soon was realized that there was a side effect in that pesticide residues on and in foods could be harmful to human health and to the environment. A typical quandary is the war against food pests. This battle involves powerful weaponry to assure an abundance of crops and may do damage to people as a side effect.

In addition to rodent, insect, and microbiological losses numerous chemical changes occur in foods that have unpleasant results. Soured milk, bitter rice, rancid fatty food, and other unpalatable edibles are thrown away. Not even animals are fed with them because their owners suspect the presence of toxic substances. The losses to the "food system" and to society are obvious. Equally obvious is the fact that such losses, along with food deterioration overall, can be avoided to a large extent through the judicious application of food technologies. That constitutes the major preoccupation of modern food processors and handlers, the custodians who take possession of food after harvesting and deliver it to end users in the expected qualities and quantities.

Food losses and food waste are enormous, although no accurate data exist. Ironically, in places where food crops are usually scarce, often because of a lack of technological intervention but also as a result of natural disasters, personal wastage is rare. In the developed parts of the world, where technology assures an abundance of food, there is usually gross disregard for optimal personal food utilization. Examples include tray waste in institutional facilities and careless housekeeping practices.

Food protection spans the spectrum from seeds to the moment of consumption. The initial responsibility lies with food producers. Agricultural research began in the nineteenth century. It has always been devoted mainly to production studies that have culminated in the use of chemical, mechanical, computer, and more recently bioengineering technologies. Each technology has had opponents, has sparked heavy discussion, and has been improved as a result. One insight has become clear: Without science and appropriately applied technologies improvement of the human condition would be slow, difficult, and painful.

Food Processing

From cutting to gamma-irradiation, the subject of food processing involves dozens of operations. Only a few can be mentioned in this brief overview. At the heart of food technology are several processing operations that are used to modify foods primarily to preserve them for later consumption. Water removal is one way to preserve a food: Raisins last longer than grapes, cheese and sausages can be stored for long periods, fruits can be converted to fermented beverages, and grains can be made into beer. In all these cases, the original food disappears but the nutritive value is preserved.

Another method of preservation is the use of chemicals, such as acids, that are antagonistic to spoilage microorganisms. During the 1990s about 5,000 people died every year in the United States from bacterial food poisoning. The human toll from poisoned food was almost unbelievably high until the advent of food technology, along with hygienic measures and medical advances. Vinegar, yogurt, and pickled foods are examples of acid-preserved foods.

The pickling of vegetables has a long history, especially in China, and has relied primarily on the use of salt (sodium chloride). The history of salt, which is considered the first "food" of commerce, is interwoven with that of food preservation (Kurlansky 2002). A high sugar content also preserves food, as in the case of candied fruit and confectionery products. The inspiration must have come from honey, the original natural preserved food.

Modern food markets provide evidence that almost everything people eat is modified before consumption. The rationale of most processing is to protect a food until it is consumed, and an understanding of food chemistry and microbiology is essential in that endeavor.

The simplest way to defeat microorganisms is to remove the water that is vital to them. Most foods that are not dried properly spoil very quickly, but substances antagonistic to microorganisms can be added directly or indirectly, as in lactic and alcoholic fermentations. The result is not only protection but also better nutrient availability and palatability. Lactic acid fermentation utilizes the destructive and digestive ability of certain microorganisms for human advantage, as in the cases of fermented cabbage and yogurt. The production of vinegar, beer, and wine provides examples of acetic and alcoholic fermentation. Other preservatives are microbial inhibitors such as spices, herbs, and salts.

Inhibition of oxidation is achieved mainly by means of the addition of antioxidants. Foods that are rancid or have lost flavor or color are considered spoiled. The mechanism is driven largely by enzymes native to foods but also by oxygen in the air. Consequently, air exclusion is a preservative technique. The first efforts at producing and sealing sterilized food were not made until the late 1700s, and plastic wraps and packaging under nitrogen were not used until the mid-1900s.

Canning is the most noteworthy achievement in food technology. It was invented by Nicolas Appert, who in 1790 in Paris preserved heated foods in bottles. Twenty years later the food-canning industry was born when the first "tin" cans were produced in England. Only with the 1864 work of Louis Pasteur on bacteria and asepsis did it become possible to understand the principles behind this food preservation technology. It was not until 1928 that Charles Olin Ball worked out the mathematical formula that made the thermal processing of foods possible. All heat sterilizing procedures in food and pharmaceutical industries in the early twenty-first century rely on Ball's work.

Legal and Ethical Issues

In 1939 in the United States the Institute of Food Technologists (IFT) was created. Similar professional associations now exist in most major countries. This represented the beginning of the coordination of all research activities and industrial development work involving foods. By 1960 several university food science departments had emerged. In the early 2000s there are nearly fifty in North America, and the IFT, headquartered in Chicago, has almost 30,000 members. This professional association publishes a number of journals and organizes well-attended annual meetings and expositions. Its mission is to establish and promote standards of professional excellence at local as well as international levels. The IFT fosters communication, contributes to public policy, and helps individuals achieve career goals. Along with its counterparts in other countries, it embraces objectives such as combating hunger, enhancing the quality of foods, and stimulating progress in the food technology industries.

IFT lists six core values in its current strategic plan:

- Act with integrity
- Foster inventive and adaptive leadership
- Demonstrate responsible stewardship
- Focus on members
- Value diversity
- Chanmpion sound science in the interest of public well-being

IFT's counterpart in the UK, the Institute of Food Science and Technology, has a somewhat more explicit code relating to ethics. Its 10 professional conduct guidelines are entitled:

- Wholesomeness of food
- Relations with the media
- Confidentiality of information
- Conflicts involving professional ethics
- Duties towards subordinates
- Scientific issues and food promotion
- Responsibilities towards students
- Responsibilities towards the environment
- Members' business interests
- Responsibility to the profession

A number of activist groups have emerged with an interest in food technology. Greenpeace International is probably the best-funded and declares to "exist because this fragile earth deserves a voice, it needs solutions, it needs change. It needs action."

The Food Ethics Council was established in 1998 in England as a charitable trust. It has reported on such ethical issues ranging from drug use in farm animals to intellectual property in agriculture research.

It was inevitable that governments would take an interest in the food supply. Modern American food law began with the Food and Drug Act of 1906, also called the Pure Food Law. In 1938 it was redone as the Food, Drug, and Cosmetic Act, with amendments. The U.S. Food and Drug Administration (FDA) enforces this law through an elaborate set of regulations. Other agencies share this responsibility, including the U.S. Department of Agriculture, the Federal Trade Commission, and the Bureau of Alcohol, Tobacco, Firearms, and Explosives.

Food regulatory work often is subject to criticism. The public can get involved in the rulemaking process, but it is mainly consumer advocates along with trade associations and only occasionally individuals that participate.

At one time mainly unprocessed and raw foods were consumed, but then cookery, pasteurization, and sterilization created the category of mildly processed foods. Milling, brewing, refining, dairy processing, and many other food operations that frequently relied on the use of so-called food additives and blending with other ingredients provided what often is termed highly processed or reformulated foods.

The newest category in this area is synthetic food, which can be thought of as engineered edible systems. An imitation orange drink powder that could be reconstituted with water at home or during space flight was the first example, appearing in the 1970s. Except for the sugar in it there is no agricultural ingredient, and the sugar could be replaced with a synthetic sweetener to make it a diet beverage or a food for diabetic persons.

It can be said that a gradual merging of the food and pharmaceutical industries is under way. The word *nutraceutical* was coined in the 1990s, and with it came many foods and food components, including beneficial bacteria, that are claimed to have health-providing properties beyond those of traditional essential nutrients such as vitamins, amino acids, and certain minerals. Opportunities to defraud the public with scientifically unproven benefits are tempting; the subject of nutritional claims is debated hotly and is only in the early stages of governmental supervision.

Since biblical times human societies and their leaders have been interested in regulating trade and safeguarding foods. Food protection has economic and public health implications: People must be protected from cheaters and poisons. Because misrepresentation and adulteration can be inadvertent as well as deliberate, a legal and regulatory framework was needed to address these concepts and allow modern societies to function smoothly and safely.

The English Assize of Bread and Beer (*assissa panis et cerevisiae*) of 1266 attempted to control the quantity (weights and volumes) of food sold by merchants, not its quality. That law established strict penalties whose basic principles would be adopted by settlers in North America hundreds of years later. Adulteration was rampant, and the tools to detect it were lacking. In 1820 Frederick Accum, a German chemist and pharmacist living in London, published his *Treatise on the Adulteration of Food and Culinary Poisons*. Microscopy was an emerging technology that became the first analytical tool to verify food adulteration, mainly in the detection of rodent hairs and feces, insect fragments, and foreign objects such as dirt and unwanted plant matter. Chemical analysis has become a more powerful tool since that time, and the food laws of many nations stipulate the employment of food analysts and analytical methods. It is now possible to detect the presence of objectionable environmental chemical contaminants in trace amounts that are not significant in physiological terms, that is, amounts considered inconsequential.

Just as the law does not concern itself with trifles, the law of Paracelsus states that a small amount of a toxin is not worth considering because it has no effect. Parcelsus taught that "the dose makes the poison," and it can be demonstrated that a grain of salt has no effect on a living organism but that a cupful is deadly. Similarly, too much of a good thing may be harmful, as evidenced by the contemporary overconsumption of calories, especially in affluent societies. Sixty-five percent of Americans were considered obese at the start of the twenty-first century, and obesity is becoming the number one human health hazard. Discussion has begun about where to lay the blame for this phenomenon. Some have pointed to the "fast-food" industry as the primary culprit, ignoring free will, discipline, and responsibility.

The concept of American fast food also touches on ethical issues and may have spawned the "slow food" movement that arose in Italy in the late 1990s, presumably to resist the replacement of culinary traditions and the disappearance of local food varieties; however, it also might have been the product of anti-Americanism, anticapitalism, and antiglobalization. All over the world, especially in developing areas, the introduction of "Western food" constitutes a threat to indigenous food crops and processing operations that have been practiced by women for centuries. The enrichment of a local diet is welcome from a nutritional standpoint, but it also is believed to undermine the potential for self-sufficiency and the value of indigenous knowledge. Entomophagy is widely accepted and always has been: Some five hundred insect species serve as food sources worldwide. The subject of underutilized species has been dealt with by the many organizations, and as a result new foods have been "unearthed." The fungal protein quorn, manufactured in the United Kingdom and sold as a meat substitute, is an example. Other potentials are seen in leaf protein concentrate, processed plankton or cellulose, and recycled waste products.

The Future

The newest trend in the food field is genetic engineering. Apart from drug manufacturing it is applied mainly in production agriculture and involves recombinant DNA and cell fusion techniques. The driving force behind this food biotechnology is the creation of higher yields from plants and animals. Critics argue that the driving force here is not a humanitarian spirit but corporate greed. Related objectives of the new biotechnology are foods with improved nutritional properties, such as the Swiss-originated vitamin A-enriched rice that is claimed to combat childhood blindness in Asian areas and the production of crops with better utilization/processing potential, including better flavor. Many of these products are already on the market. However, there has been vigorous political and even religious debate over these genetically modified (GM) crops and foods, even over GM drugs such as insulin.

New enzymes derived from GM microorganisms are being used in food processing. Indeed, knowledge about genetic maps and the amino acid sequences of proteins makes it possible to tailor-make food ingredients with specific desirable functions and properties. Among the 150 microbial enzymes in use for food production more than 40 are produced from GM microorganisms. It is surprising to many people that practically every item on an American restaurant menu has been subject to genetic modification. Since the introduction of GM foods in the 1980s a quiet revolution in the food supply has been under way. Worldwide, 46 percent of soybean acreage and 7 percent of corn fields were sowed with transgenic crops in 2001. No transgenic animals are used in food, mainly because of ethical barriers.

Disagreement about the safety of GM foods is rooted in the differences between American and European regulatory principles: regulation of the nature of the product in the United States versus regulation of the manner in which a product is produced in Europe. One consequence of the debate was the refusal in 2002 by the Zambian government to receive food aid from the United States because it involved GM food.

All new technologies seem to be accompanied by early resistance. GM crops have been embraced in the developing parts of the world, as was discussed during the Twelfth World Congress of Food Science and Technology in 2003. Food scientists are bracing themselves as the era of GM foods is unfolding. One challenge is to develop analytical methods that will differentiate between a GM species and a conventional one. The current debate seems to indicate that consumers wish to have a choice in selecting one or the other, and regulators may be charged by policymakers to monitor the trade in and consumption of these foods.

Food technology has improved the lot of humankind, but the work is far from over. Better tools will be designed, and it will be necessary to engage in transfers of food technology and institute governance, education, and transportation infrastructures so that no needy individual is left behind.

FORD, HENRY

The American automobile manufacturer Henry Ford (1863–1947) is, along with Thomas Edison and the Wright Brothers, one of those who best symbolized the use of technology to transform human life in the early twentieth century. Ford himself recognized the social orientation of his efforts. As he explained in his 1922 autobiography, he believed that successful manufacturing was rooted in public service rather than in money making. He was equally clear about his own public service goal: "To lift farm drudgery off flesh and blood and lay it on steel and motors has been my most constant ambition." Somewhat unexpectedly, however, his focus shifted when he discovered "that people were more interested in something that would travel on the road than in something that would do the work on the farms".

Ford was born on a farm in Wayne County, Michigan, on July 30 and died in Dearborn, Michigan, on April 7. As a boy he experienced the agrarian way of life that once had dominated the American economy but that during his lifetime, in part as a result of his efforts, would be replaced by manufacturing. Among the relevant features of his youth were his education in rural schools (1871–1879), the early death of his mother (1876), and his fascination with machinery. That interest led to an apprenticeship in nearby Detroit (1879–1882) and a traveling job servicing steam traction engines. After his marriage in 1888 Ford's father gave him a forty-acre farm, but rather than take up farming, Henry Ford and his wife moved to Detroit, where he became an engineer for the Edison Illuminating Company.

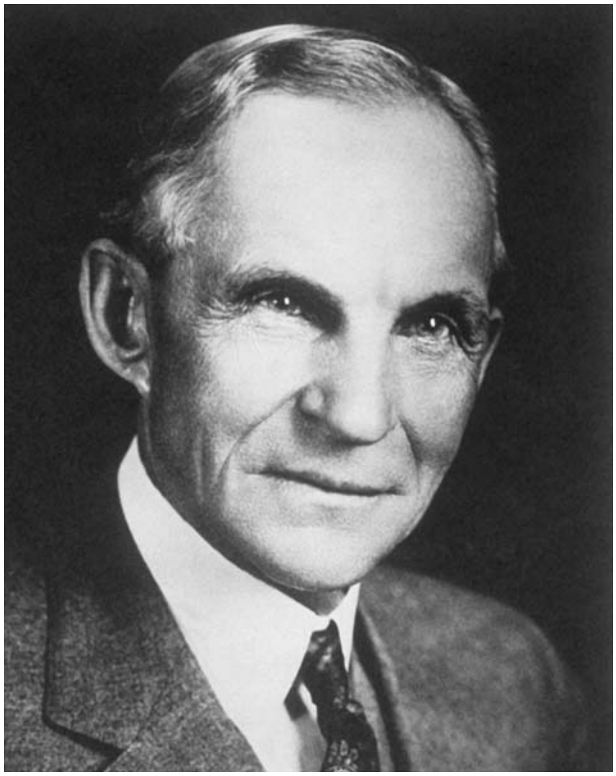
Automobile Manufacturing

By the early 1890s, when Ford turned his attention to using internal combustion engines to power road vehicles, the effort to develop automobiles had been under way for several decades. By that time American manufacturers had incorporated the general principles of machine production, interchangeable parts, and cost-based management, along with other practices of the factory system and large-scale business. Thus, Ford began neither the specific process of creating automobiles nor the overall process of industrialization. However, he would achieve lasting fame as well as notoriety by helping bring both processes to full maturity.

Ford's historic achievement was twofold. First, he rethought the basic idea of the automobile (making him more an innovator than an inventor), by aiming not for a large luxury vehicle but for one that was light and sturdy enough for unimproved rural roads and inexpensive enough for the average family. Second, he, along with the mechanics and engineers he employed, redesigned the manufacturing process to allow for the mass production of a product of unprecedented complexity.

The main features of this frequently told story include the completion of Ford's first experimental car (1896), his early interest in building race cars (driven by Barney Oldfield), the formation of the Ford Motor Company (1903), the introduction of the Model N (1906), and the successful challenge of the Seldon patent (1911), which ruled that George B. Seldon, a Rochester lawyer who was issued a patent in 1896 for the horseless carriage, was not entitled to a royalty for each car manufactured. However, looming over everything else was the Model T. First sold in 1908 for $825, the Model T remained in production until 1927, by which time 15 million had been made and the price had dropped to $290.

To lower costs and increase output, the company adopted the practices of progressive assembly at its Highland Park plant. The capstone of that effort was the continuously moving assembly line for attaching the various components to the chassis, which was put in place during the winter of 1913–1914. Although not a direct application of scientific management, Ford's system bore similarities to it, including the dramatically higher pay rate of "the Five Dollar Day" (1914). During and after World War I the company went on to construct the River Rouge plant, where production of the Model T achieved a high degree of vertical integration.



Henry Ford, 1863–1947. After founding the Ford Motor Company, the American industrialist developed a system of mass production based on the assembly line and the conveyor belt which produced a low-priced car within reach of middle-class Americans. *(AP/Wide World Photos.)*

This system was widely admired, copied, detested, and critiqued. Its place in the modern psyche can be seen in widely different cultural products, such as Charlie Chaplin's performance in the film *Modern Times* (1936) and the convention for numbering years that Aldous Huxley devised in *Brave New World* (1932): "A.F." for "After Ford."

Achievements and Criticism

Those achievements must be attributed to many people in addition to Henry Ford. Nevertheless, Ford personally led the enterprise. Before World War I the result was a highly favorable public image. However, "the Five Dollar Day" was accompanied by the systematic investigation by the Ford Motor Company of individual workers outside the plant, and after World War I that arrangement was replaced for the most part by a more traditional approach involving company spies and threats of violence. Meanwhile, with wealth and power also came the expression of personal idiosyncrasies. A newspaper Ford owned, for example, propounded anti-Semitic views that later struck a resonant chord in Nazi Germany.

From the vantage point of the present, however, probably the most significant of Ford's shortcomings was his failure to give up personal control of the company he had founded. He consolidated that control after World War I and held on to it until almost the time of his death. One result was continued production of the Model T until the company had saturated its market, making more difficult the conversion to other models (the Model A in 1928 and the V-8 engine in 1932). Limitations also can be seen in other products the company attempted to produce: submarine chasers during World War I and farm tractors and trimotor commercial aircraft in the interwar years. Even when the products were well conceived, problems arose with production or marketing; those problems could be traced back in part to Ford's personal control of the company.

Although the Ford Motor Company was his primary achievement, Henry Ford created other organizations of lasting importance, including the Ford Foundation and The Henry Ford (formerly the Henry Ford Museum and Greenfield Village) in Dearborn, Michigan.

FORD PINTO CASE

Events in the 1970s related to the Ford Pinto automobile illustrate some of the ethical issues related to technology and safety. In an effort to produce a stylish but affordable subcompact automobile with a low operating cost, Ford Motor Company management made a questionable decision regarding the positioning of and protection for the fuel tank. A safer gas tank and tank location were technologically feasible, but consumer affordability and style took precedence over safety. Ford engineers were constrained by design and cost limitations, and the case therefore illustrates how engineering decisions are often made in the context of marketing strategies. For example, the car was designed to have a short rear-end, perhaps in imitation of the extremely popular Ford Mustang. This limited the engineers' alternatives for fuel tank safety and placement. The tank was placed behind the rear axle instead of over-the-axle, a safer location that had been used in the Ford Capri. Critics charged that this decision was a result of the reduction in trunk space caused by the over-the-axle placement. Another example of a limitation on the engineers was that management apparently mandated that the car cost no more than $2000 and weigh no more than 2000 pounds. If these limitations were really stipulated, then the engineers would have been constrained in many areas related to safety. Given these design and cost limitations, is it fair to hold the engineers morally responsible for the preventable pinto fire injuries and deaths? Other issues illustrated by the Pinto events relate to the definition of *safety*, the appropriate responsibilities and professional obligations of engineers, the interactions between different parts of organizations, ethical management decision-making, and effective government safety policies.

For example, "safety" can be understood to mean "acceptable risk of harm," but how much risk is acceptable in a subcompact automobile? Additionally, did the engineers have a professional obligation to reject the Pinto design elements and management directives that seriously compromised safety? Should Ford management

People examining close-ups of a Ford Pinto wagon in the basement of a courthouse. The wagon was used as evidence in a murder trial resulting from a fatal accident in which the gas tank exploded upon collision. *(Art Shay/Getty Images.)*

have had the final word on the Pinto design or should the engineers have had a "veto" related to safety? If management really placed marketing considerations above safety, was that objective ethical and are members of management morally responsible for the preventable Pinto fire deaths? Finally, was the National Highway Traffic Safety Administration ineffective or unethical because the Ford Pintos always complied with all the government standards?

Ford produced the Pinto automobile from 1971 to 1980. Initially the car sold well, but a defect in early models made Pintos prone to leaking fuel and catching on fire after relatively low-speed, rear-end collisions. The Pinto's gasoline tank was located behind the rear axle. A rear-end collision of about twenty-eight miles per hour or more would crush the car's rear end, driving the fuel tank against the differential housing and causing it to split and the filler pipe to break loose. Sometimes the spilled fuel and sparks from the crash caused fires that produced fatalities or serious burns. Many such victims or their relatives filed civil suits against Ford Motor. This litigation generated damaging publicity for Ford and for the Pinto, and it increased public concern over fuel system integrity in general. In 1976 the National Highway Traffic Safety Administration (NHTSA) implemented a rear-impact safety regulation. The 1977 Pintos were in compliance with this standard, but earlier Pintos were not required to be in compliance and did not meet the standard. Responding to publicity about the Pinto's poor safety record, the NHTSA crash-tested some early Pintos and in 1978 announced that a safety defect existed in the fuel systems of 1971–1976 Pintos. With an NHTSA public hearing scheduled, Ford recalled the 1971–1976 Pintos to upgrade fuel system integrity.

The improvements to the 1977 and subsequent model-year Pintos and the recall of the earlier ones should have solved Ford's Pinto fuel system problems. In September 1978, however, an Indiana grand jury indicted Ford on three felony counts of reckless homicide. This indictment was related to an accident in which, after a van rear-ended a Pinto in an allegedly low-speed collision, three young women burned to death. In contrast to the previous Pinto cases, this one was a criminal trial, not a civil suit. Ford was found not guilty on all the charges because the corporation's lawyers persuaded the jury that the crash was not, in fact, a low-speed one, and hence the deaths did not result from

Ford's having kept a lethal vehicle in production in spite of an obvious fatal flaw. Ford stopped producing the Pinto after 1980, having sold about 3 million of the vehicles.

FORENSIC SCIENCE

The word forensic is derived from the Latin word *forensic*—a reference to Roman court forums in which evidence of wrongdoing was presented. Modern use of the term forensics refers to scientific principles and processes that are applied in the analysis of evidence for legal purposes. Alternatively known as *criminalistics*, forensics involves using sophisticated techniques and tools to identify, collect, analyze, preserve, and present evidence of crimes or civil wrongdoing in legal proceedings, as well as to verify identification of deceased individuals. The essential goal of forensics analysis is to verify connections between two or more physical items, for example, the blood of a homicide victim to that found on clothes worn by a suspect. Forensics involves analysis of many other types of evidentiary items such as prescription and illicit/illegal drugs, metals, glass, plastics, fuels, paints, tire/shoe prints, tool/tool marks, and latent substances such as synthetic fibers, human hair, and animal fur, among others.

Modern forensics began with nineteenth-century efforts of Alphonse Bertillon (1853–1914), director of the Bureau of Criminal Identification of the Paris (France) Police Department, to classify and identify criminals on the basis of their physical characteristics. In 1888 Francis Galton proposed a fingerprint classification method after which fingerprinting was first used for criminal identification by Scotland Yard investigators in 1901, and by New York City detectives in 1902. By 1930 the Federal Bureau of Investigation (FBI) of the U.S. Department of Justice had established a national fingerprint classification system, and in 1946 the FBI created its Identification Division that relied extensively on burgeoning fingerprint records for suspect identification in criminal cases. Since then the FBI lab has helped solve thousands of criminal cases using many forensics analysis methods, and is among the largest and most technologically capable forensic laboratories in the world.

Types of Forensics Evidence and Analysis

There are many types of forensic methods, each of which corresponds to the kind of evidence analyzed. For example, ballistics is the study of firearms, ammunition, bombs/explosives, bullets, and other projectiles. Forensic anthropology attempts to reconstruct the likeness of decomposed or dismembered bodies based on skeletal remains and other factors. Forensic odontology matches bite marks with teeth or dental records; and forensic entomologists study corpses infested with insects to determine the approximate time of death and other information. Forensic psychology and psychiatry seek to profile criminals, and also apply social work and mental health counseling practices to investigative situations. Forensic toxicology involves analysis of intoxicants, drugs, and poisons. Forensic taphonomy pertains to the examination of dead and decaying human, animal, and plant remains.

The most modern, prominent, and scientifically promising form of forensics is DNA analysis profiling which involves comparison of deoxyribonucleic acid found in human body tissue or fluids such as blood, perspiration, urine, semen, or vaginal secretions. In addition, biometrics analysis is used in forensics to verify identification of people by comparing biological traits such as finger/palm prints and iris or retina cell patterns. Other forms of forensics involve toxicology (the study of poisons and their harmful effects), computer forensics, voiceprint identification, and polygraph examinations (lie detector testing). In addition to determining the sources of criminal evidence and matching these to known sources, forensics also involves crime scene reconstruction—examining evidence to determine the nature of activities and physical dynamics of interactions among perpetrators and crime victims, series of events, directions of travel, angles and relative forces of impact, pre/post impact trajectories, and primary versus secondary causes of harm, and more.

Fundamental and Ethical Challenges in Forensics

Primary challenges in forensics pertaining to the overall validity, reliability, and credibility of evidence presented in court cases involves:

1. protecting evidence from harm before, during, and after its collection at crime scenes and in laboratories and evidence storage facilities;
2. accurately analyzing evidence and truthfully presenting findings in legal proceedings to help explain how crimes occurred and the possible guilt or innocence of individuals accused of crimes;
3. developing and maintaining expertise of forensics professionals through training;
4. acquiring, certifying, and maintaining laboratory equipment;
5. providing managerial oversight to ensure accurate analyses and truthful reporting of findings in legal proceedings;
6. truthfully testifying about analytical methods, findings, and credentials of examiners;
7. achieving laboratory accreditation by one or more nationally recognized professional membership associations.

Criticism of and concern about forensics analysis has involved all the challenges listed above. In addition, so-called *voodoo science* or *junk science* refers to the reality that all forms of forensics analysis require professional judgment in determining whether evidence collected at crime scenes matches known-source samples to the exclusion of all other possibilities. In many types of forensics analysis there is no scientific basis for employing statistical probability modeling to accurately estimate the chances that one or more evidentiary items are *not* a perfect match. Fingerprint analysis, for example, although long accepted by courts as a type of scientific evidence is actually a technical art predicated on the belief that no two people have exactly the same print patterns and that professionals conducting tests sought exculpatory evidence in addition to match points. This fundamental problem extends to other types of forensics analysis, and when combined with numerous legal cases in which forensics experts lied about their analytical findings and/or professional credentials, has resulted in considerable controversy about the reliability of evidence collection and forensics analysis procedures, and the trustworthiness of testimony in legal proceedings about forensic analysis/laboratory findings.

In *Daubert v. Merrell Dow Pharmaceuticals, Inc.* (1993), the U.S. Supreme Court scrutinized the field of forensics and established new legal standards regarding the admissibility of scientific evidence and expert witness testimony provided by forensics professionals. Standardized DNA evidence gathering and analysis championed by the National Institute of Justice of the U.S. Department of Justice, and acceptance of this form of truly scientific evidence by federal, state, and local level criminal justice systems, is important to the future of forensics, as are quality control standards such as those established by the American Society of Crime Lab Directors/Laboratory Accreditation Board. Ultimately the usefulness and reliability of forensics evidence in legal proceedings will depend on ethical (and potentially government regulated) use of forensics technologies in the public sector and in privately owned or operated laboratories.

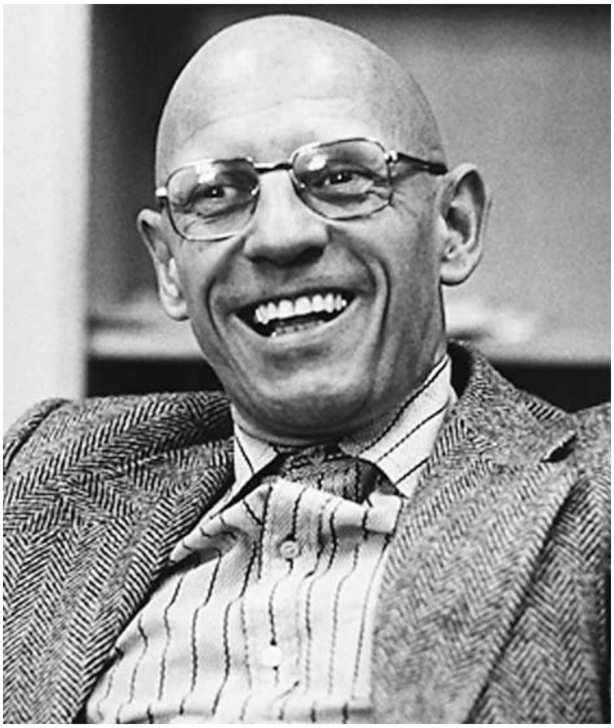
FOUCAULT, MICHEL

Michel Foucault (1926–1984), who was born in Poitiers, France on October 15 and died in Paris of AIDS on June 25, was a controversial philosopher whose interdisciplinary work has important if indirect implications for



Michel Foucault, 1926–1984. The French philosopher, critic, and historian was an original and creative thinker who made contributions to historiography and to understanding the forces that make history. *(© Corbis-Bettmann. Reproduced by permission.)*

science, technology, and ethics. His research often changed directions—archaeology and genealogy as ideas, history of the present, problematization, and modes of subjectification were prominent. In his final years he viewed these directions as theoretical tools to examine three perennially related but distinct relations: to truth, to power, and to self. Foucault was sufficiently intrigued by various sciences and technologies to devote much of his work (and personal involvement) to analyzing and questioning how they increasingly engage formative and dangerous aspects of human life.

Four themes with ethical implications highlight this intrigue. They are space, vision, biopolitics, and art of the self. Among humans space is seldom only a natural given. People instead design, build and defend, or violate a variety of spaces. Some illuminate ideals (utopias), many are ordinary (common domains), while others are designed for extraordinary times or unfamiliar figures (heterotopias). Asylums, hospitals, schools, and military camps are built to distinguish rituals and events (treating the mentally ill or sick, transforming adolescents or enlistees) that specifically aim to change our body, conduct, and self-understanding. Foucault studied how these spaces emerged, but also questioned their effect on human freedom, individuality, and justice.

Related to the technology of space are innovative kinds of vision. Obviously instruments such as the microscope introduce surprising ways to diagnose the body. Institutions repeatedly introduced strategies for observing the human body. Employing these different visions has two effects. First it renders individual subjects silent, because they are observed at a distance while their own words are discounted. Second this distance ushers in an allegedly more scientific understanding of human beings.

These effects are strikingly presented in the 1975 landmark book, *Discipline and Punish*. The book opens by juxtaposing an elaborate torture spectacle in 1757 Britain with a prison scene in 1838 France. A sign of moral progress in modern Europe? Not entirely. While English philosopher Jeremy Bentham's (1748–1832) design of an ideal prison, the Panopticon (literally, *all seeing*) was itself a practical failure, it paved the way for a radical shift from punishing the criminal to focusing on potentially deviant or abnormal persons—anyone, in principle. The result is a disciplinary society, one bent on surveillance and control. With typical rhetorical flair, Foucault asked, "Is it surprising that prisons resemble factories, schools, barracks, hospitals, which all resemble prisons?" (Foucault 1977, p. 228) Foucault acknowledged, however, that his portraits of modern society were occasionally hyperbolic.

The formation of new kinds of knowledge and their cultural effects has extensive political repercussions and culminates in what Foucault called *biopolitics*. This term refers to a political rationality in which specific knowledges and administrative technologies are used by a government to understand and regulate not only individuals but also groups or populations. Hence the ongoing links between, say, longevity and social security, health and insurance, risky behavior and family assistance, or poverty and education programs. Ian Hacking, an insightful extender of Foucault's approach, describes these relations as having looping effects, loosely but evidently intertwined in terms of a development of an expertise and its gradual influence on how human beings subsequently understand (accepting or resisting) new ideas about themselves.

During work on *The History of Sexuality* (1978–1984), Foucault began focusing on technologies of the self. Here technology is not so much about instruments or tools, but it is more a craft or care for oneself insofar as one uses available knowledge and experiences (such as diet, love, physiology, dream analysis, and structure of home life) to practice a moral life. While his scholarly attention surprisingly turned to texts of the early Greeks and Christians, Foucault cautioned against emulating them. Address the possibilities, he argued, rather than succumb to one's own blind spots.

Foucault was reluctant to spell out a theory of normative ethics. Not only was such an endeavor impossible for modern thought (see *Order of Things*, p. 328), he believed intellectuals should be wary of imposing solutions for those involved in specific struggles. In this light Paul Rabinow nevertheless identifies a four-fold of Foucault's ethics as comprising a will to truth, stylization of one's self, critical thought, and a telos or purpose that involves a dissembling of the self. Be prepared, in other words, that leading an ethical life amid scientific and technological changes will not confirm your identity, but transform you.

The work of Michel Foucault is daring in its range and depth. Although he builds on the approaches of phenomenology, Marxism, and existentialism, he takes the twentieth century European intellectual tradition into a new historical critical phase. As different strains of scientific discovery and technological innovations continue to emerge, his conceptual tools demand that one ask: How is it true? Where is its power? How might it change individuals and their relations to others?

FRANKENSTEIN

Frankenstein, or The Modern Prometheus (1818) by Mary Shelley provides the most potent, characteristic, and uniquely modern myth of science gone fatally awry. The common association of the name Frankenstein, thanks to many popular movies, is with the ugly, lumbering, murderous monster whom the book never names. In his many film versions, this lurching omen reflects the eras of his creation, from the dazed, scorned and feared working-class creature played by Boris Karloff in James Whale's depression-era *Frankenstein* (1931) to the slyly silent and sexually potent creature played by Peter Boyle in the me decade's *Young Frankenstein* (1974). But while

Boris Karloff as Frankenstein's monster in the 1931 film verison of *Frankenstein*. Karloff's portrayal of the creature is perhaps the most well-known. *(© Bettmann/Corbis.)*

movies have spread the image of *Doctor* Frankenstein and associated his name with the manlike monster he created, the novel carefully never names his creation which is, in fact, a doppelganger, a dramatic double of the obsessive undergraduate who made him.

The Modern Prometheus

The ancient myth of Prometheus took two forms: Prometheus *pyrphoros* (fire-bringer) and Prometheus *plasticator* (shaper). In the first the god steals divine fire, emblematic of the combined good and bad potentials of all technologies, for humans; in the second he shapes humans from clay and breathes life into them. In both Zeus makes Prometheus suffer endlessly for his disobedience. In the modern myth, Frankenstein shapes his creation from *charnel matter* and reanimates it (rather than *creating life*) with electricity, an occurrence, as Shelley writes in her preface, "supposed by Dr. [Erasmus] Darwin, and some of the physiological writers of Germany, as not of impossible occurrence." The bounds that Frankenstein transgresses are those of obedience to community. He makes himself a monster in two senses. The price is death not only for himself but for his family and potentially all humanity.

As Gothic novels of the supernatural became stale, authors added a twist, revealing at the end some realistic explanation for the fantastic occurrences. By moving that explanation to the beginning of *Frankenstein,* Shelley created the genre that has explored human fears of science ever since: science fiction.

Structure and Narrative of the Novel

This early science fiction is composed of letters from an explorer, Robert Walton, to his sister back in England. He cannot send the letters because his ship is mired in the arctic where he seeks to confirm the ancient Hyperborea myth of a land of warmth beyond the far north, but he writes nonetheless. On a passing floe he discovers the debilitated Victor Frankenstein whom he rescues. During Victor's recuperation, Robert remarks that "I begin to love him as a brother" (1969, p. 27). In some sense, Robert and Victor, too, are doppelgangers.

The book is a series of nested narratives. The outermost, Robert's own, contains Victor's story that tells of his pursuit of greatness and withdrawal into feverish, isolated work. He finally succeeds, but one look at his stirring creation shows him instantly that the creature is evil. He would kill it, but it flees. The reader comes to learn that the creature is the strongest, smartest, most articulate character in the book, a fit embodiment of science. He confronts Victor on a glacier (the ice imagery mirroring the situation of Robert and Victor, all three males surrounded by frozen fertility) and pleads for paternal help, requesting a bride so that he, universally shunned for his ugly exterior, can find community. Victor reports the creature's narrative which includes his plea and his reported story of Felix (happiness) and Safie (wisdom), Christian-Muslim lovers who are promised help against prejudice and the opportunity to marry by Safie's father, but are betrayed by him. The creature learns the lovers' tale overhearing them in a cottage through a knothole in the wall of the outer shed he has been occupying while altruistically providing firewood for the blind old man who lives there. With the couple on the scene, the creature learns to read just by watching their sharing aloud three books: Milton's *Paradise Lost,* which concerns disobedience and provides *Frankenstein's* epigraph, fallen Adam's plea to God ("Did I request thee, Maker, from my clay / To mould Me man? Did I solicit thee / From darkness to promote me?) (Book X, lines 743–745); *Plutarch's Lives,* a classic collection of exemplary biographies; and *The Sorrows of Young Werther,* Goethe's famous tale of unrequited love ending in death. The creature, initially the most virtuous character in the book, is driven away when the blind cottager's guests see him. Readers believe him when he says to Victor that "My vices are the children of a forced solitude that I abhor; and my virtues will necessarily arise when I live in communion with an equal" (line 1470). At the heart of *Frankenstein's* nested narratives is the betrayal by Safie's father. The rupture of community echoes throughout the book.

When Victor first absents himself to work, his father sends a letter that says, quite rightly, "I regard any interruption in your correspondence as a proof that your other duties are equally neglected" (p. 55). Victor destroys his creature's unfinished bride in sight of the monster, who then begins murdering Victor's family to force him to start again. Instead they chase each other north. While Victor never writes, Robert always writes. Robert heeds his frightened crew and turns back from his quest, saving all their lives. Victor dies, and the monster (from the Latin for *warning*) carries him further north for a funeral pyre, knowing that with his *father* dead, his hopes for any family have died, too.

Science Unbound

At the heart of *Frankenstein* is the tension between the power science confers on individuals and the just restraints of community. Frankenstein, both creator and creature, stands not for science in general but for the acquisition of scientific power foolishly pursued without the wisdom of the world. As such, Frankenstein has represented, in the films of the Great Depression, the isolation of the privileged from the suffering of the common person. When the educated *Doctor* or *Baron* in his hilltop castle, his title varying from film to film, disdained the peasants swirling up toward him with their angry torches, his doppelganger monster was inarticulate because, the movies imply, the overly powerful never heed the consequences of their power.

That image has entered the very language of the early 2000s. Genetically modified farm crops are bashed as *Frankenfoods* and contemplated human cloning for spare parts is called a *Frankenstein nightmare*. Shelley has a character say early on, "One man's life or death were but a small price to pay for the acquirement of the knowledge which I sought" (1969, p. 28). That sounds like Victor, but it is Robert, the seeker who learns the limits of seeking. *Frankenstein* is the early twenty-first century's greatest cautionary tale.

FREE AND INFORMED CONSENT

SEE *Informed Consent.*

FREEDOM

The concept of freedom or liberty is complex, with political, ethical, and psychological dimensions. In the context of modern science, technology, and ethics, freedom exhibits all of the ambiguity of human experience. The promise of modern science and technology is that the increases in knowledge and the power they afford will expand human freedom in an unqualified sense. But in opposition to this original and continuing justification are questions about the extent to which science and technology may also limit or qualify freedom. Moreover, the professional ethical requirement for the free and informed consent of human participants in scientific research situates the complexities of freedom in the heart of science itself. The issue of "free and informed consent" is a key locus for the discussion of freedom in science and technology.

Human Freedom versus Deterministic Science

The philosophical concept of freedom may be seen in opposition to that of determinism. The determinist holds that there is no freedom. For a hard determinist, all events in nature are strictly determined. As such, the idea of freedom is incompatible with that of the causal determination of all natural events. What is sometimes called soft determinism or compatibilism modifies the hard position by maintaining that freedom is compatible with the determination of natural events. A compatibilist holds that all events in nature are causally determined but that human beings can initiate new series of events and have responsibility for the outcomes of their actions. Thus, moral ideas of praise and blame make sense if people are able to act according to some causality arising from their will or for reasons of their own choosing.

Finally, it should be noted that with the development of quantum mechanics some thinkers allow for indeterminacy at the atomic level. This may allow for a notion of freedom in the sense that an action is not caused, but it may not be able to account for personal responsibility if the action is not determined in some way by the person.

Whether or not human beings are in fact free, most people think and act as if they are. Such acts of freedom have been conceptualized in two basic ways: negative and positive.

Negative Freedom

Negative freedom may be taken as an absence of obstacles to the fulfillment of one's desires or wishes. The view of the English philosopher Thomas Hobbes (1588–1679) is representative of this approach. This form of freedom depends upon the existence of favorable external circumstances for the attainment of a human goal. It can thus be considered a freedom of self-realization. One peculiar implication of this approach is that a person who wishes to be in a prison cell may be said to be free. Nor does it require that there be alternatives from which to choose. If there is only one course of action available, but that is what an individual wishes, then such a person may be said to be free. It also seems to allow for animals to be described as free. A further point is that the obstacles to human desires include physical and social ones. Thus, if persons are physically constrained or constrained by fear, they may not be said to be free to act. If, on the contrary, they are coerced to act in a certain way, they are not considered to be free nor responsible for their actions.

According to this conception, modern science and technology may be construed as eliminating any number of obstacles that have historically restrained human action. Therefore, those taking engineering approaches to science and technology tend to see modern technical methods as enhancing human freedom. With modern methods of communication and travel, for example, time and space seem to shrink in their significance. Many elderly people of the late twentieth and early twenty-first centuries have been able to act without the encumbrances of the maladies of old age that have plagued human beings for millennia. This form of freedom is a freedom from such things as disease, hunger, and fear.

Modern technologies, however, may also be seen as introducing new obstacles to human action. The automobile provides for transportation over great distances, but millions of cars on the roads produce traffic jams that obstruct a person's desire to move. The roadways also block a person's desire to walk if the destination is across a multilane highway. The very complexity of modern technological societies may represent an obstacle to human action. With all of the information that is available through the various media, many persons feel overwhelmed by information overload. Greater knowledge is thought to increase one's freedom to act, but it becomes difficult to act rationally in such an environment. Indeed, the self may become fragmented as it interacts with the technological environment.

This seems to be an outcome that is contrary to the self-realization that is characteristic of the notion of negative freedom. A further problem with the notion of negative freedom is that modern science and technology may be used to manipulate human desires, and so in a sense persons are coerced to act. Thus, propaganda techniques are used to mold consumer desires. Indeed, it has become possible to manipulate human desires pharmacologically. This possibility has been the theme of dystopias such as Aldous Huxley's *Brave New World* (1932). Huxley imagined a society in which a drug called "soma" could be taken that would make a person content in any environment. Anthony Burgess's *A Clockwork Orange* (1962) depicted a cruder reconditioning of human desires. Many thinkers in the humanistic tradition would not consider human beings to be free if there are no obstacles to the fulfillment of a person's desires, but the desires one has result from technical manipulation. It is appropriate from this perspective that B. F. Skinner should have written *Beyond Freedom and Dignity* (1971). The practical application of his behaviorism would make human freedom into an illusion because behaviorism holds that all human behaviors are molded by the environment. The control of nature, as C. S. Lewis (1898–1963) pointed out *The Abolition of Man,* easily leads to the control of some human beings by others.

Positive Freedom

The positive notion of freedom requires that individuals be able not only to act on their desires but also to choose from among the many desires they have to act upon. Such a view of freedom constitutes a theory of self-perfection. According to this conception, some desires may be more worthy than others given a standard of human life that is considered good. Only persons who have acquired virtue or a self-consciousness of their humanity may be said to be free. Contrary to the common view that people have greater freedom to act if they have more choices, in this case ideas of virtue or moral duty may lead individuals to restrict their pursuit of certain desires. Rather than simply doing what one wants, one does what one thinks one ought to do.

Moreover, one may have a desire for freedom itself that requires the subordination of one's physical inclinations. This is an example of second order desire, that is, the desire for certain kinds of desires. Here, freedom is an end to be pursued in itself rather than a means to the pursuit of other ends. A peculiar aspect of the positive notion of freedom is that it seems to require a degree of self-denial, at least the denial of the drives of the lower self for the sake of higher drives or interests. It may be that this is necessary for the fulfillment of the higher self. A certain independence of the self from the social and physical environment is also necessary for the pursuit of this form of freedom. As such, positive freedom does not depend upon external circumstances.

The positive notion of freedom is especially significant in ethical reflections on the impact of science and technology on the quality of human existence. The concern here is whether human existence is degraded by the rationalization of the world associated with modern science and technology. If all of human existence, including human beings themselves, is subject to rational control, then there may be no room for the dignity of persons; in such a scenario, persons will have been reduced to objects of manipulation and control. If technical methods are applied to political action, for example, this tends to transform what has traditionally been considered the "art of the possible" into a matter of technical necessity. Technical rationality is a rationality directed to the efficient determination of means to achieving some end. This form of rationality tends to become the dominant form of rationality in a highly developed technological society in which the only worthy ends that are recognized are those that can be pursued by the technical means available.

Positive freedom, however, seems to require a broader form of rationality that takes into consideration the choice of humanly worthy ends. In the debate concerning human cloning, for example, the President's Council on Bioethics placed special emphasis on "human dignity" by calling one of its reports, *Human Cloning and Human Dignity* (2002). Furthermore, Francis Fukuyama (2003) has described a posthuman future resulting from the genetic manipulation of human beings. If modern science and technology lead to the evolution of a posthuman era, of what value is human freedom?

Dialectical Freedom

Beyond the negative and positive accounts of freedom is a dialectical one, with roots in the work of Georg Wilhelm Friedrich Hegel (1770–1831) and Karl Marx (1818–1883), among others. According to this account, human freedom is to be understood precisely as an opposition to some obstacle. As such, freedom depends on the existence of some resistance against which we struggle. If humanity were to succeed in eliminating all obstacles to the fulfillment of its wishes as per the view of negative freedom, it would also eliminate human freedom. The dialectical approach to freedom recognizes that the obstacles human beings confront take both physical and social forms. As one obstacle is overcome, however, new ones arise, so that human freedom can be seen as developing over time as humans confront new obstacles.

From a dialectical perspective, freedom must be coordinated with the environment in which humans exercise their freedom. The first and historically most fundamental form of freedom in this scenario occurred when human beings struggled against nature. Nature provided both the means of pursuing human desires through the use of tools as well as obstacles to their use. This form of freedom was superseded by a stage in which human beings developed social institutions, which can be seen as "second nature." Social institutions provided protection from the forces of nature but also introduced new human-made obstacles. After the development of this new environment, the desire for freedom had to be directed against social institutions. The dialectical character of this view of freedom can be seen in that the liberty gained with respect to one environment gives rise to new necessities that must be overcome by creating a new form of freedom. In turn, the new form of freedom is also relevant to a new milieu.

The sociologist Karl Mannheim distinguishes a third stage, that of planning. In this stage, the totality of social institutions and other techniques are organized into a systematic whole. For Mannheim, democratic planning is the last stage in the development of human freedom, whereby human beings take conscious control over the social process. Jacques Ellul (1976) depicted this third stage as the stage of technique, which involves a new technological determination of the human person by the systematic application of techniques to human beings. He thus called for a struggle against the technological environment, especially in its ideological aspect.

The Ethics of Freedom in the Scientific and Technological World

In all of its forms—negative, positive, and dialectical—freedom is closely associated with notions of moral autonomy and political democracy. The ideals of moral autonomy and democratic politics depend on persons and citizens not being wholly determined by external forces, able to pursue personal perfection and the public good, in dialectical engagement with others and the world around them. In the contemporary technoscientific milieu, the others and the world exhibit strongly scientific and technological characteristics.

One area in which this is particularly pronounced is in research on human subjects. Especially since World War II both the scientific community and society at large have increasingly stipulated that scientific research on human subjects be limited by requiring free and informed consent of any such subjects. Participants in scientific research must not be constrained to participate either by force (as in Nazi Germany) or by ignorance (as in the Tuskegee Syphilis Study [1932–1972] in the United States); they must be able to see their participation as positive aspects of their own lives; and they will inevitably struggle against the obstacles of disease and perhaps their own lack of understanding in the process. The commitment to such freedom, which respects limitations in science, even when it also limits scientific progress, makes science more human.

In the larger technoscientific world there are further reflections of such efforts to respect freedom in the emergence of individual and collective ethical responses to the artificial environment produced by modern science and technology and the cultural aspirations to use science and technology to transform the world. Thus, Hans Jonas (1984) has called for an ethic of responsibility that posits an ethical imperative to maintain the existence of human beings. This marks a sharp contrast with those who have called for a posthuman age. Further examples include Ellul (1976), who developed an ethic of non-power to counter the technical impulse to augment human power. And, more recently, Bill McKibben has sought limits to the effort to perfect human beings in his 2003 book, *Enough*. All of these observers are concerned with establishing some humanly significant limits to the technological remaking of the world. They recognize that within a dialectical account of freedom, while the reality of human freedom depends upon the overcoming of limits, it also depends upon the recognition of limits. If the technological project has become an attempt to eliminate all limits, it may very well eliminate freedom as well.

FREE SOFTWARE

Proponents of *free* software distinguish *free speech* from *free beer,* and argue that their conception of free software is intended to evoke the former idea. That is, software is a form of speech used by programmers to express technical ideas in very specific language. Free software does not necessarily mean that the price is zero. The *free software* movement is an explicit attempt to encode in technology specific ethical values about how the world should work. The term *free software* was coined by Richard Stallman, and following his lead, free software programmers have written licenses and computer programs that they believe help create liberty.

Freedom to Use, Change, and Expand the Work of Another

In order for programmers' speech to be heard, it must be transmitted to others. Programmers' work is written in *source code,* usually a text file, which is then interpreted or compiled by other programs in order to perform some computation (for example, to calculate a statistical result or to display a web page). A central idea in the free software movement is that programmers' work, their source code, should be made available in its original form to anyone who is interested in it. A related movement refers to this as *open source.* Although in practice open source and free software often refer to the same programs, their emphases are different. Free software focuses on the goal to promote freedom, while open source focuses on the goal to make the source code available to everyone.

In order to guarantee this availability, programmers distribute free software under licenses that prohibit users from denying others the freedoms they have received. Thus free software may be used and shared by anyone who accepts the terms of the license. The most common free software license is the General Public License (GPL). The GPL offers the following:

- The freedom to run the program, for any purpose.
- The freedom to study how the program works, and adapt it to one's needs. Access to the source code is a precondition for this.
- The freedom to redistribute copies so users can help others.
- The freedom to improve the program, and release one's improvements to the public, so the whole community benefits. Access to the source code is a precondition for this.

To use free software licensed under the GPL, one must accept the license terms. If one refuses these freedoms (for example, because one wishes to keep a particular code secret), the right to use free software is forfeited. That is, if a programmer wants to use code from free software in a new application, the new application must carry the same freedoms as the original code. In order to share or distribute free software, one must pass along these same freedoms to the people to whom the software is distributed.

The Origins of the Free Software Movement

Academic computing from the 1950s through the early 1980s had been mostly unconstrained by concerns about copyright. Scientists shared source code with each other, freely commenting and critiquing each others' work. In the early 1980s, markets opened for the commercial development and sale of software, and among the first moves of the new private-sector ventures was to limit the distribution of the original source code. The limitation seemed sensible at the time—why pay programmers to produce something that customers or competitors could take for free?

Some programmers were critical of the new trend to "close the source," or restrict access to source code. The first criticisms were technical: if programmers find a bug in closed-source software, they cannot simply fix the bug, as they had previously been accustomed to doing. Broader critiques soon followed as programmers realized that in this new work environment, they could not easily share code with colleagues in other organizations. It became more difficult to share ideas and experiences.

In January, 1984, Richard Stallman crystallized the discontent with the foundation of the GNU ("Gnu's not Unix," a recursive pun) Project. In his initial announcement, he said that he and his collaborators would write an entire Unix clone from scratch with entirely free software which would be available to anyone who wanted it. The GNU Project succeeded in developing nearly all the parts of an operating system. However, the GNU Project lacked a kernel, the central part of the operating system that manages memory and connections to hardware. Using many of the GNU tools, a Finnish graduate student named Linus Torvalds released *Linux* in 1991, a kernel that provided exactly this component. Over the next five years, the GNU tools and the Linux kernel made free software a practical platform for general purpose computing.

Free software development proceeded rapidly. In the early 1990s, several other free Unixes emerged from a legal battle between free software programmers (mostly in Berkeley, California) and AT&T. The Berkeley programmers replaced nearly all of AT&T's original Unix code. There are a number of descendants of this process, called the "Berkeley Software Distribution" (BSD). In 1995, other programmers re-wrote the original Netscape HTTP web server and named it the Apache HTTP server (the name is a pun: "a patchy server"). At the time of this writing, Apache powers approximately two-thirds of the web servers on the Internet.

By the late 1990s, different positions in the free software community emerged about the relative priority of different goals. Some people felt that the most important aspects of free software was the promotion of a vigorous intellectual community and growth into new areas, especially by convincing businesses to produce free software. In this perspective, the term "free software" was deemed inappropriate because it discouraged potential allies in the corporate world from adopting it. To avoid the perceived anti-business implication of "free," in 1998 this group re-labeled the community "open source." Since then, the term "open source" has grown significantly more quickly than the term "free software." In practice, the terms refer to mostly the same programs, and even to the same licenses, but signify important differences in the license-holder's focus.

Free Software in Practice

Numerous free software programs have been published. There are free operating systems (including GNU/Linux and various versions of BSD), graphical windowing environments (gnome, KDE), Internet browsers (mozilla, konqueror), office software (OpenOffice, gnumeric), a web server (apache), computer languages (C, perl, PHP, python), and scientific software (the R statistical language, grace—a plotting package), to mention only a few of the tens of thousands of free software programs available. It is possible to do almost any computing, on the desktop or on the server, exclusively by using free software, including interoperating with colleagues using proprietary systems (such as those offered by Microsoft or Apple).

Free Software and Scientific Ethics

Many of the technical and ethical values expressed in the free software movement parallel broader values in the scientific and technical community. In particular, free software programmers prize open technical debate in which all the participants have access to the material in question for testing, benchmarking, critique, and for the creation of derivative works.

As described earlier, free software is distributed in a human-readable form called source code, the original form in which programmers write software. By studying the source code, programmers can evaluate the quality of the solution: Does it work? Is it efficient? Is it elegantly written? In this way, free software is transparent and encourages vigorous peer review. Indeed communities of free software programmers usually exist on publicly available Internet mailing lists, newsgroups, and

Internet sites The only requirement for participating in the review process is the skill to be a programmer.

The Ability and Responsibility to Share

Another central idea in free software is that every user is encouraged to share the software with other users. By sharing, programmers build on each other's ideas and accomplishments, and this serves to advance knowledge, another central scientific value. The idea that software *should* be shared is linked to the sense that tinkering with technology is intrinsically valuable, and that the ability to *open the hood* is the first step toward innovation.

However, as implied by the references to freedom, free software programmers explicitly intend their work to advance the cause of human liberty, and so sharing software has several benefits beyond peer review and encouraging exploration. For example, sharing software helps to decentralize control over the access to information technology. With the rise of technology as the mechanism by which most communication is effected, the practice of free speech depends on free access to the means of speech. Decentralizing control of communications software is one way to help to keep virtual space open to everybody.

Sharing free software also helps lower the cash cost of software, which enables more people to be able to use technology to express their ideas. In the world of free software, this means more people can be free.

Free software uses open data standards. Because the internal working of the software is available for any programmer to tinker with, it becomes relatively much easier for other programmers to figure out how to read and write the files used by a particular program. If a free software program's developers decide to change a data format, or if the developers abandon the program (such as when firms go out of business), the users themselves may choose to continue work on the software. Because the source code is available, the users always have the option of becoming developers, if necessary.

Protecting Privacy and Control

Perhaps the most fundamental aspect of free software is that users control their own computers. Users face two challenges to control of their machines. First some governments attempt to monitor or censor their citizens' use of email, the Internet, or other digital communications media. A second challenge is that some media companies (music, movies, electronic books, digital television) would like to monitor who consumes their products, as well as prevent legal or illegal copying of the content. Accomplishing these goals requires placing monitoring software in the users' computers, and it requires removing the capacity to copy the content from the user. With free software, it is difficult and potentially impossible for users to lose control of their computers in these ways. With a computer running free software, the user can (at least in theory) review all the software on the machine to assure that none of it is spying on him. Similarly if free software can present content to the user, then it can also make copies of that content.

There are a number of differences between free and nonfree software that are debated by software experts. For example, free operating systems have been nearly entirely free of the viruses and worms that plague the world of proprietary software. This may be because free operating systems are more resistant to worms and viruses, or because the virus and worm writers are attracted to more popular consumer computing platforms. Free operating systems have been relatively less frequently cracked by direct attacks, but as with viruses, it is not clear if the free systems are more secure or if attackers are more drawn to proprietary systems. The proponents of the proprietary systems often claim that free systems have no guarantee of functionality or support; proponents of free systems reply that the mere existence of a company charging money for software is no guarantee of support. Finally some charge that free software lacks *user friendliness*.

Programmers write free software because they enjoy pursuing technical challenges, and because they want the respect of their colleagues (Raymond 2001). In short, free software programmers are motivated by the same personal goals that motivate most scientists. The close fit between free software and scientific endeavors is therefore unsurprising. To a scientist or engineer, free software enables a powerful array of tools, of places where one can open the hood and tweak behavior to precise specifications; in a high-performance application, these capacities may outweigh the relatively greater complexity of free software relative to proprietary software. Combined with the richness of the Unix toolset and databases, numerical routines, and statistical software, free software can be the ideal scientific computing environment.

FREE WILL

To have free will means that in some nontrivial sense persons are able to make choices that are not determined by causes other than themselves, so that each person may be regarded as the unique author of his or her own thoughts and actions. The term *nontrivial* indicates more than the absence of external and future determinants. A snowflake is free to fall until it hits the ground, but this freedom seems trivial. Free will implies the absence of internal or prior determinations.

Notions of free will involve two closely related ideas. Moral freedom is the idea that human being are morally responsible for their actions, and so may legitimately be praised or blamed, rewarded or punished. Metaphysical freedom amounts to the more radical claim that human choosing involves a break in the chain of physical causation. The human being is thus an indeterministic system, producing outcomes that are not wholly caused by previous physical states. Modern controversies over the meaning and possibility of free will tend to pit science against morality. Free will in some sense is thought to be necessary for human dignity, but both versions of free will appear to be at odds with the causality investigated by modern science.

Historical Background

Human free will was not a problem in classical philosophy, for at least two reasons. According to Plato (c. 428–c. 348 B.C.E.), for instance, human freedom is not a given but something to be achieved through education. Most human beings are described as slaves, of their passions if not of other humans. Moreover, for Aristotle (384–322 B.C.E.) nature itself was not seen as a rigid set of causal relations; those things that are by *phusis*, or nature, have their own source of motion and rest, that is, are self-moving. Thus the achievement of human freedom is not opposed to nature but its perfection.

Augustine's *De libero arbitrio* (On free will) is the first extended analysis of the concept. For Augustine (354–430), the early Christian church father, the problem arises not from an opposition between human will and physical causation but between human will and God as the cause of everything. If God is all powerful and all knowing, including predestining humans for salvation and knowing the future, how can humans have free will? The Christian theological solution to this problem is simply to argue that God created humans with free will.

In the modern period, however, it is argued that all human beings are equally free (the democratic proposition) and that nature is a deterministic system of causal relations (the scientific proposition). The ethical implication of these two propositions is that humans should use science to control nature for human benefit (the technological proposition). There nevertheless remains a problem of how to reconcile free will and scientific determinism, in theory if not in practice.

Common Sense and Moral Freedom

Moral freedom is grounded in a commonsense interpretation of choosing (sometimes called folk wisdom). I am persistently conscious of alternatives—rare or medium rare? More importantly, I am subject to temptation—I should not break my promise, but just now I really want to. The impression that I could do either allows for a sense of moral responsibility. If you respect my rights, I ought to respect yours; if I do not, I deserve to be punished. This sense of responsibility in turn becomes the ground of all moral authority. Because I am as capable of it as anyone else, I can be ruled only with my consent. In this way, moral freedom supports the idea of individual dignity that underlies both liberty and democracy.

This folk wisdom view of free will has been vigorously challenged within the modern social sciences. Human beings are subject to any number of influences beyond any individual's control: culturally sanctioned values and taboos, character as formed over a lifetime of interactions, genetic inheritance, and more. When one thinks one is choosing, perhaps one is only expressing these social and biological forces. From this perspective, free will is an illusion. The real authors of one's choices are the various forces of social and natural history.

But it is unclear whether these challenges amount to much. Everyone recognizes powerful outside influences on their will. But our very consciousness of alternatives suggests that these influences never quite add up to a choice. A person is required to complete the action. It may be enough to recognize social forces do not act, people do. Each person stands as a unique pivot point in history, interpreting rather than merely communicating biological and social inputs. This may be an adequate ground for human dignity.

Metaphysical Freedom and Determinism

Unlike moral freedom, which largely abstracts from physical causes, the concept of metaphysical freedom focuses on causation all the way down. A person is metaphysically free only if the sum total of physical forces acting on her, including for example the momentum of every molecule in her brain, is insufficient to determine her choice. This would be to say that human choosing is not in all respects a physically caused event. At first glance modern science would seem to preclude such an account of free will. Much of science presupposes a physically deterministic universe in which the state of a system at one time rigidly determines its state at any future time. The view that the universe as a whole constitutes such a system is known generally as determinism.

Yet modern science is no longer uniformly deterministic. Quantum physics, in some interpretations, allows that very small events may be physically uncaused. But it is not clear that this does anything to save metaphysical freedom. Quantum events may have no appreciable consequences on the scale of human perception and action, or if they do this would still represent the influence of material constituents on the brain and could not explain how the person as a coherent self makes choices.

Given that metaphysical freedom involves more radical claims than moral freedom, the obvious question is whether the latter depends on the former. Call metaphysical freedom F1 and moral freedom F2. There are then three general positions. Determinists hold that F1 is required for F2, but that F1 does not exist. Thus there can be no free will in either sense. Libertarians accept the dependence of F2 on F1, but argue that F1 is possible. They then try to show how physical indeterminacy can support human choosing.

Finally, compatibilists argue that there can be F2 without F1. In fact, some have argued that F2 requires determinism. It is only because actions are rigidly determined by what a person is that we can praise that person for the actions; otherwise they would be regarded as mere luck. But this is unconvincing. We recognize that a horse's performance on the track results from its breeding and training, but we do not praise the horse for this. We praise an owner because the owner was free to make poorer choices. Compatibilism may save this sort of freedom only as a necessary illusion. We assume we are free precisely because we have no choice in the matter.

Reconciliations

All three positions rest on the assumption that determinism is the primary obstacle to moral freedom because freedom is conceived as whatever wiggle room does or does not exist between the boundaries set by causation. This is probably a mistake for two reasons. First, determinism relies on a concept of rigid causation that is neither required by theory nor possible in practice. While it simplifies our models of many phenomena to assume a perfect determination of events by antecedent states, there is no reason to believe that this perfection is real. And real or not, we can measure anything only to within some degree of precision. Past that point, things can be as messy as they please.

Secondly, the fundamental requirement of moral freedom is that my individual self is the cause of my own thoughts and deeds. To be more precise, I am genuinely free if my conscious choosing is among the causes that determine my choice. Otherwise I am indeed a puppet of forces beyond my control. But determinism is not, in itself, inconsistent with this, because it involves no theory of consciousness. It cannot rule out a role for awareness in the chain of causation. Conversely, libertarians have a hard time explaining how noncaused events can contribute to conscious choosing. If my puppet strings are being pulled by very small particles, it matters little whether those particles themselves are determined or indeterministic. Either way something besides me is in charge.

The real challenge to free will comes not from determinism but from two closely related views of consciousness. Both are examples of reductionism in so far as they attempt to explain an apparently complex thing, in this case the brain, by reference to its simpler material constituents. The epiphenomenalist claims that the conscious mind is an effect of physical events but is in no sense a cause of those events. No conscious state can be responsible for another, so there is no sense trying to think anything through. More radical still, eliminative materialists argue that consciousness does not exist at all. Like a ghost or a mirage, it is a delusion, though who is being deluded is something of a mystery. Moral freedom can scarcely survive any of these claims.

But perhaps it does not have to, because both seem to rest on an untenable dualism. They treat consciousness as something separate from the brain as a whole. A more mature view is possible. Just as sight is not produced by the eyes but is rather the activity of the eyes, nerves, and neurons, so consciousness is precisely an activity of the body and brain working in concert. The mind is a complex whole that functions to gather and store information and translate it into thoughts and actions. Its material constituents, determined or not, participate in this work only by virtue of their integration into the larger whole. It is this larger whole, perhaps, this congress of neurons, that is the seat of government. Consciousness is what happens when congress is in session.

Free will, like vision or flight, may be regarded as a product of mammalian evolution. Evolution can be understood only in the context of real time. The present is the finished product of a now vanished past. The future is, both in theory and practice, open and unpredictable. Trial and error is the engine of evolution, and free will may be understood as a small-scale model of that engine. Human beings adapt with astounding speed to unforeseen circumstances. Moreover they have constructed moral cultures and political regimes to preserve their successes. Liberal democracy using science for technological benefit is among the most effective of these precisely because it recognizes human beings for what they are. Both determinism and reductionism may have outlived their usefulness as models of the human mind.

Paradoxically, the democratic use of scientific technology may also propose more of a practical than a theoretical threat to free will. Advanced biomedical technologies for the control of human behavior and genetic nature can be interpreted as willful actions that can destroy the will. Recognition of such a possibility might then appeal to the phenomenon of free will as a good to be protected and thus as a moral limit or boundary on technoscientific action.

BIBLIOGRAPHY

Dennett, Daniel C. (2003). *Freedom Evolves.* New York: Viking. Dennett is among the most famous of contemporary compatibilists. He relies on a thoroughly Darwinian account of the human mind in order to build a philosophical account of consciousness and choice. Many critics argue that his version of free will is not genuine and that he is in fact a strict determinist.

Double, Richard. (1991). *The Non-reality of Free Will.* New York: Oxford University Press. Presents a rigorous argument against free will from the standpoint of contemporary analytical philosophy.

Hume, David. 1999 (1748). *An Inquiry concerning Human Understanding,* ed. Charles W. Hendel. Oxford: Oxford University Press. Hume is a famous early modern critic of the notion of free will. Like Dennett, he claims, in effect, to be a compatibilist, but most see his argument as determinist.

Kane, Robert. (1996). *The Significance of Free Will.* Oxford: Oxford University Press. Kane, a libertarian, is a frequent foil for Daniel Dennett. Kane argues that metaphysical freedom is both necessary for moral freedom and that it is possible.

FRENCH PERSPECTIVES

French intellectual culture, from its Enlightenment heritage, is deeply imbued with a positivist approach to human problems. Modern science and technology are simply assumed to be the proper expressions of human reason. Under such assumptions it would be meaningless to consider the possibility that either science or technology could be intrinsically problematic or that it would be appropriate to try to identify proper limits to their development. Instead, for more than a century the main philosophical debate raised by scientific and technological progress dealt with conflicting political responses to extrinsic problems, such as the uses of technology to exploit the working class.

In France, moreover, academic life is highly centralized and, as a result of their selection and training, professional intellectuals tend to live in a world situated between the Ecole Normale Supérieure and the Sorbonne. Such a context favors the reproduction of existing problems and debates, so that questioning of the intrinsic character of science or technology was at most a minor issue in the history of science. Those few thinkers who took seriously science or technology as issues in themselves remained isolated, their work largely ignored, with students who were interested in such topics systematically discouraged from appropriate programs of study. In consequence, questions of science, technology, and ethics in France during most of the twentieth century were not so much part of a tradition of critical reflection as they were associated with a series of individuals who, in somewhat eccentric manner, undertook to investigate them.

From Henri Bergson to Emmanuel Mounier

The response of Henri Bergson (1859–1941), the leading French philosopher of the first third of the twentieth century, to the disastrous experience of World War I is indicative of the basic attitude during this period. Educated at the Ecole Normale Supérieure, after teaching philosophy at a series of lycées, Bergson became a professor at the College de France, where his lectures attracted not only students and academics but even the general public and tourists. His most original reflections on creativity and time having been completed before the war, afterward Bergson served as a diplomat and worked in support of the League of Nations. His *Les deux sources de la morale et de la religion* (The two sources of morality and religion, 1932) argues a chastened but continuing commitment to the Enlightenment tradition.

Les deux sources acknowledges that there is something frenzied and uncontrolled (*frénétique et emporté*) in the race for material progress. Yet Bergson's perception of the problems raised by the scientific technology that is at the foundations of such progress is surprisingly narrow and shortsighted. He seems mostly sorry about "the search for comfort and luxury which seems to have become humankind's primary concern" (p. 322), although he quickly adds that there is no cause for worry, because humanity has always progressed by oscillating from one extreme attitude to its opposite—from a mysticism oriented toward self-control and self-possession to a materialistic mechanism aspiring to the control and possession of things. This is why "we should engage with no restraint in one direction in order to find out what the result will be: When it will no longer be possible to persist, we shall swing back with all our acquisitions, in the direction we had neglected or abandoned" (p. 321).

The dialectic of progress thus exhibits a kind of fatality that, in due time, can be expected to provide humankind, whose material body has grown dramatically, with a "supplement of soul" (p. 335). Bergson is confident that democracy will enable mechanism to satisfy everyone's true needs. Moreover, he expects that science will liberate the *elan vital* (vital impulse) from its materiality and spiritualize existence: "the material obstacle has almost tumbled down" (p. 337). Material progress fosters spiritual progress and thereby fulfills "the essential function of the universe, which is a machine for making gods" (p. 343). Understandably, a mind that entertains such lofty vistas will not be very sensitive to the concrete problems of everyday life, even those that would lead directly to a new and even more terrible war.

After World War II, French intellectuals were absorbed in the ideological and political debate for or against Marxism and communism. On the margins, such literary and religious thinkers as the Russian émigré Nicholas Berdyaev (1874–1948) and the novelists Georges Bernanos (1888–1948) and Jean Giono (1895–1970) raised pointed criticisms—as exemplified, for example, in the 1947 proceedings from a Geneva conference, *Progrès technique et progrès moral.* Against the threat of such views, Bergson's optimism was reaffirmed and turned into a technological messianism by the French personalist philosopher and founder of the journal *Esprit,* Emmanuel Mounier (1905–1950). His essay *Be Not Afraid* (1948) is a compendium of the irenic technophilia that predominated in French intellectual life until the late 1970s.

In response to the crisis of conscience that Hiroshima caused for some, Mounier dedicated himself to an unconditional justification of technology. For him, the criticisms made of "machinism" are founded on a theoretical error about the relationships between technology and society. The exponents of this view "claim to criticize the essential character of the machine, but in the main they attack the structure of capitalist society which has twisted the first services of the machine to its own ends" (pp. 31–32). Mounier thus summarizes in a nutshell the spirit of the time.

Whether spiritualists or materialists, rationalists or existentialists, most French philosophers were to adopt the Marxist doctrine that states "there is no problem of the machine as such." To the ethically scandalous problems of exploitation, economic inequality, and poor material living standards there are appropriate political responses. Concern for the environment was not yet a serious issue. Thus there was no philosophical problem of technology as such, and the leading French philosophers of the day completely ignored technology or even science as a theme calling for explicit critical assessment. Despite the fact that the work of Martin Heidegger (1889–1976) has been influential in France since the 1930s, there is little to nothing on technology in the work of Jean-Paul Sartre (1905–1980), Maurice Merleau-Ponty (1908–1961), or Albert Camus (1913–1960).

Bernard Charbonneau and Jacques Ellul

Although he does not mention them, Mounier's argument is almost certainly directed in part against the critical position of a small group of "Gascon personalists" led by Bernard Charbonneau (1910–1996) and Jacques Ellul (1912–1994). Born and educated in Bordeaux, under the shadow of World War I, the first truly industrialized war, Charbonneau passed his *agrégation* in both history and geography, but chose not to follow the standard academic career. Instead, he elected employment at a small teachers' college in order to be able to live a rural life in the Pyrenees.

Charbonneau's central intuition is that modern technoscientific development creates what he calls "the great mutation." Early on, Charbonneau became convinced that since the war humankind was experiencing an utterly new phase in its history, one that displays two basic characteristics. First, the Great War (World War I), as a total war, subordinated reality to the logic of industrial and technological imperatives, which require the mobilization of the whole population, resources (industry, agriculture, forests), and space itself. Indeed, the war achieved as well a mobilization of the inner life of the people who, on both sides, were not just affected by the war, but consented to it, thus justifying the anonymous process that would destroy them. The Great War was the first experience of what Charbonneau describes as "a total social phenomenon," insisting that it does not have to be totalitarian in order to be total.

Second, this great mutation is characterized by auto-acceleration. Human power takes hold of the entire planet at an ever-accelerating pace. This acceleration is a quasi-autonomous process. It is not a collective project, because most of its effects have not been chosen, and there is no pilot, because it simply rushes forward independent of any direct guidance. Technoscientific and industrial development fosters more and more rapid change throughout the world, across all aspects of life, without any respect for cultural meaning or purpose. The result is a radical disruption of society and nature, a state of permanent change.

Charbonneau was convinced that contemporary conflicting ideologies (nationalism, fascism, communism, liberalism) were outdated and provided no purchase on this great mutation, and that the uncontrolled development of industry, technology, and science was the problem and the not the solution. In his major books, written during the 1940s but published much later, Charbonneau insists that the issues of technoscientific development, of totalitarianism, and of ecological disruption are interrelated. In *L'Etat* (1987), he describes how the technological and industrial dynamism of liberal society has created the conditions of a total and technocratic organization of social and individual life. In *Le jardin de Babylone* (1969), he describes how the expansion of human power and of the techno-industrial order into a planetary scale deprives human beings of a harmonious relationship with nature and threatens not only ecological balance but also human freedom. In *Le système et le chaos* (1990), Charbonneau warns that the disorganizing impact of technological, scientific, and industrial development on nature and on society calls for a total organization of social life that will compromise human liberty.

Ellul was likewise born and educated in Bordeaux; together he and Charbonneau developed a version of personalism that promoted small, decentralized, and environmentally focused groups rather than centralized Parisian leadership. Unlike Charbonneau, Ellul elected a more academic career, and following his *agrégation* in Roman Law, became professor of the history of law at the University of Bordeaux.

Ellul is often characterized as a pessimistic Calvinist, urging the rejection of modern technology as an evil runaway power. But although Christian, he is neither Calvinist nor pessimistic; he firmly believes that it is possible to control and direct technological change, and indeed that technological choices are necessary and urgent. This is precisely the great political challenge that humankind must accept, otherwise politics is nothing but vain agitation. But the mastery of technological change is a difficult task, and in order to have any chance of success it is necessary to have a clear vision of the obstacles.

Ellul's analysis of the central role of technology in contemporary society is developed in three books. In *The Technological Society* (1954), he insists that the discussion of the role of machines is no longer relevant, because modern technology is not a mere accumulation of tools and machines; it is a global phenomenon which by means of propaganda, social planning and business management, and the organization of leisure subsumes all areas of individual and social life to the systematic search for efficiency. As a result there is a fundamental ambiguity of technological development, which, on the one hand, emancipates people from natural constraints and, on the other, submits them to a system of abstract and coherent functional constraints that in their own way determine social life. Technological progress fosters a technological society, more and more organized and integrated on the basis of impersonal logics.

In *The Technological System* (1977), Ellul argues that technology is now the environment in which human beings live and to which they must adapt. This technological environment is increasingly exhibiting a systemic cohesion. It is an interconnected network of technological ensembles; it organizes itself and evolves according to a process of "self-augmentation" dictated by its internal needs. This is why it is so resistant to attempts at reorganization from the perspective of non-technological values, whether ethical, political, or aesthetic. This technological system exhibits its own totalizing dynamic and tends to provide the main framework of social life. Nevertheless, Ellul adds that in spite of its capacity for auto-unification, this system is not and cannot be entirely coherent, because irrationalities and dysfunctions occur each time it is in contact with a different environment, natural, human, or social.

In *The Technological Bluff* (1988), Ellul argues that the development of the technological system parallels a cultural inability to address the problems created by technology, and that the suffusion of contemporary *mentalities* by a technicist worldview is one of the major obstacles to the mastery of technology. This is why policies aimed at controlling technological change require, in order to be effective, a change in both collective mentality and individual action. In *Changer la révolution* (1982), Ellul offers some guidelines for this new ethics of political action, which he terms an "ethics of non-power."

Jean Brun's Existentialist Interpretation

Another major contribution to the understanding of technology from an intellectual who lived and worked outside of Parisian institutions is Jean Brun (1919–1994). Like Ellul, Brun was a committed Protestant Christian who taught in the provinces at the University of Dijon. To the analysis of technology he brought an education in Greek and Roman philosophy that enabled him to once again challenge received views.

In *Le rêve et la machine* (1992), which synthesizes his major ideas, Brun maintains that the common understanding of technology as an application of rational and objective knowledge for effectively altering the world in order to satisfy human needs is dramatically one-sided and inadequate for appreciating contemporary problems of science and technology. The formal rationality of technoscientific endeavors is deceiving; it prevents people from recognizing the informal, imaginative, and often unconscious dimensions of technoscientific behavior.

Brun argues that technology is both a force of life and a force of death. On the one hand, without technology of some kind, human life would scarcely be possible. On the other, technology fosters destructive delirium, mechanized hysteria, and the planning of crazy projects. Human use of technology and the way humans develop it is often unreasonable, and its impact on nature and on human beings can be quite violent. For Brun there is a deep connection between technology and irrationality, and the obstacles to its rational uses must be appreciated.

According to Brun, technology manifests two goals: satisfying human *needs* for a better life (motives of pragmatic utility) and responding to *desires* to alter the human condition (existential motives). The study of ancient myths and ancient philosophy convinced Brun that technology is not merely an instrument useful for satisfying human needs, but also a means for empowering human desire for surpassing the ontological foundations of existence, for transmuting and overcoming the human condition. Human beings suffer and have always suffered from their finitude, from the alienation of consciousness, from physical and spiritual limitations, grounded in the necessity of living in space and time.

For Brun, the history of machines has been shaped and fueled by humanity's obstinate attempts to develop technologies of communication and transportation that attempt to break through such limitations. Beneath such obstinacy lies a hidden but fundamental despair within human consciousness regarding its separate and temporal mode of existence. Human technologies are often endowed with the power of discovering doors that open an existential labyrinth. In this respect human techniques are the offspring of human dreams as much as they are the application of positive knowledge. For Brun, "machines are both daughters and mothers of fantasies that we should call metaphysical ... [T]he utilitarian function of the machine is only its diurnal face; we must unveil its nocturnal face" (1992, p. 14).

This unveiling, which he also calls a demystification of technology, is a necessary precondition for any rational control and wise use of science and technology, as it is because humans project onto their technologies their desires for an ontological liberation that they remain fascinated by and addicted to their technologies. For the same reason, people often remain indifferent to technology's negative side effects and tend to transform the means into an end. Along with movies such as *The Fly* (1986) or *eXistenZ* (1999) by the Canadian filmmaker David Cronenberg, Brun argues for examining the ways utilitarian functions of technology are easily contaminated by its symbolic and existential functions.

The Mechanology of Gilbert Simondon

Another and quite different alternative to Enlightenment or positivist approaches to modern technology as applied science is found in the work of Gilbert Simondon (1924–1989), who proposed a general theory of the evolution of technological realities. Simondon was educated as a psychologist and philosopher at the Ecole Normale Supérieure in Paris and worked for the major part of his career in Poitiers and Paris. Because of a longtime interest in the character of machines, he studied what came to be called human factors engineering or ergonomics, which led him to attempt to understand their development somewhat independent of economic or other human interests.

In order to better clarify the human problems raised by machinism, Simondon chose the difficult path of laying the foundations of a kind of natural history of technological evolution. To this end he developed a conceptual framework for understanding the autonomy of technology and its radical alterity or otherness. As with Charbonneau, Ellul, and Brun, for him the category of instrumentality is inadequate for understanding the essential character of the technical order.

In *Du mode d'existence des objets techniques* (1958), Simondon argues that technical objects are not mere embodiments of abstract ideas, that they have their own mode of being or, as he says, of *existing*. Machines and technical objects evolve, and this evolution tends to exhibit a fundamental unity (structure). By analyzing the history of a few artifacts (motors, turbine, lamps, etc.), Simondon demonstrates how engineering practice follows the principle of functional unity, between the parts of the machine and between the machine and the exigencies of the surrounding world. "The technological being evolves by convergence and adaptation to itself. It unifies itself interiorly according to a principle of internal resonance" (p. 20).

Using as an example the evolution of the internal combustion engine, Simondon shows that each element assures the maximum possible of functions rather than attempt to realize a principle in its abstraction. Therefore, it is toward an interdependence of all the parts of the engine that its evolution converges, and it is this that leads to its progressive concretization through an organic-like integration of its diverse technical elements. According to Simondon, "The technological object exists then as a specific type that is found at the end of a convergent series. This series goes from the abstract to the concrete mode. It tends toward a state that would make the technological being a system entirely coherent with itself, entirely unified" (p. 23).

On this analytical basis Simondon develops a general theory of technology which, in the early twenty-first century, provides an intellectual framework for understanding the autonomy of technical objects and of technical systems: They develop according to a relational and reticular logic, obeying inner functional necessities that have little to do with human psychological, economical, social, and political goals. Although human beings produce technology, there is in technology something that is essentially resistant to human projects and values.

Simondon thinks that the solution to problems raised by the technicization of the world cannot be solved by politics, which relies on a poor understanding of the technical order and its dynamism. But for Simondon this is no reason for despair, and most of his subsequent intellectual endeavors aim at bridging the gap between the two cultures: the technoscientific operative one and the humanistic symbolic one. It is worth noting, in this respect, that although the second post-World War II generation of French philosophers such as Michel Foucault (1926–1984) and Jacques Derrida (b. 1930) were as silent about science and technology as their predecessors, some postmodernist authors such as Gilles Deleuze (1925–1995) have been attracted to Simondon. It may also be suggested that even those who do not share Simondon's rather optimistic and technophilic spirit may find in his thought substance for the pursuit of an authentic post-technological culture.

Supplementary Dimensions

The works of these four philosophers and the issues they wished to address were not, during their own time, well received in the French academic world. It is remarkable, for instance, that despite the 1974 French commitment to the development of nuclear power, this led to none of the kinds of public or intellectual debates typical of nuclear power developments in such countries as the United States or Great Britain. Nor has the increased technical powers of the professions of medicine or engineering engendered the kinds of discussions of professional ethics typical, especially, of the United States. Yet in the 1980s things did begin to change. One of these changes was the influence from the English-speaking world of the applied ethics movement, especially the field of bioethics.

In 1983, for instance, French President François Mitterrand created the Comité Consultatif National d'Ethique (CCNE), which consists of forty members, including representatives from different philosophical and religious schools of thought, public figures, and various scientific research institutions. Unlike similar or related commissions in other countries, the CCNE is not designed to be impartial but to elicit different points of view. Also unlike Enquette commissions in Germany or Royal Commissions in Commonwealth countries, the CCNE in not limited to specific topics but is an ongoing body. In 1994, in part as an outgrowth of its opinions, the French National Assembly passed legislation dealing with organ donation, medically assisted reproduction, and prenatal diagnosis.

Another associated activity emphasizing bioethics is the Science Generation Web site, which is cosponsored by the Institute de France, the Aventis Foundation, the Royal Swedish Academy of Engineering Sciences, the Federation of Scientific and Technical Associations, the European Council of Applied Sciences and Engineering, and the European Commission. This Internet site thus serves as a model of interdisciplinary and government-private partnership. But precisely because of their high profiles, neither the CCNE nor Science Generation represents serious critical assessment. Although both manifest an emerging concern for science, technology, and ethics issues, both focus much more on reflecting the opinions of technoscientific experts or the general public.

Another indication of the emerging French interest in science, technology, and ethics has been the stepping out of scholars more consistently devoted to these topics than has previously been the case. One example was an exchange between mathematician and historian of science Michel Serres and science studies ethnographer Bruno Latour (1990), in which the two explore how technoscientific power entails in itself ethical challenges. Still another was the creation in 1992 of the Société pour la Philosophie de la Technique (SPT), which provides an arena where competing philosophic approaches toward technology can be discussed in a constructive way.

Among the contributors to SPT discussions one may take special note of the following: Jean-Jacques Salomon (Conservatoire National des Arts et Métiers), in analyses of relations between science and politics, has raised the issue of democratic control not only of technology but also of scientific research. Dominique Janicaud (Université de Nice), with his theory of *potentialization*, has examined how progress in some types of rationality has created a potential for new forms of dehumanizing irrationalities. Gilbert Hottois (Université Libre de Bruxelles), a Belgian philosopher, has argued the inherently *an-ethicity* and autonomy of technological change, while arguing from the example of bioethics for the possibility an *accompagnement symbolique* for science and technology. And Franck Tinland (Université Paul Valéry, Montpellier) insists from an anthropological point of view on the long term autonomy of technological change and the resulting ethical problems that humankind is now facing.

FREUD, SIGMUND

The psychologist Sigmund Freud (1856–1939), who was born in Freiberg (now Príbor in the Czech Republic) on May 6 of Jewish parents and educated as a medical doctor in Vienna, founded the field of depth psychology (which he called psychoanalysis) and became one of the most influential thinkers of the late nineteenth and early twentieth centuries. His studies of the structure of the human psyche, the contents of the unconscious mind, the meaning and interpretation of dreams, repression, anxiety, and the role of the libido in the personality gave rise to many schools of psychological theory and therapy.

Ambivalence toward Science and Technology

Throughout this life Freud maintained a deep-seated belief in the value of scientific inquiry and a deep antipathy toward religion. In *New Introductory Lectures on Psycho-Analysis* (1952 [1932]), Freud stated

> Of the three forces which can dispute the position of science, religion alone is a really serious enemy. Art is almost always harmless and beneficent, it does not seek to be anything else but an illusion. . . . Philosophy is not opposed to science; it behaves itself as if it were a science, and to a certain extent makes use of the same methods. . . . Our best hope for the future is that the intellect—the scientific spirit, reason—should in time establish a dictatorship over the human mind. . . . Whatever, like the ban laid upon thought by religion, opposes such a development is a danger for the future of mankind. (p. 875)

However, Freud seemed ambivalent about the vast achievements of science and technology. On the one hand, he fully endorsed the desirability of human domination of nature. In perhaps his best-known work, *Civilization and Its Discontents* (1961 [1929]), Freud observes: "During the last few generations mankind has made an extraordinary advance in the natural sciences and in their technical application and has established his control over nature in a way never before imagined" (p. 39).

On the other hand, this domination has not brought with it a commensurate increase in human contentment. Human beings, Freud writes in *Civilization and Its Discontents,* "seem to have observed that this newly-won power over space and time, this subjugation of the forces of nature, which is the fulfillment of a longing that goes back thousands of years, has not increased the amount of pleasurable satisfaction which they may expect from life and has not made them feel happier" (p. 39).

Freud's greater worry, however, was the potential for destructive misuse of humankind's new powers. In *The Future of an Illusion* (1961 [1927]) Freud confesses his deep anxiety in a single sentence: "Human creations are easily destroyed, and science and technology, which have built them up, can also be used for their annihilation" (p. 7). This dark theme is taken up again in *Civilization* *and Its Discontents*, where he states that humans "have gained control over the forces of nature to such an extent that with their help they would have no difficulty in exterminating one another to the last man. They know this, and hence comes a large part of their current unrest, their unhappiness and their mood of anxiety" (p. 112).

Freud's psychoanalytical studies suggested to him that human beings overestimate themselves. In the middle of the calamity of World War I Freud wrote in *Thoughts for the Times on War and Death* (1952 [1915]):

> From the foregoing observations, we may already derive this consolation—that our mortification and our grievous disillusionment regarding the uncivilized behavior of our world-compatriots in this war are shown to be unjustified. They were based on an illusion to which we had abandoned ourselves. In reality our fellow-citizens have not sunk so low as we feared, because they had never risen so high as we believed. (p. 760)

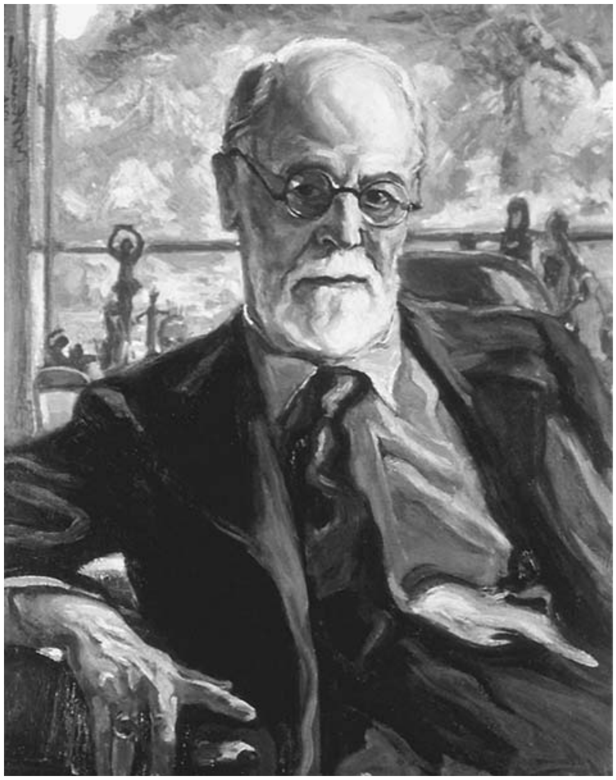
Ethics

Ethics does not constitute an important theme in Freud's major works. In *Civilization and Its Discontents* he suggested that ethics represents an attempt to accommodate the demands of a culture. The pleasure-seeking drive of the id is opposed by social restrictions in the form of the super-ego, and the ego is forced to mediate between these two poles: "Ethics is thus to be regarded as a therapeutic attempt—as an endeavor to achieve, by means of a command of the super-ego, something which has not so far been achieved by means of any other cultural activities" (p. 108)

Freud offers candid, less psychologically-oriented remarks on ethics in letters to a friend, the Swiss pastor Oskar Pfister. Writing in 1918, Freud admits a lack of interest in issues of "good" and "evil" because he has found "little that is 'good' about human beings on the whole. In my experience, most of them are trash, no matter whether they publicly subscribe to this or that ethical doctrine or to none at all. . . . If we are to talk of ethics, I subscribe to a high ideal from which most of the human beings I come across depart most lamentably" (pp. 61–62).

In a letter written a decade later Freud characterized ethics as a "kind of highway code for traffic among mankind" (p. 123). His last brief comment on ethics appears in a 1929 letter in which he states that: "ethics are not based on an external world order but on the inescapable exigencies of human cohabitation" (p. 129).

Freud's theories of the mind have been criticized, modified, extended, and even rejected by some schools of thought. Feminist writers, for example, have criticized Freud's essay on the psychology of women as deeply embedded in the gender stereotypes of his time. Yet even this critical stance must be measured against the strong presence of women in the field of psychoanalysis from its inception; Freud's own daughter Anna extended her father's work into the psychopathology of children.



Sigmund Freud, 1856–1939. The work of Freud, the Austrian founder of psychoanalysis, marked the beginning of a modern, dynamic psychology by providing the first systematic explanation of the inner mental forces determining human behavior. *(The Library of Congress.)*

More than six decades after his death, Freud continues to exert a powerful influence on how people view themselves as individuals and as a culture.

FULLER, R. BUCKMINSTER

A major contributor to scientific engineering and environmental studies, Richard Buckminster (Bucky) Fuller (1895–1983) was born on July 12 in Milton, Massachusetts, and died July 1 in Los Angeles, California. His epitaph, "TRIMTAB," sums up the worldview of the man who coined the term "spaceship earth." *Trim tab* is an aviator's term that refers to adjusting the wing's surface in order to change direction slightly. "TRIMTAB" refers to Fuller's belief that no one could actually steer the entire spaceship earth, but one could adjust the course slightly and stabilize it in times of turbulence.

Fuller entered Harvard in 1914, only to be expelled twice for "irresponsibility and lack of interest." From this inauspicious educational beginning, Fuller went on to receive forty-four honorary degrees, lecture at more than five hundred universities around the world, author twenty-four books as well as hundreds of articles, travel around the world more than forty times, and hold twenty-six patents.

Fuller was an environmentalist long before the word was popular. In 1927, Fuller designed Dymaxion House, a metal structure hung from a central mast with outer walls of glass. The unique house was heated and cooled by natural means, created its own power, included prefabrication, had rotating closets, was self-vacuuming, and was storm- and earthquake-proof. He built an example of the Dymaxion House in 1946 in Wichita, Kansas. In naming this contribution, Fuller demonstrated he was also a master of creating neologisms. *Dymaxion* is a combination of "dynamic," "maximum," and "ion." These three properties characterize his design strategy applied to many different problems.

For the 1933 World's Fair in Chicago, Fuller designed and built the Dymaxion Car. It had three wheels, was twenty feet long, carried eleven passengers, got thirty miles to a gallon of gasoline, and obtained a speed of 120 miles per hour. The car could make a u-turn within its own length.

In 1936, Fuller turned his attention to poor sanitation and the high cost of bathrooms. The five-square-foot Dymaxion Bathroom was his solution. The prefabricated bathroom consisted of four sections of either sheet metal or molded plastic. All of the necessary pipes, wires, and appliances were built in so that the entire unit merely required being hooked up. Both the sink and bath/shower allowed easy access by children and seniors.

In 1940, recognizing the need for military housing, Fuller designed and built the Dymaxion Deployment Unit (DDU). The DDU was a circular structure twenty feet in diameter made of corrugated galvanized steel, lined with wallboard on the inside and insulated with fiberglass. The house was naturally air-conditioned. Superheated air rising from the outer steel walls created a vacuum under the house that sucked cool air down the ventilator.

Fuller's Dymaxion Airocean World Map shows the continents on a flat surface without any visible distortion. On this map, the earth appears to be approximately one island surrounded by water. In the March 1, 1943, issue, *Life* magazine published Fuller's world map. That issue sold 3 million copies, the largest circulation of the magazine to that date.

In 1945, the Dymaxion Dwelling Machine house was designed and built. This was a vast improvement on the DDU house. The intention was to create a prefabricated house at low cost whose disassembled parts could be shipped anywhere in the world to meet the housing needs that were emerging at the end of World War II. The house was featured in *Fortune* magazine and generated thousands of unsolicited orders. These orders were never filled because of ethical differences between Fuller and financiers.

In 1948 Fuller created the most well known of his designs, the geodesic dome. A geodesic dome was selected for the United States Pavilion at the 1967 Montreal Exposition, where it still stands.

Buckminster Fuller was an early thinker about the entire earth. His *Operating Manual for Spaceship Earth* (1978) helped to focus world attention on one earth and the growing need to work together for survival. In poetic works such as *No More Secondhand God* (1963), Fuller also imbued technology with religious significance and called on human beings to accept responsibility for their god-like powers. He argued that human beings had to either create utopia or destroy themselves. *Synergetics* and *Synergistics 2* (1975 and 1979) is Fuller's mathematical masterpiece concerning the geometry of nature and the universe.

A truly remarkable man, Fuller's contributions all focused on what he referred to as a "Comprehensive Anticipatory Design Science." In this view, the science is directed to anticipating human problems and solving them by providing more and more support for everyone, with less and less resources. Yet Fuller often expressed himself in a vocabulary that critics sometimes found eccentric if not opaque.

FUTURE GENERATIONS

Responsibility to future generations appears at first to be an uncomplicated concept, and its widespread appearance in public pronouncements and political rhetoric testifies to its apparently widespread endorsement by public opinion. Moreover, advances in science and technology have directly increased the urgency and relevance of this concept as the present generation becomes ever more aware of its capacity to impact (with industrial chemicals, environmental exploitation, and climate change), destroy (with nuclear and biological weapons), and alter (with genetic engineering) the life conditions of the generations that will follow.

However clear and urgent the concept of responsibility to the future might seem upon casual reflection, as philosophers examine that concept with their typical meticulous analytic scrutiny, numerous puzzles, paradoxes, and quandaries emerge. Questions concerning the ontological, epistemological, and moral status of future persons (stipulated here as having non-concurrent lives with the current generation) are crucial. Most fundamentally, future persons, *qua future*, do not exist *now*, although the burdens of responsibility fall upon the living. Thus the question arises as to the attribution of such moral categories as *rights of* and *duties to* non-actual beings. Moreover, one cannot know future people as *individuals*. Instead, *posterity* is an abstract category containing unnumbered and undifferentiated members. And yet, much moral theory is based upon the principle of "respect for autonomous *individuals*." Additionally, one's relationship with future persons is unidirectional and non-reciprocal. Future persons will be unable to reward or punish the current generation, as the case may be, for the provision for their lives. Finally, because living people are ignorant of the life conditions of future persons, they cannot determine just what might *benefit* future persons—that is, what will or will not be "goods" to them. Clearly, by assigning moral significance to those not yet born, one introduces problems that are unique in moral philosophy.

Four Special Problems

One problem is that of Radical Contingency (or "The Future Persons Paradox"). Attempts in the present to improve the living conditions in the future result in different individuals existing in the future. Accordingly, in the present one cannot improve the lives of any particular future individuals (because any such attempt results in different individuals). Thomas Schwartz, who posed this paradox in 1978, concluded that present generations have no obligations to the future, other than to insure that their lives are, on balance, "worth living" (Schwartz 1978).

A rebuttal position would be to accept the paradox but to conclude that the responsibility to the future is to promote policies that will result in optimum conditions for *alternative populations*. In other words, Policy A is to be preferred to Policy B, if the lives resulting from Policy A are preferable to the lives resulting from Policy B, even though no *particular* future lives are improved thereby (Partridge 1998).

A second problem regards the duties to and rights of future persons. Do future persons have rights to clean air and water, wild areas, a tolerable climate, biodiversity, and energy resources? The question has significant policy implications regarding, for example, the use or conservation of natural resources, the depositing of nuclear wastes, or the reduction in the use of fossil fuels to minimize global warming. Rights claims have stronger moral force than mere *duties of beneficence* that are not correlated with the rights of the beneficiaries. Accordingly, by acknowledging the rights of future persons, those in the present generations may be morally obliged to accept greater sacrifices.

While many philosophers acknowledge duties to future generations, most who have written on the issue would deny that future persons have rights in the present, for the simple reason that potential persons, because they do not exist and cannot make claims, cannot be said to have rights (deGeorge 1979; Beckerman and Pasek 2001).

A contrary view contends that the denial of the rights of future persons involves an oversimplification of the concept of rights. There are, in fact, several categories of rights. While it is true that future persons, being non-actual, do not now have *active rights* to initiate or forbear activities on their own initiative, they do have *passive rights* not to be deprived of opportunities and not to be harmed. Unlike active rights, passive rights entail no initiative on the part of the rights-holder (future persons) but instead place a burden of responsibility on the correlative duty-bearer (the present generation) (Partridge 1990).

A third problem involves possible people and eventual people. Does a responsibility to future generations entail a duty of procreation—a duty to *create* future people (*possibles*)? Or is it confined to a duty to individuals who will, in any case, exist in the future (*eventuals*)? Clearly, the question has important implications for population policy. If current generations have a duty to bring possibles into existence, then the morally optimal future population will be much larger than if the duty of present persons is confined to eventual people. The issue also entails some deep ontological puzzles. For example, if a person is very pleased to be alive, would that person have been "harmed" if he or she had not been born? If so, then who is the "victim"? By stipulation, there is none. If no victim, then wherein is the harm? And yet, it is generally regarded as irresponsible to conceive a child who is certain to lead a brief and miserable life (e.g., a victim of Tay Sachs disease). Herein lies a paradox that is much discussed by moral philosophers (Warren 1981; Parfit 1984).

Finally, there is the problem of average utility versus total utility. When the utilitarian proposes to "maximize utility" (variously defined), does this mean *average* or *total* utility? With reference to a given (e.g., the current) population, there is no difference: raise the total and the average raises, and *vice versa*. However, the difference arises with the issue of population policy: That is, how many persons should be brought into existence in the future? Full commitment to either average or total utility leads to counter-intuitive conclusions. According to the average utility principle, Adam and Eve alone, before the fall, lived in a better world than a hypothetically later world of thousands or millions of individuals who, though quite happy on average, were slightly less so than the original couple. On the other hand, the total utility principle requires fertile couples to produce children whose lives will be on balance slightly happier than unhappy—an obligation that applies even in an overcrowded world. The average versus total utility dilemma leads to a question that lies at the very foundation of utilitarian philosophy: are those living in the present obliged to create people for happiness (total utility), or should they create happiness for people (average utility)? (Sikora and Barry 1978).

Policy Guidelines

Once one has accepted a moral foundation for a responsibility to future generations, the question remains: How might this moral obligation best be fulfilled?

The question is complicated by current necessary ignorance of the essential needs, of the cultural "goods," and of the technological conditions of future generations. Past generations, out of a sense of responsibility to those of the present, might have uselessly preserved a continuing supply of whale oil (not knowing about petroleum) and taken no heed to preserving semi-conducting substances. How would current generations, similarly, avoid wasting effort and treasure by preserving "goods" that would prove to be of no value to their successors?

One begins by taking inventory of some firm assumptions of the condition and needs of future generations. These assumptions would include:

(a) that they will be humans, with well-known biotic requirements;
(b) therefore, that they will need to be sustained by a functioning ecosystem;
(c) those future persons to whom one has obligations will be *moral agents*, and thus bound by such familiar moral categories as *rights*, *responsibilities*, and the *demands of justice;* and
(d) that they will require stable social institutions and a body of knowledge and skills that will allow them to meet and overcome cultural and natural crises that may occur during their lifetimes.

These considerations entail the following three essential policy guidelines:

- *First do no harm.* Because of current generations' ignorance regarding future cultures and technologies, and considering also the above list of basic needs, it is much easier to identify future harms than future benefits. Accordingly, one should favor policies that mitigate evils over those that promote good. The pains and tribulations of future persons, like those of the currently living, can often be clearly attributed to disruptions in the fundamental biotic, ecosystemic, psychological, and institutional conditions listed above, while their pleasures and satisfactions will come from a future evolution of culture, taste, and technology that one cannot even imagine.
- The *critical Lockean proviso.* John Locke's proviso that one leave "as much and as good" for one's successors, while applicable to the preservation of just institutions and sustainable ecosystems, cannot apply to non-renewable resources. If, for example, current generations were to share fossil fuels equally with all future generations (hypothetically setting aside an ignorance of their numbers), their share might reduce to cup of oil and a lump of coal—in any case, this resource would be useless, and the current industrial civilization would collapse (deGeorge 1979). Instead, the obligation to the future is to supply not fossil fuels but what fossil fuels provide, namely energy. Thus this obligation entails aggressive research and investment in a successor source of energy, presumably renewable. The critical Lockean proviso also entails a utilization of "interest-bearing" renewable resources, such as sustainable forestry, fisheries, and agriculture, and this in turn validates the need to preserve natural ecosystems.
- *Preserve the options.* This rule is clearly entailed by the previous two. While one cannot predict the technological solutions to future resource scarcity, the currently living owe future generations a full range of options and opportunities for research and development of these technologies. This in turn entails a continuing investment in scientific and technical education and research. Happily, such an investment benefits the current generation and that of its immediate successors, as well as the remote future (Partridge 1994).

Historical Background

The issue of the duty to posterity, though recurrent in the history of philosophy, has only recently attracted close scrutiny. Of the approximately one million doctoral dissertations listed in *Dissertation Abstracts* in 2004, the first to contain the either the terms "future generations" or "posterity" in its title was completed in 1976. Of the nearly two hundred entries in *The Philosophers Index* listed under "future generations" and "posterity," all but three have been published since the first Earth Day, April 22, 1970.

An explanation of this sudden appearance of interest in the topic of the responsibility to future generations may be found in an analysis of the concept of *responsibility*. Two criteria that appear to be essential to the concept are *knowledge* of the consequences of an act, and *capacity* to select among alternative anticipated consequences. Accordingly, the issue of responsibility to future generations has arisen with the extraordinary advances in science (knowledge) and technology (capacity).

During the first half of the twentieth century, the very idea that human activities might seriously and permanently affect the global atmosphere and oceans, or the gene pool of the human species and others, seemed preposterous. Now the sciences have disabused humankind of such assurances: technology has produced chemicals and radioactive substances unknown to nature, and evidence proliferates of permanent anthropogenic effects upon the seas, atmosphere, and the global ecosystem. Furthermore, such consequences of industrial civilization as ozone depletion, global warming, the contamination of aquifers, and the deposition of radioactive waste, although the byproducts of benefits to the present generation, exact postponed costs to remote generations. With science providing knowledge of these possible hazards for the future, and technology providing the capacity to deal with them, current generations have the responsibility to act with caution and moral insight, so that they might proceed toward a secure and prosperous future.

The authors perceive no great burden of obligation to the future.

deGeorge, Richard. (1979). "The Environment, Rights and Future Generations." *Ethics and Problems of the 21st Century*, ed. Kenneth Goodpaster and Kenneth Sayre. Notre Dame, IN: University of Notre Dame Press. A denial of the rights of future generations combined with an affirmation of a "duty of non-malevolence" toward the future. Argues that current obligations to the future are severely constrained by ignorance of future conditions or the capacity to affect these conditions.

Parfit, Derek. (1984). *Reasons and Persons*. Oxford, UK: Clarendon Press. Through skillful and insightful uses of "thought experiments," Parfit reveals deep paradoxes and puzzles regarding future persons—imaginable, possible, and eventual. These analyses have profound implications for population policy and procreation decisions.

Partridge, Ernest. (1990). "On the Rights of Future Generations." In *Upstream/Downstream: Issues in Environmental Ethics*, ed. Donald Scherer. Philadelphia: Temple University Press. A qualified defense of the present rights-claims of future generations. Concedes that future persons do not currently have "active rights" (to act or to forbear action). However, they have "passive rights" to resources, knowledge, and just institutions that entail moral duties that apply to present persons.

Partridge, Ernest. (1994). "Posterity and the 'Strains of Commitment.'" In *Creating a New History for Future Generations*, ed. Tae-Chang Kim and James Dator. Kyoto, Japan: Institute for the Integrated Study of Future Generations. Explores the psychological capacity of present persons to make moral provision to the future. Lists several policy implications of this capacity.

Partridge, Ernest. (1998). "Should We Seek a Better Future?" *Ethics and the Environment* 3(1): 81–96. A reply to Thomas Schwartz's radical denial of obligation to future generations (see below). Concedes Schwartz's argument that there are no duties to individual persons in the future, but that nonetheless, present persons have a duty to enhance the life prospects of the class of eventual future persons.

Schwartz, Thomas. (1978). "Obligations to Posterity." In *Obligations to Future Generations*, ed. Richard Sikora and Brian Barry. Philadelphia, PA: Temple University Press. An original, influential, and logically compelling presentation of "the future persons paradox": namely, the conclusion that because significant policy decisions cause different individuals to come into existence, no obligations are owed to particular individuals in not-distant future (i.e., approximately six generations).

Sikora, Richard, and Brian Barry, eds. (1978). *Obligations to Future Generations*. Philadelphia, PA: Temple University Press, 1978. An important early collection of essays on the issue of responsibility to future generations. Discusses many issues, most prominently the utilitarian problems of average versus total utility and population policy.

Warren, Mary Anne. (1981). "Do potential people have rights?" In *Responsibilities To Future Generations*, ed. Ernest Partridge. Buffalo, NY: Prometheus Books. Examines "the person-affecting principle"—that the morality of an act is to be evaluated in terms of its benefit or harm to persons. Thus stated, the "principle" seems axiomatic and indisputable. But when applied to "possible" future persons, and to the decision of present persons to procreate, profound ethical and even ontological questions arise. (See also Parfit, above.)

G

GAIA

First articulated by the British chemist James Lovelock in the 1970s, the Gaia hypothesis (named for the Greek goddess who personified the earth) proposes that the biosphere, atmosphere, oceans, and surface rocks make up a single, self-regulating, homeostatic system (Lovelock 1979). Key observations that Lovelock used in support of Gaia include the long-term stability of chemical disequilibria in the atmosphere and oceans despite both high fluxes of many chemicals within the earth system, and the fact that these persistent (in some cases for billions of years) yet nonequilibrium conditions are particularly well-suited for life as it has evolved. To Lovelock, the implication of these and related observations is that the biosphere must actively modulate the chemical make-up, temperature, pH, and other attributes of the earth system in order to maintain conditions under which life can flourish. In particular, the composition of the atmosphere must be regulated by the biosphere to maintain near-optimal concentrations of chemicals such as hydrogen, oxygen, and nitrogen.

Lovelock and his followers have promoted Gaia as an integrative framework for the study of the earth system. It raises scientific questions and demands experiments that would not be recognized under the traditional disciplinary and reductionist regimens dominant in the earth and environmental sciences. Gaia is thus not only an attempt to specify a unifying framework for the operation of the entire earth system, but also an explicit critique of the existing organization of knowledge inquiry.

Gaia has had little effect on research agendas, however, and the number of working scientists willing to be associated with the hypothesis is small—perhaps less than a dozen. Critique of the hypothesis focuses on three lines of argument. Gaia is said to be tautological because it asserts that life exists under exactly those conditions that are suitable for life. It is said to be teleological because it implies that the earth system must have evolved according to a design concept. And it is said to be trivial because, even so, Gaia adds little to existing knowledge about feedbacks among physical, chemical, and biological processes (Kirchner 2002). In response it is argued that Gaia is an emergent phenomenon that cannot be understood through traditional, disciplinary, and reductionist cause-and-effect reasoning. Lynn Margulis, a forceful advocate of Gaia, suggests: "The Gaian viewpoint is not popular because so many scientists, wishing to continue business as usual, are loath to venture outside of their respective disciplines. At least a generation or so may be required before an understanding of the Gaia hypothesis leads to appropriate research" (Margulis and West 1997, p. 223).

But it remains to be seen if the type of interdisciplinary synthesis that Gaia demands is even possible. Interdisciplinarity founders not just on the administrative boundaries between disciplines, but also on the differences in subject, method, time and spatial scales, types of data, definition of problems, and criteria of proof among various disciplines. These differences cannot easily be transcended or reconciled. This disunity of science is not entirely capricious, but in part reflects the richness and diversity of nature. How actually to move from reductionism and disciplines to Gaian synthesis remains far from clear.

Indeed while the need for interdisciplinarity is accepted by many scientists, strategies in the early twenty-first century—exemplified by the construction of highly complex, mathematical models aimed at simulating the coupled ocean-ice-atmosphere system—are still essentially reductionist in nature, building a story from first principles and supporting bodies of observational data. Gaia's claim is that such approaches can no more yield a comprehensive understanding of the earth system than a mapping of synapses can reveal the workings of an individual's consciousness.

Thus at least at this point in the evolution of science and society, Gaia's greatest impact may be largely metaphorical. On one level this metaphor may continue to challenge science to engage nature more synthetically, just as the Cartesian metaphor of nature as a clockwork helped to advance the cause of reductionist science. But on a broader, societal level Gaia has already been embraced as a cautionary symbol of the earth's complexity, interconnectedness, and inscrutability. Wrote Václav Havel, "Our destiny is not dependent merely on what we do for ourselves but also on what we do for Gaia as a whole. If we endanger her, she will dispense with us in the interests of a higher value—that is, life itself" (Havel 1998, p. 171).

GALENIC MEDICINE

Galenic medicine (also called humoralism or Galenism) derives its name from the Greek physician and philosopher Galen (129–c.216C.E..). Galen's prolific writings were rooted in the Hippocratic corpus as well as the philosophical doctrines of Plato, Aristotle, and the Stoics. Medicine was identified with Galenism for 1,300 years, and was institutionalized in the European universities of the eleventh century after Arabic translations of Galen's writings were retranslated into Latin. Though Galenism was eclipsed in Europe by the rise of modern medicine, it still survives as *Unani* (Greek) medicine in some parts of India and Pakistan.

The foundation of modern medicine rests on the divorce of medicine from philosophy, two disciplines wedded in Galenism. Both philosophy and medicine were practical arts that sought to answer the Socratic question: How should a person live the good life? (Hadot 2002). The good life demanded a striving toward excellence (*arête*), in the gymnasium no less than in the symposium. In medicine, health was the excellence expressed by the proper blending of the humors (*krasis*). In philosophy, virtue required knowing what was moderate or intermediate between excess and deficiency. As such, bodily health was analogous to moral virtue and the physician like the philosopher was a guide to living according to the mean (*mesotes*)(Tracy 1969).

The Galenic physician could only assist nature (*physis*) to restore the proper balance in the patient because it was inherently good. Nature thus constituted both the source and the limit of the physician's art. In order to gain insight into the workings of nature, the Galenic physician incorporated the three parts of philosophy (natural philosophy, logic, and ethics) into diagnosis, prognosis, and therapy. How deeply the physician was steeped in the study of philosophy also distinguished true medicine from quackery (Galen 1997).

The study of natural philosophy allowed the physician insight into both human nature and the nature of the universe. The Galenic body was fluid because it was composed of humors—blood, black bile, yellow bile, and phlegm—which were formed by the same elements that constituted the cosmos (fire, water, air, and earth). Disease resulted from the imbalance (*dyskrasia*) of the humors or the predominance of one or another quality (hot, cold, wet and dry) Humors and their qualities linked humankind to the macrocosm and established a correspondence or proportion between them.

Logic was necessary to make sound judgments about conditions of illness and health. The good physician was urged to train and sharpen the senses, which included not only the five external senses but also the common sense (*koine aesthesis*) through which the givens of the senses were synthesized and delivered to the intellect (Nutton 1993). Hence both reason and sense experience were essential for the discovery and confirmation of the true nature of things. Logic also led to the search for causes within a teleological cosmology that demanded the inference of the invisible from the visible; the hidden causes from the manifest signs.

Ethics was the domain of human action and conduct. In Galenism, the patient, the physician, and their mutual relation were subjected to an elaborate *askesis* aimed at cultivating certain dispositions and habits (*hexis*) to restore the balance of body and soul (Edelstein 1967). Galenic therapeutics throughout the Middle Ages placed a strong emphasis on *dieta,* the art and craft of moral and somatic virtues. Health required the good ordering of the *naturals* (elements, humors, parts of the body, and faculties) and the regulation of the *non-naturals* (rest, motion, food and drink, evacuation, passions, and errors of the soul). The virtuous character of the physician hastened the healing powers of nature by forging a relationship of trust and friendship (Entralgo 1967).

The union of philosophy and medicine in Galenism was founded on the norms of a teleological nature. The medical art was practiced within the bounds of the natural order that tended toward health and virtue as the right proportion of the humors and the passions. The replacement of Galenism with scientific medicine occurred in the seventeenth century when nature lost its *telos* and was construed as an inert mechanism to be manipulated at will. In Galenism, the foundation in teleological nature made the medical art inherently ethical. By contrast, medical ethics in the twenty-first century is the mere application of established rules to a professional field.

GALILEI, GALILEO

Mathematician, astronomer, and natural philosopher, Galileo Galilei (1564–1642), who was born the same year as William Shakespeare in Pisa, Italy, on February 15, contributed fundamentally to the scientific revolution of the sixteenth and seventeenth centuries in which Ptolemaic geocentric cosmology and Aristotelian were successfully challenged by Copernican heliocentric cosmology and a new science of motion. Galileo's participation in the astronomical revolution included the best-known cases of his technological innovation and ethical/religious conflict, namely, his application of the telescope as an astronomical instrument and his engagement with the Roman Catholic Church over matters of biblical interpretation and the Copernican hypothesis. He died on January 8 in Arcetri near Florence where he was living under house arrest that had been imposed following his conflict with the church.

Natural Philosopher and Inventor

Galileo's career as a natural philosopher involved an ongoing study of natural motion, especially inertial motion and that of falling bodies, projectiles, and pendulums. His work helped lay the foundation for the new science of classical mechanics, which found its early modern culmination in the genius of Isaac Newton (1642–1727). In addition to the telescope, which he first turned toward the heavens in 1609, evidence suggests that Galileo contributed to the technological development, improvement, and scientific application of no fewer than eight other scientific instruments. These included the *pulsilogium,* a device that applied a

Galileo Galilei, 1564–1642. The Italian scientist is renowned for his epoch-making contributions to astronomy, physics, and scientific philosophy. *(The Library of Congress.)*

pendulum to measure the human pulse, in 1583; a hydrostatic balance which he developed for his experiments on floating bodies, in 1586; the *thermoscope,* an early thermometer, in 1593; a geometrical and military compass, in 1597; a natural magnet called a loadstone used to further the new science of magnetism, in 1601; the microscope, in 1610; the *giovilabio,* which was an obscure tool developed to compute the distances and periods of revolution of Jupiter's moons, which Galileo had discovered with his telescope in 1612; and finally, a number of *vibration-counters,* some derived from his study of pendulums, which he applied to the mechanisms of clocks by 1637.

That the majority of Galileo's technical instruments were measuring devices is indicative of his philosophical commitment to a quantitative science. Well-know for his aphorism that mathematics is the language in which the book of Nature has been written, Galileo sought mathematical regularities in his scientific description and placed a premium on the collection of quantitatively accurate data. Indeed it was Galileo's unswerving commitment to an ideal of scientific knowledge grounded in rigorous measurement and observation that fostered his commitment to Copernicanism, which led to his famous struggle with authorities of the Roman Catholic Church.

Galileo did not invent the telescope. He learned in 1609, however, that a Dutch lens grinder had secured a patent the previous year for a device that magnified distant objects by combining two lenses. On the strength of this news, Galileo crafted his own telescope and turned the tool, which had originally been conceived for terrestrial purposes, toward the heavens. He reported his observations, which included details of lunar topography, descriptions of previously unobserved stars and constellations, and an account of Jupiter's four principal moons, the following year in his best-selling book, *The Starry Messenger* (1610). By this time Galileo was fully convinced of the truth of Copernican (sun-centered) theory. Hence as his book popularized astronomy, it introduced Copernicanism to the common people. This move did not help his reputation among contemporary natural philosophers.

Argument with the Church

Galileo's Copernicanism placed him in opposition to common sense as well as to reigning scientific and theological opinions. During Galileo's lifetime conclusive scientific evidence sufficient to establish the Copernican system as true was not yet available. Galileo believed his theory of the tides provided the needed empirical proof, but he was mistaken. This error made him overconfident. He was originally attracted to Copernicanism by its mathematical elegance and aesthetic superiority, not because he possessed irrefutable evidence. Galileo's principal opponents, Aristotelian natural philosophers (that is, the scientific community), did not believe that such evidence would ever be found. Moreover many of these opponents disliked Galileo for reasons unrelated to the Copernicanism. Galileo had inherited from his father a feisty spirit and taste for intellectual combat. He had engaged anti-Copernican natural philosophers on other scientific questions related to such matters as floating bodies, sunspots, and a new supernova. In each case he had distanced himself from the established scientific authorities and embittered his opponents, many of whom wished to see Galileo silenced, by the Church if necessary.

The Catholic Church, in the absence of conclusive scientific evidence for Copernicanism, followed the lead of natural philosophers in rejecting it. Moreover this seemed to be in accord with a straightforward reading of relevant Biblical texts (Gen. 1; Eccles. 1:4–5; Josh. 10:12; Ps 19:4–6; Ps 93: 1; Ps 104: 5, 19), the interpretation of which rested with church authorities. As a loyal Catholic, Galileo was interested in persuading church leaders to reject geocentrism and thereby be saved from future embarrassment. To do so, however, would require scientific evidence he could not provide. Just as importantly, it would also require expert theological skill in interpreting those biblical texts that seemed to refute Copernicanism. Although a layman, Galileo attempted to provide such advice on biblical interpretation. His "Letter to the Grand Duchess Christina" (1615) was offered as guidance "concerning the use of Biblical quotations in matters of science." It ranks among the classic statements on the relation of the Bible to science. In it Galileo argued that because God is the author of both the book of nature (i.e. the physical world) and the book of revelation (the Bible), it is not possible for genuine conflict between science and scripture. When there appeared to be such a conflict regarding matters of the physical world, the advice of Cardinal Baronius (1538–1607) should be recalled, namely, "That the intention of the Holy Ghost is to teach us how one goes to heaven, not how the heaven goes" (Drake 1957, p. 186). Because, argued Galileo, the Bible is a religious and moral text, not a scientific text, passages that seemed to treat subjects of scientific inquiry should be interpreted with deference to scientific opinion.

Although Galileo had made a compelling argument, two factors counted against him. First the weight of scientific opinion did not yet favor Copernicanism. Second he was a layman presuming to instruct on principles of biblical interpretation. This was an especially dangerous thing to do in the early seventeenth century in the wake of the Protestant Reformation and the Council of Trent (1545–1563). Predictably and defensibly the Catholic Church acted with prudence by upholding both contemporary scientific judgment and received biblical interpretation. Thus in 1616 the Theological Consultors of the Holy Office (advisors to the Pope) declared the Copernican theory foolish and heretical. This opinion was not uniquely Catholic either: Both Martin Luther and John Calvin disapproved of Copernicanism. After the publication of his *Dialogue Concerning the Two Chief World Systems: Ptolemaic and Copernican* (1632), Galileo was judged by church authorities to be *vehemently suspected of heresy* and sentenced to house arrest. It is interesting and important to note, however, that despite the opposition of so many church leaders to Galileo's Copernicanism, the Church never formally condemned the Copernican theory *ex cathedra*. That is, it never formally made rejection of terrestrial motion a matter of ecclesiastical dogma. Galileo had been punished for transgressing a theological boundary by engaging in biblical interpretation as a layman, even though the question was of scientific relevance. Here a key ethical/philosophical dimension of the affair turned on the question of whether or not Copernicanism was a matter of religious faith. Galileo did not believe that it properly was. Church authorities disagreed. Viewed in such a light, the Galileo affair, ultimately, stands as a religious debate between Roman Catholics about biblical interpretation.

Galileo's achievement as a scientist rests not only on the fact that history has vindicated his Copernicanism. His achievements in the fields of dynamics, technical instrumentation, optics, astronomy, and philosophy of science combine to place him among the greatest of scientific minds. His engagement with the Catholic Church was a complicated affair that testifies to the vigor of his scientific ability and to his Christian faith. Although it has often been presented as a clash between modern science and religion, the Galileo affair is not best understood in this way, because all players were committed churchmen. Rather the affair evidences the complicated religious and ethical dimensions that surface when human beings seek to construct a coherent worldview that also does justice to deeply held convictions about matters both scientific and religious.

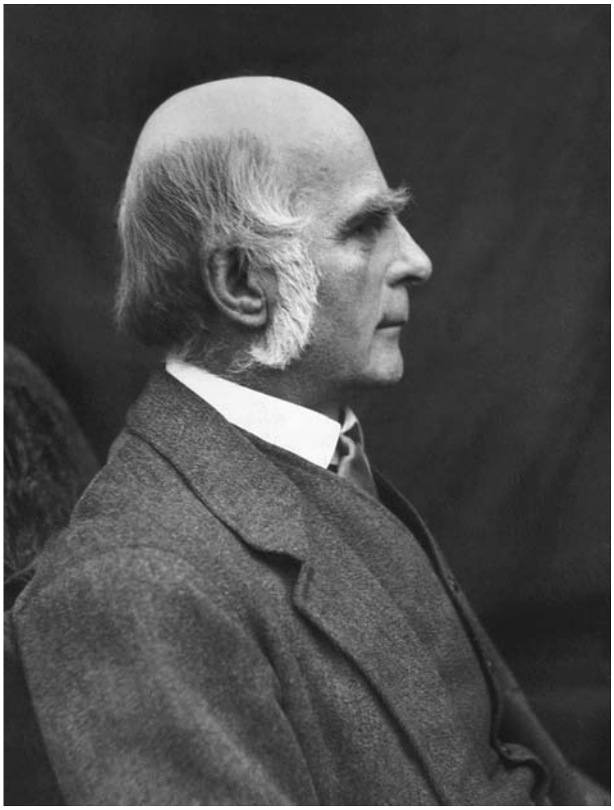
GALTON, FRANCIS



Francis Galton, 1822-1911. The English scientist, biometrician, and explorer founded the science of eugenics and introduced the theory of the anticyclone in meteorology. *(© Corbis-Bettmann.)*

Francis Galton (1822–1911), the scientist who created and promoted eugenics, the notion that a fitter human race might be created through selective breeding, was born near Birmingham, England, on February 16, and died in Haslemere, Surrey, England, on January 17. Originally oriented toward a medical career, Galton switched to Cambridge University to study mathematics, graduating with an ordinary degree. But his Cambridge experience was crucial to Galton's future career, during which he attempted to introduce quantitative analysis into whatever problem on which he happened to be working. His quantitative interests led Galton to discover the important statistical concepts of regression and correlation. He applied these in his anthropometric studies whose ultimate goal was to contribute to the improvement of humanity through eugenics, a term coined by Galton, that has profound ethical implications.

Galton's decision to abandon medicine was strongly influenced by his cousin, Charles Darwin (1809–1882), thirteen years his senior. They were grandsons by different marriages of Erasmus Darwin (1731–1802), a physician, scientist, poet, and inventor.

Like Darwin, Galton began his career as an explorer. Several years after graduating from Cambridge, he financed his own expedition and traveled through northern Namibia, a region of Africa not previously visited by Europeans. Galton took careful measurements of latitudes, longitudes, and altitudes, published his results in the *Journal of the Royal Geographical Society* in 1852, and was awarded a gold medal by the Society the same year. He also wrote a nontechnical book about his journey, *Tropical South Africa* (1853), but is best remembered for *The Art of Travel* (1855), an immensely popular guidebook for amateur and professional alike who ventured into the bush. The book went through many editions, grew in size, and Phoenix Press reissued the fifth edition in 2001. Subsequently Galton was active in the Royal Geographical Society for many years commenting frequently at Society meetings. During this part of his career he also became interested in meteorology. This led to his discovery of the anticyclone, a weather feature characteristic of a high-pressure system.

The second part of Galton's career commenced when he read Darwin's *On the Origin of Species* (1859). Galton concluded that it should be possible to improve the human race through selective breeding just as was true for domestic animals and cultivated plants. In 1865 he published a two-part article entitled "Hereditary Talent and Character" in a popular periodical called *MacMillan's Magazine*. The *MacMillan's* article was a precursor for Galton's book *Hereditary Genius* (1869). In both the article and the book Galton attempted to show that what he called *talent and character* were inherited. The book contained sections on judges and statesmen among others. Galton's thesis was that if he picked an eminent judge, for instance, that judge's immediate male relatives (e.g., father and son) were more likely to be eminent than those whose relationship was more distant (e.g., grandfather and grandson). Women were excluded from the analysis. Galton believed that analysis supported his thesis while recognizing, as others argued, that environment (for example, the father might obtain a good position for the son) might also be responsible for the correlation.

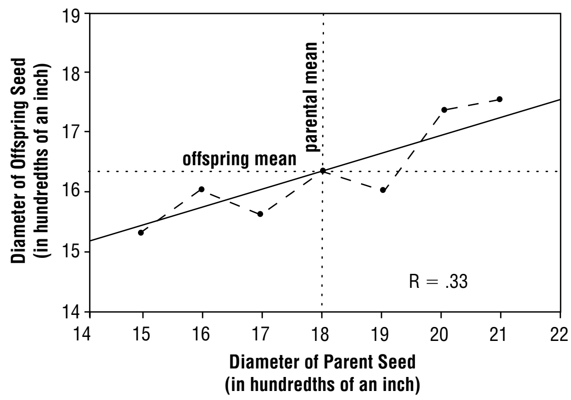
Galton was intensely interested in the analysis of quantitative data. By the time he had written *Hereditary Genius* he had become aware of the normal distribution and its application. In the book he used the bell curve to calculate a hypothetical distribution of the estimated 15 million males in the United Kingdom according to their natural abilities. Later Galton described two important new statistical concepts: regression and correlation. In experiments with sweet peas he found that seed diameter was normally distributed, but the diameter of seeds of progeny of large seeded and small seeded plants tended to be closer to the mean of the population as a whole than they did to the parental seed from which they had come. He dubbed this property regression to the mean. Regression to the mean has been documented over and over again since (for instance, in the case of different classes of mutual funds such as ones specializing in growth versus international stocks).

Galton also found he could draw a straight line on a graph comparing the diameters of parental and progeny seeds (Figure 1). This was the first regression line and from it he computed the first regression coefficient. Later he obtained comparable numerical data for humans (e.g., height) in the anthropometric laboratory organized at the International Health Exhibition of 1884 held in South Kensington, London. After the exhibition ended the laboratory reopened in the Science Galleries of the South Kensington Museum. Because Galton collected data on both parents and children, he once more demonstrated regression to the mean (e.g., for height).

FIGURE 1

Inheritance in Size of Sweet Pea Seeds

THE FIRST "REGRESSION LINE"



SOURCE: Galton, Francis. (1877). Royal Institution lecture, London. In Gillham (2001b).

While plotting forearm length against height he discovered another important statistical concept, correlation (i.e., tall men have long forearms). He reported the first correlation coefficient, countless numbers of which have been calculated since. Galton also became interested in fingerprints and their classification and used his anthropometric laboratory to collect scores of fingerprints. His work was central to the development of fingerprinting as a forensic technique.

Galton collected many of these important observations together in his book *Natural Inheritance* (1889). He began to acquire disciples. One of these, Karl Pearson (1857–1936), a superb mathematician, was able to develop statistical theory and go far beyond Galton in its formulation.

The Legacy of Eugenics

All the while Galton had been promoting eugenics. The notion that fitter people could be bred through selection began to gain great momentum in the first decade of the twentieth century. Positive eugenics envisioned the selective reproduction of those regarded as fit, while negative eugenics discouraged or prevented the reproduction of those deemed unfit. Sadly negative eugenics prevailed. In the United States eugenic sterilization laws were passed in many states leading to the involuntary sterilization of thousands of people who were thought to be mentally deficient or *feebleminded*. Developments in the United States were followed with interest elsewhere, especially in Germany. When the Nazis came to power they passed an involuntary sterilization law that resulted in the sterilization of hundreds of thousands of individuals. After World War II eugenic sterilization gradually came to an end. Although eugenics is Galton's unfortunate legacy, he also leaves important accomplishments such as statistics and the development of fingerprinting technology.

GAME THEORY

Game theory is the analysis of choices made by individuals, institutions, or governments, which are termed players; the results of one player's choice depend on the choices made by the others. Anticipations by players about how others may respond or may anticipate their actions thus influence choices of actions. An important attempt to use game theory involved the formation of nuclear deterrence strategy by the United States during the Cold War (1945–1990). However, game theory has many more general implications that go beyond those involving intentional choice.

Despite the fact that game theory matured only toward the end of the twentieth century, it has become a central tool in some of the behavioral sciences and doubtless will extend its influence into all disciplines that attempt to explain the behavior of living organisms. Indeed, game theory provides a language that transcends and potentially unites the various disciplines that deal with human behavior. Moreover, it provides an experimental methodology that allows for the rigorous construction and testing of strategic interaction because it forces an experimenter to be explicit in defining the actions available to the subjects, the payoffs, and the distribution of information among the subjects.

An Illuminating Example

A fox is chasing a rabbit through a wooded area. Foxes are faster than rabbits, and so if the rabbit runs in a straight line, it will be caught and eaten. The rabbit therefore periodically veers left or right, gaining ground on the fox. If the rabbit changes course too rapidly, its average forward movement will be so slow that it will be caught, but if it changes course too slowly, the fox will be so close that a small misstep by the rabbit will lead to its immediate demise. Therefore, the rabbit must choose the average rate of veering to optimize its probability of escaping.

In game theory it is said that the rabbit has *actions*: R_t = "Veer Right after t seconds" and L_t = "Veer Left after t seconds." The rabbit also wants to randomize its choice of Veer Right and Veer Left, because if the fox discovers a pattern in the rabbit's movement, it may be able to anticipate the rabbit's next move, thereby gaining ground on it. The proper mix of Veer Left and Veer right is doubtless 50 percent Left and 50 percent Right, for the fox potentially could exploit an imbalance in either direction.

However, suppose that there is an open field some distance to the east of the wood and that foxes run much faster than rabbits do in an open field. Then the fox might run constantly a little to the west of the rabbit, forcing the rabbit to turn east more often than it turns west. The rabbit in turn may risk being caught by veering west more frequently than it would otherwise, trying to keep away from the open field. It can be seen that both the rabbit and the fox choose actions to maximize the probability of winning, with each anticipating the effect of its actions on the other. This is the type of situation studied in game theory.

How important is game theory? It is central to understanding life in all its varied forms. This may sound excessive, but one must step back from this interaction between a rabbit and a fox to ask more basic questions. For example, why are rabbits bilaterally symmetrical about the axis along which their movement is most rapid and energy-efficient (left leg and right leg symmetrically placed and equally strong, left eye and right eye symmetrically placed and of equal size and discriminating capacity, and single external body parts such as the nose and tail arrayed along the axis of movement)? The answer is that if rabbits had strength biased to the right, it would be easier for them to jump left than jump right, and that would give an advantage to their natural predators, the foxes. Foxes are bilaterally symmetrical for similar reasons. Game theory thus explains important facts about life that otherwise appear arbitrary and incomprehensible.

This simple game theoretic argument explains a major fact about the organization of life. Animals that run to escape predators or capture prey have body forms that are bilaterally symmetrical about a vertical axis along the direction of their most rapid motion. This applies to most animals and fish but not to plants, which do not run and are radially symmetrical, or to squid, octopuses, and other sea creatures whose primary motion is up and down.

To avoid the conclusion that game theory deals only with conflict, one can consider an example that is called the Cooperation Game. A group of ten hunters in a village spread out in the jungle every day to look for large game. They hunt individually, climbing tall trees and waiting quietly and attentively for long hours until the prey appears. At the end of the day the hunters share the day's kill equally. Of course, each hunter could spend the day sleeping in a tree. Suppose that by working each hunter adds an average of 3,000 calories to the total kill, of which his share is 300, but expends 500 calories of energy hunting as opposed to sleeping. A selfish hunter thus will sleep rather than hunt, saving 200 calories but costing the other group members 2,700 calories. This is a game in which there are n players and each player (i.e., each hunter) has two actions: Work or Shirk. If m hunters Work, the Shirkers' payoff is $3{,}000m/n$ each, whereas the Workers' payoff is $3{,}000m/n - 500$.

A *best response* of a player in a game can be defined as a strategy (in this case an action) that maximizes that player's payoff in light of the strategies of the other players. It is easy to see that a self-interested player's best response in this game is to Shirk no matter what the other players do. A *Nash equilibrium* of a game is defined as a choice of strategies made by the players such that each is a best response to the other players' choices. It is clear that in the Cooperation Game there is only one Nash equilibrium, in which everyone shirks ($m = 0$) and no one eats.

Suppose another rule is added to the game. If a hunter is caught shirking, he is punished by being prohibited from hunting and sharing the kill for two days. Further, suppose the probability of being caught shirking is 0.50. To see that having everyone hunt is now a Nash equilibrium, one must decide whether a single hunter in a group of ten could do better by shirking and risking getting caught. The hunter saves 200 calories by shirking, but half the time he is caught and then loses two days' payoff, which is 5,400 calories. Thus, that hunter loses an average of 2,500 calories a day by shirking, and so his best response to hunt with the others. The conclusion is that with this new punishing mechanism full cooperation by each hunter becomes a Nash equilibrium.

History and Analytics of Game Theory

Game theory presupposes rational choice theory because it assumes that players have rational preferences in regard to the game's outcomes. It also presupposes rational decision theory because choice under conditions of uncertainty is the rule in most game situations. Because rational choice theory and decision theory were codified only in the late twentieth century, it is not surprising that game theory is still an incomplete and rather underdeveloped science. Before about 1950 games were assumed to be zero-sum; that means that what one player loses, the other player wins. The rabbit-fox game described earlier is zero-sum, but the hunter game is not because with the proper strategies all the hunters gain by cooperating.

With the zero-sum assumption cooperation never leas to a gain, and this would undercut some of the major contributions of game theory to the understanding of cooperation in biology and economics. Moreover, the three mathematicians who developed game theory—Ernst Zermelo (1871–1953), Stefan Banach (1892–1945), and John von Neumann (1903–1957)—assumed that each player will choose a strategy that minimizes the maximum gain for an opponent. This so-called *minimax* analysis cannot be extended to more general strategic contexts.

Modern game theory was born in 1950 after the publication of a paper by the young Princeton mathematician John F. Nash, Jr. (b. 1928; winner of a Nobel Prize in economics in 1994), who introduced the novel idea of a game equilibrium as a set of mutual best responses. The central term in modern game theory, the Nash equilibrium, acknowledges his work. Several conceptual problems had to be cleared up before game theory could attain a central position in the behavioral sciences. In 1965 Reinhard Selten (b. 1930; winner of a Nobel Prize in economics in 1994) developed the concept of *equilibrium refinement*, which showed why certain Nash equilibria are likely to be of empirical relevance and others are not. In 1967 and 1968 John Harsanyi (1920–2000; winner of a Nobel Prize in economics in 1994) showed how to apply game theory when the players have incomplete knowledge of the other players and the payoffs.

Until the 1980s it was believed by many people that game theory could be applied only to highly intelligent, so-called rational players because an analysis of the best responses is intellectually demanding. However, in 1972 the biologist John Maynard Smith (1920–2004) applied game theoretic notions to explaining animal conflict, a process that culminated in his publication of *Evolution and the Theory of Games* (1982). The innovation here is the idea that evolution can provide an alternative to high-level mental reasoning. For instance, rabbits veer optimally when chased by foxes not because each rabbit logically compares and empirically tests the alternatives but because running behavior is encoded in a rabbit's genes and those genes which render the rabbit most capable of eluding the fox are favored by natural selection in successive generations of rabbits. Inefficient genes simply become fox food.

The Ultimatum Game and Altruistic Preferences

An example of such research is the *ultimatum game*, in which under conditions of complete anonymity two players separately are shown a sum of money, say, $10. One of the players, called the proposer, is instructed to offer any number of dollars from $1 to $10 to the second player, who is called the responder. The proposer can make only one offer, and the game is never repeated with the same players facing each other. The responder can accept or reject this offer. If the responder accepts the offer, the money is shared accordingly. If the responder rejects the offer, both players receive nothing.

If the responder cares only about her own payoff in the game (it is said that she is *self-regarding* in this case) and the proposer knows or supposes this, the proposer will make the responder the minimum offer of $1, the responder will accept, and the game will be over. However, when the game actually is played, the self-regarding outcome almost never is attained or even approximated. In fact, as many replications of this experiment have documented, under varying conditions and with varying amounts of money, proposers routinely offer responders very substantial amounts (50 percent of the total generally is the modal offer) and responders frequently reject offers below 30 percent (Camerer 2003).

Are these results culturally dependent? Do they have a strong genetic component, or do all "successful" cultures transmit similar values of reciprocity to individuals? Alvin Roth (Roth, Prasnikar, Okuno-Fujiwara, and Zamir 1991) conducted ultimatum games in four different countries (the United States, Yugoslavia, Japan, and Israel) and found that although the level of offers differed slightly in different countries, the probability of an offer being rejected did not. This indicates that both proposers and responders have the same notion of what is considered fair in that society and that proposers adjust their offers to reflect that common notion. The differences in the levels of offers across countries were relatively small.

This ultimatum game result, along with that of many other similar games, suggests that many human subjects are strong reciprocators. Strong reciprocators come to strategic interactions with a propensity to cooperate (*altruistic cooperation*), respond to cooperative behavior by maintaining or increasing their level of cooperation, and responds to noncooperative behavior by punishing the "offenders" even at a cost to themselves and even when they cannot reasonably expect future personal gains to flow from the imposition of such punishment (this is called *altruistic punishment*).

Behavior in the ultimatum game thus conforms to the strong reciprocity model: Fair behavior in the ultimatum game among college students is a fifty-fifty split. Responders reject offers under 40 percent as a form of altruistic punishment of a norm-violating proposer. Proposers offer 50 percent because they are altruistic cooperators or 40 percent because they fear rejection. To support this interpretation it can be noted that if the offers in an ultimatum game are generated by a computer rather than by the proposer and if the respondents know this, low offers very rarely are rejected (Blount 1995). Moreover, in a variant of the game in which a responder's rejection leads to the responder getting nothing but allows the proposer to keep the share she suggested for herself, responders infrequently reject offers and proposers make considerably smaller offers.

The strong reciprocator is not a representative of one of the types of human nature found in traditional political philosophy. A strong reciprocator thus is neither the selfless altruist of utopian theory in the tradition of Jean-Jacques Rousseau (1712–1778) or that of Karl Marx (1818–1883) nor the selfish hedonist found in traditional economics and described by the economist Adam Smith (1723–1790) in *The Wealth of Nations*

(1776). Such a person is a conditional cooperator whose penchant for reciprocity can be elicited in circumstances in which pure selfishness would dictate a different action. Indeed, the strong reciprocator is more akin to the empathetic individual found in Adam Smith's other important work, *The Theory of the Moral Sentiments* (1759) except that Smith there emphasizes the sweet side of human nature, playing down the willingness to punish transgressions that is uncovered routinely in behavioral games.

Social Dilemmas

Another important behavioral game that sheds light on human nature and increases people's understanding of human social interaction is the *social dilemma*. A social dilemma is a group interaction in which all the players benefit if they all cooperate but each individual has an incentive to shirk and benefit from the cooperation of others.

An experimental representation of a social dilemma is the so-called *public goods game*. A typical public goods game consists of a number of rounds, say, ten. In each round each subject is grouped with several other subjects, say, three others. Each subject is given a certain amount of money, say, $20. Each subject, unseen by the others, then places a fraction of his or her money in a common account and puts the remainder in his or her private account. The experimenter then tells the subjects how much was contributed to the common account adds to the money in the common account enough so that, when divided among the four players, the private account of each subject can be increased by a fraction, say, 40 percent, of the players' original contribution to in the common account. Thus, if a subject contributes his or her whole $20 to the common account, the experimenter adds an additional $12, so each of the four group members will receive ($20 + $12)/4 = $8 at the end of the round. In effect, by putting the whole endowment into the common account, a player loses $12 and the other three group members gain in total $24 (= $8 × 3).

A self-regarding player will contribute nothing to the common account. However, only a fraction of subjects conform to the self-regarding model. The subjects begin by contributing on average about half of their endowments to the public account. The level of contributions decays over the course of the ten rounds until in the final rounds most players behave in a self-regarding manner. This is exactly what is predicted by the strong reciprocity model. Because they are altruistic contributors, strong reciprocators start out by contributing to the common pool, but in response to the norm violation on the part of the self-regarding types they begin to refrain from contributing.

How can it be known that the decay of cooperation in the public goods game is due to cooperators punishing free riders by refusing to contribute? Subjects often report this behavior retrospectively. More compelling, however, is the fact that when subjects are given a more constructive way of punishing defectors, they use it in a manner that helps sustain cooperation. For instance, Ernst Fehr and Simon Gächter (2000) set up an experimental situation in which the possibility of punishment for personal gain was removed completely. They used six- and ten-round public goods games with groups of four and with costly punishment allowed at the end of each round, employing three different methods of assigning members to groups.

They found that when costly punishment is permitted, cooperation does not deteriorate; indeed, if the same players stay together for the whole session, despite strict anonymity cooperation increases almost to full cooperation even on the final round. In effect, even though the groups had some selfish players, there was a sufficiently large fraction of strong reciprocators to ensure that it was not in the interest of the selfish to act selfishly.

The Epistemological Foundations of Game Theory

One can characterize the choice situation facing an agent in terms of its level of complexity. The least complex situation occurs when an agent must choose from a set of fixed alternatives. Analytically complete axiomatic models of choice in this situation are well developed and empirically successful. Of intermediate complexity is a situation in which an agent must choose from a set of alternatives, each of which is a *probability distribution* over determinate outcomes. Analytically complete axiomatic models of choice in this situation are also well developed and empirically successful, although some important anomalies in human behavior have been noted in regard to decision theory. The most complex situation is the one described by game theory: An agent's choices affect not only that agent but other agents as well, the other agents also are engaged in making choices that affect themselves and others, and all agents take into account the strategic nature of their interactions. One of the most widely known attempts to illustrate such a game theoretic situation is the Prisoner's Dilemma.

It would be gratifying to have a fully successful analytical model of strategic interaction applicable to the highly complex level, but despite the efforts of theoreticians since the second half of the twentieth century, none exists. Ignoring the Prisoner's Dilemma for now, one can consider three simple games that dramatize the problems in developing such a theory, which then can be used to outline some important contributions to the epistemological underpinnings of game theory.

EVEN-ODD GAME. The first is the simple Even-Odd game. This game has two players, each of whom can show either one finger (One) or two fingers (Two). The two players show their fingers simultaneously, with player 1 winning if his choice matches that of the other player (i.e., if One-One or Two-Two occurs) and player 2 winning if her choice does not match it (i.e., if One-Two or Two-One occurs). Figure 1 shows the normal form of this game (the normal form specifies the moves that each player can make and the payoffs for each player as a function of the moves of both players).

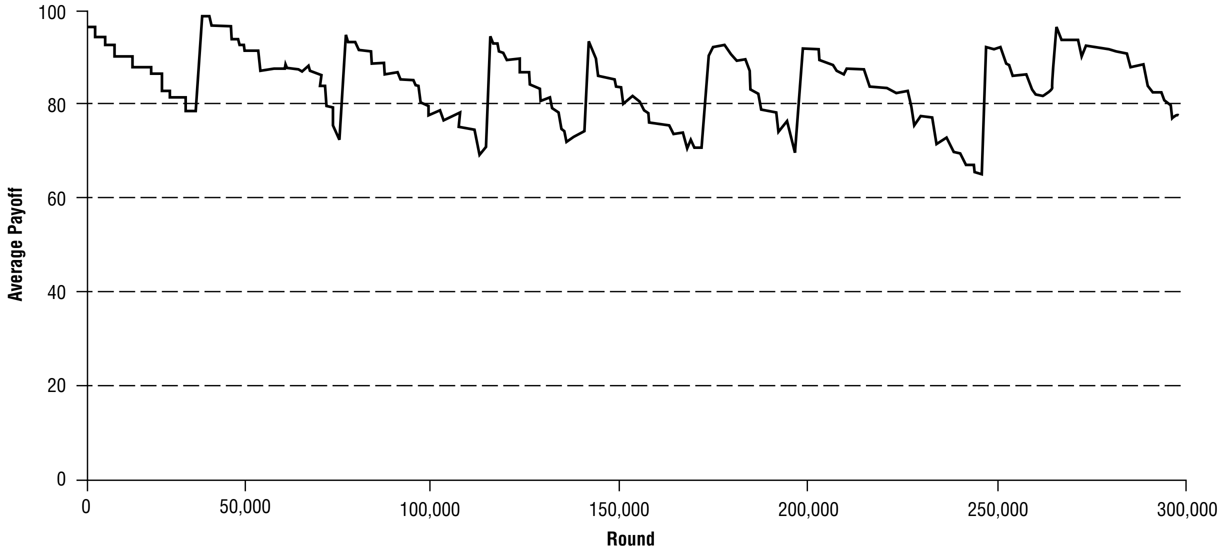
This game obviously has no Nash equilibria in the "pure" strategies: One and Two. However it does have a unique Nash equilibrium in which each player plays One with probability 1/2 and plays Two with probability 1/2. Doubtless many people remember this solution from schoolyard days, when they learned to "mix up" their choices so that an opponent could not discover their next move. The problem is that this game is played just once (it is a *one-shot* game). Hence, if a player's opponent randomizes as suggested by the Nash equilibrium, it does not matter what the first player does: The expected payoff is zero whether the first player chooses One, Two, or a probability distribution over One and Two. However, the same is true for the opponent. Therefore, there is no reason for either player to randomize, yet that is the solution suggested by game theory.

An important step toward dealing with this problem is to note that each player chooses a best response not to the actual strategy of the other players but to his or her own conjecture about what the other players will do. Robert Aumann and Adam Brandenburger (1995) prove the following theorem for a two-player game. Suppose ϕ_1 is player 1's conjecture concerning player 2's strategy and ϕ_2 is player 2's conjecture concerning player 1's strategy. If both players know each other's conjectures and each knows that the other is rational (i.e., chooses a best response to his or her conjecture), (ϕ_2,ϕ_1) is a Nash equilibrium.

BATTLE OF THE SEXES. This is a fine solution for Odd or Even, which has only one Nash equilibrium. However, one must consider another famous game, the Battle of the Sexes, which is depicted in Figure 2. In this game Rowena and Colin love each other and get one point by being together. However, Rowena loves the ballet and Colin loves gambling. Each gets a point for attending his or her favorite event. Thus, if both go to the opera, Rowena gets 2 and Colin gets 1, whereas if they both go gambling, Colin gets 2 and Rowena gets 1. Moreover, when they are not together, it is assume that they are so unhappy that each gets zero. It is easy to find two Nash equilibria: Both go gambling, and both go to the opera. It turns out that there is also a third Nash equilibrium in which each party goes to his or her favorite place with probability 2/3 and to the other's favorite

FIGURE 4

Average Payoff in Dynamic Centipede Game



SOURCE: Courtesy of Herbert Gintis.

place with probability 1/3. This is called a *mixed strategy equilibrium*.

To see that One gambling with probability 2/3 and Two gambling with probability 1/3 is a Nash equilibrium, one should note that the expected payoff to One from gambling equals $2 \times 1/3 + 0 \times 2/3 = 2/3$, whereas the expected payoff to One from ballet equals $0 \times 1/3 + 1 \times 2/3 = 2/3$. Because these probabilities are equal, One can do no better than his probability 2/3 gambling, probability 1/3 ballet strategy, and a similar argument holds for Two.

In the case of Battle of the Sexes it is unreasonable to posit that each player knows the other's conjecture because there is no way of explaining how this mutual knowledge would have come about. Indeed, it is not even plausible to suppose that the players have conjectures concerning what the other will do unless there is more to the social situation than has been explained. Moreover, the players still have no incentive to play according to their partners' conjectures (Binmore 1988).

The problem becomes even more implausible when there are more than two players. In this case Aumann and Brandenburger (1995) show that if all players assign the same probability distribution to player types, it is known mutually that all players are rational (i.e., choose best responses), and the players' conjectures are commonly known, these conjectures form a Nash equilibrium. One says that a fact is commonly known if all players know the fact, all know that the others know it, all know that all know that the others know it, and so on (Lewis 1969).

CENTIPEDE GAME. There are simple games in which the very notion of rationality and the adequacy of the concept of the Nash equilibrium are brought into question. Consider, for instance, the Centipede Game. The players, Mutt and Jeff, start out with \$2 each, and they alternate rounds. On the first round Mutt can defect (D) by stealing \$2 from Jeff, and the game is over. Otherwise Mutt cooperates (C) by not stealing and receives an additional \$1. Then Jeff can defect (D) and steal \$2 from Mutt, and the game is over, or he can cooperate (C) and receive an additional \$1. This continues until one player or the other defects or until each player has \$100. The game tree is illustrated in Figure 3.

This game has only one Nash equilibrium outcome, in which Mutt defects on the first round. To see this, let round k be the first round in which either player defects in a Nash equilibrium. If $k > 1$, the other player's best response is to defect on round $k - 1$. Of course, common sense indicates that this is not the way real players would act in this situation, and empirical evidence corroborates this (McKelvey and Palfrey 1992). People in this game will cooperate up to round 90 and beyond before considering defecting.

It would be difficult to fault players for not being rational in this case because they do much better playing the way they do rather than the way dictated by the Nash equilibrium concept. The concept of rationality is problematized for the following reason: If Jeff believes Mutt is rational, Jeff will defect in round 2. This is why Mutt defects in round 1. But suppose Mutt cooperates in round 1. Then Jeff will recognize that his assumption concerning Mutt must be false. Jeff probably will say to himself, "I don't know what strategy Mutt is using, but since he cooperated once, perhaps if I cooperate now, Mutt will cooperate a second time." Thus, Jeff will tend to cooperate in round 2. Now Mutt, who is very smart, can foresee what Jeff will be thinking and hence will cooperate even if he is rational. One can conclude that agents who use best responses will not play the Nash equilibrium in this game. It is easy to see the problem by referring to the analysis of Aumann and Brandenburger (1995): The two players do not know each other's conjectures.

Evolutionary Game Theory

To this point the focus has been on so-called classical game theory, which depicts the strategic interaction among a number of *rational agents*. The interaction is socially disembodied, with the agents having neither history nor substance outside this particular interaction. All socially relevant aspects of the actors must be captured by their beliefs and conjectures, which are totally disembodied and unmotivated. A similar degree of social minimality has given rise to powerful models of decision making when strategic interaction is absent, as in rational choice theory and decision theory. However, this does not extend to game theory, in which a more socially embedded approach is needed to derive plausible results.

The most promising alternative foundation for strategic interaction is known as *evolutionary game theory* (Maynard Smith 1982, Samuelson 1997, Gintis 2000). The central actors in evolutionary game theory are not players but strategies. Suppose a group of agents periodically plays a certain classical game G. One assumes a large population of agents, each of whom adopts a particular strategy in playing G. One does not assume that the strategies represented in the population are in any way optimal, although one does assume that there is enough random variation and mutation across time that all pure strategies are represented.

In each period agents from the population are assigned randomly to play G. Their scores are tallied, and the change in the population over time is governed by an evolutionary dynamic in the sense that agents whose strategies are very successful tend to be copied by agents whose strategies are less successful. Thus, the population ecology of strategies moves over time in accordance with the notion of survival of the fittest. This is called a *replicator dynamic* (Hofbauer and Sigmund 1998, Gintis 2000).

The fundamental theorem of evolutionary game theory is that every equilibrium point of an evolutionary dynamic is a Nash equilibrium. This provides a justification for the concept of the Nash equilibrium without the need for the epistemological assumptions of classical game theory. Moreover, evolutionary game theory shows that many Nash equilibria of classical game theory are not evolutionarily stable and thus cannot explain observable social behavior.

A case in point is the Centipede Game described earlier in this entry. The author of this entry has created a computer program to simulate the evolution of behavior in the Centipede Game (this is called an *agent-based simulation*). The author created a population of 200 agents, each supplied with a strategy *sk* of the following form: "cooperate until round k, then defect." Initially, these strategies are assigned randomly to the agents, and they play 300,000 rounds, with a mutation rate of 0.001 (a mutant assumes a random strategy *sk* where $1 \leq k \leq 101$). The results are shown in Figure 4.

It can be seen that cooperation quickly increases until after only a few rounds the average payoff is more than 95. Then cooperation erodes, as might be expected, until the average payoff dips below 80. At that point a pair of agents who choose strategies near $k = 100$ do very well, and those strategies grow at the expense of the strategies that involve defection on rounds near $k = 80$. Cooperation shoots back up to nearly perfect. The cycle repeats for 300,000 rounds and shows no signs of changing its basic character.

Even though the only Nash equilibrium of the stage game uses strategy s_1, it can be seen that the evolutionary dynamic never remotely approaches this equilibrium. This is the case because the Nash equilibrium involves such poor payoffs that even a small number of mutant players can invade a population of all-defectors, and the system quickly ramps up to almost full cooperation (changing the mutation rate does not alter this result). Thus, evolutionary game theory shows that the behavior observed when people play the Centipede Game is easy to model in a dynamic framework.

Game Theory and Ethics

Game theory has been applied to ethical theory by John Harsanyi (1992). Harsanyi (1920–2000; winner of a Nobel Prize in economics in 1994) develops a theory of justice very close to that of the philosopher John Rawls (1921–2002) and shows that it can be derived from basic game theoretic reasoning. Other important contributions to the game theoretic analysis of ethics include those of Brian Skyrms (1996) and Ken Binmore (1998).

Perhaps the first indication that game theory would be important to ethical theory was the famous tit-for-tat computer competition run by Robert Axelrod (Axelrod and Hamilton 1981). Axelrod asked what a successful strategy in the repeated Prisoner's Dilemma might look like. In that game the dominant strategy is to defect. However, if the game is repeated several times, players may be able to use the threat of defecting in the future to induce their partners to cooperate in the present.

Axelrod recruited fourteen game theorists from economics, mathematics, and the behavioral and computer sciences to submit computerized strategies for playing 200 rounds of the Prisoner's Dilemma. Those strategies were paired with each other in a round robin tournament with the result that the absolutely simplest strategy won. This strategy was *tit-for-tat*, supplied by Anatol Rapoport, a mathematician at the University of Toronto. Tit-for-tat cooperates on the first move and then does whatever its partner did on the previous move. Tit-for-tat is thus a simple reciprocity enforcer, cooperating when its partner cooperates and defecting when its partner defects.

After publishing these results (Axelrod and Hamilton 1981) Axelrod decided to stage a second tournament. More than sixty researchers from six countries submitted new programs, many of which were aimed explicitly at defeating tit-for-tat. Nevertheless, tit-for-tat again won handily.

This result relates to ethical theory because it shows the success of a strategy that is *nice* (never defect first), *punishing* (always retaliate against a defector), and *forgiving* (always revert to cooperating if your partner cooperates). These responses, of course, represent three important ethical principles. A fourth common ethical principle—*always turn the other cheek*—certainly would not fare well in this encounter, as it would be beaten by any program that could detect "wimps" (those who do not punish) and defect consistently in playing against them.

It is clear that the ethical principles behind the strong reciprocity associated with social dilemmas represent a higher development of tit-for-tat. Whereas tit-for-tat applies only to dyadic relationships, strong reciprocity applies to *n*-player social dilemmas.

Mohandas Gandhi, 1869–1948. Gandhi was an Indian revolutionary religious leader who used his religious power for political and social reform. Although he held no governmental office, he was the prime mover in the struggle for independence of the world's second-largest nation. *(© Corbis-Bettmann.)*

GANDHI, MOHANDAS

Mohandas Karamchand Gandhi (1869–1948) was born in Porbandar, Gujarat, India, on October 2, and led India to independence from Great Britain on August 15, 1947, by preaching and practicing nonviolent resistance. After studying jurisprudence at University College, London, Gandhi began practicing law in Durban, South Africa, in 1893. It was here that he started his political career by fighting discrimination against Indians. Following World War I he returned to India and became involved with the Indian National Congress and the movement for national independence. He was repeatedly imprisoned for his use of civil disobedience, fasting, and boycotts as methods of social reform. In addition to his nonviolent opposition to Western colonialism and capitalism, Gandhi advocated the reformation of the caste system and the harmonious coexistence of Muslims and Hindus in a unified India. His critiques of modern technoscience also influenced later theoretical developments and social movements. Gandhi was assassinated by a Hindu radical in New Delhi on January 30.

Nonviolence and Westernization

Gandhi initially defined his method of social action as *passive resistance,* but later refined and strengthened his ideals into a principle called Satyagraha. The term is derived from two Sanskrit words highlighting his central beliefs: *satya,* truth, and *agraha,* firmness—but practiced with *ahimsa,* non-injury to living things. As a method of direct social action, Satyagraha is a nonviolent insistence on truth in the political realm. Gandhi employed this principle with its offshoots, noncooperation and civil disobedience, in order to vindicate the truth by inflicting self-suffering rather than forcing his opponents to suffer. His persistence provoked anger in the British, including Winston Churchill, who called Gandhi "a malignant subversive fanatic" (Hardiman 2004, p. 238). The political success of this social reform method demonstrated the efficacy of nonviolence to the world and inspired other peace activists such as Nelson Mandela (b. 1918) and Martin Luther King Jr. (1929–1968).

Gandhi's experiments with Satyagraha made him aware of the economic, social, and political exploitation of people around the world, especially the uneducated and impoverished in South Africa and India. He believed that the root of this oppression and poverty was the culture of violence that resulted from Western materialist values, and he maintained that adopting the culture of nonviolence is the only way to attain truth, peace, and harmony. Thus Gandhi's nonviolent social reform was directly targeted against the globalization of Western values and material culture in the form of capitalism and imperialism.

He described the culture of violence in terms of the *seven social sins* of the world: wealth without work; pleasure without conscience; knowledge without character; commerce without morality; science without humanity; worship without sacrifice; and politics without principles. Gandhi's philosophy of nonviolence requires one to live life as an eternal quest for truth. It is often interpreted dogmatically or rejected as impractical, although it is founded upon the positive and near-universal values of love, respect, understanding, acceptance, and appreciation.

Gandhi believed that the westernization of India would destroy its culture and result in an unequal distribution of wealth and resources. Unlike his political heir, Jawaharlal Nehru (1889–1964), he did not believe that the systems of political organization that develop around Western science and technology could ever promote justice and human dignity. Gandhi maintained that the benefits of westernization would never trickle down to the poor because capitalist technology thrives on exploitation and creates a cycle of greed and consumption that never brings fulfillment.

Gandhi did not espouse communism, and in fact believed that capitalism could work if based on compassion rather than greed. Furthermore he understood that humans have legitimate material needs. The Western model of human development, however, sacrifices morality by overemphasizing materialism. He argued that human relationships ought to be guided by *trusteeship and constructive action*, meaning that human beings do not own their talents but hold them in trust for humanity. This fosters constructive action by helping the disenfranchised achieve greater self-confidence and self-sufficiency.

Gandhi's Reforms

Gandhi's opposition to Western values created an ideological gulf between him and other Indian political leaders. This motivated him to institute several societal reforms (he referred to them as the *constructive program*) even as the country struggled for independence, because he knew that his vision of an agrarian, self-sufficient, and traditional India would not be championed by his successors.

He developed small-scale technologies such as the *charkha*, or spinning wheel that helped liberate poor peasants from England's textile monopoly. Gandhi also helped in the effort to expand and improve basic education. Students learned reading and writing as well as best practices in agriculture. They were exposed to other cultures and religions in order to develop character and foster tolerance.

This education plan was a part of Gandhi's two part social reformation: promoting Hindu-Muslim unity and eradicating the caste system. Acutely aware of the multiethnicity of India and the tensions therein, Gandhi practiced interreligious harmony in his prayers by incorporating hymns from every major religion. His courage in the face of religious and ethnic violence inspired many Muslims to remain in a predominantly Hindu India.

Gandhi worked quietly to eradicate the caste system. He was cautious not to incite bitterness, because he feared the British would capitalize on divisions within India to strengthen their rule. Gandhi wished to change the name of *untouchables* from the derogatory *Bhangi* to the respectful *Harijan* (Children of God). With typical wisdom, he argued that by their suffering the untouchables had earned the right to be called Harijan, but other members of Hindu society will also earn that right when they atone for their sins.

Alternatives to Modern Science and Technology

When asked what he thought of Western civilization, Gandhi famously replied, "I think it would be a great idea." Thus he did not equate increasing scientific and technological sophistication with progress in civilization. In *Hind Swaraj* (1909), one of the earliest critiques of modernity as a development paradigm, Gandhi defined civilization as the ethical performance of one's duty and the attainment of mastery over passion. He also argued that "all research will be useless if it is not allied to internal research, which can link your hearts with those of the millions" (Gupta 2002 Internet site).

Nonetheless admitting there are lessons to be learned from modernity, Gandhi wrote that his "resistance to Western civilisation is really a resistance to its indiscriminate and thoughtless imitation based on the assumption that Asiatics are fit only to copy everything that comes from the West" (Hardiman 2004, p. 71). Gandhi believed that technoscience must be guided toward true human fulfillment and the alleviation of suffering. The fact that it is often used instead in the service of oppression, slavish consumerism, and war fueled Gandhi's conviction that Western values were bankrupt. In 1935, he initiated a movement called Science for People, which sought small-scale technological solutions for the problems faced by the rural poor. This indicated his vision for an alternative Indian future, which influenced especially ideas related to *alternative technology*.

For example, E. F. Schumacher's calls for a more humane economic system built upon small-scale *intermediate technology* were inspired by Gandhi. Likewise the Ghandian economists J. C. Kumarappa and D. R. Gadgil developed the concept of *appropriate technology* to counter the injustices that arise from the application of universal science in mass production processes. Although Gandhi is not explicitly mentioned, parts of Ivan Illich's *Medical Nemesis* (1975) echo Gandhi's *Hind Swaraj*. Gandhi's thought has also informed workers at development nongovernmental organizations (NGOs) such as Oxfam and ecological activists such as Ramachandra Guha and those participating in the Chipko and Narmada movements.

Faced with the pressures of economic and technoscientific globalization, Gandhi's vision of a traditional India has largely failed to materialize. It may be that the forces of westernization are too difficult to resist. As Chakravarti Rajagopalachari, a former Governor-General of independent India, wryly assessed, "The glamour of modern technology, money, and power is so seductive that no one . . . can resist it. The handful of Gandhians who still believe in his philosophy of a simple life in a simple society are mostly cranks" (Rushdie Internet site). Yet this does not diminish Gandhi's inspirational legacy or his teaching that life is more than science and technology.

GATES, BILL

Born in Seattle, Washington, on October 28, 1955, William Henry Gates III, founder of the Microsoft computer empire, is, in the year 2003, the world's wealthiest person, as well as the founder of the world's largest philanthropic foundation. Superlatives and paradoxes stick to Gates. Having scored a perfect 800 on the math portion of the Standard Aptitude Test (SAT), he later dropped out of college. Praising technology for "enhancing our leisure time" (Gates 1996, p. 284), his idea of a slow week (after marrying Melinda French in 1994) was to cut his workday to twelve hours a day during the week and eight hours a day on weekends.

Bill Gates, b. 1955. The co-founder and chief executive officer of Microsoft became the wealthiest man in America and one of the most influential personalities on the ever-evolving information superhighway and computer industry. *(© Jim Lake/Corbis.)*

Paradoxes also demarcate his ethical stances, both in business and technology. In 1975 he caused a stir among libertarian computer hackers by arguing in a letter to *Computer Notes* that software programs were "intellectual property" and should be legally protected through copyrights (Lowe 1998, pp. 86–87). As a result of his efforts, copying computer programs became illegal. However over the years a host of other computer companies have complained that he freely borrows their ideas.

A fierce competitor, Gates has said that "business is a good game [with] lots of competition and a minimum of rules" (Lowe 1998, p. 156), yet has been criticized for monopolistic practices. His competitors argue that he "cuts off the oxygen of the competition" (Lowe 1998, p. xiii). In 1998 the U.S. Justice Department sued Microsoft, alleging that the company had forced computer makers to sell its Internet Explorer browser as part of the licensing agreement for its Windows 95 software. Judge Thomas Penfield Jackson declared Microsoft a monopoly a year later. While accused of hardball tactics, it is important to note that Gates votes Democratic (i.e., more rules) more often than Republican and he vows to give away 95 percent of his wealth to charity (Lowe 1998, p. 178)

An unabashed optimist about the future, Gates believes technological "doomsayers vastly underestimate the potential of technology to help us overcome problems" caused by technology (Gates 1996, p. 291). Problems he considers self-correcting with the help of technology include unemployment, overpopulation, environmental dangers, globalization, and virtual reality, as well as privacy and security issues. Quoting H. G. Wells's belief that "human history becomes more and more a race between education and catastrophe" (Gates 1996, p. 293), Gates's foundation invests billions of dollars in the areas of education and global health issues.

Two problems he is less sanguine about include terrorism and artificial intelligence. In the short run terrorism worries him because of the inability of defensive weaponry to keep pace with advances in offensive developments. In the long run he is also concerned that "computers and software could achieve true intelligence" (Gates 1996, p. 290).

But, as a gambler, Gates clearly bets education will trump catastrophe, unlike, for example, Jacques Ellul's dire predictions in his *La technique ou l'enjeu du siecle* [Technology or the Bet of the Century] (Paris: Colin, 1954). The secret to Gates's worldview is poker. Part of Microsoft's startup costs came from Gates's poker winnings at Harvard. As he says, "In poker, a player collects different pieces of information . . . and then crunches all that data together to devise a plan for his own hand. I got pretty good at this kind of information processing" (Gates 1996, p. 43). A extraordinary understatement from a superlative intellect.

GENE THERAPY

Gene therapies (gene transfer technology) involve one or more experimental techniques for correcting or altering genes, including defective genes associated with physiological or psychological disorders. As has historically been the case with many other novel interventions (such as those that depend on drugs or surgery), debates have arisen between those who believe there is a moral obligation to pursue gene transfer research and those who challenge them as illegitimate or unnatural. As yet there is no strong consensus regarding distinctions between what is morally unacceptable, simply permissible, or obligatory.

Technical Aspects

There are a number of approaches to gene alteration including replacing an "abnormal" gene (i.e., DNA sequence) with a "normal" gene through homologous recombination, repairing an "abnormal" gene through selective reverse mutation, and altering the regulation of a particular gene. The term "abnormal" is placed in quotation marks, indicating that there remains room for disagreement about what constitutes a normal gene, is certainly one source of disagreement about these procedures.

Typically, for mostly practical reasons, gene therapy research involves the insertion of a functional gene into a non-specific location in the genome without removal or correction of the disease-causing gene. This can be done in vitro or in vivo. In vitro techniques require cells to be removed from an organism, corrective genetic material added in culture, and the altered cells returned to the organism. The advantages of this approach are twofold. If there is a problem with the genetic manipulation, the altered cells need not be transferred to the organism; also, the risk of unintentionally affecting non-targeted tissues is reduced. Alternatively, the corrective genetic material may be delivered to the targeted cells in vivo using a vector (often a virus that has been altered) to carry the gene into the cells. Retroviruses, adenoviruses, adeno-associated viruses, and herpes simplex viruses are among the viruses altered for vector use.

There are two categories of future gene therapy: somatic cell gene therapy and germ-line gene therapy. Somatic cell therapy involves the genetic alteration of nonfunctioning or malfunctioning somatic (i.e., non-reproductive) cells. These alterations are not passed on to subsequent generations. Germ-line therapy involves the genetic alteration of the germ (i.e., reproductive) cells or the early embryo prior to the development of gonadal tissue. Any resulting genetic changes will be inherited.

Use of gene transfer technology is not limited, however, to therapeutic goals. The technology can also be used for enhancement purposes to improve the functioning of normal genes—for example, the introduction of a growth hormone gene into a person of normal stature.

Ethical Issues

From the beginning, there has been considerable debate about the ethics of future gene therapy (Parens 1995, Walters and Palmer 1997, Stock and Campbell 2000). Some insist that somatic cell gene therapy is a logical extension of available techniques for treating disease; others argue that such genetic interventions are dangerous or inappropriate. Out of this debate emerged a moral demarcation line between somatic and germ-line gene therapy, the latter being widely described as ethically unacceptable because of the risks of physical and social harms (Anderson 1989).

In the late 1980s and early 1990s, with the move to clinical trials involving somatic cell gene transfer (and the possibility of inadvertent germ-line modification), debate about the ethics of germ-line gene transfer resurfaced. Some argued that germ-line gene transfer could be an effective and efficient treatment for diseases that affect many different organs and their cell types (such as cystic fibrosis); for diseases expressed in non-removable or non-dividing cells (such as Lesch-Nyhan syndrome); and for diseases that develop in the very early embryo that could be prevented through germ-line genetic intervention (such as albinism linked to tyrosinase). Indeed, some even argued that in such cases there was a moral obligation to reduce the incidence of disease in subsequent generations using germ-line gene transfer, instead of continuing to treat each successive generation with somatic cell genetic interventions. In opposition, questions have been raised about whether such work is an appropriate use of limited research funds when other efforts might have a more general public benefit, with some also objecting to the pursuit of a kind of biological perfectionism.

Controversial History

The history of gene transfer research in humans is a checkered one, mired in controversy (NRCBL 2002, Johnston and Baylis 2004). Martin Cline of the University of California Los Angeles (UCLA) conducted the first human gene transfer clinical trial in July 1980. The unsuccessful trial involved two patients with thalassemia, one in Israel and the other in Italy. Cline did not inform the UCLA Institutional Review Board (IRB) of his research, and did not fully disclose details of the trial to the Israeli research ethics review committee (at the time, Italy did not have an ethics review system). News of the unauthorized trial became public in a *Los Angeles Times* story published in October 1980. An internal investigation by UCLA and an external investigation by the U.S. National Institutes of Health (NIH) followed, resulting in significant sanctions for Cline. It would be another decade before an officially approved human gene therapy trial would begin in the United States.

The first federally approved gene transfer into humans in the United States came in 1989. The research involved the autologous transfer of gene-marked lymphocytes into five patients with terminal melanoma. The purpose of this research was to demonstrate safety.

A year later, in 1990, the first gene transfer experiment was approved. This research began with four-year-old Ashanthi DeSilva. DeSilva suffered from an adenosine deaminase (ADA) deficiency (a rare immune defect). She was the first of two children to be injected with her own blood cells that had been altered by a retroviral vector to contain functioning ADA genes. DeSilva and the other child research participant also received a new drug, PEG-ADA (a synthetic form of the ADA enzyme).

Around the same time, a similar trial, also involving two patients with ADA deficiency, was conducted by Italian researchers. In both cases the combined interventions proved successful, although the efficacy of the genetic intervention remains unclear since the children continue to receive PEG-ADA therapy.

The pace of gene transfer research picked up after 1990. As reported on the U.S. Center for Disease Control website, gene transfer clinical trials worldwide jumped from one in 1989 and two in 1990 to sixty-six by 1995. Meanwhile, there was growing concern about the hype surrounding gene therapy. In December of 1995, an NIH-appointed ad hoc committee reported that: "[W]hile the expectations and the promise of gene therapy are great, clinical efficacy has not been definitively demonstrated at this time in any gene therapy protocol" (Orkin and Motulsky 1995). In the same report, concerns were raised about the relationship between gene transfer researchers and industry.

A major setback for gene transfer research came at the end of the 1990s with the death of a small number of research participants in different gene therapy trials. The most widely publicized death was that of Jesse Gelsinger, an eighteen-year-old patient with a rare liver condition who was enrolled in a study at the University of Pennsylvania. In September 1999, Gelsinger received an injection of adenovirus vectors designed to carry corrected ornithine transcarbamylase (OTC) genes to his liver. Four days later, he died of multiple organ failure as a result of the experimental intervention (Raper, Chirmule, Lee, et al. 2003).

A few years later, there was yet another major setback. In October 2002, researchers in France with the first apparently unequivocal success in gene transfer research announced that one of the nine boys in their gene transfer trial for X-linked severe combined immunodeficiency disease (X-SCID) had developed a leukemia-like condition. Three months later, in December 2002, a second X-SCID child in the trial was also showing signs of a leukemia-like disease (Johnston and Baylis 2004).

As of early 2005, there had been no unqualified successes in human gene transfer research. Research continues on ways to improve gene control and targeting, effectively integrate DNA into the genome, limit the risk of stimulating an immune response, and avoid the problems with viral vectors that can result in inflammation and toxicity. Only when these problems are resolved will the promise of gene transfer research begin to be realized—assuming the research is deemed morally acceptable.

GENETHICS

The term *genethics* first appeared in the literature with the publication of a book of the same title by David Suzuki and Peter Knudtson (1989), a volume that dealt with the moral guidelines for genetic research and engineering. In a second book of the same title, David Heyd (1992) extended the definition to the field that focuses on the mortality of creating people—that is, decisions having to do with people's existence, number, and identity. Since then, the term has spawned several other books (Bayertz 1995, Burley and Harris 2002), a number of periodicals including *GenEthics News*, and numerous web sites, many of which are no longer active.

Is Genethics Necessary?

There has been some debate over whether the introduction of the term is advisable. While Suzuki and Knudtson and others were arguing for a genethics to deal with the problems raised by the new genetics, John Maddox in a 1993 *Nature* article played down the notion that the sequencing of the genome and related developments in molecular biology created ethical problems that are intrinsically unique. For Maddox, "this new knowledge has not created novel ethical problems, only ethical simplifications" (1993, p. 97). Darryl Macer (1993), in a follow-up letter, agreed that there is no inherent value clash between genetics and human values as Suzuki and Knudtson had proposed. Macer argued that the concept of genethics "should be stopped" and that what is needed instead is "a revival and renewed discussion of ethical values as society interacts with technology, and reassurance that scientists are responsible" (1993, p. 102). Society does not need a new ethics to cope with the impact of genetic technology.

Despite these objections, the term genethics is still in use and its development has received impetus from the Human Genome Project (HGP), the multi-billion dollar public-private, international initiative to map out the entire human genome begun in the 1990s and completed in 2000. Genethics was particularly fostered through the establishment of the Ethical, Legal and Social Implications (ELSI) program, under which the U.S. Department of Energy and the National Institutes of Health devoted 3 to 5 percent of the annual HGP budget toward examining such issues in relation to the availability of genetic information flowing from HGP. Specific areas of funding included the fair use of genetic information, privacy and confidentiality, stigmatization, conceptual and philosophical implications, and clinical and reproductive issues. Through this significant investment, ELSI became the largest bioethics program in the world and spawned similar endeavors elsewhere, often under the genethics moniker.

Although in some quarters the term has become a catchword for ethical issues raised by human interventions only, it is generally used more broadly to encompass the full range of ethical issues raised by advances in the science and technology of genetics and genetic engineering. In this broader sense, genethics cuts across all areas of science and technology related to engineering of genes, from human research and applications, to genetic modification of crops and animals, to other biotechnological applications such as drugs and potential terrorist and warfare uses of this knowledge (Reiss and Straughan 1996; Burley and Harris 2002). It might also be tied to secondary consequences of genetic technology such as eugenics and the link between genes and human behavior alleged to exist in drug or alcohol addiction or violence. Because some specific applications are discussed in other entries, attention here will focus on the issues surrounding human applications, largely the product of the HGP.

Increasing Knowledge

Knowledge of human genetics has undergone an accelerating expansion in the last several decades in large part as a result of the HGP. This increased knowledge and the emerging capacity to apply it for diagnostic and therapeutic purposes promise benefits to individuals and to society as a whole, but they also carry risks. These promises and risks have attracted the interest of bioethicists and social scientists as well as leading researchers. The issues raised in genethics relate directly to the almost daily announcements of new findings in molecular biology and related scientific fields and the development innovative technological applications.

Genetic intervention is especially controversial because of rapid advances in knowledge and the shortened lead time between basic research discoveries and their application. It has been estimated that knowledge in molecular biology is doubling every year, and a cursory survey of journals and Internet sites suggest that, although the shortened lead time might be exaggerated by some observers on either side of the debate, there is a rapid diffusion of applications, giving society less and less time to access their impact. In addition to challenging basic values, human genetics for some persons raises the specter of eugenics and social control (Kevles 1985). References to a "brave new world" scenario, in which human reproduction is a sophisticated manufacturing process and a major instrument for social stability, are commonplace. The notions of designer or made-for-order babies accentuate concern over this apparent quest for the perfect child (McGee 1997). Human genetic engineering is often criticized as playing God or interfering with evolution. Not surprisingly, opposition to genetic and reproductive intervention in this context is frequently intense and pits opponents against the research community and some commercial interests.

Diagnostics and Therapy

A complicating factor is the selective nature of genetic diseases. The success of genetic screening efforts often depends on the ability to isolate high-risk groups. In targeting such groups, however, problems of stigmatization, due process, and invasion of privacy arise. For instance, the early experience with screening for sickle-cell anemia in the early 1970s led to perceived and real threats to the African-American community when they experienced discrimination based on their carrier status by employers, insurance companies, and even the Air Force Academy that denied admission to those identified as having the sickle-cell trait. As DNA tests are developed to identify individuals at heightened risk for alcoholism, personality disorders, aggressive and antisocial behavior, and so forth, the fear of eugenics is bound to reemerge, thus making any attempts to screen most controversial. In this case, however, the "eugenics" is most likely to flow from decisions by individual parents who use the techniques to maximize their children's characteristics, not a social program. Some fear that once the tests become accepted as legitimate by society, it is likely that legislatures and courts will promote professional standards of care that incorporate increasingly intrusive testing.

Following the development of techniques to diagnose genetic disorders are emerging capacities to provide gene therapy. These techniques would act to correct genetic defects by acting directly on the affected DNA and could be directed at either somatic or germline cells. This move from diagnostic to therapeutic ends accentuates sensitive issues concerning the role of government in encouraging or discouraging human genome research and applications. The huge financial investment of government in many human genome initiatives clearly demonstrates a commitment to genetic technology and eventually gene therapy. In turn, however, any developments in gene therapy will raise ethical questions concerning safety, parental responsibilities to children, societal perceptions of children, the distribution of social benefits, and definitions of what it means to be human.

Both diagnosis and therapy constitute expansions of genetic knowledge, which can pose ethical challenges both for social and personal use. Socially, there is the problem of discrimination in attitudes not only toward individuals with certain genetic diseases but also toward how individuals might handle such possible knowledge. Personally, some individuals might choose not to know, and it is not clear that this would always be as equally acceptable as knowing.

Immediate genethics issues involved with this expanding genetic knowledge center on problems of discrimination and stigmatization. Genetic information of the type now promised is self-defining and can easily stigmatize individuals, thus enabling others to discriminate against them on the basis of such information. In fact, no information is potentially more invasive of personal privacy than tests that provide precise and inclusive knowledge of a person's genetic makeup. One issue that requires urgent attention concerns access to sensitive information collected through voluntary screening programs. Because such information is potentially embarrassing and humiliating, individuals must be protected from unauthorized disclosure. Even when confidentiality is assured, maintaining the security of genetic records will be difficult, though these are mostly questions of policy not ethics.

This problem is even more difficult, however, because there are circumstances that may warrant disclosure despite risks to patient privacy. Because genetic traits may be present in other family members, one question concerns the possible rights of these family members to any information relevant to their own well-being. Under what circumstances may a genetic counselor or physician disclose genetic information that might affect another family member or even future progeny? These issues of confidentiality and privacy, of course, are heightened significantly if mandatory genetic screening programs are instituted. Given technological developments, genetic tests are soon likely to be routine health indicators, only more precise and accurate than conventional ones. This will lead employers and insurance companies to screen potential employees or those applying for insurance for an array of genetic traits. At the same time, companies might want to include such tests in health promotion or preventive medicine programs with, for instance, persons identified as having a genetic proclivity toward hypertension placed into early diagnosis programs.

When, if ever, is an individual right to genetic privacy to be sacrificed to the interests of an employer? Under what circumstances does the responsibility of a genetic counselor or physician to society outweigh responsibility to the patient? As health care costs continue to escalate, employers will find it attractive to use genetic screening to exclude individuals who might cost them large sums of money in terms of future health bills. This is particularly critical if predictive tests are developed for general health status or for susceptibility to heart disease, cancer, diabetes, or alcoholism. Insurance companies, too, have a stake in data obtained through these methods. Genetic tests could be used either to determine insurability or to establish premium rates on the basis of test results. Life insurance companies traditionally have excluded people who are poor health risks and could easily extend this through tests that place certain individuals at risk for a wide range of conditions or diseases. Likewise, health insurers know that a large proportion of health care costs are attributable to a small proportion of the population, and as tests become available to identify individuals who are genetically predisposed to ill health, this is likely to put pressure on employers to screen prospective employees.

Confidentiality questions become more problematic when DNA or gene data banks are created where thousands of samples of blood, hair, or other tissue are stored for future use. The creation of such banks for criminal investigations elicits intense controversy. The issue is even more complex because unlike traditional fingerprints or other records (medical, credit, criminal) that are currently maintained, the DNA record contains potential as well as actual information. New genetic discoveries permit new information to be decoded from old samples. As science and technology advances, samples collected for a specific use could be used for totally unrelated purposes. Given the uncertainty of just how much and what type of data may be decoded from samples in the future, it is all but impossible to provide fully informed consent. Furthermore, questions remain as to who has proper access to this storehouse of knowledge on potentially millions of individuals.

Commercialization and Allocation of Resources

Although considerable public resources are being invested in human genome initiatives by governments, genetic tests and other applications will largely be influenced by commercial interests. Huge profits are likely to be made, especially as predictive tests for common disease categories are developed. Moreover, it is likely that DNA banking will include a significant entrepreneurial component in both the testing and data development components. Some observers argue that it is critical in light of ethical concerns over record-keeping, confidentiality, and so forth, that the emerging genetic industry be monitored closely and regulated where appropriate to guard sensitive data, control for the possibilities of error, and protect the economic and personal stakes involved.

Other issues inherent in the development of the new genetics involves decisions as to how these resources will be distributed and how high a priority they should be given in funding. Although resource allocation questions have not generally been at the center of genethics, they are becoming more critical because whereas resources are finite, demands and expectations fueled by new technologies have few bounds. While it is premature to speculate about the relative costs and benefits of yet undeveloped procedures, it is logical to assume that gene therapy will be a complicated, costly procedure. Will access be equitable and coverage universal, and, if so, how will it be funded? Or, will it be yet another reproductive technology available to the affluent but largely denied to persons who lack sufficient resources?

Should these technologies be available to all persons on an equal basis? Maxwell J. Mehlman and Jeffrey R. Botkin (1998) make a persuasive case that access to the benefits of genome technologies is bound to be inequitable. The traditional market-oriented, third-party-payer system leaves out many people. The debate over whether or not the government has a responsibility to facilitate access will intensify as the scope of technological intervention possibilities broadens. What criteria should be used to determine who gets the benefits of the HGP, especially given that considerable research has been financed with public funds?

More broadly, what priority should the search for genetic knowledge and ever-expanding uses of this knowledge have vis-à-vis other strategies and health care areas? What benefits will it hold for the population as a whole, compared to other policy options? In recent decades there has been a proclivity to develop and widely diffuse expensive curative techniques without first critically assessing their overall contribution to health. Similarly, research has been rapidly transferred to the clinical setting, thus blurring the line between experimentation and therapy. In contrast, the availability of effective and inexpensive genetic tests could provide valuable information for disease prevention and health promotion by targeting individuals who are at heightened risk for diseases that could be reduced by early intervention. Therefore, to the extent it furthers preventive efforts, genetic technology could be cost-effective.

The Genethics Controversy

This brief discussion of genethics and the new scientific and technological environment of genetic knowledge and expanding capacities to apply it demonstrate the challenges facing all societies. The revolutionary nature of such developments and the far-reaching implications of how people view themselves and others, requires a reevaluation of how far human genetic intervention should proceed. Additional questions to be addressed more clearly by genethics concern the impact of each potential application of the HGP on society, on individual members, and on the way members of that society relate to each other. Here genethics has been criticized by some observers.

One criticism of genethics and genetic policymaking to date is that they have been largely reactive in scope, pointing out potential problems without assurance they will occur, but offering little in the way of anticipatory solutions in the event they do. Although national commissions or similar bodies have studied these issues and made recommendations in many countries, and the ELSI program has produced innumerable academic studies, most governments have chosen either to take an affirmative stance through funding genome research and encouraging diagnostic and therapeutic applications, or they have attempted to avoid the issues raised.

Another criticism of genethics is that it has been almost exclusively the domain of ethicists and journalists, who in some cases make little effort to communicate with the genetic science and research community and often take a combative stance on the issues (Maddox 1993). Not surprisingly, some in the genetic research community see genethics as an irritant at best and a hostile force against scientific and technological process at worst. In the process, the broader public is often sidelined. Although enlightened public debate over goals and priorities related to the issues raised here seems warranted, it can be argued that genethics has not gone beyond providing a framework for action by clarifying the ethical and moral issues surrounding the science and technology of genetics. While this might be a start, Bartha Maria Knoppers (2000) sees as discouraging the "general failure to develop and include the ethics of public interest, public health, and the notion of civic participation in genetic research for the welfare of the community or for the advancement of science" (p. s38). By focusing on the problems and issues raised by the new genetics, genethics might be overlooking a variety of potential societal benefits. The costs of avoiding admittedly risky technologies out of the fear of potential stigmatization, commodification, or other ethical problems for the individual, then, might be high if it means foreclosing benefits for individuals and society.

In summary, genethics is inextricably related to science and technology and is a product of rapid developments in molecular biology and related fields since the mid-twentieth century. Although one could widen the concept of genethics to include the study of eugenics pre–double helix, the term as applied today represents a direct response to molecular biology and the science and technology surrounding the genome, and thus it is inextricably tied to and guided by it.

The authors propose a set of genetic principles that emphasize individual rights and confidentiality with regard to genetic screening, caution in violating boundaries across species, and a ban on biological weapon development and the genetic manipulation of human germ cells.

GENETICALLY MODIFIED FOODS

The production of genetically modified foods has provoked an ethical debate about whether it is right to use technology to create new forms of plant and animal life that otherwise would not exist. However, throughout human history agricultural crops have been genetically modified. There is nothing "natural" about food crops because most of them would be unable to propagate or survive without human intervention. What have changed over the years are the technologies that have been used to bring about genetic modification.

In general, humans have used three methods to modify plants genetically.

Conventional Breeding

At one time farmers practiced selective breeding and cross-breeding, or what is termed conventional breeding. Conventional breeding is less precise and predictable and therefore arguably less safe than genetic modification or, more correctly, *transgenic* plant breeding. The process has worked well because humans practicing conventional plant breeding have been able to increase yields in agriculture and support a larger population and/or improve human nutrition. The high-yielding dwarf varieties of wheat and rice that produced the Green Revolution were the result of conventional breeding.

Until the twentieth century most plant and animal breeding was largely a matter of selection and cross-breeding. Occasionally crosses between separate species were made as a result of human action or an unexplained “natural” happening. Wheat is a product of two or three different transpecies crosses of plants with different chromosomal structures.

In the 1920s advanced pollination techniques were used to create hybrid maize, a major but accepted genetic modification that far outyielded normal or “natural” maize. However, seed saved from hybrid maize for planting reverts to its original form and yields much less than the hybrid does. This means that a farmer has to buy new seed each year, but the increased yield normally makes that effort worthwhile. Hybrid maize has become the number one food crop in Africa.

Mutagenesis

The next method in this technological continuum involved the use of nuclear radiation or chemical mutagens to bring about mutations. This method is called *mutagenesis* and has the least-predictable outcome of all forms of plant breeding, but the technology is accepted and has escaped the label *genetic modification* presumably because these techniques have been used for more than half a century. The only advantage of the powerful and sometimes lethal genetic mutagens is that they produce a great many more mutations than occur naturally, thus generating the variability that breeders need for finding and introducing new characteristics into their plants. The Food and Agriculture Organization/International Atomic Energy Agency’s Mutant Varieties Database Register (December 2000) lists over 2,252 crops in the more than seventy countries in which these mutant varieties are used. Key varieties are grown and/or eaten in virtually every country. Barley used in commercial beers around the world as well as wheats used to make pasta are products of radiation mutation breeding.

Genetic Engineering

With the discovery of the structure of DNA (deoxyribonucleic acid) in the 1950s, followed over the decades by a greater understanding of the process of inheritance, the way became clear for transgenic technology, or genetic engineering. This allowed desirable characteristics expressed by a gene or a small group of genes from any organism to be transferred to another organism. By the early 1980s the first genetically engineered pharmaceuticals were released, and they have been followed by an increasingly sophisticated array of new drugs. By the late 1980s transgenic enzymes and bacteria were involved in the production of cheese, bread, wine, beer, and vitamins that are consumed on a daily basis by numerous people.

Biotechnology is done under precisely controlled conditions in which a gene, together with a marker, is incorporated in plant tissue, which then is grown in tissue culture to produce plants. At this stage the plant is subject to initial evaluation to ensure that the gene has been transferred successfully and stably and produces the desired trait and that there are no unintended effects on plant growth or quality.

The gene transfer process is far more precise than the other accepted procedures and allows desirable plant transformations to be performed that are not possible using conventional breeding.

Benefits

Since their introduction in the mid-1990s transgenic crops engineered for herbicide tolerance, by expressing a protein that is fully digestible by humans and other animals, have brought about a decline in pesticide use, something critics of those crops have long claimed to favor. There have been enormous benefits from plants engineered to resist certain pesticides. Modern conservation tillage (or reduced-, minimum-, or no-tillage) agriculture using pesticides for weed and pest control conserves water, soil, and biodiversity better than does any current or previous form of tillage. In addition, this method saves fuel and therefore releases less carbon into the atmosphere. Conservation tillage is improving soil and soil quality. Planting with a drill, possibly disking the field, preserves soil structure and vegetative cover and the diversity of life therein, such as earthworms and other life forms that often are destroyed by deep plowing and other older forms of conventional agriculture. Conservation tillage has led to a reduction in overall pesticide use as a less toxic broad-spectrum pesticide is substituted for multiple sprayings of an array of targeted pesticides and herbicides.

Popular Fears of the Dangers of Frankenfoods

Genetic modification or engineering of crop plants has generated far more adverse reactions than did the informed guesswork that preceded it. Those products have been called *Frankenfoods,* a pejorative term for genetically modified foods that evokes the film version of Doctor Victor Frankenstein's monster from the novel by Mary Shelley (1797–1851). The fears are based on the extraordinary power of this new technology but concentrate principally on two issues: concern for human health and concern for the environment. Exhaustive tests have been carried out to determine whether genetically modified crops carry an increased risk of allergic reactions or other effects in people who eat them. There is no evidence so far that this or any other adverse reaction or nutritional problem has been caused in consumers of these crops after nearly ten years of production on more than 400 million acres of products consumed by more than 1 billion people.

Damage to the environment has been postulated to be a possible result of growing transgenic crops. Fears include the escape of genes into related wild plants, adverse effects of insect toxins (in the case of crops with the Bt gene) on desirable insects, and transfer of antibiotic resistance. Several factors lessen the likelihood of damage to the environment. Some crop plants and their wild relatives are self-pollinated, and so there is no opportunity for gene transfer to take place. Others have no wild relatives in the local flora, and so the local environment does not have suitable gene recipients. Transfer of antibiotic resistance from transgenic plants into the soil microflora is very unlikely and has not been demonstrated convincingly. Even if there were transfer, these genes already are ubiquitous in the soil microflora.

The most prominent public phobias in developed countries involve *chemicals* (a code word for industrially produced chemicals), which are all assumed to be carcinogenic; and radiation, which is assumed to cause cancer and mutations. One wonders why there has been no outcry about the use of *chemicals* and radiation in plant breeding, particularly in light of the fact that many critics of transgenics also oppose the irradiation of foods to kill microorganisms (a technique that has been used for more than forty years). Starting with a blank slate of public opinion on plant breeding, it would be far easier to frighten people about chemical and radiation breeding than about the insertion of a single gene plus a promoter and a marker. The promoter is simply a DNA sequence that allows the gene to be expressed, whereas current techniques require the use of marker genes.

Conclusion

The process and result of genetic modification have been subject to close scrutiny by some of the world's best scientists. The plants and the foods derived from them are extensively tested to assure consumers that these products are safe for the environment and for humans. In a joint report issued in July 2000 the National Academies of Brazil, China, India, Mexico, the United States, the United Kingdom, and the Third World Academy of Sciences concluded: "It is critical that the potential benefits of GM technology become available to developing countries." They also concluded that "steps must be taken to meet the urgent need for sustainable practices in world agriculture if the demands of an expanding world population are to be met without destroying the environment or natural resource base. In particular, GM technology coupled with important developments in other areas should be used to increase the production of main food staples, improve the efficiency of production, reduce the environmental impact of agriculture and provide access to food for small scale farmers" (Royal Society 2000).

GENETIC COUNSELING

Genetic counseling is an educational service that aims to help people become informed and responsible consumers of genetic tests and to cope with the results. With nondirectiveness as a basic rule and autonomous decision making its goal, genetic counseling exemplifies a shift of the professional-client relationship from *doctor knows best* to *patient decides best*.

There is a widespread consensus in advanced scientific and technological societies that in order to guarantee a client's informed choice any genetic test, whether prenatal (by amniocentesis or chorion villus sampling) or adult (for example, for hereditary breast cancer), should be prepared for and followed by genetic counseling. Prior to testing, counselors determine a risk profile by examining a client's medical history and family tree for potential genetic risks. The risk profile determines an array of test options with their risks, potential results, and possible actions, all of which are discussed with the client. After genetic testing, a counselor explains the significance of the test result and reviews treatment options. For example, if a prenatal test result shows a fetal chromosomal aberration, the counselor describes the average development of the fetal population in which the unborn child is placed by its cytological anomaly and offers the possibility of terminating the pregnancy. Both before and after testing, the counselor emphasizes that any decision is the client's.

History

The first *hereditary counseling clinics* opened in Germany and Denmark in the 1930s, and in Britain and the United States in the 1940s. Their explicit goal was to improve the population gene pool by avoiding the birth of children probably affected by illnesses or handicaps. For geneticists of the time, all but a few sympathizing with eugenic ideas, giving *marriage advice* was an instrument for breeding a better society. After World War II, when Nazi Germany brought eugenics into public discredit, geneticists shifted their focus from public to individual prevention without losing track of its effects on the population's quality of health.

In order to differentiate individual decision making from state eugenic programs, the geneticist Sheldon Reed coined the term genetic counseling in 1947 (Reed 1947). Ahead of his time, Reed argued that clients should make their own decisions. Most of his colleagues, however, either told their clients what to do or assumed that, after having been enlightened about genetics, they would make the *right choice*. Before amniocentesis was introduced into prenatal care in the 1970s, there were not many options a geneticist could offer anyway: The counselor drew a pedigree and, on the basis of Mendel's laws and empirical data, established the recurrence risk for some disease in question. In cases where the risk was considered high, all the expert could do was advise clients to remain childless. Because people were not yet accustomed to consulting doctors about health problems that might, with some statistical probability, occur in the future, there was no great demand for this kind of expertise.

In 1975 the American Society of Human Genetics adopted a definition of genetic counseling that was purified of all traces of eugenics. The clients' informed decision superseded prevention as the primary goal of the procedure. Genetic counseling was redefined as a *communication process* (Ad-Hoc-Committee on Genetic Counseling 1975) with the aim of informing clients and leading them to a decision that would fit their goals and values. This definition was adopted internationally.

Genetic Counseling in the Early-Twenty-First Century

Demand changed dramatically when chromosomal tests of cells from amniotic fluid and the option of terminating pregnancy allowed geneticists to enter the field of prenatal care. By the end of the 1950s, researchers determined the normal number of human chromosomes and identified deviations such as Trisomie 21 (Down Syndrome). In the 1970s, amniocentesis was introduced into prenatal care and abortion laws liberalized in most Western countries.

Originally intended as special treatment for a defined fraction of pregnancies, namely those diagnosed as being *at risk*, within a few years the chromosomal checkup expanded into a routine procedure. As prenatal monitoring techniques such as ultrasound or maternal serum screening, designed to track down potential risks, became standard, increasing numbers of pregnant women were classified as at risk and in need of professional guidance. Thus the major and still increasing clientele of genetic counselors are pregnant women.

Apart from chromosomal checkups in prenatal care, genetic tests have only limited application in medical practice. Most of them test Mendelian hereditary diseases (such as cystic fibrosis or Huntington's chorea), which are relatively rare. In 1994 a test for *familial breast cancer* opened a new field of counseling activity: the offer to help people cope with test results that cast a shadow over their future. It is estimated that at most 5 to 10 percent of all breast cancer cases can be classified as hereditary. Those who possess a mutation in the BRCA-genes are told that they have a lifetime risk of about 80 percent of actually getting this particular cancer—though further research has provided evidence that these numbers are too high for a general penetrance estimate (Bregg 2002). As a result of human genome research, geneticists expect a growing number of such predictive genetic tests for widespread diseases such as different forms of cancer, coronary heart disease, or Alzheimer's disease.

Risk Communication as Social Technology

Genetic tests go beyond the scope of the traditional doctor-patient relationship because, strictly speaking, there is no medical indication for performing them. Most patients are eligible for testing because they are classified as being at risk. This means, for the most part, they are—and might remain—completely healthy. The test result does not provide a diagnosis in order to determine an appropriate treatment. Instead a positive gene test will leave them with *bad news* about their future without offering any cure. In the case of a prenatal test, the *patient* is not yet born, and the only *therapy* would be an abortion. Predictive tests, such as those for familial breast cancer, result in risk figures for a tomorrow that might never occur.

This heterogeneity between a medical diagnosis and the attribution of a risk profile is generally overlooked. Statistical probabilities express nothing but frequencies in statistical populations. But in the counseling session these numbers jell into risks and chances, indicating to clients a threat to them or to a coming child. Clients expect the counselor to say something relevant about them as individuals, while, by definition, risk measures the frequency with which something happens in the statistical universe from which the sample has been taken.

Because genetic counseling educates clients regarding genetically derived risk figures, it serves as a powerful social technology that individualizes social hazards. Members of various disability communities have criticized such testing as a way to extend prejudices toward those who have only some risk of becoming disabled rather than promoting compassion and social inclusion for those with special needs. Appealing to clients to make autonomous decisions, the counselor invites them to take responsibility for a future that can be statistically assessed but is as yet unknown, so that genetic counseling opens up a completely new possibility for victim blaming: No matter what a client decides, the client becomes responsible.

Professionalization and Ethics

Anticipating the evolving demand for professional guidance provoked by prenatal testing, a two-year masters program was started at Sarah Lawrence College in New York in 1969 to train genetic counselors as collaborators of medical geneticists in hospitals and clinics. Since then, genetic counseling as a profession has grown widely throughout North America and is largely populated by women. In 1979 the National Society of Genetic Counselors (NSGC) was founded. In 1992 NSGC launched its own journal (*Journal of Genetic Counseling*) and adopted a code of ethics (National Society of Genetic Counselors 1992). Genetic counselors have been certified by the American Board of Genetic Counseling since 1993.

In most European countries, genetic counseling is not yet fully professionalized. With the expansion of prenatal testing and, gradually, predictive genetic testing, countries such as the United Kingdom, Norway, and the Netherlands have followed the U.S. model and introduced masters programs for genetic counselors who are not medical doctors. In France and Germany, however, doctors blocked inroads into what they consider their own field of competence. In these countries, medical geneticists usually deal with special cases and predictive testing whereas prenatal diagnostics is left to obstetricians (Godard, Kääriäinen, Kristoffersson et al. 2003).

Genetic counselors insist on nondirectiveness as their basic principle. Originally a psychotherapy precept (Rogers 1951), nondirectiveness has become the cornerstone of a counseling concept that is based on patient autonomy. However there is no consensus about what this actually means in practice. The context and the conception of the encounter between genetic counselor and patient gives rise to different social and ethical conflicts, and so does the nature of the imparted information (Clarke 1994).

In general, an expert's information can cause misunderstandings fraught with consequences for the client. Technical terminology almost inevitably clashes with colloquial language. A term such as *syndrome* can evoke horrifying associations and, as a consequence, clients might expect a child to look monstrous (Chapple, Champion, and May 1997). In order to enable clients to make an informed choice, they are told about test options and their respective risks and benefits. In the case of prenatal testing, women are asked to weigh the probability of detecting a fetal chromosomal or genetic abnormality against the risk of inducing a miscarriage which is about 0.5 percent in case of amniocentesis and at least 1 percent in case of Chorion Villus Sampling. Nevertheless, those interventions are offered as a routine part of prenatal care regardless of women's age and family history, which means that on the long run there are more pregnancies lost than abnormalities detected. Scientific denotation and everyday connotations diverge grossly on the subject of risk figures. Clients inevitably personalize the numbers; they fail to grasp the statistical nature of probabilities and interpret them as personal threats (Rapp 1999, Samerski 2002). This gap between professional information and lay understanding widens with clients from different ethnic backgrounds (Rapp 1999, Browner et al. 2003).

According to their notion of autonomy, genetic counselors are bound to respect both the *right to know* and the *right not to know*. The right to be informed is generally taken for granted because knowing about probabilities, test options, and test results facilitates autonomous decision making. But genetic information may also profoundly change the client's perceptions and lifestyle, and therefore genetic counselors respect confidentiality and the *right not to know*, especially in cases of late-onset diseases (for example, Huntington's chorea) when there is no third party involved. In prenatal diagnostics, test results can only serve to provide grounds for terminating the pregnancy. Even though the moral status of abortion is controversial in most countries, it is generally legalized and socially accepted as pertaining to reproductive autonomy. The decision to abort or not after positive test results is the client's, even though the counselor's judgment might differ considerably. Yet, the options of testing and aborting put new pressures on women: Abnormal children are considered to be avoidable. A new sense of responsibility for the existence of a disabled child after having been offered a choice, fear of stigmatization, and the intimidating effect of professional diagnosis cause most women to terminate their pregnancies in case of abnormal test results. Out of respect for patient autonomy a growing number of genetic counselors would even recognize prenatal sex selection as an acceptable option (Wertz and Fletcher 1998). The call to limit prenatal selection to medically approved conditions is countered by members of the disability community who argue that just like the discrimination of women, "disability" is a social issue. The continuing efforts to track down a "gene for" homosexuality substantiate fears about a new, genetic discrimination of minorities (Schüklenk, Stein, Kerin, and Byne 1997).

There is a growing market of commercial laboratories promising to optimize health and well-being by genetic testing combined with "personalized" guidance on lifestyle, diet, and drugs. But consumer mentality is only one aspect of the seamy side of patient autonomy. The idea of *informed choice* seems to increase autonomy, but could force people to become managerial decision makers on their own behalf and on the behalf of their children. Genetic counseling burdens people with decisions on the basis of statistical probabilities, which makes them responsible for events they cannot control. Wrongful life actions, in which parents argue that the birth of their affected child was an avoidable consequence of misinformation or bad advice, reinforce the idea that misfortune can be avoided by correct information and decision making.

GENETIC RESEARCH AND TECHNOLOGY

• • •

The early twenty-first century is an era of genetics. Genetic science, genetic technologies, genetically based diseases, animal and human cloning, and genetically modified organisms are regular visitors to the news and entertainment culture. Together with the revolution in information technologies, and sometimes going hand in hand, the biotech revolution promises to transform the world. The well-known successes of molecular biology in the 1950s and 1960s have transformed biology and especially genetics. But because from the very beginning genetics has been intimately involved with human values, the revolutionary changes of this science and technology have challenged moral reflection.

A brief historical review of the development of genetics research will help place such challenges in context. For present purposes this history may conveniently be divided into three periods. The first, and longest, period was one of protogenetics, in which human values played a dominant role. The second period saw the emergence of genetics as a science and its revolutionary research successes. During this period, the science aspired to a complete independence of any specific moral interests that were not directly entailed by the pursuit of scientific knowledge itself. Finally, the third period, although still trying to promote an ideal of value neutrality, may be characterized as making some efforts to bridge science and ethics.

Protogenetics: From Premoderns to the Eighteenth Century

Humans have long interacted with plants and animals, seeking to improve human life through their manipulation. Thus, before there was a formal science of genetics, humans developed tacit or implicit knowledge of how to genetically alter plants and animals for human use. Human needs and values guided these manipulations and search for knowledge. Plants and animals were selectively bred for their usefulness, and microorganisms were used to make food items such as beverages, cheese, and bread.

Early farmers noted that they could improve each succeeding harvest by using seeds from only the best plants of the current crop. They noticed that plants that gave the highest yield, stayed the healthiest during periods of drought or disease, or were easiest to harvest tended to produce future generations with these same characteristics. Through several years of careful seed selection, farmers could maintain and strengthen such desirable traits.

The ancient Greeks also gave careful attention to the heredity of humans. The accounts given were largely speculative, and many aimed at the continuation of noble lineages. Plato (428–347 B.C.E.) in *The Republic*

FIGURE 1

SOURCE: Courtesy of Immaculada de Melo-Martín.

proposed strict laws governing human reproduction in order to perfect and preserve an ideal state. He presented what is known as the "noble myth," according to which rulers were fashioned from gold, those who would occupy the middle rung in the state were fashioned from silver, and the farmers and artisans were fashioned with bronze. Such an ideology would explain to people that differences between them were in their very nature and needed to be preserved by laws governing procreation.

The fourth century B.C.E. also brought the theory of pangenesis, according to which, the reproductive material included atomic parts that originated in each part of the parental body. This theory was used to explain the transmission of traits from parents to children. Hippocrates (460–377 B.C.E.) also determined that the male contribution to a child's heredity is carried in the semen and argued that because children exhibit traits from both parents, there was a similar fluid in women. Aristotle (384–322 B.C.E.) rejected pangenesis, in part because traits often reappear after generations, which the theory could not explain. He argued that an individual's development was determined by internal nature, and that semen alone determined the baby's form; the mother merely provided the material from which the baby is made.

During Roman and medieval times in Europe, little was added to human understanding of reproduction and heredity. During the seventeenth century, a new conception of natural science began to develop. This new understanding of the scientific enterprise focused on experimental designs and empirical proofs. The belief that the natural sciences were completely value free and, therefore, the best means to understand the natural world began to take root. In this context, the development of the natural sciences brought a renewed attention to human reproduction and heredity. William Har-

SOURCE: Courtesy of Immaculada de Melo-Martín.

vey (1578–1657) concluded that plants and animals alike reproduced in a sexual manner and defended the idea of epigenesis, that the organs of the body were assembled and differentiated as produced. Opposing epigenesis, Marcello Malpighi (1628–1694) developed the idea of preformation, according to which new organisms are fully present and preformed within either the egg or the sperm. By the middle of the seventeenth century, however, the idea of preformation was called into question by a variety of scientists. Pierre-Louis Moreau de Maupertuis (1698–1759) rejected preformationism by appealing to observations about the blending of traits. Also, the development of a theory of the cell by Kasper Friedrich Wolff (1734–1794) further supported epigenesis.

The Rise of Modern Genetics: From Mendel to Watson and Crick

The late eighteenth century and the beginning of the nineteenth century in Europe saw the advent of vaccinations, crop rotation involving leguminous crops, and animal-drawn machinery. The growth of modern science and of scientific technologies further contributed to the idea that science should be pursued for its own sake.

MENDELIAN GENETICS. Throughout this period, a number of hypotheses were proposed to explain heredity. The one that would prove most successful was developed by Austrian monk Gregor Johann Mendel (1822–1884). (The part of Austria where Mendel was born and lived is now located in the Czech Republic.) Through a variety of experiments, Mendel realized that certain traits showed up in offspring plants without any blending or mixing of the parent's characteristics. The traits were not intermediate between those of different parents. This observation was important because it contested the leading theory in biology at the time. Most of the scientists in the nineteenth century, including Charles Robert Darwin (1809–1882), believed that inherited traits blended from generation to generation.

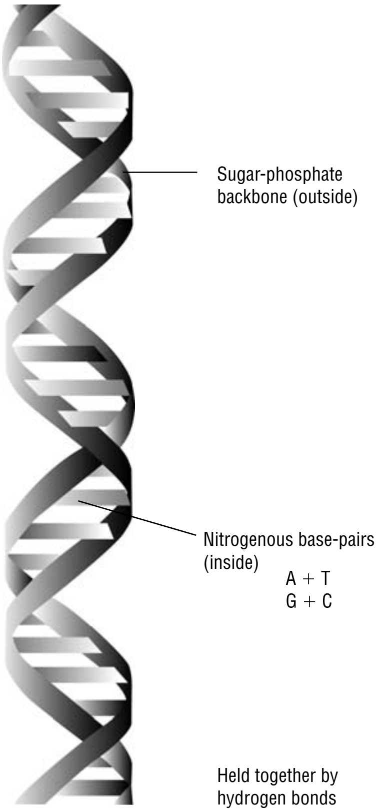
Mendel used common garden pea plants for his research because they could be grown easily in large numbers and their reproduction easily manipulated. Pea plants have both male and female reproductive organs. As a result, they can either self-pollinate or cross-pollinate with another plant. In cross-pollinating plants that produce either yellow or green peas exclusively, Mendel found that the first offspring generation (f1) always had yellow peas. However, the following generation (f2) consistently had a 3:1 ratio of yellow to green (See Figure 1).

This 3:1 ratio occurred in subsequent generations as well. Mendel thus thought that this was the key to understanding the basic mechanisms of inheritance (See Figure 2). He came to four important conclusions from these experimental results:

- that the inheritance of each trait was determined by "units" or "factors" that were passed on to descendents unchanged (now called "genes");
- that an individual inherited one such unit from each parent for each trait (the principle of segregation);
- that a trait might not show up in an individual, but could still be passed on to the next generation;
- that the inheritance of one trait from a particular parent could be independent of inheriting other traits from that same parent (the principle of independent assortment).

FIGURE 3

The DNA Double-Helix



SOURCE: Courtesy of Immaculada de Melo-Martín.

Mendel's ideas were published in 1866. However, they remained unnoticed until 1900, when Hugo Marie de Vries (1838–1945), Erich Von Tschermak-Seysenegg (1871–1962), and Karl Erich Correns (1864–1933) independently published research corroborating Mendel's mechanism of heredity.

POST-MENDEL DEVELOPMENTS. By the late 1800s, the invention of better microscopes allowed biologists to describe specific events of cell division and sexual reproduction. August Friedrich Leopold Weismann (1834–1914), who coined the term "germ-plasm," asserted that the male and female parent each contributed equally to the heredity of the offspring and that sexual reproduction generated new combinations of hereditary factors. He also argued that the chromosomes were the bearers of heredity. Edouard van Beneden (1846–1910) discovered that each species has a fixed number of chromosomes. He later discovered the formation of haploid cells during cell division of sperm and ova.

The publication of Darwin's *The Origin of Species* (1859), together with an incomplete understanding of human heredity, were used as grounds to support the idea of carefully controlling human reproduction to perfect the species. In 1883, Sir Francis Galton (1822–1911) coined the term *eugenics* to refer to the science of improving the human condition through "judicious matings." In the twentieth century, eugenics would be used to justify forced sterilization programs and immigration restrictions in the United States, and human experimentation in Nazi Germany.

After 1900, the pace of advance in genetic science and technology was rapid. During the first decade, William Bateson (1861–1926) coined the terms *genetics*, *allelomorph* (later *allele*), *homozygote*, and *heterozygote*. The cellular and chromosomal basis of heredity (*cytogenetics*) was identified by Theodor Heinrich Boveri (1862–1915) and others. And Sir Archibald Edward Garrod (1837–1936) developed the subspecialty of biochemical genetics by showing that certain human diseases were inborn errors of metabolism, inherited as Mendelian recessive characters.

During his investigations with the fruit fly Drosophila, Thomas Hunt Morgan (1866–1945) proposed that genes located on the same chromosome were linked together and could recombine by exchanging chromosome segments. Alfred Henry Sturtevant (1891–1970) drew the first genetic map, using cross-over frequencies between six sex-linked Drosophila genes to show their relative locations on the X chromosome. And in 1931, Harriet Creighton (1910–2004) and Barbara McClintock (1902–1992), and Curt Stern (1902–1981) working independently, found in cells under the microscope the first direct proof of crossing-over.

THE DISCOVERY OF DNA. In the 1940s, Oswald Theodore Avery (1877–1955), Colin Munro MacLeod (1909–1972), and Maclyn McCarty (1911–2005) offered evidence that DNA was the hereditary material. The challenge then was to determine the structure of this molecule. In 1953, James D. Watson (b. 1928) and Francis Crick (1916–2004) published in *Nature* the three-dimensional molecular structure of DNA, presenting what would be a breakthrough discovery in the biological sciences. They relied on the methods of Linus Pauling (1901–1994) for finding the helical structure in a complex protein and on unpublished x-ray crystallographic data obtained largely by Rosalind Elsie Franklin (1920–1958) and also by Maurice Wilkins (1916–2004). Watson and Crick determined that the DNA molecule was a double helix with phosphate backbones on the outside and the bases on the inside. They also determined that the strands were antiparallel and that there was a specific base pairing, adenine (A) with thymine (T), and guanine (G) with cytosine (C) (see Figure 3).

It is difficult to overstate the importance of the discovery of the structure of the DNA molecule. It has not only revolutionized the field of biology, but has become a cultural icon. The metaphor of the DNA as the "blueprint" of life has become engrained in much talk about human traits, diseases, and development. And with it, the ideology of genetic determinism, the idea that genes alone determine human traits and behaviors, has gained strength, despite the fact that practically every geneticist alive has disavowed it. Indeed, psychologist Susan Oyama has argued that genetic determinism is inherent in the way that what genes do is represented, because they have been given a privileged causal status. To describe and think about DNA in any way other than through this problematic representation of the power of DNA, is ever more difficult.

The Challenge of Genetic Knowledge and Power

The Watson-Crick model of DNA resulted in remarkable theoretical and technological achievements during the next decades. The genetic code was deciphered, the cellular components as well as the biochemical pathways involved in DNA replication, translation, and protein synthesis were carefully described, and the enzymes responsible for catalyzing these processes were isolated.

DNA RESEARCH. A striking result of these theoretical advances was the newly found ability to use a variety of techniques that would allow researchers to control and manipulate DNA. The discovery of restriction enzymes was one of the most important steps in this ability to manipulate DNA material. These enzymes are bacterial proteins that can recognize and cleave specific DNA sequences. They act as a kind of immune system, protecting the cell from the invasion of foreign DNA by acting as chemical knives or scissors. The capacity to cut DNA into distinct fragments was a revolutionary advance. For the first time, scientists could segment the DNA that composed a genome into fragments that were small enough to handle. Human chromosomes range in size from 50 million to 250 million base pairs, and thus are very difficult to work with. Additionally, methods for synthesizing DNA and for using messenger RNA to make DNA copies provided reliable means for obtaining DNA.

Moreover, they now had the opportunity to separate an organism's genes, remove its DNA, rearrange the cut pieces, or add sections from other parts of the DNA or from other organisms. The use of plasmids, extra-chromosomal genetic elements found in a variety of bacterial species, and of bacterial viruses as vectors or vehicles to introduce foreign DNA material into living cells served as a major tool in genetic engineering. Once introduced into the nucleus, the foreign DNA material is inserted, usually at a random site, into the organism's chromosomes by intracellular enzymes. In some rare occasions, however, a foreign DNA molecule carrying a mutated gene is able to replace one of the two copies of the organism's normal gene. These rare events can be used to alter or inactivate genes of interest. This process can be done with stem cells, which will eventually give rise to a new organism with a defective or missing gene, or with somatic cells in order to compensate for a nonfunctioning gene.

No less important for the ability to understand and manipulate genetic material were the development of techniques to sequence DNA, the establishment of the methodology for gene cloning, and the development of the polymerase chain reaction (PCR). With these techniques it was possible to obtain and analyze unlimited amounts of DNA and RNA within a short period of time. Additionally, PCR would prove an invaluable method to identify mutations associated with genetic disease, to detect the presence of unwanted genetic material (for example in cases of bacterial or viral infection), and to use in forensic science.

Researchers working on organisms such as worms developed technologies that allow mapping of their genomes. These mapping techniques permitted the location of the positions of known landmarks throughout the organism's chromosomes. Furthermore, as these molecular techniques improved, their application to cancer studies became more and more common, leading to the discovery of viruses that were able to transform normal cells into cancer cells, the description of oncogenes, cancer suppressor genes, and a variety of other molecules and biochemical pathways involved in the development of cancer.

HUMAN GENOME PROJECT. This new venture traces its origins back to Los Alamos national laboratory and the Manhattan Project. After the atomic bomb was developed and used in Hiroshima and Nagasaki, the U.S. Congress charged the Atomic Energy Commission and the Energy Research and Development Administration, the predecessors of the U.S. Department of Energy (DOE) with studying and evaluating genome damage and repair as well as the consequences of genetic mutations. There was a special interest in focusing the research on genetic damages caused by radiation and chemical by-products of energy production. From this research developed the plan to analyze the entire human genome.

The automation of DNA sequencing in the 1980s brought to the forefront of the scientific community the possibility of not just mapping the human genome, but also sequencing it. Thus, while gene mapping allowed researchers to determine the relative position of genes on a DNA molecule and the distance between them, sequencing let them identify one by one the order of bases along each chromosome.

It was in this context that discussions began about launching a human genome program. During a series of informal meetings, researchers and government officials attempted to assess the feasibility of different aspects of a project to map and sequence the entire three billion bases of the human genome. Although the majority of scientific opinion by the end of the 1980s was that sequencing the entire human genome was feasible, not all researchers were persuaded that such a project was a good idea. Many of them saw it as a massive work in data gathering rather than important research. Many scientists were also worried that the potential huge costs of such a project would diminish the funds dedicated to basic biological research.

In spite of the concerns, in 1990 the Human Genome Project (HGP) was formally launched as a fifteen-year plan coordinated by the U.S. Department of Energy and the National Institutes of Health. James Watson had been asked to head the project and did so until 1992. He resigned then because of his opposition to the patenting of human gene sequences. Francis Collins, who in 2005 is still the director of the National Human Genome Research Institute (NHGRI), replaced him in 1993. The main goals of the project were to identify all the genes in human DNA and to determine the sequences of its three billion chemical base pairs. Other important objectives of this international project were to improve the existent tools for data analysis and store the information obtained about the genome in databases.

The main focus was the human genome. However, important resources were also devoted to sequencing the entire genomes of other organisms, often called "model organisms" and used extensively in biological research, such as mice, fruit flies, and flatworms. The idea was that such efforts would be mutually supportive because most organisms have many similar genes with like functions. Hence, the identification of the sequence or function of a gene in a model organism had the potential to explain a homologous gene in human beings, or in one of the other model organisms.

The International Human Genome Sequencing Consortium published the first draft of the human genome in the journal *Nature* in February 2001, with about 90 percent of the sequence of the entire genome's three billion base pairs completed. Simultaneously the journal *Science* published the human sequence generated by Celera Genomics Corporation headed by Craig Venter.

Although the original expected conclusion date for the project was 2005, in April 2003, coinciding with the fiftieth anniversary of the discovery of the DNA double helix, the full sequence was published in special issues of *Nature* and *Science*. The early conclusion of the program was the result of a strong competition between the public program and the private one directed by Venter. His announcement in 1998 that his company would be able to sequence the entire human genome in just three years, forced the leaders of the public program to increase the pace, so as to not be left behind. The involvement of private capital in a project of this magnitude was a major turning point in science policy because it called into question the common belief since World War II that only the federal government had sufficient resources to fund "big science."

In December 2003, the NHGRI announced the formation of the social and behavioral research branch. This new branch has as its purpose developing approaches to translating the discoveries from the completed human genome into interventions leading to health promotion and disease prevention. The launching of this new branch is evidence of the shift of the NHGRI from genome sequencing to behavioral genetics.

ETHICAL, LEGAL, AND SOCIAL ISSUES. Because of the well-known abuses of eugenics during the beginning decades of the twentieth century in the United States and then in Nazi Germany, there was an unprecedented decision to attend to the possible consequences of the research into the human genome. Thus a significant goal of the HGP was to support research on the ethical, legal, and social issues (ELSI) that might arise from the project. Funds were dedicated to the examination of issues raised by the integration of genetic technologies and information into health care and public health activities and to explore the interaction of genetic knowledge with a variety of philosophical, theological, and ethical perspectives. Similarly, part of the ELSI budget was dedicated to supporting research exploring how racial, ethnic, and socioeconomic factors affect the use, understanding, and interpretation of genetic information; the use of genetic services; and the development of public policy.

Of course, the HGP, and the scientific and technological advances that permitted it, are extremely significant because of the theoretical knowledge it has produced on how, for example, genes work and what their contribution to health and disease is. It is difficult, however, to clearly separate theory and practice in molecular genetics given that this science is very technique intensive. In any case, the research supported by the HGP is also noteworthy because it has grounded the development of a variety of what are now common biotechnologies. Hence, genetic tests and screening for several human diseases such as Tay Sachs, sickle cell anemia, Huntington's disease, and breast cancer are now part of medical practice. Agricultural products such as corn plants genetically modified to produce selective insecticides or tomatoes engineered to prevent expression of a protein involved in the process of repining are common in food markets. Animal cloning does not make the front page anymore. Genetic therapy and pharmacogenetics are more and more often presented as the new medical miracles. And, of course, discussions of genetic enhancement and the hopeful, or frightening, possibility of designer babies are regular features of the news and entertainment media.

Given the increased presence of biotechnologies in people's lives and the significance of the genetic sciences, it is not surprising then that both the so-called theoretical research on human genetics and the practical applications of such knowledge have raised heated debates about ethical, legal, and social implications. Consider, for example, the following issues that have emerged in discussions of medical and agricultural biotechnologies.

GENETIC INFORMATION. The increasing use of genetic knowledge and genetics technologies in medical practice has been a subject of concern, though to different degrees, for both those who support such use and those who are skeptical of its benefits. One of the topics that has attracted the most attention among bioethicists working on ELSI issues is related to the availability and possible abuse of genetic information. Hence, the availability of genetic information has opened discussions about privacy and confidentiality. Questions have arisen about whether medical practitioners have an obligation to inform the family members of a patient with a genetic disease, or whether such information should be available to insurers and employers, for example. The concern for the possibility of genetic discrimination has been such that many states have proposed and passed legislation prohibiting insurers from discriminating on genetic grounds. Similarly, given past experiences with eugenics, there are good reasons to have some concern about the possible stigmatization of individuals due to their genetic makeup.

GENETIC DIAGNOSIS AND HUMAN RESPONSIBILITY. The use of genetic diagnosis for a variety of medical conditions has received no less attention. Concern about fair access to these technologies, the reliability and usefulness of the tests, the training of health care professionals, the psychological effects they might have on people, and the consequences for family relationships are common. Similarly, many of the tests being developed, and some of the ones already in use, point to genetic susceptibilities or test for complex conditions that are linked to multiple genes and gene-environment interactions. Thus, such tests provide information not of a present or even a future disease, but of an increased risk of suffering such a disease. In many cases, these tests reveal possibilities of disorders, such as Huntington's disease, for which no available treatments exist. Given these issues, concerns about regulation of these tests, whether they should be performed at all, or whether parents have a right or an obligation to test their children for late-onset diseases are certainly justifiable. Moreover, the use of genetic diagnosis techniques in reproductive decision-making can also have serious implications for reproductive rights, our view of human beings, the expectations people might impose on their offspring, and the way we might treat people with disabilities.

The emphasis on people's genetic makeup might also have implications for their ideas of human responsibility, views regarding control of behavior and health status, their notions of health and disease, and their conceptions of treating a disorder or enhancing a trait. Such emphasis also has consequences for the kind of public policies people support regarding education, health promotion, disease prevention, and environmental regulations.

AGRICULTURAL BIODIVERSITY. Discussions about agricultural biotechnologies focus not just on the effects that these technologies might have on human beings, but also the consequences for animals and the natural environment. Genetic recombination techniques are used to create genetically modified organisms (GMOs) and products. These technologies enable the alteration of the genetic makeup of living organisms such as animals, plants, or bacteria, by modifying some of their own genes or by introducing genes from other organisms. GM crops, for example, are now grown commercially or in field trials in more than forty countries and on six continents. Some of these crops, including soybeans, corn, cotton, and canola, are genetically engineered to be herbicide and insecticide-resistant. Other crops grown commercially or field-tested are a sweet potato resistant to a virus that could decimate most of the African harvest, rice with increased iron and vitamins, and a variety of plants able to survive weather extremes. Research is being conducted to create bananas that produce human vaccines against infectious diseases such as hepatitis, fish that mature more quickly, fruit and nut trees that yield years earlier, and plants that produce new plastics with distinctive properties. It is unclear at this point how many of this research lines will be successful.

Questions about whether genetically modified organisms and products are safe for humans, whether they might produce allergens or transfer antibiotic resistance, whether they are safe for the environment, whether there might be an unintended transfer of transgenes through cross-pollination, whether they might have unknown effects on other organisms or result in the loss of floral and faunal biodiversity, for instance, are at the forefront of these debates. But the use of these technologies has also raised concern about possible implications for people's conceptions of other animals and the environment, their views of agricultural production, and their relationships with natural objects. Thus, many have wondered whether the use of these techniques constitutes a violation of natural organisms' intrinsic value, whether humans are unjustifiably tampering with nature by mixing genes among species, or whether the use of animals exclusively for human purposes is immoral. Debates also have been sparked about access to these technologies and the effect that this might have on non-industrialized countries. Some have questioned whether the domination of world food production by a few companies might not be putting food production at risk, and poor farmers in poor countries at an increasing dependence on industrialized nations. Issues about the commercialization of these products through the use of patents, copyrights, and trade secrets are also relevant when analyzing the implications of these technologies. Thus, many have called attention to the accessibility of data and materials.

Assessment

It is important to point out that although the ELSI program of the HGP has certainly had a significant effect on the understanding and evaluation of the consequences of new genetic technologies, the prevalent idea that humans must pay attention exclusively to the consequences of scientific or technological advances might be a reason for concern. A focus on consequences reinforces the incorrect view that science and technology are value-neutral. Issues about scientific or technological advances are thus framed as questions related to the implementation of scientific knowledge or technological practices. Hence, under the presumption that such practices are not the problem, but the use that people make of them might be, an evaluation of the scientific practices themselves appears illegitimate. This prevents researchers from trying to analyze the values that might underlie the current focus on genes, or attempting to propose different value assumptions to guide scientific research. Moreover, the emphasis on consequences directs attention to analysis of means and away from an evaluation of ends. Thus, scientists are encouraged to evaluate whether a particular technology is good to solve certain problems, but cannot analyze the goals for which such a technique has been developed. Technical discussions of biotechnology that focus on impacts presuppose that these goals are unquestionable. Thus, attention must be paid to the fact that assessments of new technologies must require not only discussions of risks and benefits—that is, discussions of means—but also reflections about ends. Of course, these issues apply to a variety of bioethical problems and not just to ELSI work.

GENETICS AND BEHAVIOR

Despite longstanding hostility to the biological explanation of human behavior, there are presently three general research programs aimed at the study of genetic influences on behavior: sociobiology and evolutionary psychology, behavioral genetics, and developmental psychobiology. Evolutionary psychology and its forebear, sociobiology, aim to discover species-typical traits that are adaptations (that is, traits that are in most cases the result of natural selection): Why do humans behave aggressively? What is the evolutionary source of altruism? Behavioral genetics aims primarily to uncover and disentangle genetic contributions (as distinct from environmental contributions) to individual differences in behavior: What are the predictors of aggressive versus nonaggressive behavior? Why does one person perform well on an IQ test, and another not? Developmental psychobiology aims to elucidate developmental pathways to particular behaviors: What is the mechanism by which organisms come to behave aggressively? What are the determinants of central nervous system development?

Such sample questions are by no means exhaustive; they are meant simply to illustrate the focal differences between these three approaches to genetics and behavior (see Table 1), the latter two of which will be the focus here. That is, rather than focus on how biological evolution as a whole has affected species-specific behaviors, the emphasis will be on how genetics can account for individual differences within species and on the more detailed pathways by which DNA causally influences human behavior.

Born of Controversy

Both behavior geneticists and developmental psychobiologists aim to move beyond the nature/nurture dichotomy, according to which traits are either genetically influenced (nature) or environmentally influenced (nurture), in favor of some collaborative interaction. What nature-*and*-nurture or nature-*via*-nurture actually means in practice is not always clear, however, because most scientists continue to partition correlational and causal influence in traditional terms (Schaffner 2001, Robert 2003).

The modern roots of the nature–nurture controversy are to be found in the writings of Francis Galton (1822–1911), a cousin of Charles Darwin, in the latter half of the nineteenth century. In 1869 Galton published *Hereditary Genius*, in which he attempted to discern what makes some humans geniuses and others exceptionally stupid. Based in part on anecdotal observations of twins, along with a questionnaire he administered to a small group of twins who were believed to be more similar in their youth than at the time of testing, Galton eventually concluded that "nature prevails enormously over nurture" in explaining variance in cogni-

TABLE 1

Three Approaches to the Study of Genetic Influences on Behavior

Problem domain	Explanatory focus	Content of explanations
Sociobiology and evolutionary psychology	Species-typical social and individual behaviors (adaptations)	Evolutionary vs. cultural, stochastic, or volitional explanations of species functional behaviors
Behavioral genetics	Individual differences, heritabilities	Genetic vs. environmental explanations of variability
Developmental psychobiology	Developmental pathways to phenotypic outcomes	Causal explanations of the role of DNA, other developmental resources, and environments (in evolutionary context)

tive outcome (Galton 1875, p. 576). Galton later coined the term *eugenics* as part of a program to increase the number of so-called desirables in a population and to decrease the number of so-called undesirables (Kevles 1985). The "eugenics movement" has, of course, had its own very controversial history—including the rationalization of human rights violations in the United States, Nazi Germany, and other countries.

Since its modern incarnation, then, and however well-intended, behavior genetics has been associated with the justification of class-based and racial prejudice, exemplified more recently with the argument of Arthur R. Jensen (1969) that genetic differences between "races" influence the lower intelligence (or the poorer performance on IQ tests) of blacks as compared with whites. While most behavior geneticists have disowned this and related work, in 1995 the outgoing president of the Behavior Genetics Association (BGA), Glayde Whitney, celebrated Jensen's putatively brilliant and bold 1969 work in his presidential address. Whitney's speech was widely disparaged, and the editor of the BGA journal, *Behavior Genetics*, refused to publish it.

Classical Behavior Genetics

Three key concepts in classical genetics that referred originally not so much to behavioral but to anatomical characteristics that need to be clarified are genotype, phenotypes, and allele. The genotype is simply the genetic make-up of the organism, its complement of DNA. Genes, now known to be sections of chromosomes, manifest themselves as the organism's phenotype, its outward appearance. Any one gene may also come in different or alternative forms called alleles. For example, the founder of genetics, Gregor Mendel (1822–1884), in his research with pea plants, identified that one gene controls seed color, and the two forms of this gene give either green or yellow peas. That is, one allele (for yellow pea color) will be expressed as one phenotype (yellow peas), whereas another allele (for green pea color) will be expressed as another phenotype (green peas). One question for behavior genetics is whether and to what extent there are genotypes with different alleles that control for phenotypical behavior as well as physical characteristics.

The attempt to answer this question through the practice of observing twins continues to this day—though now with considerably more sophistication and computational power. Modern behavior geneticists establish correlations between genes and behavioral outcomes on the basis of two general types of study, involving classical or quantitative genetics (family, twin, and adoption studies) and molecular genetics and genomics (linkage, association, allele sharing, quantitative trait locus mapping, and DNA microarray studies). Although it is not necessary to know the complete meaning of the technical terms here, linkage and association refer to kinds of connections between genes, alleles (as already explained) are different forms of the same gene, trait locus mapping seeks to locate genes at specific points on a chromosome, and DNA microarray studies aim to show which genes are expressed at any given time. Classical studies are used to reveal the relationship between genetic variation and variation in phenotypic outcome.

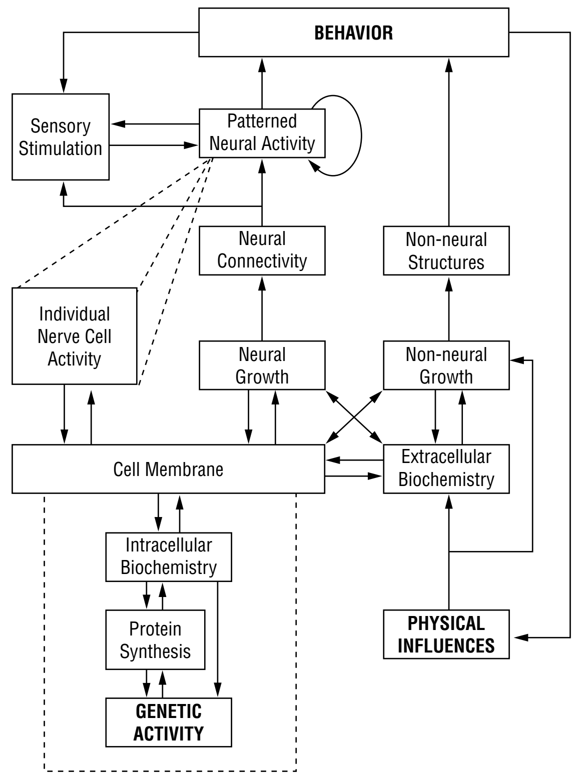
Twin studies, for instance, are premised on the notion that, on average, identical (monozygotic, or MZ) twins share almost 100 percent of their genes in common, while fraternal (dizygotic, or DZ) twins share approximately 50 percent of their genes in common. A fundamental assumption is that both kinds of twins are affected by their rearing environments in a similar way, and that their "equal environments" cannot make MZ twins any more alike than DZ twins. On the basis of this assumption, behavior geneticists argue that what makes MZ twins more alike than DZ twins is that they are more genetically similar.

In any given population, *heritability* refers to the proportion of phenotypic (or apparent, expressed) variance that can be explained by genotypic (or hidden, genetic) variation, and is quantified as between zero (no variation explained by genetic inheritance) and one (all variation explained by inheritance). In humans, the heritability of having two legs is just about zero: Because almost all humans are born with two legs, there is very little phenotypic variance to be explained. By contrast, the heritability of eye color in a random human population approaches one, inasmuch as the variation in eye color can be explained almost exclusively by genetic variance. T the heritability of height is somewhere in between. Like physical characteristics, behaviors of interest to behavior geneticists have nonzero heritability (often in the range of 0.4 to 0.6), though it is often unclear what inferences are justified on the basis of a heritability estimate (Turkheimer 1998).

Behavior geneticists distinguish between traits that are either present or absent, and those that are continuously distributed. Where presence/absence is appropriate, scientists calculate *concordance rates*. Where the trait is continuous, scientists calculate *correlation coefficients*. So if MZ twins both exhibit some noncontinuous phenotypic outcome (say, depression), they are said to be "concordant" for that trait; and where the concordance rate for MZ twins is greater than that for DZ twins, the greater concordance is attributed to genes. Where MZ and DZ concordance rates are similar, this is attributed to shared environmental influences. And where MZ twins are discordant for a trait, this is attributed to nonshared environmental influences. In many cases, genes, shared environment, and nonshared environment are invoked to partially explain phenotypic differences (Baker 2004, Parens 2004), although nonshared environmental effects remain very difficult to discern (Turkheimer 2000).

FIGURE 1

A Model of Behavioral Development



SOURCE: Adapted by Tim Fedak from Johnston and Edwards (2002), p. 28.

Molecular Behavior Genetics

Classical studies can reveal associations between genetic variance and phenotypic variance, but do not identify the particular genes that may generate a trait. In the 1980s, behavior geneticists began to take advantage of emerging molecular techniques to attempt to identify specific genes. *Linkage studies* are employed to detect genes of major effect shared by a disproportionately large number of family members manifesting a condition or trait of interest. Successful linkage studies require three conditions to have been met: that a gene of major effect is implicated; that there is only one such gene segregating in a given family; and that the mode of inheritance is known (Robert 2003). For most complex behaviors, at least one of these conditions is violated; for many complex behaviors, all three are violated.

Allelic association studies are employed to discern whether alleles or different forms of particular genes are transmitted preferentially to family members, or whether there are differences in the frequency of alleles between individuals and control populations. These studies avoid the requirement for a single gene of major effect; moreover, in the company of now-possible genome-wide scans, there is no need even to identify candidate genes or regions in order to turn up possible correlations. Further, success with these studies does not depend on knowing a specific mode of inheritance. But correlations are not causes, and allelic association studies risk turning up correlations that are causally spurious. For instance, where an allele is in linkage disequilibrium with another allele, allelic association studies will positively correlate both alleles with the phenotype, even if only one is actually involved in generating the phenotype.

Behavior geneticists are now using still more sophisticated techniques to reveal associations between genes and phenotypic outcomes. These include quantitative trait locus mapping and DNA microarray technology. Most phenotypes, especially of behaviors, are complex combinations of traits and thus governed by more than one gene. Quantitative trait locus mapping attempts to determine in quantitative terms what set of traits define a complex phenotype. DNA microarray technology, using what is variously called a biochip, DNA chip, or gene chip, allows for large-scale gene expression studies in order to identify interacting genes. Progress has nevertheless been slower than initially anticipated (e.g., Hamer 2002), and very few specific genes have been identified.

According to behavior geneticist Michael Rutter (2002), "knowing that a trait is genetically influenced . . . is of zero use on its own in understanding causal mechanisms" (p. 4). Some developmental psychobiologists take this as evidence of the sterility of behavior genetics (e.g., Gottlieb 1995). If the focus of behavior genetics is on the establishment of correlations and other associations between inherited genes and particular behavioral outcomes, the focus of developmental psychobiology is on the identification of the developmental pathways that lead to those outcomes. Often, these pathways involve heritable elements, including genes; sometimes, other levels of analysis are more apt to yield developmental insights.

Developmental Psychobiology

Behavior geneticists do not study behavior as such, but rather differences in behavior. Moreover, behavior geneticists study associations between genetic variance, environmental variance, and interactions between the two, not causal relationships between developmental factors. By contrast, developmental psychobiologists seek to unpack genetic and other influences on complex behavioral phenotypes by elucidating causal mechanisms and pathways within the developing organism.

There is a long history of research in animal behavior (ethology) and comparative psychology, including experimental studies of animal behavior. Many historians begin with the work of Konrad Lorenz (1903–1989) on innateness. Lorenz's research was not entirely well-received among "English-speaking ethologists," as he called them, particularly Daniel S. Lehrman (1919–1972). Lehrman's criticisms of Lorenz (1953) continue to inspire developmental psychobiologists (e.g., Johnston 1987, Lickliter 2000, Oyama 2000), while classical ethology has generally been dislodged by sociobiology and evolutionary psychology. (Developmental criticisms of the concept of innateness preceded the work of Lorenz; see, for instance, Kuo 1921.)

Experimental analyses of animal behavioral development have revealed aspects of development from conception through senescence, including factors, mechanisms, and causal interactions involved in central nervous system development. Coupled with results from brain science, developmental psychobiologists are shedding light on the pathways of neural, cognitive, and motor development in a wide range of animals, including those chosen as models for understanding human development. Nonetheless, developmental psychobiology has yet to yield a fully integrative account of behavioral development, in large part because of the complexity of the task.

Yet a framework for the integrative project is now in place. Timothy D. Johnston and Laura Edwards's series of increasingly specific (or "unpacked") representations of a model of the development of behavior are not intended to specify every molecular or cellular aspect of the complexity of development, but rather to provide "a useful intermediate level of detail that captures that complexity while at the same time rendering it reasonably comprehensible" and open to empirical investigation (Johnston and Edwards 2002, p. 31). Genes, neurons, and experience have indirect and reciprocal effects on the development of behavior, though their activity is mediated through multiple levels of biological, ecological, and social organization. The model is meant to focus investigative attention on developmental interactions and specific mechanisms, as depicted in Figure 1.

Any particular concrete use of this model would represent only a snapshot of a specific developmental moment. The model could also be transformed from two dimensions to three with the addition of information regarding the timing of individual influences on development, though this would obviously make it considerably less easy to represent graphically. This model of behavioral development can be used to organize existing knowledge and to make predictions about behavioral development that can be empirically investigated, yielding support for or requiring alteration of the underlying model.

In using this model of behavioral development in a research context, it is evident that scientists cannot do the kinds of studies with humans that would yield results of interest. There are limits on what is acceptable with human subjects. Accordingly, developmental psychobiologists (like all developmental researchers) must infer from animal models, a process that is both conceptually and ethically fraught (Gottlieb and Lickliter 2004). Are the behaviors observed (or created) in animal models in fact homologous (or even analogous) to human behaviors? How does a passive–aggressive rat or an alcoholic monkey behave? What can be learned about human neural development from a fruit fly? These challenges beset any attempt to understand human behavioral development on the basis of studies with nonhuman animals.

Ethical and Social Considerations

While both behavior genetics and developmental psychobiology continue to provide important insights into the development of behavior, ethical concerns persist. These range from eugenic fears about the discovery of so-called gay genes and genes predisposing to antisocial behavior, to worries about the possible genetic enhancement of human cognitive function.

Following the mapping and sequencing of the human genome, a project that was sometimes viewed in exaggerated terms, there has been a shift to functional genomics, that is, attempts to determine what genes do and how they interact. Some hope that functional genomics will tell us not just how genes produce certain proteins but also how genes produce phenotypes, including behavior. But according to one policy commentary in *Science* magazine:

> The genetics of behavior offers more opportunity for media sensationalism than any other branch of current science. Frequent news reports claim that researchers have discovered the "gene for" such traits as aggression, intelligence, criminality, homosexuality, feminine intuition, and even bad luck. Rarely is it mentioned that traits involving behavior are likely to have a more complex genetic basis. This is probably because most journalists—in common with most educated laypeople (and some biologists)—tend to have a straightforward, single-gene view of genetics. (McGuffin et al. 2001, p. 1232)

Thus there is clearly a place for the lowering of expectations with regard to behavioral genetics.

More broadly, though, simply to study genetics and behavior by any means is to study what makes humans behaviorally different from one another. For many, any advances in this domain threaten to impinge, at least conceptually, on precisely what it is that distinguishes human from nonhuman nature. While these concerns may be ill-founded, behavioral scientists must take seriously the imperative to assuage these fears by promoting socially responsible public engagement with the science.

GENOCIDE

The word *genocide* is relatively new, even though the act of genocide is not. Yet in part because of its twentieth-century origins, genocide is often associated with the use of modern science and technology. The extent to which this is the case is one of the contentious ethical issues associated with the term.

Origins and Controversies

Polish jurist Raphael Lemkin introduced the term genocide in 1944 to describe the widespread killing of civilians that occurred during the first half of the twentieth century. He created the term as an amalgam of the Greek *genos,* meaning race or kind, and the Latin based suffix *-cide,* indicating killing (Smith 2002, Hinton 2002). At the time genocide was not a distinct crime, but Lemkin lobbied strongly to get it recognized as such.

The result was the 1948 United Nations Convention on the Prevention and Punishment of the Crime of Genocide which 136 countries have ratified. In the convention, genocide is defined as "any of the following acts committed with intent to destroy, in whole or in part, a national, ethnical, racial or religious group, as such: (a) Killing members of the group; (b) Causing serious bodily or mental harm to members of the group; (c) Deliberately inflicting on the group conditions of life calculated to bring about its physical destruction in whole or in part; (d) Imposing measures intended to prevent births within the group; (e) Forcibly transferring children of the group to another group."

As with any legal document, the UN definition of genocide has been scrutinized by scholars and politicians. The current definition, which limits genocide to ethnic, racial, religious, and national identity, describes human characteristics that are inherent to one's person. Race, ethnicity, and to a lesser extent, nationality and religion are determined at birth. Some critics argue that these criteria are too narrow in that they exclude particular social groups, such as political affiliation. Joseph Stalin slaughtered millions in the Soviet Union for largely political reasons, yet his actions do not constitute genocide under the UN definition. Indeed the Soviet Union lobbied the United Nations to remove any reference to political groups that had existed in an earlier draft.

The UN definition also excludes other social groups such as mentally ill or mentally challenged people, of which Nazi Germany exterminated tens of thousands. Homosexuals, bourgeoisie, the educated, and city-dwellers are all social classes that have been victims of genocidal acts although their deaths do not constitute genocide under existing law. Some scholars suggest expanding the definition of genocide to include mass killings in general (Gellately and Kiernan 2003). Others argue that it is beneficial to define mass killings and genocide separately so as to understand the origins of each and learn how to prevent them (Staub 2002). According to Helen Fein, one important component of the UN definition that sets genocide apart from other heinous acts, such as terror, war, oppression or torture, is "the perpetrators' sustained and purposeful attempt to destroy a collectivity" (Hinton 2002, p. 6).

Another phrase related to genocide is *ethnic cleansing,* and sometimes people conflate the two phrases. But as Paul Mojzes explains, "while every genocide is an ethnic cleansing, not every ethnic cleansing is a genocide. If an ethnic cleansing does not genuinely threaten the existence of a group, it would not qualify as genocide" (Mojzes 2002, p. 54). Genocide is also confused with *crimes against humanity,* which describes a "widespread or systematic attack directed against any civilian population" (Rome Statute of the International Criminal Court Internet site), including murder, torture, kidnap, rape, and forced expulsion. Another related phrase is *war crimes* which describes "grave breaches of the Geneva Conventions of 12 August 1949" such as willful killing, torture, unnecessary destruction of property, and denying prisoners of war the right to a fair trial, among others (Rome Statute of the International Criminal Court Internet site). Together genocide, crimes against humanity, and war crimes all fall under the jurisdiction of the International Criminal Court.

How society defines genocide is more than academic; it is a matter of life and death for millions of people. While the international community may respond with force to stop acts of genocide, it may not respond to ethnic cleansing and probably would not respond to mass killings. Thus it is important to understand the moral and ethical consequences of how genocide and related terms are defined, and to clarify the legal basis of controlling them.

Historical Developments

Historical records are rife with accounts of mass killings and genocidal acts perpetrated against tribes, cities, clans, and races in premodern times. The Romans, after defeating Carthage in the Third Punic War, killed the inhabitants, burned the city, and "sowed the ground with salt to symbolize that it should forevermore remain barren" (Alvarez 2001, p. 28). Greeks, Mongols, Christians, Assyrians, and others all committed such acts, yet at the time such killings were an accepted component of war and conquest and not considered a crime against humanity (Rittner et al. 2002). Although acts of genocide have been perpetrated throughout the ages, it was not until the twentieth century that society began to ask whether genocide was wrong. Two reasons explain this process: the rise of science and technology, which enabled acts of genocide on a massive scale, and the growing appreciation of human rights.

The twentieth century began as a century of promise and hope with an expectation that solutions to human problems could be solved through scientific and technological progress. Sadly the century ended as the deadliest in human history. While most persons commonly think of war as the major source of death, and primarily to young men, it was actually genocide that killed more people in the twentieth century than any other human activity, and most of the victims were civilians (Smith 2002). (Others would point out, of course, that more people also survived in the twentieth century.) Some experts place the number of state-sponsored killings, which includes acts of genocide, at more than 150 million—four times higher than those killed in warfare (Fein 2002).

Science, technology, and the nation-state all contributed to the escalation and scale of genocide. First, the development of more efficient guns, bullets, and bombs enabled perpetrators to kill more people more rapidly. Gun-toting Germans easily slaughtered the Hereros of German Southwest Africa, a primitive culture, in one of the first acts of genocide in the twentieth century (1904–1905). Transportation, improved infrastructure, and bureaucracy enabled Nazi Germany to coordinate and carry out murder more effectively in its attempt to annihilate all Jews (1933–1945). Scientific and technological progress also created new methods of mass killing such as the development and proliferation of weapons of mass destruction (WMDs). Saddam Hussein was the first to use WMDs against his own people (1987–1988), killing thousands of Iraqi Kurds with poison gas. The nation-state, another product of modernity, was very successful at perpetrating genocide on scales that are almost unfathomable. An estimated 20 million civilians died under Stalin's regime in the Soviet Union (1922–1953), and millions more under Mao Zedong (1949–1959) in China and the Pol Pot (1975–1979) regime in Kampuchea. Indeed science, technology, and political institutions of modernity have combined to make genocide possible on a historically unique scale.

Despite efforts by the United Nations and international community to stop genocide, it has not been eliminated. Marginalized groups around the world are increasingly vulnerable, especially with the development of newer and more deadly WMDs. It may be possible in the not-so-distant future to design genetically engineered diseases or poisons that affect only a certain ethnic or racial group that share similar genes. Then again, genocide can also be extremely low-tech, as illustrated in the Rwandan massacres (1994) in which 800,000 Tutsis were slaughtered by machete-wielding Hutus.

GEOGRAPHIC INFORMATION SYSTEMS

Geographic information systems (GIS) are computer-based information systems that work with geographic or spatial data. The term GIS is also used to describe the whole discipline dealing with geographic information systems or geographic information science. A GIS can produce maps, but its unique attribute is the ability to integrate and analyze spatial data and related statistical or descriptive data. GIS has been described as "perhaps . . . the most significant event in spatial data handling since the invention of the map" (Pickles 1995, p. 49). Like maps and any information production system, from writing to scientific research, GIS involves basic ethical questions of truthfulness, equity, and power. Maps are graphical depictions of the nature and spatial relationships of objects—they are generalized, simplified representations of reality. Cartographers strive to produce value-free, objective maps, but maps are also cultural and rhetorical texts imbued with social significance (Harley 2001). The symbols and projection used, the items included and excluded, and the graphic design of maps convey information, but they are also expressions of power that are made all the more effective by being hidden behind a "mask of seemingly objective science" (Harley 2001). The same elements characterize GIS, with the addition of a mask of technology. Cartographic historians and philosophers have developed methods for analyzing the social significance of maps—similar techniques are needed to analyze the statistical and graphic output of GIS.

GIS is founded on developments in computer science, geostatistics, and geography; as well as information from cognitive science, landscape architecture and planning, and many other fields. Roger Tomlinson conceived the architecture of GIS in 1963 and the first system, used to support Canadian national land-use planning, became fully operational in 1971. The U.S. Census Bureau adopted GIS for the 1970 census and was the first to digitize street maps efficiently. As computing power, datasets, and graphical interfaces have improved, GIS has become pervasive in both the public and private sectors.

GIS is not just technology—people are also critical components. Technology may constrain the capacity of a GIS, but the user's choice of data and analytical methods influences the output. Spatial data present complex analytical challenges: very different, but equally valid, results may be obtained by using different analytical methods on the same data. There is an ethical obligation on those using GIS to explain the meaning, limitations, and uncertainty embedded in the output of a GIS. Such explanations may also limit the legal liability of the producer for any subsequent use or interpretation of the information.

Much GIS work deals with the physical infrastructure of the planet and is generally uncontroversial. When GIS is used to examine socioeconomic data, however, its impact can be contentious. Presently there are so many geographic information systems holding large amounts of data, much of it related to individuals, that it is virtually impossible for people to know who holds information about them, the accuracy of that information, and the use to which it is being put. Laws that balance personal privacy with the potential commercial and administrative benefits of comprehensive databases are still being developed.

Approximately 80 percent of government data has a spatial component, so all levels of government are heavy users of GIS. Civilian use of GIS by the U.S. government is strictly regulated. Agencies must have a reason for collecting data. They must protect the privacy of individuals, provide people with access to data pertaining to them and an opportunity to make corrections, and make databases publicly available for the cost of dissemination without copyright restrictions. The U.S. government treats its non-secure databases as a public good; most other countries, and many U.S. state and local governments, regard data as a commodity that may be restricted and sold.

In the United States, GIS use in the private sector is much less regulated than in the federal sector. Marketing companies, realtors, insurance companies, credit-rating agencies, and many other organizations use GIS to assess risk, predict markets, and monitor social changes, among other activities. The private sector holds, and can provide, much of the information on individuals and national security sites that federal agencies go to great lengths to mask. Databases are weakly protected by copyright law in the United States; the European Union provides stronger protection for data compilations.

Military and intelligence use of GIS by governments is difficult to quantify but is known to be extensive. GIS could be described as a non-destructive weapon, a tool that is used to plan and execute actions, to identify targets, to organize infrastructure, and to detect suspicious patterns in individual and group behavior. Information is a global commodity, and many countries and groups monitor and analyze activities both inside and outside their borders. There are concerns that security databases may be used to compromise individual and group liberties.

GIS is not an objective technology, it is a tool used for many ends. Society has not yet found the mechanisms to guarantee the aspirations expressed in Article 1 of the French *Loi No 78-17 du 6 Janvier 1978* which states, "Computer science must be at the service of each citizen; its development has to operate within the framework of international co-operation; it should not damage human identity, human rights, private life or individual and public liberties" (Keane 1991, p. 134).

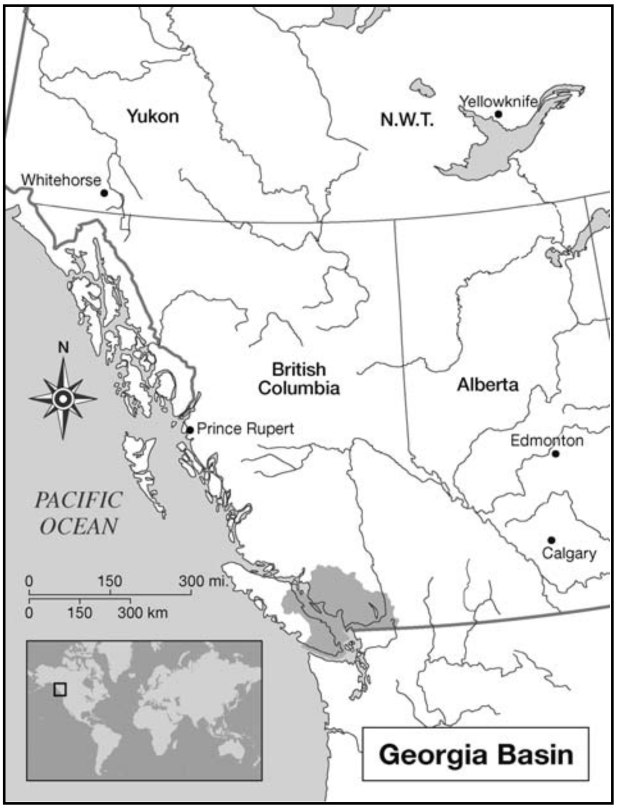
GEORGIA BASIN FUTURES PROJECT

The Georgia Basin Futures Project (GBFP) is a five-year regional participatory integrated assessment whose purpose is to combine public values, preferences. and beliefs with expert knowledge in the production of scenarios for the future of the area in western Canada known as the Georgia Basin (see map) over the next forty years. The key goals are to increase public involvement in the discourse about issues of sustainability, explore pathways to sustainability in the region, and create a database of public preferences, values, and acceptable and unacceptable trade-offs that can be analyzed to provide a picture of how participants feel about sustainability issues and evaluate the relationship between the use of computer-based simulation tools and the beliefs, values, and behaviors of the users of those tools (Tansey, Carmichael et al. 2002).

Background

The GBFP is based on a long tradition of futures studies in the environmental field. From the extensive literature associated with this tradition four concerns have been identified that have influenced the project design significantly. The first is a concern with undertaking research that integrates natural and physical science analyses of environmental systems with social science, health science, and humanities research on the human systems that interact with the environment. The second is a focus on the future and on studying the various ways people can work collectively or individually toward bringing about a more sustainable world.



The population of the Georgia Basin is 2.9 million people and the GDP is about C$65 billion.

The third is a growing recognition of the need to involve various interests, or "stakeholders," in the research process. The fourth is a concern with the appropriate temporal and spatial scale of analysis. Although issues such as climate change are inherently global in scope, research that is truly problem-centered, policy-oriented, and connected to users must establish temporal and spatial scales that are relevant for decision makers.

All these strands came together in the development of the conceptual and methodological framework of the Georgia Basin Futures Project, which was funded by the Social Sciences and Humanities Research Council of Canada (SSHRC) in early 1999 and is supported by financial and in-kind contributions from governmental, nongovernmental, and industrial partners in the Georgia Basin region.

Project Design

Research in the project is organized into six major components undertaken by a core team of twenty coinvestigators and research collaborators, three research staff members, about thirty graduate students, and several administrative staff members working in conjunction with sixteen nongovernmental organizations, government, and private sector partners in the community.

Using expert analysis of key relationships among the social, ecological, and economic systems in the Georgia Basin and relying on initial consultations with stakeholders, the project has built a number of software tools for engaging stakeholders in sustainability issues. These tools have been used in several interactive processes, including workshops and classroom applications. The effect and effectiveness of this approach to engaging different publics with interactive software tools also are being evaluated.

Model Development: The QUEST Approach

The project's approach to modeling and scenario analysis is based on three key elements:

- A backcasting approach that involves the exploration of the feasibility and consequences of trying to reach desirable futures rather than the prediction of the most likely outcomes (Robinson 2003)
- A design approach to modeling that focuses on the physical flows of matter and energy through the economic system, the economic flows of currency through the economic sectors, and the economic benefits and costs incurred as a result of environmental and socioeconomic decisions (Gault 1987)
- An interactive social science approach to use of the model that requires that the local community be actively involved in both the design and the use of the modeling tool. (Caswill and Shove 2000)

The methodological core of the project is the development and use of the GB-QUEST modeling system (Rothman, Robinson, and Biggs 2002). QUEST is a computer-based system for scenario generation and evaluation that was designed to encourage public participation in thinking about sustainability in a regional context. Through QUEST users explore different scenarios for the future in terms of their social, economic, and environmental characteristics. The goal is to acquaint users with the complex realities of decision making, specifically the uncertainties involved, the necessary trade-offs, and the role of subjective values. For the GB-QUEST modeling system the geographic range encompasses the whole of the Canadian side of the Georgia Basin. The temporal scale is forty years.

Through the adoption of the "feel" and user-friendliness of a computer game, QUEST scenarios actively involve the user in their creation and evaluation. The user-selected scenario choices include choices involving the future patterns of population, economic activity, transportation, the density of urban growth, the style of neighborhoods, agricultural development, forestry practices, and consumption. The consequences of these decisions affect human well-being, environmental quality, economic and social health, and the long-term ability to maintain all these results.

QUEST does not provide a picture of the most likely future and is not intended to reflect a detailed understanding of all the complex systems involved. Instead, it enables users to learn about the linkages between choices and possible consequences and the trade-offs society faces in deciding among available options.

Community Engagement

A critical element of the project relates to the involvement of stakeholders and community partners in the research process. The project builds on the tradition of participatory integrated assessment modeling (Kasemir et al. 2000, van Asselt and Rijkens-Klomp 2002) and has adopted an interactive social science approach that is based on an explicit recognition of the value-laden nature of scientific analysis and modeling and the resultant need to incorporate community-based partners and the interested public directly into the research activities in two ways. First, by working with partner organizations in the community, the project has incorporated public values, preferences, and concerns into the process of model design and implementation. Second, through an elaborate process of community engagement that also involves the partners, the project has included the interested public in the generation of preferred sustainability scenarios using those modeling tools.

The key method for obtaining community engagement is the use of GB-QUEST in various ways, including three regional case studies; expert workshops; classroom use; a large exhibition space at Science World, a local science museum; and Web-based interaction.

The regional case studies involve working with three local municipal or regional governments in the Georgia Basin to use GB-QUEST in workshops with government staff members and stakeholders to explore regional sustainability scenarios, with the goal of contributing to the development of policies for sustainability. These workshops are followed by workshops to explore policy implementation issues, using a conceptual model of policy development that has emerged from the health promotion field. The expert workshops involve working with partner organizations and stakeholder groups to develop desired future scenarios and explore the implementation measures that would be required to realize those scenarios.

A teaching and learning team has tested GB-QUEST in the classroom at the high school level. This group is responsible for creating a set of curriculum guides and resource packages supporting QUEST that focus on sustainability in several classes and at different grade levels.

Since the fall of 2001 a twenty-minute-long video-based version of QUEST has been playing twice per day, five days per week at Science World. Approximately 15,000 people, mostly elementary school students, have played this version of QUEST, using interactive touch pads set into the seat arms of the 200-seat theater at Science World.

Based partly on funding from another project, a Web-based version of GB-QUEST is being developed that will incorporate information visualization and landscape visualization techniques to improve playability and comprehension of the complex contents and results of QUEST scenarios. A prototype was scheduled to be operation in April 2004.

The project also is studying the effect of playing QUEST on the mental models of sustainability, preferences, and behaviors of QUEST users. The GBFP culture and cognition team is holding impact workshops in which QUEST users are interviewed intensively and observed while playing QUEST.

Strategies

An important focus of the Georgia Basin Futures Project (GBFP) is the policy measures required to implement the scenarios that GB-QUEST generates. Both the case study and the expert workshops involve analysis of implementation requirements. In addition, GBFP is creating a database of all the scenarios developed in the project. That database, though limited in quantity, will present an informative picture of the values, preferences, and preferred options of QUEST users with regard to the future of the basin. The project will analyze those scenarios in terms of their policy and implementation requirements.

Other Tools

In addition to GB-QUEST, several interactive software tools have been developed in the GBFP, including the refinement of a personal Climate Change Calculator and the Sustainability Tools and Resources website for helping community groups and individuals establish themselves and interact with other groups. In addition, the GBFP has combined forces with a research group at Natural Resources Canada to develop a prototype of a Georgia Basin Digital Library (GBDL), a Web-based digital library that will be used to integrate natural and social science information (Geographic Information System maps, images, and text) into a comprehensive and interactive information resource to support sustainability research, community-focused decision making, and public consultation activities in the Georgia Basin.

Some Preliminary Results

While the GBFP is still ongoing, some preliminary findings are beginning to emerge. An immense interested has been demonstrated by participants from the general public and local government agencies in exploring desirable futures. Timeframes of forty years are no barrier to participation but the spatial scale of a region the size of the Georgia Basin (about 5.6 million hectares) is a challenge for participants who tend to want to focus on more local issues. In virtually all cases, however, participants are interested in exploring the nature of the choices and consequences of their future scenarios.

The use of interactive tools such as GB-QUEST was found to contribute to community activities to promote sustainability at the municipal scale in several communities. It has been less successful in contributing to the specific needs of regional government policy development. These findings suggest that a preferred audience for such engagement may be individuals and groups, including politicians, who do not have expert knowledge of specific sustainability issues. Classroom pilots of quest-based curriculum indicated a possible significant role for such techniques in school curricula.

Users of GB-QUEST are strongly disposed to make choices about preferred future conditions that reflect a strong environmental ethic. There is a desire to find scenarios that express those values without compromising other goals, such as economic growth or employment. The discussions that ensue explore issues that are not typically part of public and political debates in the region, suggesting a strong latent and unmet demand for such interactive processes.

Science, Technology, Ethics, and Public Policy

The GBFP exists at the interface of science and society. It is intended to combine expert knowledge and public attitudes, preferences, and values in ways that incorporate the best understanding of complex ecological, social, and economic systems and that will be useful to stakeholder and institutions that are grappling with the practical problems of sustainability.

What distinguishes the GBFP approach is a fundamental commitment to interactivity that recognizes that the role of science in the policy process is inherently value-laden and that stakeholder input into both the development of integrated assessment tools and the development of scenarios is essential for two reasons. First, policy decisions about sustainability are inherently normative. The challenge is to combine those normative considerations with scientific understanding through the use of "boundary objects" such as QUEST and the GBDL. Second, it is clear that a major potential obstacle to achieving sustainability involves public acceptance. Politicians cannot make policy decisions that require significant change without a supportive political constituency. New means of engaging different publics in the complex public policy issues that surround sustainability are essential to build understanding of the policy trade-offs in the public and to learn what trade-offs and choices may be acceptable. In this way a process of community engagement that is appropriately designed may increase the sophistication of discussion about key choices affecting the sustainability of the region and help make explicit the points of conflict between stakeholders in the community that will affected by a decision.

An important question raised by the use of computer-based tools in the GBFP is the degree to which information technology can provide ways to engage large numbers of people in sustainability issues without trivializing the issues or misleading users about the consequences of particular choices. An important danger is the possibility of converting normative questions of deep moral and political significance into technical questions related to the choice of technology or behavior. For this reason the GBFP separates the analysis of the consequences of particular technological and behavioral choices (the realm of the scenario analysis using QUEST) from the discussion of the desirability of those outcomes and the means that may be required to realize them (a discussion that occurs outside the model). In this sense the role of the technology is to provide a basis for stimulating informed discussion of ethical and political questions.

The GBFP is based on the view that science and technology embed normative values that must be made explicit if informed choices are to be made (Jasanoff and

Wynne 1998). The project is testing the idea that complex public policy issues can be illuminated by the development and use of scenario analysis tools that allow citizens to express their views about their preferences and point out the consequences of their choices. The key is that these scenarios are created not by experts but by the users. This makes the process more engaging, creates a higher degree of user buy-in to the process and a greater sense of responsibility for the outcomes, can lead to significant learning, and produces results that embody ethical and moral judgments about the desirability and acceptability of alternative future scenarios.

GERMAN PERSPECTIVES

Contemporary discussions of science, technology, and ethics in Germany take place largely in the context of developments in the philosophy of technology. Although during much of the second half of the twentieth century philosophical discussion of technology was divided up into various schools and approaches, by the beginning of the twenty-first century such divisions were giving way to a new problem-orientated approach that emphasized the social, cultural, human, and ethical dimensions of the production and use of technoscientific knowledge. Reflections on technological development and transfer, for instance, became less ideological and more eclectic, pragmatic, and interdisciplinary than in the past. Nevertheless, discussions of ethics related to the hybridization of science and technology in such fields as information technology and genetic engineering continue to occur against a specifically German philosophical background. Thus the following notes on German approaches to science, technology, and ethics are themselves hybrid introductions to schools and problems, theory and practice.

Background: Gehlen and Heidegger

Arnold Gehlen (1904–1976) and Martin Heidegger (1889–1976) were the two main philosophers to deal with technology during the second half of the twentieth century. Gehlen's anthropological approach was to interpret human beings as deficient beings who use technology to compensate for their organic shortcomings. The characteristic activity of technology involves the creation and use of *Organersatzes*, that is, substitutes for or supersedings of those organs with which humans are endowed by nature. "There are two aspects to this tendency: artificial materials replacing those organically produced; and non-organic energy replacing organic energy" (Gehlen 1980, p. 5). The earliest humans strengthened their hands with wood and stone instruments, then replaced old materials in these instruments with new ones that defined entire ages (the Bronze Age, Iron Age, etc.), a substitution process that has continued into synthetic chemistry. But of even greater significance has been the replacement of human and animal power with coal, oil, electricity, and nuclear power.

Because of this substitution process technology develops a tendency to deny its roots and become independent. The technological world becomes progressively abstract and not tied to any immediate need. This is the starting point for Gehlen's criticism of modern technology as it has developed especially since the Industrial Revolution. According to Gehlen, technology develops an opposition to its previous cultural contexts and tends to become something pursued for its own sake. Coherent social orders decline under a flood of external stimuli, and social institutions lose their stability. Primitivisms such as "sex and drugs and rock-and-roll" become manifest throughout technological civilizations, along with extreme forms of individualism and subjectivism. In response Gehlen becomes a conservative critic of culture. Gehlen's anthropological analysis of the origin of technology leads to a criticism of technological culture.

Heidegger advanced two approaches to technology: first, in *Sein und Zeit* (1927; English trans. *Being and Time,* 1962), that of technology as an implicit or hidden presence in the human lifeworld; second, after the famous *Kehre* (turn), that of technology as a form of truth or revealing. The early Heidegger developed an understanding of (technological) experience in *Being and Time,* paragraphs 14–18. In the analysis of human existence as a *being-in-the-world* he discovered the everyday character of engagement with equipment as prior to any theoretical presence of objects. As is implicit in the Greek naming of objects as *pragmata,* Heidegger argues that technical praxis is the experiential context from which all science is abstracted. It is more accurate to describe science as theoretical technology than technology as applied science. But this *Being and Time* analysis of human interaction with entities or beings is no more than a moment in Heidegger's larger attempt to understand the "meaning of Being."

Turning from the focus on the meaning of Being that predominates in his early work, Heidegger's later thought develops a more explicit philosophy of technology. In "Die Frage nach der Technik" (1954; English trans. *The Question Concerning Technology,* 1977) he argues that technology is not just a practical engagement with the world but a revealing, a disclosure or truth about the world. What modern technology in particular reveals is the world as *Bestand,* that is, stock or resources subject to human manipulation. The coming upon the world as *Bestand* that is operative throughout modern technology as such Heidegger names *Gestell* (enframing), the promotion of which is for contemporary human beings not something that they simply choose to use or not but a *Geschick* (destiny). Like any destiny, however, technology as *Gestell* carries with it both opportunity and danger. The opportunities provided by technology are pervasive in the modern world, but the dangers are more hidden and go deeper than the simple risks so commonly associated with technology, such as the risks of automobile accidents or environmental pollution. The most profound danger is that the disclosure of the world as resource will overwhelm the event of disclosing itself, that the experience of one particular kind of truth will obscure the more primordial truth of Being. The ultimate challenge of modern technology is to be true to the greater human destiny of disclosing in the midst of a technological destiny.

The Frankfurt School and Social Risks

During the 1960s questions of ecological and social risks came to the fore in many discussions of science, technology, and ethics. But in the Frankfurt School it was social risks that held center stage, and a social risk of a particular kind: the risk of failure to use science and technology to realize the Enlightenment ideal of an autonomous humanity for which they were intended.

Criticism of technology in the Frankfurt School is based on the critical theory of Max Horkheimer (1895–1973) and Theodor W. Adorno (1903–1969), especially their post–World War II analysis of what they termed the "dialectic of Enlightenment." Analyzing the social histories of Nazism, Stalinism, and American capitalism they argued that formal rationality—positivism and pragmatism—had been transformed into an instrumental rationality that degraded its users and the things used. In the totalitarianisms of the twentieth century and even in consumer capitalism Enlightenment humanism had been used to justify dehumanization and exploitation. Enlightenment humanism thus runs the risk of becoming its dialectical opposite, a kind of antihumanism. The science and technology that emerged out of Enlightenment commitments have been used to promote new forms of irrationality and barbarism, which must thus be dialectically criticized in order to save the Enlightenment project.

The critical theory of technology may be summarized in four theses:

(1) Knowledge is power. In the modern world science has become functional and instrumental knowledge, developed in order to achieve the goals of the Enlightenment by establishing human power over nature.

(2) Modern technology leads to technocracy. The Enlightenment values of humanity, emancipation, and social justice are to be realized by means of technical instruments.

(3) But rather than realizing democratic enlightenment, technology develops surrogates for enlight-

enment, especially in the forms of film and advertisement. Entertainment and the culture industry become technological substitutes for the genuine enlightenment to be found in aesthetics and the arts.

(4) Progress thus calls for a dialectic criticism of false enlightenment in the name of true enlightenment. Critical theory points out the ambivalence of progress brought about by technology.

Horkheimer and Adorno thus saw instrumental or calculative rationality (scientific technology) as a paradox: It provided the knowledge and power necessary to liberate human beings from unenlightened subservience to their own superstitions and to nature, enabling them to become autonomous individuals. But instrumental rationality has in fact been deployed by ruling groups to pacify the masses either violently or through material goods and services. The Enlightenment project has failed to prevent itself from being misused. What is needed is a new assertion of the Enlightenment ideal, which Horkheimer and Adorno nevertheless find difficult to derive from their social scientific studies.

It is to this problem that Jürgen Habermas responded with a philosophical deepening of critical theory and an extended reaffirmation of the norms of the Enlightenment ideal in the face of its corruption in contemporary culture. The human lifeworld is characterized by self-reflection, language, labor, and morality. Technological development follows the logic of labor, which is necessary for interacting with nature; technology is not something that can be renounced. At the same time, communicative action through language or a symbolic interaction among human beings engenders social norms. This too is an important aspect of what it means to be human and is not to be renounced. Technological rationality becomes a threat when it overwhelms or obscures symbolic interactions and its cultural traditions from which arise all justifications for using power, whether political or technological. Insofar as Habermas criticizes such a technological colonization of the lifeworld he reiterates Horkheimer and Adorno. But insofar as critical theory only criticizes instrumental rationality, it fails to rehabilitate a sophisticated form of rationality. Only a recovery and articulation of the principles of the communication rationality that is the basis of symbolic interaction can substantiate the critical theory project.

Cybernetics and Systems Theory

Cybernetics and systems theory have developed a scientific conception of technological action in order to control and shape this kind of action. Günter Ropohl's work on "technological systems theory" and "technological enlightenment" is a good extension of this aspect of cybernetics. According to Ropohl, the social dimension of technology is best grasped as an extended action system. It is not technology that formulates aims but certain action systems. These action systems produce technological artifacts, which in turn open up possibilities for new action functions. In this way Ropohl criticizes the ideas of technological determinism or a technological imperative. The physical constraints addressed by technological developments, for instance, are not technical but social in character. According to Ropohl the legitimation crisis of technological progress—that is, public doubts about whether technological change is always for the better—cannot help but promote "enlightenment" about the true character of the technological process (Ropohl 1991).

Klaus Kornwachs has also developed systems theory in ways that can be used to describe technological systems. The principles of any system are as follows: Every system has an author. The term *system* has both descriptive and prescriptive dimensions: Descriptive dimensions involve explaining how a system is to be constructed; prescriptive dimensions involve explicitly identifying the interests a system serves. As people learn to deal with any system it takes on an objective character and can thus become an object of scientific study. The structure of a system is given by the relationships among its elements. Large technological systems can be described at more than one level, and these levels must be integrated in a full description. Paradoxically, expanding systems are often easier to control than systems in equilibrium (Kornwachs 1993).

Contributions from the German Democratic Republic

From 1949 to 1990 the German Democratic Republic (GDR) developed discussions of science, technology, and ethics—and of the philosophy of technology—that were heavily influenced by the thought of Karl Marx (1818–1883), especially as interpreted in the Soviet Union. At the same time, scholars in the GDR attempted to maintain a certain level of independence by analyzing the connection between science and technology against the background of social developments. This in turn was influenced by and influenced the Dresden school of the technological sciences, especially since reunification.

Although its origins are unclear, the term *Technikwissenschaften* (technological sciences) was already in use during the nineteenth century in Germany and the German empire. After what in the Soviet Union was termed the scientific-technological revolution, that is, the unification of science and technology in has also been called "technoscience," the engineering sciences increased in significance for the establishment of socialism. But even though the notion of science implies a (not always realized) degree of stability, the engineering sciences have undergone substantial changes to which engineers must adjust.

The inner structure of any technological science has emerged from a long historical process of analyzing cause-and-effect relations, structures, functions, combinations of materials, and classification principles (Banse and Wendt 1986). In the technological sciences technological rules may be thought of as request systems, which in the process of invention must negotiate oppositions between idea and material possibility. Extending new scientific knowledge into the technological sciences involves the formulation of new technological rules, which are also increasingly required to take into account changing social circumstances. Only in this way can a connection be maintained between technological and social progress. But there is often a tension between technological parameters and those of economic and social effectiveness, not to mention the long-range effects on economy and society.

According to Johannes Müller, who worked for many years with scientists and engineers in the GDR, the technological sciences deal with a class of scientific analyses, operations, procedures, and means for determinate human actions. Their objective is to find solutions for tasks and problems with the help of rules, methodologies, problem-solving operations, procedures, algorithms, and norms. Contemporary construction work has to negotiate the relations among epistemology, technological science, logic, and psychology. Yet the main criterion for technological action and technological design is not truth but fulfillment or, more precisely, the possibility of technological fulfillment or practicality. Scrutiny of the possible realization of technological designs is done on the base of what may be called systematic heuristics (Müller 1990).

Erlangen-Konstanz Constructionism

The universities of Erlangen and Konstanz in Bavaria and Baden-Württemberg, respectively, were in the 1960s sites for the revival of the philosophy of science in Germany. The distinctive approach of philosophers in these two universities was the development of a nonempiricist, constructivist philosophy of science that strongly distinguished itself from logical empiricism. This school of constructivism sought, for instance, to identify a "protophysics" or "prephysics" that could prescribe in advance the measuring instruments necessary to any empirical physics. Peter Janich has added a "protobiology" and "protochemistry" to this prototheory. And from the philosophy of science this type of constructivism, because it focuses on the instrumentization of science, has easily been extended to the interpretation of technology as a way to criticize naturalism, especially in the field of cognitive or information technologies.

Janich has further argued for a constructivism in anthropology that he and Dirk Hartmann (1998) term "methodological culturalism." Along with this "cultural turn" comes the priority of action theory over language philosophy. The claim is that cultural relativism can be rejected on the basis of a preactive and preconscious agreement whenever human beings have achieved a certain level of cultural development. Taking technological development as a model for cultural development, the artificial character of all technological products becomes subject to a means–ends assessment that takes place before subjective or consumer evaluations. That is, the suitability of certain means for certain ends can be judged by their success or failure in achieving or failing to achieve those ends. The success of technological action cannot be reduced to the acceptance or rejection of certain groups but must be demonstrated first by practical reliability at any time in any transcultural context. Rational justification nevertheless remains as a philosophical and ethical issue. The Europäische Akademie zur Erforschung von Folgen wissenschaftlich-technischer Entwicklungen (European Academy for the Study of the Consequences of Scientific and Technological Advances) in Bad Neuenahr-Ahrweiler, under the direction of Carl Friedrich Gethmann, has been inspired by this approach.

Technology Assessment

Extending the social sciences and social philosophy of technology, the basic concern of technology assessment (TA) is systematic research into the preconditions and (potential) consequences for the introduction and use of technologies in order to identify and analyze social conflict areas, especially those that may evolve from the use of technologies. TA thus demonstrates and evaluates action possibilities for the improvement of technologies or their modes of use. The aim of TA is not the obstruction of technological innovations but the reflective design of sociotechnological systems (Petermann 1992).

TA analysis should anticipate conditions of realization and the potential consequences of use of technologies, and thus function as an early warning system. The main theoretical problem of TA is to predict changes caused or influenced by technology. The development of early indicators for effect-chains, which can show the diffusion of technological developments with high reliability, is a major challenge.

A useful assessment of technology should not be satisfied with simply discussing technological innovations but should reflect on the basic human–nature relation as it varies from culture to culture and is practiced in concrete social organizations for action (Bungard and Lenk 1988). The development, production, and initial use of technologies require special knowledge and capital. The elite of the economy, politics, and technological sciences profit from early successful uses of technology, but it is difficult to develop a specific methodological program for the assessment of technologies. There is neither a sophisticated theory of technological consequences nor a well-developed theory of valuation (Ropohl 1996). TA must always contend with unintended, ambivalent, and uncertain consequences. It has to make a functional distinction between scientific identification of possible consequences and their assessment, but must also integrate both steps in a common discourse.

The aforementioned European Academy clearly stresses methodologies related to the technico-philosophical construction of an ethical TA program. Critics from the social sciences reject any such ethical analysis, and thus technological ethics, appealing instead to social pluralism, the differentiation of social subsystems, decentralized technology, and the unpredictability of technological consequences. But surely it is reasonable to pursue ethics as a reflective analysis of right behavior. The responsibility of engineers can at least be based on the way they take concrete actions that result in technological solutions, even if they are subject to a number of influences and basic conditions. The development of technological solutions, equipment, machines, control devices, or consumer goods always includes ideas about users (Grunwald and Saupe 1999) that can be subject to critical assessment.

The Society of German Engineers

The Verein Deutscher Ingenieure (VDI, or Society of German Engineers) has a long history of philosophical ethical reflection on modern technology, as has been surveyed by Alois Huning and Carl Mitcham (1993). In the 1920s the VDI was a locus for extended discussions of the cultural and metaphysical significance of science and technology. In the 1950s it became the primary site for efforts to renew the ethical tradition in German engineering after a period of collaboration with and corruption by the Nazi regime.

As part of this renewal the VDI created a special interdisciplinary "Mensch und Technik" (humanity and technology) study group to examine relations between engineering, the technological sciences, philosophical ethics, and the humanities. Beginning in the 1950s the Mensch und Technik group convened a series of conferences dealing with ethics, industrialization, social impact, education, and philosophy, and issued a wide-ranging series of publications. Out of these discussions—with participation by philosophers such as Huning, Hans Lenk, Friedrich Rapp, and Ropohl—came influential analyses of professional engineering responsibility and technology assessment. Indicative of how Mensch und Technik discussions, even though existing within a professional engineering framework, sought to go beyond what in other national contexts might be considered the appropriate boundaries of engineering interest, were expressed concerns about the way nature was coming to be treated in the same way as artifacts, available simply for human control and manipulation.

During the 1990s a new generation of philosophical contributors to VDI discussions continued their work. Representative of these contributions has been the studies of Christoph Hubig, who argues for an extension of analyses of instrumental action in ways that can lead to a rehabilitation of substantive value ethics (Hubig 1993). For Hubig, the challenge of applied ethics, especially in science and technology, is to build a bridge between principles and specific actions, with an awareness of the complex inner structure of practice. Such a pursuit of ethics in relation to science and technology can be done only by means of interdisciplinary dialogue. Within the technological practice there is always an implicit catalog of values, with conflicts between values being a regular occurrence. The task of discussion-management institutions and organizations is to provide standard approaches for dealing with such conflicts when they occur (Hubig 1997). Taking seriously his own recommendations to work in an interdisciplinary manner, Hubig has worked with the VDI to develop a report on *Ethische Ingenieurverantwortung* (2000), and then led the team that drafted the 2002 VDI code of ethics, *Ethische Grundsätze des Ingenieurberufs*.

Method versus Language, Practice versus Theory

Recent work in the philosophy of technology has tended to emphasize methodology over language, practice over theory. Descriptive propositional knowledge (knowing that) is seen as less important in technology and science than prescriptive skill (knowing how) or productive knowledge. Insofar as this is the case, the explanation–understanding controversy has been replaced by a more pragmatic epistemology (see Zimmerli 1997). From the mid-1980s the expansion of technology has brought with it transformational experiences such as the digitalization of everyday life and associated challenges to tradition and changes in values. Yet it is the lack of practical (not theoretical) orientation in these experiences that gives new life to philosophy. How should we live in the new world we are creating? What should we do with our artifice? During this second modernization the hybridization of technology and science has brought with it a new "dialectic of enlightenment" that is manifested in the philosophy of culture.

In order to address such practical questions philosophers such as Lenk, Walther Zimmerli, and Bernhard Irrgang have been developing a hermeneutic understanding of both technology and ethics. The structures of technological practice, professional activity, and everyday life, together with the background of an implicit technological knowledge, are the basis of collective technological action in a cultural context. The meaning of a technology does not necessarily have to be linguistically articulated in order to be present in a culture. The ways technological practices themselves structure actions include different forms of meaningfulness. This leads to a kind of existential pragmatics of technological action and its models of representation (Corona and Irrgang 1999). Such an approach provides a recursive and reflexive assessment of technological actions. But the impacts of any interpretation of technological actions must also prove successful in psychological, sociological, technical-historical, and cultural-historical terms (Irrgang 2001, 2002). At the same time, reflective modernization depends on the continued existence of such institutions as universities and research centers even as they are altered by globalization.

Reflective modernization must also distinguish the self-understandings of scientific and technical professionals from the external descriptions of their roles. The traditional epistemological foundation for a social role description has been the notion of science as knowledge, but technological science is not another science. Technological science is an action science and thus also contains prescriptive statements as well as descriptive ones. The integration of scientific method into the technological sciences has resulted in new disciplinary formations from more than one perspective: by objects studied, by methods, and by professional fields. A metatheory of the technological sciences is needed to determine the relation of these various disciplinary formations and to search for unity within the technological sciences. A related question concerns the relation between disciplinary, interdisciplinary, and transdisciplinary technoscientific knowledge. Epistemological and professional distinctions ultimately interact with practice-orientated and institutional differentiations in an integrated technology-reflective culture (Irrgang 2003).

Appendix: Ethics in Practice

To this point observations have indicated some of the abstract approaches brought to bear in Germany on issues related to science, technology, and ethics—approaches that serve repeatedly to emphasis the importance of practice. By way of a concluding appendix, it remains to comment on specific practices themselves. In this regard there are at least two practices within technoscience deserving special notice: those having to do with research misconduct and with stem cell research.

RESEARCH MISCONDUCT. In June 2000 the Deutsche Forschungsgemeinschaft (DFG), which is the main Germany research funding agency, after initial allegations of misconduct emerged in 1997, concluded an investigation into the practices of the hematologist and cancer researcher Friedhelm Herrmann of the University of Freiburg Medical Center. According to the DFG report, of Herrman's 347 scientific papers published between 1988 and 1992, at least 52 contained falsifications and another 42 were suspect. A previous investigation of more recent publications had identified 37 papers with falsification and data manipulation. This discovery of such egregious misconduct on the part of a respected member of the scientific community led the DFG in 2002 to require that any institution receiving DFG funds adopt a strong definition of scientific misconduct prohibiting falsification and fabrication of data, unacknowledged data selection, graph and figure manipulation, the inclusion of false information in a curriculum vitae, destruction of primary data, sabotage of others' work, and plagiarism. Previous German policies had been more relaxed; in one step this new policy placed the German scientific research community at the forefront of misconduct policy development.

STEM CELL RESEARCH. As has been explained by Jens G. Reich (2002), among others, the discussion of stem cell research in Germany reflects both philosophical and political history. Philosophically, under the influence of Immanuel Kant (1724–1804), German ethics tends to be strongly deontological, stressing the primacy of treating human beings as ends not as means. Indeed, the first article of the German *Grundgesetz* (Basic Law) of 1949 states that "the dignity of the human being is untouchable." There is also a strong awareness of German failures during the Nazi period to respect human dignity. In a determined stance to respect human dignity in the present, the German Embryo Protection Law of 1990, which was supported by a large majority of the public, explicitly defines human life as beginning at conception. It prohibits manipulation of a human embryo for any purpose other than its implantation into the uterus of the woman from whom the originating ovum was derived. This law thus forbids stem cell creation and applies to privately funded embryo research as well as to publicly funded research.

The law has, however, come under interpretative stress as a result of emerging opportunities for stem cell research. In 2002 the German parliament (Bundestag) reaffirmed the ban on stem cell creation but allowed the importation of stem cells created in other countries provided certain stringent conditions are met. Only stem cell lines created before 2002 are eligible, and then only with the informed consent of the parents of the embryo from which the stem cell line was derived, and on the conditions that the parents have received no payment and that the intention behind the original fertilization was a pregnancy that was abandoned for reasons not related to the embryo—that is, the embryo could not have been rejected as defective. Clearly stem cell research in Germany takes place under more detailed ethical guidelines than in perhaps any other country. It is also worth noting that human cloning, whether for reproductive or therapeutic purposes, is prohibited in Germany, but there are also more liberal positions in bioethics (Irrgang 1997, Irrgang 2005).

GIRARD, RENÉ

Born in Avignon, France, on Christmas Day, René Girard's (b. 1923) work has been a blend of history, literature, and philosophy with implications for science, technology, and ethics that have only begun to be appreciated. He graduated from the Ecole des Chartes in Paris in 1947 (as a specialist in medieval studies) with a thesis on private life in his hometown of Avignon in the second half of the fifteenth century. A year's trip abroad turned into a Ph.D. in history from Indiana University, after which Girard remained in the United States, where he retired as a professor of French Language, Literature, and Civilization from Stanford University in 1995.

Girard's early historiographic publications soon shifted to an avalanche of literary criticism. His first book, *Deceit, Desire and the Novel* (1966), contrasted the romantic lie of individualism with the novelistic truth of what he called *imitative* or *mimetic desire*. Among five major novelists Girard discovered a triangular structure to desire where the protagonists struggled with the fact that their deepest aspirations were mere imitations of a model or rival. Adultery remains the archetype for this phenomenon as illustrated in Dostoevsky's novella, *The Eternal Husband*. The husband is obsessed by his wife's lovers, who inflame, validate, and aggravate his own desire. Girard's students have likened his discovery of imitation in the social sciences to Newton's discovery of gravity in the physical sciences. The vast secondary literature on mimetic desire now extends these early insights into the diverse fields of economics, sociology, psychology, theology, and anthropology.

His second book, an anthropological study of *Violence and the Sacred* (1977), proposes a rational explanation for sacrificial rituals (as well as religious myths and prohibitions) in what he terms the *victimage mechanism*. Mimetic desire is inevitably conflictual. "Rivalry does not arise because of the fortuitous convergence of two desires on a single object; rather, *the subject desires the object because the rival desires it*" (Girard 1977, p. 145).

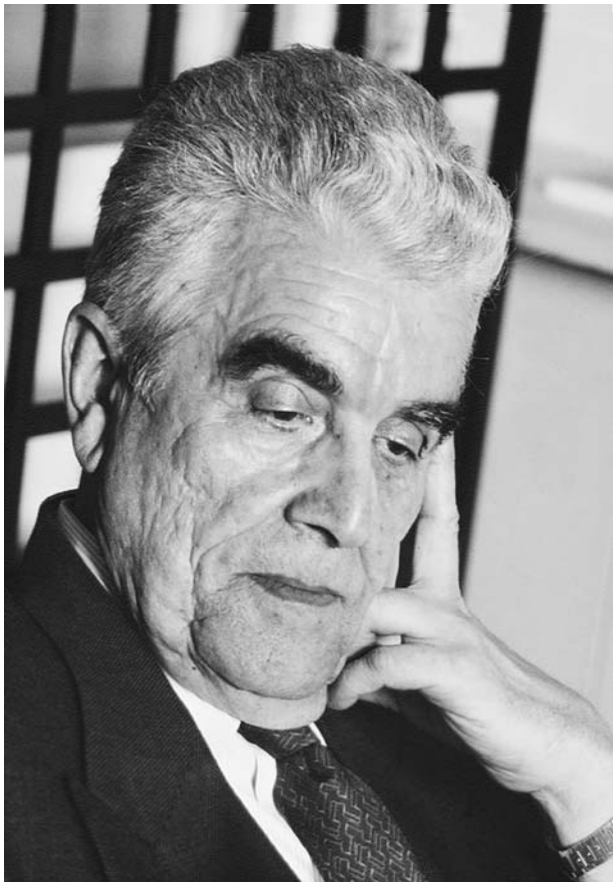
Ancient religion developed as an unconscious method of keeping the peace where the mimetic war of all against all is replaced by the more efficient war of all against one—the community's sacrifice of a scapegoat. Sacrifice acts as a kind of vaccination whose small doses of violence inoculate the community against greater violence.

The publication of *Things Hidden Since the Foundation of the World* (1987), a conversation with two French psychiatrists, included discussion of a *founding murder* among mimetically hysterical primates that initiated the long, slow process of hominization as well as sacrificial mechanisms. Girard sheds new light on the often-discarded speculations on primal murders found in Freud's *Totem and Taboo*. He also proposes the controversial thesis that the Judeo-Christian revelation of the victimage mechanism provides the anthropological tools necessary to demythologize pagan religious practices, which for Girard includes much of Western Christianity.

According to Girard, Christ's death was not a sacrifice willed by an angry God to atone for an original sin, but simply a revelation of human brutality and violence by a loving God. The remainder of Girard's major works (aside from a delightful work on Shakespeare) focus on biblical criticism, including *The Scapegoat* (1986), *Job: The Victim of His People* (1987) and *I See Satan Fall Like Lightning* (2001).

For Girard modern science and technology are an inevitable consequence of the demythologization of sacrificial violence and magical thought. Magical thought always seeks a social/moral explanation for pain. For example the Black Plague was often attributed to the Jews poisoning the water supply. As Girard quips, "Those who are suffering are not interested in natural causes" (Girard 1986, p. 53). However, with a loosening of magical thought, the search for natural causes slowly becomes a more reasonable path toward the "relief of man's estate" (Francis Bacon). "The invention of science is not the reason that there are no longer witch hunts, but the fact that there are no longer witch hunts is the reason that science has been invented. The scientific spirit, like the spirit of enterprise in an economy, is a by-product of the profound action of the Gospel text" (Girard 1986, p. 204).

Yet Girard's attitude toward science contains a certain Freudian ambivalence. Science is necessarily part of the Christian concern for victims and is a consequence of this charitable impulse. At the same time, modern technology has an apocalyptic edge to it. With the loosening of ancient sacred restraints and prohibitions, modern technology, like modern economy, unleashes the phenomenon of mimetic desire in a wave of consumerism, ethnic rivalry, media frenzy, and politically correct victimology. For Girard it is no accident that names for nuclear weapons are "taken from the direst divinities in Greek mythology, like Titan, Poseidon, and Saturn, the god who devoured his own children" (Girard 1987, p. 256).



René Girard, b. 1923. With work encompassing the disciplines of philosophy, literary criticism, theology, and anthropology, Girard is chiefly known for pioneering the mimetic theory of desire and the concept of the "scapegoat mechanism." *(© Bassouls Sophie/Corbis Sygma.)*

GLOBAL CLIMATE CHANGE

Global climate change refers to the ways in which average planetary weather patterns alter over time. The term *global warming,* though common, is a misnomer, for under some scenarios it is possible that part of the earth could cool, even as most of the planet gets warmer. The global climate change debate offers a superb case study of the relations existing in the early twenty-first century among science, technology, politics, and questions of meaning and value.

Defining the Problem

Because of the long timescales involved, climate change is difficult to experience directly; knowledge of meteorological variation generally falls under the classification of "weather." Science and technology—in forms such as the uncovering of the basic physical principles of atmospheric science, geologic evidence such as glacial moraines and plant remains, and determinations of ancient atmospheric concentrations derived from ice cores taken from the Greenland and Antarctic ice sheets—is needed to identify even the possibility of climate change. This fact has encouraged the assumption that both the definition of and the human response to possible climate change should be fundamentally scientific and technological in nature.

Geologists have known since the mid-nineteenth century that local, regional, and global climate undergoes change through time. Indeed, adding the term *change* to climate is nearly a redundancy, because climate varies on all timescales from decades to millions of years. This makes it difficult to clearly distinguish between the concepts of *weather* (transient variations) and *climate* (the long term status of the system).

For instance, the earth experienced an ice age that peaked 18,000 years ago; but considering the larger span of the earth's history, it is still in an ice age. While the norm for humanity, geologic evidence suggests that the earth has had ice on its poles for only a very small fraction of its history.

It was the Swedish chemist Svante Arrhenius (1859–1927) who in 1896 first suggested the possibility of human-induced climate change through the burning of fossil fuels. Climate change came to general notice in the 1970s, when concern was voiced about the possibility of global *cooling* leading to a new ice age. This remains a live possibility: Evidence of ancient climates shows that in the last 800,000 years the planet has seen a series of oscillations between ice ages, of approximately 100,000 years in duration, and interglacials, of around 10,000 years in length. Earth is thus overdue for a cold spell.

The 1980s saw the rise of concern about the "greenhouse effect" caused by increasing levels of human-produced carbon dioxide and other gases that trap heat in the atmosphere. Concern exploded in the summer of 1988, which saw record warmth throughout the United States. This warming trend appears to be continuing: Nine of the ten hottest years since the beginning of record keeping in 1880 have occurred between 1990 and 2003.

Ethical, Political, and Philosophical Issues

What defines climate change as a "problem" at all? This question relates to a long-standing debate within environmental ethics on whether nature has only instrumental value for human beings or has intrinsic value outside of any considerations of its value to humans. The first (anthropocentrist) position claims that concern about the environment should be motivated by an interest in human welfare. The second (ecocentrist) position believes that animals, species, ecosystems, and even rock formations and climate patterns can have qualities that make them the objects of moral concern.

On the first view, climate change is a problem only from the perspective of human wants, needs, and obligations to one another. Rising sea level is a physical event; it is only when it floods New Orleans or the Maldives that it becomes a problem. From this point of view, climate change has become a crisis in two senses in the early 2000s. First, human populations, structures, or the ecosystems societies depend upon may be exposed to climate-induced dangers such as rising sea level, changes in temperature and/or precipitation, changes in the frequency of extreme events such as hurricanes, and changes in vegetation and the growing season. Second, if climate change is partially or wholly human-caused—that is, if it is anthropogenic in nature—then the persons, industries, or societies that have caused these problems may fairly be held accountable.

This latter question has spawned a global debate about the respective responsibilities of developed and developing nations to address climate change. The debate turns on the fact that most of the increase of greenhouse gases to date has been caused by industrial nations, especially the United States, whereas most of the future contribution of greenhouse gases to the atmosphere is likely to come from developing countries such as China. Should developed countries be required to address questions of greenhouse gas emissions first, because they caused the problem, allowing developing nations to pollute more as they develop their industries? Or is such an approach self-negating, in that any real solution to greenhouse gas emissions requires a common global effort?

On another view, however, climate change is a more than a human affair. Climate change is certainly an issue for any species driven to extinction by ecosystem change. It is here that the question of global climate change touches upon core questions within the philosophy of nature. Species come into and go out of existence constantly; does it matter whether a species' extinction is caused by natural climate variability or anthropogenic change? In the mind of some, the difference is crucial: Change (including extinction) that is natural in origin should be tolerated and adapted to, whereas human-caused change or extinction should be addressed and mitigated. Making the question even more vexed are claims that there is no "natural" left in the early twenty-first century. On this view the entire earth, including its atmosphere, has become an artifact through centuries of inhabitation, cultivation, and pollution (Allenby 1999, McKibben 1999). These aspects of the climate change debate point toward religious and metaphysical considerations concerning the status of nature rather than to more and better data and predictions. In ways similar to the current debate concerning genetic engineering, questions are increasingly being asked about whether nature represents a limit that should be acknowledged and in some sense obeyed.

The Scientific Effort

Concerns about global climate change have led to a massive, unprecedented, and worldwide scientific, technological, and political effort to understand the causes and consequences of climate change. The basic assumption underlying all of these efforts is that climate change science is necessary for the devising of climate change policy.

The United States leads the world in climate change research, funding more than half of all the work. Approximately half of the nearly $2 billion annual budget for the U.S. Global Change Research Program (USGCRP, The U.S. Government's Interagency Research Program On Climate Change) is devoted to satellites and other data systems. The rest supports research across a wide range of sciences such as physics, atmospheric chemistry, oceanography, and ecology. A significant part of this research is conducted through computer simulations, the best known of which are global climate models (GCMs) that run on the world's fastest computers. Products of a truly global scientific and technological effort, GCMs have produced sets of predictions concerning the possible state of the atmosphere in 2100. (There is, of course, nothing magical about the year 2100; it was picked for symmetry and because this period was thought to be within the moral horizon of most people. In fact, computer models predict that change will accelerate after this date.)

Research into the social and political aspects of climate change—broadly known as "human contributions and responses to global change"—receives around 2 percent of the USGCRP budget, or $50 million. Even then, the overwhelming majority of this investment goes toward quantitative (often economic) social science research. While questions of ethics and values have often been voiced in public debate, research into such questions has been pursued only at the margins. The overall definition of the problem of climate change thus remains deeply immersed in science: The USGCRP seeks to identify the basic facts of the matter, leaving questions of value and justice to the political realm. More to the point, the assumptions remain quite positivistic: It is assumed that ethical and political solutions will somehow be derived from advances in climate science.

After two decades of concerted research, the community of climate change scientists have reached a high degree of consensus on several basic points: The global climate is warming; this warming is largely anthropogenic in origin; and the consequences of this warming could be quite severe. In the words of the National

Research Council's Committee on the Science of Climate Change, "Greenhouse gases are accumulating in Earth's atmosphere as a result of human activities . . . Temperatures are, in fact, rising" (NRC 2001, p. 1).

Science Meets Policy

Climate science research in the United States and other nations (principally the European Union and Japan) feeds into a global political effort to manage the problem of global climate change. The Intergovernmental Panel on Climate Change (IPCC) lies at the center of these efforts. The World Meteorological Organization and the United Nations Environment Programme founded the IPCC in 1988 "to assess scientific, technical and socio-economic information relevant for the understanding of climate change" (IPCC). The IPCC consists of:

- Working Group I, which assesses the scientific aspects of the climate system and climate change
- Working Group II, which focuses on the vulnerability of socioeconomic and natural systems to climate change, the consequences (both negative and positive) of climate change, and possible options for adapting to climate change
- Working Group III, which evaluates options for restricting greenhouse gas emissions and other ways to mitigate climate change
- The Task Force on National Greenhouse Gas Inventories, which runs the IPCC National Greenhouse Gas Inventories Programme

In addition, a series of special reports supports the working groups, the most important being the Special Report on Emissions Scenarios (SRES), which provides baseline sociological, political, and economic parameters for GCMs. Since 1990 the working groups have issued a series of joint assessment reports on a five- to six-year basis. These reports represent a remarkable synthesis of technoscientific research. Each assessment directly involves hundreds of scientists who collectively spend thousands of hours collating and synthesizing the available information on the above topics in a thick set of volumes. After a series of reviews, each volume is then boiled down to a "summary for policymakers" that attempts to extract insights most relevant to decision makers worldwide.

These IPCC reports are created to support the United Nations Framework Convention on Climate Change (UNFCCC), which seeks to devise a global political strategy. In late 1997 the UNFCCC gathered representatives from more than 160 nations in Kyoto, Japan, to negotiate binding limitations on greenhouse gases for developed nations. The resulting Kyoto Protocol called for developed nations to agree to limit their greenhouse gas emissions as compared with the levels emitted in 1990. The bulk of the political efforts to address the challenges of climate change have centered on negotiating the particular provisions of the Kyoto Protocol.

The results, however, have not been encouraging. Even if the Kyoto Protocol were to be ratified—and the Bush Administration announced its rejection of the protocol in 2001—the proposed limitations to greenhouse emissions would not come anywhere near the estimated 50 to 75 percent reduction scientists believe is necessary to stabilize atmospheric levels of carbon dioxide. What is more, the $25 to $30 billion the United States spent on climate change research from the early 1980s to the early 2000s highlights the questionable structure of the existing global climate change debate. Across this twenty-year period, the range of uncertainty for the predicted amount of change in global mean temperatures by 2100 actually *increased*, from 1.4 to 5.4 degrees Celsius in 1980 to 1.4 to 5.8 degrees Celsius in 2001. This increase in the range of possible warming has provided cover for politicians to call for more research instead of devising plans of action.

Future of the Problem

The paradox is that at the same time that a scientific consensus has formed on the reality of climate change, the actual range of future outcomes has increased rather than shrunk. A number of factors contribute to this increase of uncertainty, including a greater appreciation of the complexity and attendant lack of understanding concerning some parts of the climate system (for instance, the behavior of clouds, and the ocean–atmosphere interface), the difficulties in matching differing types of data, and the possibility that a system as complex as world climate is fundamentally unpredictable in nature. But the core difficulty lies elsewhere: The computer simulations used to model the atmosphere for the year 2100 are themselves fundamentally dependent on future sociological and economic indicators that are essentially unknowable. This is the significance of the SRES scenarios, which provide the basic inputs and parameters for the GCMs.

The SRES scenarios consist of six different imagined future patterns of energy use, technological progress, and social, political, and economic development. These six possible development paths explore future choices concerning population, lifestyle, the degree of globalization and economic integration, the development of non-carbon-based energy sources, and the possibility of carbon sequestration—choices that are not predictable in ways analogous to physical systems. Moreover, the point is not just that future social conditions cannot be predicted, but that they are in large part a function of human choices. The future does not simply befall humanity; individually and collectively humans exercise a significant influence over what happens. Rather than treating the future as if it were beyond human control, the challenge of global climate change calls for public debate about desirable futures.

It is thus arguable that while scientific research on climate change has greatly increased the knowledge and appreciation of the problem, the focus of attention should now shift toward two other areas that complement climate science: better understanding the nature of the social, ethical, political, and political dimensions of the problem, and devising ways to increase the resilience of both natural and social systems to a global climate that is already undergoing alteration. This approach would involve a shift in attention away from precisely modeling the climate system and toward devising a "no-regrets" strategy tied to sustainable development, social justice, and the modification of desires. The problem, however, is that such a "soft" approach to global climate change runs up against 300 years of tradition in which humankind has attempted to engineer its way out of problems rather than developing personal and political means for modifying its behavior.

GLOBALISM AND GLOBALIZATION

Without science neither globalism nor globalization would be conceivable; without technology they would not be practical possibilities. The extent to which the internal ethics of science and the codes of behavior of various engineering professions influence globalism and globalization, or the degree to which independent ethical assessments should be brought to bear on all science, technology, and globalist synergies, remains open to critical discussion. What follows is an analysis that aims to provide a background for such considerations.

Terminology

The terms *globalism* and *globalization* came into use during the last half of the twentieth century. The question of when, and by whom, is contentious. But irrespective of origins the two terms are used in distinct ways. Globalization refers to a multidimensional economic and social process beginning in the late 1970s and early 1980s and that embraces a variety of interlinked economic, communicational, environmental, and political phenomena. Globalism, although it has older roots as a synonym for internationalism, has come to be used as the name of a broad *ideological commitment* in favor of the process of globalization—that is, of a view that sees the process of globalization as entirely or predominantly positive in its implications for humankind (Steger 2002).

Globalists are people who wish the process of globalization to continue, and indeed intensify, although they may also wish to have it politically regulated or controlled in various ways. Globalists are often (though not always) also convinced that globalization, whatever its implications for human welfare, is an *inevitable process* that cannot, and should not, be reversed. They are often contrasted with "localists," who seek to escape or overcome the problems posed by globalization through small-scale forms of economic and cultural development and political organization that minimize involvement in the global economy (Mandle 2003).

In short then, there are theorists and writers on globalization both for and against the process they are analyzing, but those in favor of the process are generally called "globalists" or advocates of "globalism." In the early twenty-first century, enthusiasts for globalization do not call *themselves* "globalists" (this terminology is used only by globalization's opponents), although there is the potential for this to change as the debate unfolds further.

Globalization: Its Characteristics

There are innumerable definitions of the term globalization in the academic literature, but all, in one way or another, refer to essentially the same phenomena. These are:

(1) The increased depth of economic integration or interdependence in the world economy as a whole. Increased depth here usually refers to the integration of different parts of the world and different working populations in the world in the process of economic production itself (Dicken 2003).

(2) The central role played by electronic means of communication and information transmission in facilitating this new deep integration of the world economy.

(3) The much increased importance of global markets in both money and capital in the world economy as a whole (Thurow 1996).

(4) The historically unprecedented scale of international population migration occurring in the world economy in response (primarily) to new work opportunities created by the development of a genuinely global economy.

(5) Sharply increased economic inequalities both within and between different parts of the globe occurring primarily as a result of the very social and spatial "unevenness" of the globalization process.

In addition, there are conceptions of globalization that embrace, but go beyond, these economic aspects of the process to encompass political and cultural phenomena. These include:

(6) The ineluctable spread of a single, materialistic, consumerist culture driven by the Western-dominated global mass media (including both the Internet and television), which in the early twenty-first century forms dominant images of the desirable or good life everywhere on the globe (Castells 1996).

(7) The more or less rapid weakening of the political power of the nation-state in the global economy, a weakening shown by the reduced ability of such states to control crucial economic variables that determine the welfare and standards of living of their populations (Martin and Schumann 1997).

(8) Enhanced cultural and political conflicts in the world caused both by the increasing intermingling of culturally diverse populations in states receiving ever-larger numbers of global labor migrants, and by the so-called clash of cultures or civilizations in

different parts of the world, a clash in part produced by the very information and communications revolution referred to in (2) above. Greatly increased cross-cultural contact also makes different populations aware both of the ever-increasing inequalities among them—see 5 above—and of the different value orientations different cultures may embody. In this conception both global terrorism and the security threats it poses are themselves aspects of globalization (Wade 2001).

Globalization: Its Causes

There is broad unanimity on the origins and causes of globalization. As an economic process globalization dates from the mid- or late 1970s when the postwar "long economic boom" came to an end. The ending of the boom, and the initiation of a much slower growth trajectory for the world economy as a whole, created much more competitive conditions for all firms operating in that economy. The most common firm responses to these heightened competitive conditions were to:

(1) Reduce labor costs by increased automation and "technologization" of production;

(2) Subcontract or "outsource" design, transport, customer service, and even some managerial functions to "independent" consultancy or other firms, thereby reducing "core" labor and payroll costs;

(3) Transfer labor-intensive production activities, that could not be automated to lower wage regions, either in the "home" country or outside the home country altogether.

In addition:

(4) the development and commercial application of computer and information technology from the 1970s onward much facilitated processes (1) to (3) above, and

(5) the ending in roughly the same period (late 1970s and early 1980s) of the postwar Bretton Woods regime of fixed exchange rates facilitated the rapid expansion of global capital and money markets, markets that are themselves deeply dependent on sophisticated information technologies—4 above—for their functioning (Dicken 2003).

In short then, globalization as an economic process dates back no earlier than the mid-1970s, and its political, cultural, and security aspects have also all developed since that time.

Globalization: Its Originality

Although the causality and chronology of contemporary globalization is not disputed, its originality or uniqueness is. Globalization skeptics argue that the nineteenth-century global economy saw flows of investment capital and of international labor migrants that were *proportionately* larger in relation to global economic output or to the then existing world population than contemporary flows are. The nineteenth century also saw very rapid average annual increases in world trade, at periods on occasion larger than contemporary increases. Globalization skeptics even doubt whether modern communications technologies (such as satellite television or the Internet) are any more "revolutionary" in contemporary conditions than was the nineteenth century introduction of the electric telegraph to a world that had previously moved international mail by horse or sail and steamship (Hirst and Thompson 1999).

Although such skeptical arguments have some merit, they understate both the multidimensionality and variety of contemporary communications technologies and the absolute size of current trade, capital, and labor flows. Both the absolute size of the global economy and of the world population are much greater than they were in the nineteenth century. Most importantly of all, such globalization skeptics appear to confuse the "shallow" integration of nineteenth-century economies with the "deep" integration of the contemporary global economy. That is, contemporary international trade is structured (through the massive movement of raw materials and of semifinished goods) so that national economies are tied together *within the production process itself*. The production of everything from cars and other motor vehicles, to electronics, to clothing, footwear, and fashion accessories involves dovetailing inputs from factories located in several different countries through the global trade in goods and services. In this process of deep global economic integration, trade and production become increasingly difficult to distinguish (Dicken 2003). This is a very different situation from that of the nineteenth century, and it makes all countries involved much more vulnerable than ever before to a breakdown, or even to any significant disruption, of the global trade/production system.

Globalization: Its Merits and Demerits

The most discussed and disputed aspect of globalization focuses on the human welfare and economic distributional aspects of the process.

There is broad unanimity that the globalization period in recent history has also been a period of rapidly increasingly income and wealth inequalities both within individual national economies and societies and within the global population as a whole. Agreement ends at this point, however, and there are fierce debates about:

(1) Whether this growing inequality is a product of globalization itself or of the political form globalization has taken—most notably the generally neoliberal political and policy framework—that tends to discourage significant political control or guidance of the process.

(2) Whether this growing inequality matters in any case, if globalization has a tendency to significantly reduce world poverty.

(3) Whether globalization is even achieving poverty reduction, however, is itself a matter of debate, specifically over such matters as how poverty is measured and how increases or reductions in its magnitude are to be assessed (Kitching 2001, Collier and Dollar 2002, Wade 2001).

(4) Whether economic globalization is environmentally sustainable. Here connections are made between economic globalization, especially the spread of industrialization in Asia, Central America, and elsewhere—and such phenomena as global warming.

(5) The strong regional disparities in the spread of globalization and its benefits (and especially the disparity between East and Southeast Asia, on the one hand, and sub-Saharan Africa and the Middle East, on the other).

(6) The very poor labor and environmental conditions existing even in those countries and regions of the world, such as China and East Asia, that are supposedly benefiting from the process. Here it is suggested that regional benefits may not convert into human benefits at all.

(7) Finally, whether there is any connection between the globalization process, and its admitted inequalities, and the upsurge of political terrorism in the world. It is widely admitted, however, that if there is such a connection it is not directly economic. For although contemporary Islamist terrorism is centered in a part of the world (the Middle East) that has fared comparatively poorly in globalization, its militants and activists do not appear to be particularly poor. Moreover there is no terrorist threat emanating from sub-Saharan Africa, the region of the world that is universally admitted to have fared worst in globalization. If there is a connection between globalization and terrorism it is much more likely to be of an indirect cultural and political sort, not of a direct economic sort.

Conclusion: Globalization, Regulation, and Ethics

Conflicting assessments of the merits and demerits of globalization are often tied to different assessments of alternatives to it. The most obvious "total" alternative to globalization is withdrawal of local or regional communities from the world trade/production system into some form of local self-sufficiency or autarky (so-called localism). But this response seems feasible, even in principle, only if populations opting for it are prepared to accept very large reductions in their material standards of living. And whatever may be the situation in the rich parts of the globe, such a policy is unlikely to be attractive to the already poor majority of the world population (Mandle 2003).

In practice therefore, debates and disputes over globalization are most often focused, not on entirely "undoing" its economics, but on the possibility and desirability of politically regulating it so as to reduce its economic volatilities, inequalities, and negative environmental impacts. The central issue at the heart of such debates (aside from whether such regulation is desirable or possible at all) is whether nation-states can continue to be the prime political regulators of the global economy or whether globalization has passed beyond the regulatory capacity of states, so that the task must be turned over to supranational economic and political bodies such as the International Monetary Fund (IMF), World Bank, World Trade Organization (WTO), and International Labour Organization (ILO). But if the latter are to do so, many believe that their responsibilities and powers will have to be enhanced. Advocates of the supranational regulation of globalization are often (though not always) also advocates of a more or less radical restructuring of such bodies in order to make them more genuinely responsive to global public opinion and not simply to the views and preferences of the richest and most powerful states in the world (Stiglitz 2002).

The latter notion recalls the original post-World War II understanding of globalism as a promotion of internationalism in response to the threat of nuclear warfare. Proposals for the international control of nuclear weapons were, for instance, often promoted and stigmatized as one-worldism. To what extent, one may ask, were mid-twentieth century efforts such as the creation of the United Nations and the formulation of the

Universal Declaration of Human Rights the foundations for subsequent economic globalization or institutions and ideals that may help guide it.

From this perspective one may also consider a host of issues related to science, technology, and ethics. Certainly globalization as a phenomenon would not be possible with both science and technology. But does globalization imply or require the universalization of ethics and ethical standards in the same way that it implies and promotes the universalization of technical standards? Can research protocols that are appropriate for HIV/AIDS drugs in Europe and North America be transferred to Africa and Asia? Do professional ethics codes for scientists and engineers function in the same way countries with strong and weak civil society institutions? It is such questions that suggest the importance of both globalism and globalization to the ethical promotion and assessment of science and technology.

GLOBAL POSITIONING SYSTEM

The Global Positioning System (GPS) allows users to pinpoint their location anywhere on Earth to within a few meters. GPS technology was developed for military use, but by the early twenty-first century it had acquired numerous civilian applications including navigation, mapping and surveying, optimizing emergency response systems, and precision agriculture. The major ethical and legal challenges of this technology relate to national control and the potential end-uses of GPS-derived locational data. The U.S. Department of Defense provides the global GPS infrastructure; civilian use is maintained at the discretion of the U.S. government. Personal privacy is a concern because GPS capabilities, embedded in devices such as cell phones, can allow third parties to track the location of individuals. Regulations and laws covering such surveillance are not fully developed.

GPS almost always refers to the NAVSTAR system, the most widely used Global Navigation Satellite System, developed and maintained by the United States government. The U.S. Department of Defense originally developed GPS to locate submarines accurately and thus calculate trajectories for ballistic missile launches. The system depends on twenty-four satellites that continuously broadcast radio signals, positioned in precise orbits approximately eleven nautical miles above Earth. The first satellite was launched in 1978 and the network was completed in 1994. The signals and satellite locations are monitored and corrected as necessary from five ground control stations. A GPS receiver picking up signals from four satellites can compute its location, often to an accuracy of less than ten meters, anywhere on the globe.

GPS depends on the accurate maintenance of the satellites, signals, and related control systems—all of which are entirely under the control of the United States government. The United States deliberately degraded the signal available to civilian users until May 2, 2000. A full-precision civilian signal has since been available to all users, and the United States says that it intends to maintain free worldwide access to the signal. As a result, GPS is increasingly an international utility provided by one nation. The satellites broadcast a separate code for military use, and the U.S. military can jam the civilian signal to selected areas.

GPS itself is an inert provider of locational data. To be used as a tracking device, it must be linked to a communications system. Using GPS in monitoring, surveillance, or intelligence systems raises questions about the invasion of individual privacy, and the legal requirements for warrants and informed consent. GPS-communications devices are often placed on emergency and delivery vehicles to track their locations and optimize their usages. This technology can also be used to track the movements of personal vehicles and to monitor the movements of people including Alzheimer's patients and criminals. The U.S. Federal Communications Commission has directed that cell phones should be locatable in case of an emergency call; placing a GPS link in cell phones is one way to achieve this. The legal implications of being able to monitor a person's location and movements remotely have not been fully established.

An essential component of modern warfare, GPS is integrated in many advanced weapons and sensors. Combined with communications and geographic information systems, GPS provides comprehensive information on the location and movement of troops and assets, and allows accurate targeting of missiles. Some people have ethical concerns about the military applications of GPS, while others argue that accurate location information lowers collateral damage in warfare.

GPS has evolved from a military system into a widely used global utility, although the basic signal remains available at the discretion of the U.S. National Command Authorities. Individual jurisdictions have yet to decide acceptable parameters for the use of data derived from the GPS signal.

GOVERNANCE OF SCIENCE

Scientific research is a human activity governed by human choice. Governance is exercised at many levels, from the individual scientist deciding how to design an experiment or interpret and report data, to scientific organizations that advocate research funding, to government bureaucrats allocating resources among various projects or programs, to elected representatives establishing budgetary and programmatic priorities, and citizens lobbying to support (or oppose) a particular type of research or technology. Because the consequences of science so powerfully affect the constitution and evolution of society, appropriate governance mechanisms are a key ethical issue for democratic society.

A Republic of Science?

In an influential and powerfully argued paper titled "The Republic of Science, Its Political and Economic Theory" (1962), Michael Polanyi made the case that science was best understood as an autonomous, self-governing activity. Scientists were best positioned not only to understand how to conduct their own research, but also to determine the appropriate directions and levels of effort for new investigations. Likened to the *invisible hand* of the economic marketplace, Polanyi portrayed the governance of science as an emergent consequence of a continual confrontation between an open community of researchers carrying out unconstrained inquiry and nature itself. Interference with this process would lead only to the automatic and inevitable diminution of the ability of science both to advance knowledge and to benefit society.

Polanyi's argument was provoked by attempts in the Soviet Union to subjugate certain scientific disciplines (notably agriculture and genetics) to Marxist dogma, and efforts in England to tie public research agendas more directly to social needs (Polanyi 1964). It also reflected the intellectual conviction that successful scientific endeavor demanded adherence to a clear set of behavioral norms, collectively characterized as "organized skepticism," that were shared by the scientific community as a whole, and which were the only appropriate constraints on the governance of scientific inquiry (Merton 1942).

The practical embodiment of these ideas was articulated by Vannevar Bush, director of the U.S. Office of Scientific Research and Development during World War II. Bush argued, in the seminal policy tract *Science, the Endless Frontier* (1945), that while the public interest would be advanced by a robust, publicly supported science enterprise, the governance of that enterprise was best left entirely in the hands of scientists.

Yet this view, at least in its most extreme form, was explicitly rejected by politicians who believed that no publicly supported enterprise should be fully shielded from democratic accountability (Kevles 1987). Moreover the tremendous expansion of publicly funded research and development enterprises in the United States and other developed nations since the middle of the twentieth century has been accomplished through a variety of political means, in response to a variety of external pressures (notably, the Cold War, but also societal concerns about health, economic performance, and the environment). The details of this political history utterly vitiate any notion of science advancing according to its own lights, and governed according to its own rules (Greenberg 1967, 2001). Thus, while it is certainly the case that the *conduct* of science is significantly governed by norms and practices that are internal to the research system itself, the more important point is that *directions and velocity* of scientific advance reflect a multitude of factors, many of which are external to science itself (Sarewitz 1996, Kitcher 2001).

Yet the power of Polanyi's position remains strongly in evidence to this day, in the rhetoric used to defend the scientific enterprise from the influence of politics, and in the attitudes of a U.S. public that continues to view science largely as an ungovernable and ungoverned activity whose benefits to society are at once inevitable and unpredictable. For example, National Science Foundation (NSF) survey data consistently show exceptionally strong public support for the statement: "Even if it brings no immediate benefits, scientific research that advances the frontiers of knowledge is necessary and should be supported by the Federal Government" (National Science Foundation, ch. 7).

Documents promoting particular avenues of publicly funded science do so not by invoking the right and obligation of a democratic polity to choose the kind of science it will have, but by repeating what are essentially metaphysical arguments about the autonomous progress of science and its automatic connection to social benefit (Sarewitz 1996). Indeed it is fair to say that a sort of schizophrenia exists between the reality of a science and technology enterprise that is highly governed by decisions made at many levels of society, and the rhetoric of public discourse that perpetuates the illusion of an autonomous, internally governed *Republic of Science* (see, for example, U.S. House Science Committee 1998). This tension is deeply problematic because, concealed by the illusion, is the diverse array of human beings, working in diverse institutions, and ranging from scientists in laboratories to legislators casting votes and corporate executives determining market strategies, that in fact do govern the enterprise by making choices every day about what science to do and how to do it. The persistent notion that science is ungoverned or self-governed, that is, shields from scrutiny those who actually govern.

Political Reality

Nor do different types of research activities—embodied, for example, in the axiomatic taxonomy of unguided basic research, applied research, and development—carry implications about levels or appropriateness of governance. While Polanyi and Bush before him were centrally concerned with an idealized notion of basic research, the politics of science have made no such distinctions. The advance of basic biomedical research has ridden such political campaigns as the *war on cancer* (which was initially much opposed by medical researchers), while such *pure* fields as subatomic physics were justified in practical terms of the Cold War or economic competitiveness. The Republic of Science has, at one time or another, systematically failed to pursue research relevant to vast areas of socially important inquiry, such as diseases characteristic of poor people and regions, and alternative (nonhydrocarbon and nonnuclear) sources of energy. Conversely political action, motivated by interest groups rather than scientists, has been responsible for moving scientific priorities toward areas that had been explicitly avoided by the Republic of Science, for example, research on women's health, and on alternative (non-Western) medicine.

Even the norms and practices of science itself are subject to external governance. Most obviously, the rights of human subjects who participate in scientific experiments are protected by external mechanisms ranging from the Nuremberg Code (a response to Nazi Abuses) and the Helsinki Declaration to decentralized Institutional Review Boards (IRBs) operating in U.S. universities and laboratories (Woodward 1999). These governance mechanisms dictate, for example, that human subjects can participate in experiments only if they have given prior informed consent, a condition that sharply limits the types of science that may be conducted on humans. Additionally, partly in response to political activism that highlighted instances of unnecessary, and unnecessarily cruel, use of animals in research, regulations, norms and practices have progressively evolved in the United States since the 1960s to both reduce the use of, and suffering by, animals in science.

Scientific practice is governed in other arenas as well; for example, national security concerns have dictated where and how certain types of science are conducted, and how scientists can behave in and outside the laboratory. In response to fears of biopiracy, a growing number of nations have passed laws that prohibit foreign scientists from collecting biological samples. The overall point is that, as a societal activity, science is necessarily, appropriately, and unavoidably governed by society. The scientific community, similar to other interest groups, reactively opposes new governance structures, but the scientific enterprise as a whole has demonstrated itself to be remarkably resilient and productive under a wide variety of governance regimes, provided that such regimes do not seek to influence or control the actual results of scientific research (Sarewitz 2003).

Governing the Genome

Some of the most far reaching questions of scientific governance in the early twenty-first century are those associated with human genomics. These questions can only partly be laid at the door of the ongoing debates over abortion and the moral status of embryos. With science already able to intervene in reproductive processes (for example, screening for genetic attributes ranging from sex to particular diseases), and on the verge of a capacity to engineer both individual humans and human germ lines (Stock 2003), profound and complex ethical questions emerge whose resolution may strongly influence future directions of both science and of society (Fukuyama 2002, Wolbring 2003). In most developed countries, these questions are sufficiently conspicuous to command the close attention of government leaders and citizens alike (for example, U.S. presidents Bill Clinton and George W. Bush both convened advisory panels on bioethics), and sufficiently troubling to legitimate the possibility that some lines of scientific endeavor, such as those that could lead to human cloning or manipulation of the human germ-line, should simply not be pursued.

Opposition to a stricter governance of genomics research relies on three lines of argument: first the need to protect freedom of inquiry from societal interference; second the loss of potential social benefits (for instance, enhanced medical treatments); and third the likelihood that even if one country decides to prohibit or restrict a given line of research, others will surely decide to move ahead at full speed.

The first two arguments have little practical validity. Inquiry is never entirely free, and while science surely should be protected from inappropriate societal interference, the definition of what constitutes *appropriate* governance is constantly being renegotiated within society. Similarly choices about what science will be supported by society are continually being made in the public and private sectors, and any such choices entail opportunity costs. There is no reason to believe that the organization of scientific inquiry at any given time will yield optimal results for society.

The third argument is ethically troublesome, but difficult to dismiss in practice. While nations may decide to forego areas of research for moral reasons, the global science enterprise is so institutionally, sectorally, and geographically diverse that uniform compliance with any particular governance decision is likely to be impossible. Despite a fairly broad, global consensus against reproductive cloning, for example, it is inevitable that humans will be cloned at some point simply because the state of the science will allow it to be accomplished. Similarly the vast commercial potential for a wide variety of genetic enhancement and germline interventions is likely to be attractive enough to ensure that they will be aggressively pursued somewhere. Of course this likelihood neither justifies participation in such research, nor implies that restraint is without value. For example, the choice not to engage in some lines of research may allow particular nations or cultures to protect cherished values, and could influence choices made by other nations in the more distant future. Moreover, by slowing the advance of science in some areas (just as progress toward reproductive cloning has been slowed), society affords itself more time to develop effective principles and regulations for governance of such unprecedented innovations.

Modulation, not Control

Thus while science is, and will remain, a highly governed activity, this governance should not be confused with control. Rather it is a process by which the momentum and direction of scientific advance are subject to some degree of modulation via human decision making. Particular governance decisions may (or may not) be wise, may (or may not) reflect a commitment to the common good, and so on. The point of this entry is simply to explain that such decisions cannot and *therefore should not* be avoided. As science acquires the capacity to reengineer humanity itself, the choice to slow down, or orient this capacity in particular directions while avoiding others, remains open, but the balance among the attraction of commercial opportunities, the prerogatives claimed on behalf of the Republic of Science, and ethical concerns about the appropriate limits of science remain to be negotiated.

GRANT, GEORGE

Philosopher and Canadian nationalist, George Grant (1918–1988), born in Toronto, Ontario on November 13, rose to prominence in the 1960s through his concern that the homogenizing nature of modern technology would lead to the destruction of Canadian independence. He came from a family of prominent Canadian educators. A Rhodes scholar, Grant taught at Dalhousie University in Halifax, Nova Scotia, and McMaster University in Hamilton, Ontario. His meditations on the character of technology led to election to the Royal Society of Canada, several honorary degrees, and an appointment to the Order of Canada.

Grant saw the origins of the Western predicament as follows: Natural law philosophers such as philosopher and religious Thomas Aquinas (c.1225–1274), following the tradition of antiquity, taught that there were moral laws beyond space and time that were absolutely and universally binding on all human beings. In the seventeenth century a British philosopher, Francis Bacon (1561–1626), envisaged a radically new scientific project equally binding: In the future, science was to make human beings the masters of nature. Their moral authority for this dominion was enhanced by the eighteenth century philosopher Immanuel Kant (1724–1804), who maintained that the essential characteristic of human beings was their freedom and that they were bound only by moral rules to which they had freely assented. Aquinas, Bacon, and Kant together had forged the modern world.

Each of their positions seemed, by itself, true and necessary for human well-being. Yet they were, in principle and in practice, incompatible. Grant's philosophical contribution was to reveal the implications of these contradictions and alert his contemporaries to the need for a resolution. Grant was genuinely perplexed. As his early writings show, he understood technology as the dominance over human nature, but the tools it developed—the automobile, the washing machine, penicillin—led to genuine improvements in the human condition and in human freedom. Yet the same technology also brought the holocaust and the atomic bomb. He laid out these contradictions in his first important work, *Philosophy in the Mass Age* (1958), but offered no resolution.

Grant's View of Technology

One quality of modern technology, Grant came to understand, lay in its tendency to impose uniformity. The French philosopher Alexander Kojève (1902–1968) theorized that the whole world was moving relentlessly toward a universal and homogeneous state. For Kojève such an outcome was desirable, since it was a prelude to a universal peace where war between classes or nations no longer existed. In the work that made him famous throughout Canada, *Lament for a Nation* (1965), Grant accepted this understanding of the impact of technology, but for him it was not a cause to rejoice. He maintained that Canada's geographical position next to the dynamic center of technological modernity, the United States, would lead to its eventual disappearance as a independent country, since Canadians and Americans shared the same commitment to technological modernity. "Our culture floundered on the aspirations of the age of progress." (Grant 1965, p. 54)

In *Technology and Empire* (1969), Grant's concerns about the dangers of technology became more intense. Science, he now argued, no longer limited itself to the domination over non-human nature; it now increasingly attempted domination over human nature as well. Some critics of technology believed that it was something *out there* that people could control should they so choose. Grant rejected this view. For him technology was not something outside of people that they could choose to use for good or ill. Human beings lived in a society (and increasingly a world) in which technology determined all existence. "For it is clear that the systematic interference with chance was not simply undertaken for its own sake but for the realisation of freedom . . . [but] how do we know what is worth doing with that freedom?" (Grant 1969, p. 138).

The predicament of modernity was that those men and women who were the driving forces behind technological modernity believe that their project promotes "the liberation of mankind" (Grant 1969, p. 27). The older tradition of Plato, Aristotle, and Aquinas held that there were some things that it was absolutely wrong to do and perhaps even wrong to contemplate. By contrast Grant often attributed to J. Robert Oppenheimer (1904–1967) the view that, in modern science, no matter how terrible the possible outcome of an experiment might be, if you see that something is technically balanced, you do it.

When asked whether computers were neutral instruments, Grant observed that their existence required the work of chemists, metallurgists, and mine and factory workers; the use of algebra and other mathematics, Newtonian and other physics, and electricity; as well as a society in which there are many large corporations. Such a society contains an elite trained to think in a particular way and excludes other forms of society. Technology can never be neutral because of its historical, social, and conceptual preconditions.

Technology for Grant, then, was not just a way of making things or even a way of doing business. It was a way of thinking and it was becoming a way of being. So when the U.S. Supreme Court handed down its historic decision in *Roe* v. *Wade*, 410 U.S. 113 (1973), an abortion case, Grant was profoundly worried. The account of justice given there, influenced as he thought by technological modernity, seemed to put into question what it was to be a person. Consequently modern liberalism seemed unable to answer the question: "What is it about any members of our species that makes the liberal rights of justice their due?" (Grant 1998, p. 78).

Grant never denied that science had delivered the dominance over nature it promised, but it failed in a much more important way. "Brilliant scientists have laid before us an account of how things are, and in that account nothing can be said about justice." (Grant 1986, p. 60) But above all justice mattered. In his last book, *Technology and Justice* (1986), he argued that the technological understanding of the world was fundamentally flawed. Love was a primary fact of human existence; modern human beings "cannot hold in unity the love they experience with what they are being taught in technological science" (Grant 1986, p. 67).

Grant's writings still actively influence Canadian politicians, political scientists, theologians, and scholars interested in technology. Most philosophers are indifferent or hostile.

Grant, George. (1965). *Lament for a Nation*. Toronto: McClelland & Stewart. Grant's masterpiece, a complex interweaving of politics, philosophy, and religion that made him a nationally known figure. It explored the idea that technological modernity would lead inexorably to the destruction of Canadian independence.

Grant, George. (1969). *Technology and Empire*. Toronto: House of Anansi. The collection of essays that contained Grant's most concentrated meditations on technological modernity. In these essays Grant came increasingly to see technology in metaphysical terms. He saw it as darkness that prevented human beings from being aware of the absence of divine light in the world.

Grant, George. (1986). *Technology and Justice*. Toronto: House of Anansi. Grant's last collection of essays and his most positive affirmation that Simone Weil's understanding of love shows human beings an alternative to technological modernity.

Grant, George. (1995). *Philosophy in the Mass Age*, ed. William Christian. Toronto: University of Toronto Press. Grant's first book, originally a series of radio lectures, explored the problems of technology as they were arising in the aftermath of the second world war and the new materialism of the 1950s.

Grant, George. (1998). *English-Speaking Justice*. Toronto: House of Anansi. After the *Roe* v. *Wade* decision, Grant worried that technology threatened the very idea of what it was to be human. This work, written in the mid-1970s, attempts an examination of implication of the U.S. Supreme Court's ruling.

GREEN IDEOLOGY

Green is the color of vegetation, in particular of healthy, growing leaves. At least in the growing season it is the predominant color of undeveloped land in nonpolar, non-arid regions. Green as a quality of the landscape was what was destroyed or threatened by the Industrial Revolution in Britain. Thus William Blake, in the poem that has become the hymn *Jerusalem*, contrasted the *green and pleasant land* that England should be with the *dark satanic mills* of his time (early-nineteenth century). And Richard Llewellyn's 1939 novel *How Green Was My Valley* tells the heartbreaking story of the gradual transformation of a rural landscape, where young boys caught trout in the river, to a polluted industrial wasteland where the wastes from coal mining, dumped on the sides of the narrow South Wales valley, threatened to engulf the miners' houses.

Green as undeveloped land, free from industry, is what is evoked by the term *green belt*. Green belt is a planning designation of land around cities or towns intended to prevent urban sprawl, for the benefit of both city and countryside. Green belt land is to be permanently *open*, the presumption being against built development except in special circumstances (UK Office of the Deputy Prime Minister 2001).

Because green is the color of vegetation, and thus plants, it has been linked with agriculture. *Green Europe* was a newsletter on the European common agricultural policy, published by the European Commission. The *green revolution* of the late-1960s and 1970s was about increasing crop yields through the development of new varieties that required high inputs of fertilizers and pesticides. That this form of agriculture was, by the 1990s, considered very un-green is a sign that between the 1970s and 1990s green took on a particular political and philosophical meaning.

Greenpeace was the name taken by a small band of nonviolent, direct activists who, in 1971, tried to take a small boat to Amchitka, an island off the west coast of Alaska where the United States was conducting underground nuclear tests. Greenpeace subsequently became a major environmental nongovernmental organization, campaigning for a *green and peaceful future*. What Greenpeace sees as at stake, threatened by modern technology and economic growth, is not simply a green and pleasant countryside but *the ability of the Earth to nurture life in all its diversity*.

The first political party that took the name *Green* was the West German Green Party, *Die Grünen*. The federal party was formed at the beginning of 1980, but was preceded by numerous local or state-level groups that put up Green or *Rainbow* lists of candidates for elections and, in the case of Bremen Green Slate, won seats in the state parliament. The 5 percent barrier to representation under the West German system of proportional representation meant that there was considerable incentive for a wide variety of different groups to come together as Die Grünen in order to achieve political representation. These groups included those concerned with environmental pollution, protestors against nuclear power, feminists, Marxists, and socialists disillusioned with the Social Democratic Party. They united under the four pillars of ecology, nonviolence, social justice, and grassroots democracy, which have since come to define what it means to be Green.

In the federal elections of 1983 Die Grünen won 5.6 percent of the vote and sent twenty-seven members to the Bundestag. Following this success, parties in other countries with similar philosophies, such as the Ecology Party in the United Kingdom, changed their name to the Green Party. Green parties were also started in other countries, including the United States in 1984. The word *green* evokes rejection of industrialization and protection of life in all its diversity, but also freshness, immaturity, and naivety. The Greens have thus proclaimed themselves to be a fresh force in electoral politics, different from the political elites of the *grey* parties, who the public view as increasingly remote and answerable only to vested interests. Although Greens are often charged with being unrealistic, it is a measure of their success that being green no longer means being naïve.

Newness is also encapsulated in the idea that Green is *neither left nor right but forward*. The influence of anarchism on Green ideology and the resulting rejection of hierarchical structures, results in an emphasis on individual responsibility and initiative akin to that of the right. Greens can also be seen as conservative with respect to technology. They are often skeptical about new technologies that traditional socialism welcomes as enhancing human capacities, defending older technologies and smaller, close-knit communities, though they welcome other innovations, such as solar power and modern wind turbines. However, in their critique of capitalism and the free market, the Greens are firmly on the side of the left. What is new in the green critique is the emphasis on environmental limits: It is the environmental crisis, not the suffering of the proletariat, that makes it imperative to move toward a different economy, technology, and society. This new green society will protect the planet by respecting nature—ecosystems, non-human species, and the rights of animals—and will also be better for the health and well being of humans and their communities.

Green politics and philosophy presents a holistic vision in which monetary reform, participative democracy, meaningful work, social justice, and equality are all of a piece with renewable energy, organic agriculture, protection of wildlife, recycling, and non-polluting technologies. This vision can be sought by the green consumer as well as the voter through boycotting certain goods and buying others (Elkington and Hailes 1988).

Despite this broad holism, green is narrowed in many instances to refer simply to reduced environmental impacts. Thus *green travel plans*, now a condition of many planning permissions in the United Kingdom, are plans introduced by employers to attempt to reduce the use of car transport by their employees. A *green building* is one designed to have reduced impact on the environment during its construction and use.

GREEN REVOLUTION

The Green Revolution (not to be confused with "green" as in the environmental movement) was a dramatic increase in grain yields (especially wheat and rice) in the 1960s and 1970s, made possible by the Rockefeller Foundation's development of high-yielding wheat and rice varieties starting in the 1950s. The moral good of producing more food seems unquestionable. Indeed, Norman Borlaug (b. 1914), the scientist who spearheaded the Green Revolution, received the 1970 Nobel Peace Prize for his work. Yet the Green Revolution did spur ethical disputes over the social and environmental changes its technologies produced, especially in the developing world. Proponents argued that increased food supply benefited society generally; opponents pointed to the ways that poorer segments of societies were disproportionately hurt by the Green Revolution. In the early twenty-first century, Green Revolution technologies continue to promote conflict between those who see them as tools in service of society and those who argue that they promote injustice.

Competing Views of Development

The controversy over the social justice of the Green Revolution was apparent from the start of the Rockefeller Foundation work in Mexico. Encouraged by U.S. Vice President Henry Wallace, the Rockefeller Foundation in 1941 offered to send agricultural advisors to Mexico to help improve its wheat crop. The Rockefeller family had both a history of humanitarian work and valuable oil properties in Mexico. Both the family and Wallace were concerned about increasing social unrest in Mexico and sought solutions that would not reawaken interest in the previous Mexican administration's attempts to redistribute land to the poor (Wright 1990). The Rockefeller Foundation officers believed that they could stabilize Mexican society by increasing the supply of cheap, domestically-grown food. The Rockefeller Foundation's survey team of cutting-edge agricultural scientists, including plant breeders and agricultural chemists, unsurprisingly advocated technologies that had proved successful in the United States: the development of new, high-yielding varieties of major crops. North American farmers had profited from this system, despite the increased cost of purchasing new seed stock every year, and Rockefeller expected the same results of *modernization* in Mexico (Fitzgerald 1986).

Critics attacked the plan as inappropriate for small farms, which they believed ought to be the target of any agricultural improvement in Mexico. Carl Sauer, a geographer from the University of California Berkeley, argued that the plan would be disastrous for the peasant economy of Mexico, as peasant farmers would be unable to standardize on expensive new seeds. Other critics argued that by excluding experts on Mexican society from the survey team, Rockefeller risked forcing an inappropriate scientific solution on Mexico. The Rockefeller team fired back that Sauer and other critics simply wanted to keep Mexico backward, and were unwilling to let it modernize (Wright 1990).

Behind this sniping was a fundamental disagreement over how to benefit Mexican society. For Rockefeller's critics, improvement had to target economically-pressed peasants to be beneficial. Rockefeller argued Mexico had to rapidly start producing more food, using the best science and technology available. For Rockefeller, *modern* evoked the moral superiority of doing whatever was necessary, socially or technologically, to produce increases in the food supply. Critics argued that the science and technology should be *appropriate* for the majority of Mexican farmers. Both held moral commitments, but to different visions of the Mexican future.

Expected and Unexpected Consequences

Rockefeller adopted the survey team's recommendations. Borlaug's group employed traditional and novel scientific methods to produce high-yielding semidwarf wheat varieties that exceeded all expectations. Semidwarf varieties are stalky plants that can hold a heavy head of grain. These varieties, used with plentiful water, fertilizers, and pesticides, produced dramatically high crop yields. Interest in semidwarf varieties spread quickly, especially where food security was a concern. The Indian government asked Borlaug to help it develop wheat varieties for India; these were ultimately credited with preventing a major famine (Perkins 1997). Governments lauded the social good of the technology that allowed them to import less food despite growing populations and green revolution science was soon extended to other staple grains, especially rice. Rice-producing countries around the world adopted these new rice varieties as readily as had wheat producers. Those who adopted Green Revolution technologies often experienced increases in their standards of living, although in some places, government-mandated food prices sometimes undercut the economic benefits of higher yields (Leaf 1984).

The fears of critics were also realized, especially in the early years. Medium-sized and large farms could adopt the new technologies easily, and their high yields led to declining food prices. While urban populations benefited, small farmers watched the profits from their own harvests decrease. Some smaller farmers were able to adopt the technologies and improve their standards of living, but others were forced into rural labor or to move to the cities. Because people went hungry despite growing food supplies, critics argued that the Green Revolution could create food, but not relieve hunger (Sen 1981). They pointed to regional inequities, as areas suited to Green Revolution grains and favored by government attention flourished, while poorer regions fell behind. For critics, the Green Revolution failed the test of social justice (Shiva 1991).

Later, unanticipated environmental effects fed ongoing debates about social justice. The issue of monocropping highlights the environmental angle. Monocropping (producing a single crop in a field) helps produce uniform, high-yielding crops. However, it also produces microenvironments in which crops are more vulnerable to insects. Scientists responded by recommending heavy use of pesticides, with serious systemic consequences: sometimes toxic levels of pesticide exposure for farm laborers (who were often those disenfranchised by the Green Revolution), and rapid adaptation by insects requiring constant innovation and resulting in higher prices. Extensive monocropping sometimes led to less diversity in local food supplies, which critics have argued disproportionately affected the nutrition of the poor. In Green Revolution areas, the poor have come to depend almost exclusively on grains, decreasing the nutritional value of their diet (Shiva 1993). In each critique, the question of justice, whether for the poor or for future generations, is the central concern.

Reconsiderations

The attention that critics have paid to social justice, while sometimes questioned by supporters of the Green Revolution, have not fallen on deaf ears. The agency responsible for the scientific development of Green Revolution crops, the Consultative Group on International Agricultural Research (CGIAR), has responded vigorously. Scientists have decreased the amounts of pesticide needed, reducing risk to farm workers and lowering the cost of inputs. They increased the number of food crops for which they have developed high-yielding varieties, including some crops traditionally cultivated by the poor. Scientists have given attention to developing high yielding crops using less water, an important consideration in arid regions. In the 1990s, scientists began to research ways to introduce Green Revolution technologies to the poor regions of Africa that had been previously bypassed.

Advocates have also argued that making Green Revolution technologies socially just is not only the responsibility of scientists, but also of regional and national governments (Hazell 2003). In places where agricultural credit is accessible, more small farmers have been able to retain or expand their land and benefit from the technologies. Such efforts are not lost on critics, but neither have they quieted the criticism that Green Revolution technologies promote injustice. Supporters are equally steadfast that Green Revolution technologies produce social goods that outweigh shortcomings. A widely agreed-upon ethical judgment of the Green Revolution remains unlikely, because the complex social and environmental consequences of this technology continue to unfold.

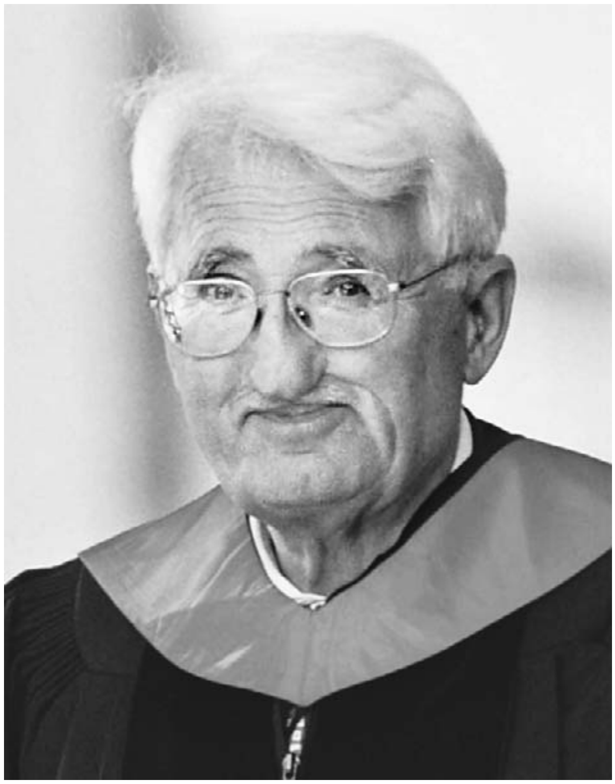
H

HABERMAS, JÜRGEN

Jürgen Habermas (b. 1929) was Germany's foremost social theorist and philosopher in the second half of the twentieth century. Born in Düsseldorf, Germany, on June 18, Habermas is the leading representative of the second generation of the so-called Frankfurt School of critical social theory, taking inspiration from Max Horkheimer, Theodor Adorno, and Herbert Marcuse. At the same time Habermas was strongly influenced by the linguistic turn in analytic philosophy from Ludwig Wittgenstein to John L. Austin and John Searle, as well as by the classics of German thought from Immanuel Kant and Georg W. F. Hegel to Karl Marx and Max Weber. In his magnum opus, *The Theory of Communication Action* (1981), Habermas explained the genesis of modern society in terms of basic categories derived from the philosophical study of language and rationality. This analysis reveals that the processes of rationalization characteristic of modernity have been crucially one-sided, privileging the *instrumental* or *strategic rationality* of selecting the most effective means to ends at the expense of the *communicative rationality* of reaching a shared understanding of ends on the basis of reasons that everyone can accept in free discussion.



Jürgen Habermas, b. 1929. The German philosopher and sociologist challenged social science by suggesting that despite appearances to the contrary, human beings are capable of rationality and under some conditions are able to communicate with one another successfully. *(© Darren McCollester/Getty Images.)*

Science, Technology, and Politics

A central strand in Habermas's narrative of modernity is thus the intrusion of quasinatural scientific and technological imperatives into the realm of politics. This raises the practical and theoretical issue of the proper relationship between science and politics. Habermas outlines three possible views of this in his early "Technology and Science as 'Ideology'" (1968). On Weber's *decisionistic* model, there is a strict separation between the functions of the politician and the expert: The former makes decisions on the basis of values that are at bottom irrational and the latter carries them out as effectively as possible on the basis of scientific knowledge. *Technocrats*, in contrast, see contemporary politics as bound by objective exigencies of preserving the stability of the system. Experts present policy alternatives as necessary for the achievement of goals like economic growth that are presumed to be grounded in objective needs. Thus whereas decisionists see values as irrational, technocrats consider them irrelevant.

But *techne* cannot be substituted for praxis. Needs must be interpreted in the light of values and cultural meanings before they can guide action. Habermas prefers, therefore, the third, *pragmatist* model of John Dewey. Means and ends are interdependent: On the one hand, the horizon of values in a society guides scientific research, on the other, value convictions persist only insofar as they are connected to potential satisfaction through instrumental action. Consequently technology cannot be value-neutral. Practically relevant scientific achievements must be subjected to free public discussion to make possible a "dialectic of enlightened will and self-conscious potential" (Habermas 1970, p. 73) that both allows new technologies to alter public self-understanding and lets that self-understanding determine the course of future research. Insofar as such discussion is governed by the "unforced force of the better argument," it yields decisions on ends that are rational in a sense decisionists failed to recognize.

Such domestication of technological development is impossible if technology as such amounts to ideology. Marcuse claimed that this is indeed the case since the progress of science and capitalism had undermined the legitimacy once enjoyed by religion and tradition. In partial agreement, Habermas argues in *Knowledge and Human Interests* (1968) that empirical science as such is bound up with an anthropologically deep-seated (and therefore *quasitranscendental*) *technical interest* in potential control and manipulation that is constitutive of its object domain. In contrast to Marcuse, however, he sees this interest as invariant, since it is rooted in the universal conditions of material reproduction of human life. As a result, there is no such thing as *alternative science*.

Normative Issues

Where, then, does one find the normative resources to counteract the insidious form of social domination that legitimizes existing inequalities with an appeal to scientific (such as economic) necessity and placates the public with commercialized mass media and slow but steady growth in material comfort brought about by technological development? Habermas's strategy in his early work is to locate two equally fundamental human cognitive interests pertaining to interaction rather than work. As social beings whose very identity depends on mutual recognition in linguistic interaction, people have a *practical interest* in solving problems of communication and understanding within and between traditions. This is the task of the hermeneutic or cultural sciences (*Geisteswissenschaften*). The *emancipatory interest* in countering the effects of *systematically distorted communication* through critical reflection is exemplified on the individual level by psychoanalysis and on the social level by critique of ideology that reveals the particular economic, political, and social interests that bias self-understandings embedded in human traditions. The ideological aspect of positivist views of science and technology consists in conflating the practical with the technical and thus obscuring the possibility of rationalization along these other dimensions. The problem is the universalization of instrumental thinking, not instrumental thinking itself.

In later work, Habermas replaces appeals to interests with references to the necessary structures of communication elaborated in *formal pragmatics*, but he remains concerned with the effects of technology on human interaction. *The Future of Human Nature* (2001) addresses the specific problem of *liberal eugenics*, genetic intervention designed not to prevent health problems but to create abilities that parents consider to be useful for the child. Habermas argues that this is ethically unacceptable. First, knowledge that they have been preformed according to someone else's preferences makes it impossible for children to view themselves as the sole ethically responsible authors of their own lives. Second, such engineering introduces a fundamental, irreversible asymmetry among the programmers and the programmed that is contrary to the basic principles of symmetric mutual recognition among free and equal persons that are grounded in the very structure of linguistic interaction.

In sum, Habermas's key contribution to the ethics of science and technology is a plausible theory of intersubjective rationality. Such rationality does not reduce to instrumental efficiency and can therefore be used to set nonarbitrary goals and limits to technical development, if implemented in suitable democratic institutions.

HACKER ETHICS

Originally the term *hacker* was used to refer to someone who is enthusiastic about computing, spends a lot of time figuring out how computers work, and is adept at using computers to accomplish extraordinary feats. *Hacking* referred to the activities of hackers. In the early days of computing hackers were exploring the full potential of computers: They were figuring out what it was possible to achieve with computers, doing things that had never been done before. In this sense hackers were like the imaginative mechanics of the early Industrial Revolution, automotive hot-rodders, barnstorming airplane pilots, and ham radio operators. In those early days there were few laws or policies specifying what individuals were allowed to do or prohibited from doing with computers. Many of the feats that hackers accomplished subsequently became illegal, for example, breaking into private systems, examining what was in those systems and how the systems worked, copying and distributing information and programs, and telling others how to do the same things.

The meaning of the terms *hacker* and *hacking* changed somewhat over time, and *hacker* began to be used to refer to those who engage in illegal computer activity. Many hackers objected to that usage and insisted that a distinction be made between hackers, who are generally law-abiding, and crackers, who use their computer skills to engage in illegal activity. Currently, the term *hacker* is used in both ways. Occasionally the term "hack" is used more broadly to refer to a playful feat involving scientific or technological expertise, for example, when a group of students break into a campus building undetected and leave visible and fanciful evidence of their success at breaking in (Laszlo 2004).

The Hacker Ethic

Individuals who identify with the original concept of hacking continue to exist and share ideas with one another online. They constitute a subculture that has coalesced around computer technology and the Internet. Members of that subculture share an attitude toward computing and a set of beliefs about how computers and the Internet should be used. This attitude and set of beliefs often is referred to as the hacker ethic.

Although expressions of the hacker ethic have varied over time, at the heart of the subculture is a view of the potential of computing that has two elements: the principle that all information should be free and the belief that access to computers should be unlimited. Surrounding these elements are enthusiasm about computing, a sense that computing is fun and even joyful, and the conviction that computing can be used to bring about positive change in the world by countering mainstream trends toward centralization and privatization. On one Internet site (Raymond 2003) the hacker ethic is defined as follows:

1. The belief that information-sharing is a powerful positive good, and that it is an ethical duty of hackers to share their expertise by writing open-source code and facilitating access to information and to computing resources wherever possible.
2. The belief that system-cracking for fun and exploration is ethically OK as long as the cracker commits no theft, vandalism, or breach of confidentiality.

From an ethical perspective the vision put forward by hackers points to the potential of computing to create a world in which there is no gap, or at least a smaller gap, between the haves (information-rich people) and the have-nots (information-poor people) and in which those who have expertise use it to help others. Moreover, insofar as hackers create open source software and encourage data sharing and access to the Internet, their activities can be seen as furthering the potential of computer technology for social good.

Criticisms and Defenses

The activities of hackers become subject to moral criticism only when hackers engage in illegal activity; using more precise terminology, moral questions arise when hackers become crackers. Once the law is broken, cracking behavior is not just illegal but also seems likely to cause others to be treated unfairly and to harm their interests. For example, when hackers launch viruses that disrupt the use of the Internet, their behavior interferes with the activities of innocent users; when they copy and distribute proprietary software, they are violating the legal rights of individuals to own and license software; and when they break into systems and examine files, they are violating the privacy and property rights of others.

In their defense crackers may argue that (1) they are doing no harm, meaning no physical harm to human beings; (2) they are liberating information that should be free; (3) the laws involving computing are bad and even unjust; or (4) they serve in the role of vigilantes testing and revealing the vulnerabilities of computer systems. All these claims rely on the deeper or prior presumption that sometimes it is permissible to break the law.

In moral philosophy and in democratic theory cases of justifiable law breaking are well recognized. The defense of hacking sometimes is couched in terms of civil disobedience. Acts of civil disobedience are those in which an individual refuses to obey a law either because obeying the law would violate the individual's conscience or because an individual wants to protest the law on the grounds that it is unjust. Although there may be particular acts that fit the definition of civil disobedience, in general cracking does not seem to fit into that category. Indeed, most cracker behavior seems difficult to defend, though there may be particular actions that can be justified.

Cracking behavior is difficult to justify because the laws that have been created around computing, though far from perfect, are aimed at defining the rights and responsibilities of users, and once rights and responsibilities are allocated, illegal behavior becomes *prima facie* harmful. Viruses disrupt the activities of computer users and force them to invest more resources (time, effort, and money) in securing their systems, resources that could be used in other ways. Pirating software deprives individuals of their legal rights of ownership. Gaining unauthorized access to systems and files violates privacy and property rights.

In recent years scholars have begun to explore new forms of behavior on the Internet that are related to but different from hacking. For example, the term *hacktivism* is used to refer to activists who use their computer skills to make political statements and protest actions by government or industry; in other words, those persons engage in political activism by using computers. Hacktivism may or may not be illegal depending on the actions taken. *Cyberterrorism*, by contrast, refers specifically to political action that involves violence against persons or property.

HALDANE, J. B. S.

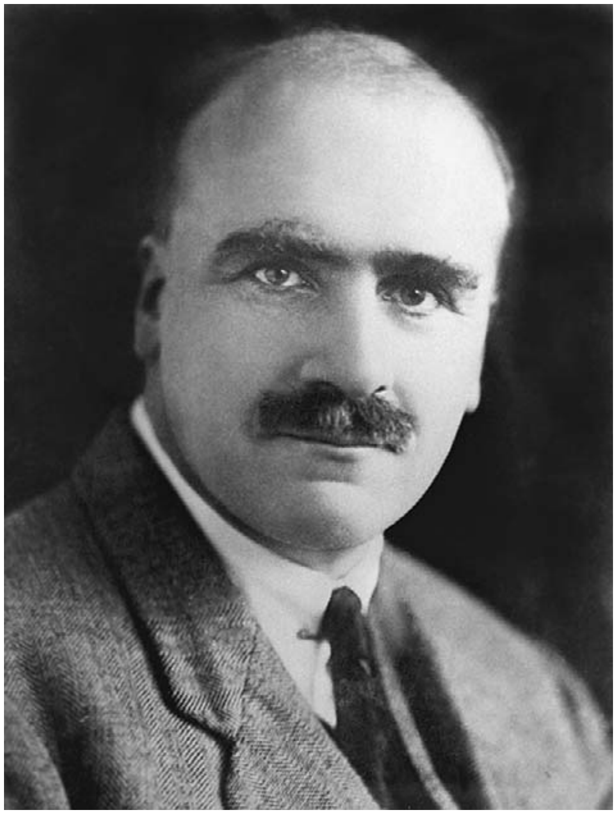
John Burdon Sanderson or J. B. S. Haldane (1892–1964) was born in Oxford on November 5 and, as the author of *The Causes of Evolution* (1932), became a founder of what was later called the modern evolutionary synthesis of population genetics. Haldane was also an influential popularizer of science who in essays, fiction, and even verse emphasized the need to develop an ethical framework within which human beings may assimilate emerging technologies. He died on December 1 in Bhubaneswar, India.

With remarkable prescience, Haldane foresaw discoveries in molecular biology and genetic engineering. In *Daedalus or Science and the Future* (1923), he argued that scientific progress in these areas would bring confusion and misery to humankind unless accompanied by progress in ethics. Ideas from Daedalus influenced his friend Aldous Huxley's novel *Brave New World* (1932), and Haldane served as the model for the biologist in Huxley's *Antic Hay* (1923). Forty years later, in 1963, Haldane also introduced the concept of clonal reproduction that has since inspired much controversy and discussion in bioethics.

Haldane further maintained that science provides at least one of the key ingredients to moral progress, this being high regard for truth and a refusal to jump to unjustifiable conclusions. Indeed in one statement of this agnostic attitude, Haldane suggested that "the Universe is not only queerer than we suppose, but queerer than we can suppose" (1927, p. 298).

Haldane's views in regard to the ethical influence of science were opposed by Bertrand Russell (1872–1970) in *Icarus or the Future of Science* (1924). Russell argued that technical scientific knowledge does not make people more sensible in their aims or more self-controlled and kind. In his advocacy of a science-based ethical framework, Haldane thought that science would exert an essentially progressive influence on society and politics, and that general agreement could be reached on conceptions of the good, a view that remains highly controversial.

Seeing it in part as a bridge between science and ethics, Haldane was also for years attracted to Marxist Communism, which he embraced during the 1930s. He later abandoned this affiliation when the science of genetics was suppressed in the Soviet Union under the direction of Trofim Lysenko (1898–1976). Ironically that crisis proved one of his own predictions about Soviet science, that "there is . . . a very grave danger for science in so close an association with the State . . . it may lead to dogmatism in science and to the suppression of opinions which run counter to official theories. . . ." (1932, p. 225.)



J. B. S. Haldane, 1892–1964. Haldane was an English biologist who utilized mathematical analysis to study genetic phenomena and their relation to evolution. *(The Library of Congress.)*

Another essay by Haldane, "On Being the Right Size" (1927), virtually created analytic morphology. By pointing out, for instance, that exoskeletons can only get so large before the internal organs collapse under their own weight, this essay has influenced fields as diverse as the criticism of mass urbanization, the alternative technology movement, and decentralized economics.

Also important is the fact that Haldane conducted many scientific experiments on himself (Dronamraju 1968, p. 267–275). His ethics precluded making others the subject of experiments when he himself could serve that role, a practice also followed by his father, Oxford physiologist John Scott Haldane (1860–1936).

Throughout his life Haldane emphasized how science and technology create new ethical situations, although different sciences impact ethics in different manners. Physics and biology affect our ethical outlook by altering views about the fundamental nature of the world and the interrelationships between all living beings. For Haldane, Darwinian evolution imposes a new set of ethical values on the relationship between humans and other species. Anthropology shows that any given ethical code is only one of a number practiced with equal conviction and almost equal success. Advanced communication technologies create new duties by pointing out previously unexpected responsibilities for world events.

In 1957 Haldane moved to India, where he was deeply influenced by Hinduism. He saw the Darwinian theory of evolution from a fresh perspective, noting that Christian theologians had drawn a sharp distinction between humans and other species, whereas no such distinction had been made in India. According to Hindu, Buddhist, and Jain ethics, for instance, animals have rights and duties, and the adherents of these religions are duty-bound to adopt a non-violent approach to biological research. He followed this principle in directing the research of his students in India in animal behavior, genetics, human genetics, and the biometry of both animal and plant species.

HARDIN, GARRETT

Garrett James Hardin (1915–2003), born in Dallas, Texas, on April 21, was sometimes called the "father of human ecology" for his efforts to popularize a biological understanding of human beings that also draws out ethical implications. He was a strong advocate for controlling population growth and limiting immigration into the United States, because of the ecological implications of these issues. His two best-known essays, "The Tragedy of the Commons" (1968) and "Lifeboat Ethics" (1972), in their description of a problem and presentation of a response, became standard points of reference in bioethics broadly construed. Hardin died in Santa Barbara, California, on September 14.

Hardin earned a B.A. in zoology (University of Chicago, 1936) and a Ph.D. in microbiology (Stanford University, 1941). His most influential mentors were microbiologist Cornelius Bernardus van Niel (1897–1985) and Nobel Prize–winning geneticist George W. Beadle (1903–1989). In 1946 Hardin accepted an appointment in human ecology at the University of California, Santa Barbara, where he spent the next thirty years of his career, retiring in 1976.

In "The Tragedy of the Commons," which was first published in *Science* magazine and then widely reprinted, Hardin employed the historical analogy of the deterioration of common pasturelands in seventeenth-century England to explore the contemporary problems of resource utilization and environmental pollution. When a common resource such as a pasture that will support three cows in good health is available to three families, any one family is tempted to introduce a second cow, because although now all four cows will, like the pasture, be slightly less healthy, the combined value of two modestly healthy cows is greater than one healthy cow. This tendency to exploit a public good for private gain, when the gain belongs to one person but the cost is shared by all, results in the overgrazing and deterioration of the commons.

To solve this problem, personal property ownership must be introduced so that owners have an interest in maintaining the productive capacity of the land because they now share the full costs of any excessive exploitation. The general principle is that individuals will exploit anything that is free to maximize their own gain, with a cost to society. The commons cannot possibly work once the population has become too great. Hardin applied this principle to human reproduction, arguing that people who have many children are imposing a cost on society that they do not fully bear. Hardin argues that coercion is necessary to reduce reproduction of children, just as the freedom to rob a bank is curtailed by criminal law.

In "Lifeboat Ethics," Hardin argues that immigration is a major cause of population increase in the developed world, and he advocates the reduction of immigration to nearly zero. The analogy is that a lifeboat (developed nation) can hold a certain number of people. If more people (developing nation) climb into a boat that is full (to carrying capacity), the lifeboat sinks and everyone drowns. The rational course of action for those already in the boat is to refuse additional passengers.

This is, Hardin admits, a "tough-love ethics" founded on the principle that Earth has a limited carrying capacity for the size of population it can accommodate. Hardin believes the optimum carrying capacity of the United States was reached in the middle of the twentieth century, and that further increases in population will degrade the quality of human life. As the number of people increases, so do pressures on the natural resource base, resulting in suffering and misery.

A further argument in Hardin's work is that multiculturalism provides another reason to reduce immigration. For Hardin, social disorder is promoted by increasing the diversity of the groups encouraged to reside in the United States: "Diversity within a nation destroys unity and leads to civil wars. Immigration, a benefit during the youth of a nation, can act as a disease in its mature state. Too much internal diversity in large nations has led to violence and disintegration" (Hardin 1993, p. 42).

Hardin's prescription for the Third World population explosion is for First World nations to cease food aid, allowing Third World nations to solve their problem of having exceeded their carrying capacity. Food aid leads to more babies being born and surviving, increasing population size, and requiring more assistance in the future. The only aid First World countries should give to the Third World is information about birth control and contraceptives. If a country is poor and powerless because of too many people, it will become even poorer and more powerless by increasing its population.

Merging biological principles with ethical considerations, Hardin argued for the responsible assessment of the environment to optimize the quality of life for present and future generations. He confronted the human condition and its intricate connection with the natural world in an effort to encourage society to effectively deal with the population-resource equation so that posterity will not be subjected to enforced processes of poverty, starvation, and social disorder.

HARDWARE AND SOFTWARE

The invention of the computer hardware/software distinction is credited to computer scientist John Tukey (1915–2000), who also first used the term *bit* for memory capacity. Many think that the difference between hardware and software is obvious. One rule of thumb defines hardware as the computer stuff one can bump into. But others emphasize the logical equivalence of computer hardware and software: "Any operation performed by software can also be built directly into the hardware . . . any instruction executed by the hardware can also be simulated in software." (Tanenbaum 1999, p. 8)

Often computer hardware conjures up an image of a central processing unit (CPU) or a memory chip, not the wire that connects the mouse to a keyboard. But all physical entities that are part of a computer should be considered hardware, although some hardware is more directly involved with the symbol manipulation power of a computer than other hardware.

Tangibility and Functionality

Ruminations about the distinctions between hardware and software can lead to interesting contrasts. The hardware is a machine whose state changes as it operates, but whose form is difficult to change. (A light switch alternates between on and off positions, but one rarely changes its constituent parts.) As it executes, a software program remains static (except for self modifying programs, an exception that proves the rule), but the program causes changes in the hardware state (memory) and external devices (such as printers). And that same software that is static during execution is far easier to change between executions than the hardware that constantly changes its state during execution. To better understand the hardware/software distinction, it is useful to consider three distinct aspects of both: tangibility, functionality, and malleability.

Tangibility: If a computing entity is defined by its physical presence, it is hardware. If an entity is independent of any particular physical form, it is software. Notice that a tangible "hardware" can take many physical forms. The double helix spiral of DNA uses proteins as its hardware. The genetic patterns coded therein are software.

Functionality: If a computing entity has as its primary purpose a physical function, it is hardware. If the entity has as its primary purpose a logical function, it is software. Here "logic" is used to mean symbol manipulation, the transformation of bits according to syntactic and semantic rules. A particular set of bits could mean an integer or printable characters, depending on the rules in force. The bits themselves are represented by hardware, but the rules governing their interpretation are software.

Malleability: If a computing entity is relatively easy to change, it is software. If the entity is relatively hard to change, it is hardware. Of the three aspects, this is the one most in flux. The increasing range of options with respect to malleability has led to an intermediate designation, firmware.

Two early examples of computing illustrate the first two distinctions, tangibility and functionality. The first example is the Jacquard loom, the second a Turing machine.

In 1801 Joseph Jacquard invented a weaving loom using stiff pasteboard cards with holes that controlled rods for each step in the weave. These cards led to the punched cards used by Herman Hollerith for computing machines. Jacquard's physical loom, wood and metal, was hardware. The pasteboard of the punched cards was hardware. But the pattern of holes in the cards, and the desired pattern in the cloth, were software. Even in this *ancient* example of computing, there is an interplay between hardware and software. The software of the weaving pattern is realized in and by the loom hardware. In an almost mystical way, the cloth pattern is in, with, and under its hardware implementation. The threads that go through Jacquard's loom are tangible, and fall under the category hardware. But after the loom does its work, the threads become an embodiment of the software pattern represented (indirectly) by the punched holes in the pasteboard cards.

A Turing machine is a theoretical construct in computer science, and is composed of states, a recording tape, and a read/write head (Turing 1936). A computation proceeds by changing states and by reading and writing symbols to the tape. Turing machines are thought experiments, not physical objects, but *could* be manufactured. A recording head and its tape are tangible hardware with a primarily physical function, the recording of symbols. Whatever medium is used to represent different states inside the Turing machine would also be hardware. But the algorithm embodied in the states and the transitions between them is logical, and software. Note that whatever medium is used to embody an algorithm *is* tangible, but that the algorithm itself does not depend on the details of any particular medium. The same algorithm could simultaneously exist in a human brain, on a piece of paper, and in a Turing machine. Each manifestation would simultaneously be physically different and logically identical.

In the same way that a building embodies an architect's plans, a Turing machine embodies an algorithm. The Turing machine analog to an architectural plan is an algorithm; the Turing machine analog to a building is the Turing machine hardware. The architectural analogy is more apt for a Turning machine than for modern, multipurpose computers, because each Turing machine is customized to a single algorithm. Contemporary computers are far more complex than Jacquard's loom or a simple Turing machine. But the relationship between computer hardware and software is consistent with the relationship illustrated in these examples. In all computing machines, hardware implements software, and the software is embodied in the hardware. The software instructs the hardware, and the hardware manifests the actions described in the software.

Despite these examples, controversies remain. There is not much controversy about some hardware/software distinctions in modern computers. CPUs and memory chips are hardware. The algorithms implemented on that hardware are software. But not everyone agrees on other classifications. For example, some people label data as computer software, whereas others explicitly exclude data from being either computer software or hardware. But source code is a widely accepted example of software, and source code is data to the appropriate interpreter or compiler. If data is not software, then the same program is or is not software, depending on how one looks at it.

Some computing scientists and engineers include designs, user manuals, and online help as software, while others explicitly exclude such entities from consideration. It may be misleading to label all documents associated with a program as software. But designs and specification documents are closely related to algorithms. Some designs can be automatically transformed into machine language with minimal human intervention. It may thus be useful to classify as software documents directly related to program development.

Algorithms used when a computer is powered on are typically stored in special memory devices called read-only memory (ROM), that comes in various forms (PROM, EPROM, and EEPROM). These kinds of devices are easier to change than other hardware but harder to change than programs stored on a hard drive. The term *firmware* was coined to designate this intermediate form of malleability. Malleability (or its opposite, resistance to change) is the third criterion for hardware and software: If a computing entity is easy to change, it is software; if an entity is difficult to change, it is hardware; and if it is intermediate in this aspect, it is firmware. A closer argument is required here: The *state* of hardware may be easy to change (much computer hardware is a variation on the on/off switch); but the hardware itself (think of a light switch attached to a wall) is difficult to change. Thus an arithmetic/logic unit is hardware because it has permanently etched silicon algorithms for its calculations, and a C++ program residing on a hard drive is software because it can be more readily modified and recompiled. Although the use of firmware is commonplace, the ethical implications of the hardware/software distinction do not require this middle ground of malleability as a separate category.

Implications of the Hardware/Software Distinction

Some interest in the hardware/software distinction is associated with legal issues. Insofar as a computing entity is a mechanical device (hardware), it is subject to the same body of law that governs ladders and lawnmowers. Insofar as a computer entity functions as an algorithm (software), the laws of intellectual property and professional service are more germane. Hardware designs can be patented, software programs can be copyrighted.

The hardware/software distinction also has ethical implications. On an abstract level, algorithms are pure software. But to have a physical effect, an algorithm is embodied in some physical entity. The nature of the embodiment, the particular hardware chosen, has important ethical implications. For example, if an algorithm is embodied exclusively in a single brain, its ownership as a private thought is uncontroversial; but when the thought is shared as a written document, ethical issues of intellectual property instantly arise. Similarly an algorithmic thought has few consequences for others until it is implemented; when implemented, the algorithm can have important consequences.

When deciding how to embody an algorithm, one must select a location on the malleability continuum. Typically an emphasis on hardware implementation (for example, etched permanently in silicon) will encourage a more reliable implementation and less complex functionality than an implementation in software (such as using a high level programming language). Hardware implementations are more economically feasible when they are mass produced, so widely used algorithms for the many are more likely to be implemented in hardware, whereas customized algorithms for the few are more likely to be implemented in software. The questions of delivery schedules, *how good is good enough*, and a developer's obligations to customers are examples of the ethically charged issues inherent in any implementation decision. As the costs of fabricating hardware fall and the costs of writing software rise, judgments with regard to such issues may have to be reconsidered.

As computing becomes ubiquitous, software tends to replace hardware to deliver certain functionalities. Airplanes provide a dramatic example of this trend. First fighter jets and then commercial airliners have substituted complex computer algorithms for mechanical controls. The computer algorithms enable the newer airplanes to fly more efficiently and economically. But the redundancy of hardware is difficult to replicate in software (software defects tend to reoccur in a way that hardware defects do not), and this has consequences for the reliability of life-critical systems that rely increasingly on software for their safety. These differences result in ethically significant choices between more efficient operations using software and more expensive but safer hardware devices. As these tradeoffs becoming increasingly common, the different traditions of professionals in different engineering fields can become an ethical issue. For example, software engineers are rarely licensed (in the United States, only Texas issues a software engineering license, and corporate software engineers aren't required to obtain that license either), but other engineers in safety critical applications can be licensed. In this case, the hardware/software distinction may help determine the state's interest in certifying professional competence.

A final example of the ethical importance of the hardware/software distinction has less to do with computing professionals and more to do with the non-programming public and how they view problems with computing. Computers can be a handy scapegoat: "We can't help you with that right now; the computer's down." "Impossible. There's no way to type that into the computer." "I don't remember that email. I guess the computer ate it."

Most people know that *software bugs* are the responsibility of programmers. But organizations and individuals can sometimes hide behind the hardware of their machines. Emphasizing the hardware aspects of computers can help create an artificial distance between the general public and human errors in software. This de-emphasis of human accountability is a danger lurking in the hardware/software distinction. The reality is that algorithms are human artifacts for which humans are responsible, no matter how they are implemented.

The ethical challenges lurking within the hardware/software distinction are reflected in legal and political controversies. There is freeware, shareware, and open source software; but there is no parallel movement to declare computer hardware free. The patent system has been, in the main, successful at protecting hardware innovations, but copyright, patent, trademark, and trade secrecy have each proven problematic in a different way when applied to computer software. Controversies over new laws that criminalize what was once considered legitimate reverse engineering of software have highlighted the importance of understanding the differences between hardware and software.

HAZARDOUS WASTE

SEE *Waste.*

HAZARDS

Hazards are low-probability, high-magnitude phenomena that have the potential to cause large negative impacts on people. While this definition is unavoidably imprecise (what counts as a "phenomenon"? what probabilities qualify as "low"? and what impacts qualify as "large" or even "negative"?), in general hazards can be understood as acting outside of daily human expectations to adversely affect the quality of life of those exposed to them. Hazards refer to a prospect or risk of an occurrence; a particular occurrence of a hazard is more typically termed a "disaster" or sometimes an "extreme event"; when they are technological in origin they may be termed "accidents."

The remains of a trailer park in Miami, Florida, destroyed during Hurricane Andrew. Andrew was one of the most destructive hurricanes ever to hit the U.S., raging from August 16 to August 28, 1992. *(© Tony Arruza/Corbis.)*

Some types of phenomena—such as hurricanes, earthquakes, landslides, and reactor meltdowns—are unambiguously classified as hazards, whereas others, especially those that are less temporally or spatially discrete, such as droughts, famines, and epidemics, may or may not be included under the term, depending on who does the classifying. Wars and other types of human conflict are generally not categorized as hazards.

A related use of the word "hazard" refers to existing conditions of the environment that may pose a risk to humans, such as a toxic waste site or even the edge of a cliff. Similarly, hazardous materials are those that may create a risk to human or environmental health if exposure to them is not regulated and controlled. This entry, however, focuses on hazards as dynamic phenomena, not as static conditions or material properties.

In the ten-year period 1992 to 2001, hazardous events, or disasters, worldwide were responsible for more than 620,000 deaths. Drought caused almost 45 percent of these deaths; floods, earthquakes, and windstorms caused most of the remainder. An additional 2 billion people required immediate assistance (60% as a result of floods), and the direct costs due to the destruction of infrastructure, crops, homes, and so on was more than $600 billion (with earthquakes, floods, and windstorms making up about 90% of this total). To put these numbers in some perspective, every year hazards seriously disrupt the lives of as many people as the entire population of Brazil or Indonesia, and cost about as much as the entire economic output of Pakistan or Peru (World Health Organization, United Nations Development Programme 2002).

Hazards Are Not Natural

Hazards are commonly divided into two types: natural and technological. Technological hazards are those arising from the failure of technological devices or systems to behave as intended. Natural hazards arise from nonhuman forces and can be subdivided into geophysical hazards, such as volcanoes, earthquakes, and tsunamis, and hydrometeorological hazards, such as hurricanes, floods, and tornadoes. Natural and technological hazards, however, are often related to each other, in that natural disasters may trigger technological failures, for example of power grids or dams. Moreover, natural hazards must be understood not simply as the result of natural phenomena, but as arising from the socioeconomic context within which such phenomena occur.

Human *exposure* to hazards results from humans living in areas where hazards are present; human *vulnerability* to hazards arises from the types of development exposed to hazards. The consequences of hazards are determined as much or more by the extent of exposure and level of vulnerability than by the characteristics of the hazard itself. Thus, for example, when a magnitude 6.9 earthquake struck a densely populated region in Armenia in December 1988, more than 25,000 people died and 1.6 million were directly affected. When, ten months later, a similar magnitude earthquake struck a highly populated region of California (the October 1989 Loma Prieta event near Santa Cruz), sixty-three people died and fewer than 10,000 were affected. This stark difference in impacts was largely a reflection of poor design and construction standards for buildings in Armenia compared to those in California. Moreover, despite Armenia's much lower level of economic development, its economic losses from the 1988 event, estimated at about $14 billion, were greater than the estimated $6-to-$10 billion price tag of Loma Prieta.

The inseparability of hazards from their social context is clearly illustrated by historical trends in disasters, which show a continual and rapid increase in the number of disasters, rising from a worldwide average of about 100 per year in the early 1960s to between 300 and 500 per year by the early 2000s. ("Disasters" here is defined by the World Health Organization's Collaborating Centre for Research on the Epidemiology of Disasters [CRED] as events that kill at least ten people, affect at least 100, result in a call for international assistance, or result in a declaration of emergency.) While some of this increase reflects changes in reporting, most of it arises from increased exposure and vulnerability throughout the world because of growing population, expanding economies, migrations to coasts and other vulnerable regions, increasing urbanization, and related factors. These changes are especially reflected in the costs of major disasters, which according to the German insurance company Munich Re rose more than tenfold in the second half of the twentieth century, from an average—in real (2002) U.S. dollars—of about $4 billion per year in the 1950s to more than $65 billion in the 1990s.

It is important to emphasize that these increases are best explained by changes in social context, not changes in the occurrence or type of hazardous events. For example, it has been well documented that rapidly increasing economic losses from hurricanes striking the U.S. eastern seaboard are caused by growing population and wealth, not by increased frequency or magnitude of storms. The great Miami hurricane of 1926 caused about $76 million in damage (in inflation-adjusted dollars); when Hurricane Andrew, of similar force, struck south Florida in 1992, it caused more than $30 billion in damage (Pielke and Landsea 1998).

Complexity of Hazards

Because hazards are socially embedded, their impacts arise from the complex interaction of many variables. In Armenia, steel that had originally been produced to reinforce buildings was diverted to weapons construction instead, thus revealing cold war geopolitics as one source of vulnerability to the 1988 earthquake (Mileti 1999).

Hurricane Mitch, which in October and November of 1998 killed more than 10,000 people and caused severe economic and social disruption in Central America, was responsible for triggering a mudslide in Nicaragua that killed about 2,000 people (Olson et al. 2001). The mudslide, however, was created not just by the torrential rains brought by Mitch, but also by land-use patterns that led to deforestation of a steep mountain slope, which collapsed when it became saturated with water. Eighteen months later, a debris flow in Manila, Philippines, triggered by normal monsoon rains, killed about 200 people. But in this case the disaster occurred on the flank of a huge landfill where thousands of people scavenged garbage for a living.

In Chicago, a heat wave in the summer of 1995 led to the death of more than 700 people. The temperatures in Chicago were no higher than those regularly experienced in many places; the huge number of casualties was instead caused by a combination of failed social services (for example, insufficient number of emergency vehicles and workers) and the large number of people, mostly poor and elderly, living alone, without resort to social networks (Klinenberg 2002).

Such examples also show that a preliminary event may trigger additional hazards that may themselves be damaging or that may combine with the principal hazard to multiply damages. For example, the Chicago heat wave led to technological failures in the form of power outages and water service interruptions that made it more difficult for people to cope. Major disasters may also trigger disease outbreaks, especially when water supplies are cut off or contaminated. The 1906 San Francisco earthquake is often called the San Francisco Fire because of the disastrous conflagrations it caused throughout the city. These sorts of complexities also underscore the futility of making a clear distinction between natural and technological hazards.

Uneven Distribution of Hazard Impacts

The impacts of hazards are disproportionately borne by poor people living in poor regions and countries; thus, hazards are a manifestation of socioeconomic inequality and an issue of social justice. While the poorest thirty-five countries account for only about 10 percent of the world population, they suffered more than half of the disaster-caused deaths between 1992 and 2001. Of those directly affected by disasters during that decade, almost 90 percent lived in Asia, where dense populations combine with high vulnerability and widespread poverty in nations such as India, China, and Indonesia. As the contrast between the Armenia and Loma Prieta earthquakes starkly shows, the benefits of affluence include a capacity to protect against the most direct and devastating effects of hazards, and a significant component of this capacity is the scientific and technological infrastructure that typically accompanies (and fuels) the growth of affluence.

Not surprisingly, affluent nations suffer the greatest absolute economic losses from hazards. The disproportionately large sizes of their economies create the potential for much greater economic damage from the impacts of hazards. For the decade 1992 to 2001, the forty-five richest countries (making up about 18 percent of global population and accounting for 82 percent of global wealth) experienced about 62 percent of total global economic damage from hazards. As a percentage of gross national product (GNP), however, the economic effects of hazards on poor countries are about 100 times greater than for rich countries. Damages from Hurricane Mitch, for example, were estimated at between $5 billion and $7 billion, which was about the same as the annual combined total GNP of the two most affected nations, Honduras and Nicaragua. The magnitude 6.7 Northridge, California, earthquake of 1994 was the most costly disaster in U.S. history, causing between $20 billion and $40 billion in losses; the total, however, was equivalent to only between about 2 and 4 percent of California's economic activity for that year.

Disparities between rich and poor will compound over time. Global population growth is mostly concentrated in poor countries and leads to rapid urbanization, usually in vulnerable coastal zones, as well as dense rural populations. Unregulated land use translates into widespread environmental degradation, especially deforestation, which in turn exacerbates flooding and related phenomena such as mudflows, debris flows, and landslides. Design and construction standards are typically low, and even when adequate building codes exist, corruption, lack of enforcement, and insufficient resources result in an unsafe built environment. Emergency response capabilities are often inadequate, and hazard insurance is usually unavailable, slowing the recovery process. Technological infrastructure, such as communication and transportation systems, is typically fragile, and capacity to repair damaged systems is limited. Such factors reinforce one another to magnify the vulnerability of poor people and nations to hazards, and they act as a brake on development.

Mitigation

In the affluent world, numerous approaches have been adopted to mitigate the effects of hazards, including building codes that are appropriate to known risks; land-use regulations for floodplains, coastal zones, and seismic zones; and dams, levees, and other engineering interventions for floodplain management. There is little question that such measures, combined with early warning systems for hurricanes, tornadoes, and floods, and coordinated emergency response plans, have limited the human and economic toll of hazards in the developed world. Nevertheless, while the number of people killed and injured has declined for some hazards, and stayed relatively stable for others, the economic costs of hazards appear to be rising at an exponential rate. Absent mitigation efforts, they would be rising more rapidly still.

Despite aggressive mitigation efforts, affluent nations are not exempt from major disasters. The magnitude 7.2 earthquake that struck Kobe, Japan, in January 1995 killed 6,000 people and led to an estimated $100 billion in damages, yet Japan is justifiably considered to have the world's most sophisticated and effective earthquake hazard mitigation practices. In the U.S. Midwest, decades of flood control engineering preceded the 1993 Mississippi River basin floods that caused $18 billion in damages and that arguably constituted, in the aggregate, the worst flood in U.S. history (Changnon 1996).

Such events point to the complexity of mitigating hazards. While mitigation efforts may protect against anticipated or typical hazards, they may also have the effect of attracting more people to live and work in hazardous areas, thus increasing exposure over the long term to even larger events. (This trend is reinforced by the apparent security provided by hazard insurance and disaster relief programs.)

Mitigation of hydrological hazards in particular can alter the function of natural systems in ways that are not sustainable over the long term, both because such altered systems may behave in unanticipated ways and because "unprecedented," and thus unplanned-for, events will inevitably occur at some point, in some areas. Mitigation efforts, it seems—especially those focused on trying to control the behavior of the environment through engineered structures—may have the affect of trading a number of smaller, more manageable events in the short-to-medium term for much greater disasters in the more distant future. This can become a self-perpetuating and self-amplifying process, because after a disaster occurs political pressure inevitably focuses on allowing people to return to their homes and businesses to reopen, which in turn requires increased commitment to environmental control via structural hazard mitigation.

Policy Assessment

While societies have an obligation to limit the negative effects of hazards on people and economies, such action should be informed by the inevitability of hazards, rather than a vain quest to eliminate their impacts or occurrence. Such a perspective focuses on the characteristics of human development, rather than the control of nature, as the cornerstone of effective mitigation. For example, environmental degradation invariably exacerbates hazard damages by altering or destroying natural features that buffer the impacts of hazards—such as forests that stabilize steep slopes, floodplains that allow for dispersion of floodwaters, and coastal lagoons that absorb storm surges. Mitigation policies that keep such features intact, and govern land use in ways that protect them over the long term, are likely to be successful both because they preserve natural function and because they thereby limit human development in particularly hazard-prone areas. In acknowledgement of these realities, after the 1993 floods in the Midwest, the U.S. government increased efforts to *remove* floodplain structures—thus returning some of the natural function of the river—and relocate flood-prone communities to higher ground.

Yet it remains to be seen if it is possible to actually stabilize or reduce the costs of natural hazards in developed countries characterized by continual growth of wealth, infrastructure, urban centers, coastal and wildland development, and overall interconnectedness. Hazards may simply be an unavoidable overhead cost on the growth of affluence.

Outside of the developed world, however, the path to reducing the toll of hazards is clear, if difficult to follow. Poverty and the conditions associated with it—poorly constructed and maintained housing and infrastructure, degraded environmental conditions, rapidly increasing populations, insufficient or ineffective social and emergency services, lack of technical capacity—are the nutrients of hazards. At the global scale, reducing poverty, and the environmental degradation and failures of governance that accompany it, will continue to be the most effective strategy for hazard mitigation.

HEALTH AND DISEASE

Why care about the precise definitions of the words *health, disease,* and *illness?* Their meanings seem self-evident: Health is the absence of disease, illness the experience of disease. However the multiple dimensions of these concepts, their moral underpinnings, and the purposes for which they are used are enormously complex, especially in a technological society strongly oriented toward the production of health.

Health and disease are more than just medical terms; they have social, political, moral, and economic dimensions. For example, a pharmaceutical company may advertise its new compound as the cure for a heretofore-unnamed disease such as erectile dysfunction or attention deficit disorder (ADD). Medical or disability coverage is granted or denied based on sociopolitical interpretations of what constitutes a disease or disability. A couple decides to use in vitro fertilization and preimplantation genetic screening to avoid creating a baby with a genetic disease or one who will be a carrier of a diseased gene. Or perhaps a soft drink producer enhances sales by touting the benefits of its new and improved *healthier* beverages. Professional codes of ethics commonly commit engineers to protect public safety, health, and welfare. The concepts of health and disease are invoked in various ways, for purposes weighty and mundane.

Indeed health has been construed not simply as the absence of disease (whatever that is), but much more. In the preamble to its constitution, the World Health Organization (WHO) defines health as "a state of complete physical, mental and social well-being not merely the absence of disease or infirmity." Such statements rely on medico-moral presuppositions of what a disease actually is, how and which diseases ought to be treated, and ultimately on visions of what it means to live the good life.

Recognition of the complexity of the concepts of health and disease has stimulated scholarship in the fields of history and philosophy of medicine, sociology of medicine, and the medicalization of deviance, as well as crucially important policy developments in managed care and resource allocation. Philosophical questions range from clarifying the ontological status of disease (What is a disease?) to understanding particular conditions and the meaning of being diseased. The social sciences, including medical sociology and anthropology, examine the extent to which disease is a value-laden concept shaped and socially constructed. How do power relations influence what is considered to be normal and healthy or abnormal and diseased? On the level of individual experience, still other questions emerge: What is the personal meaning of being healthy or sick? At what point, if any, are the sick blameworthy for their illnesses? What role ought a sick person play in society? How does stigma affect the sick? More broadly framed questions regarding matters of policy ask what responsibilities society has to care for those who are diseased or ill.

Different responses to such questions are associated with diverse historical and philosophical approaches to health and disease. Sociological contributions to the debate and their policy implications also deserve consideration. This simple conceptual breakdown is appropriate for present purposes, but it is important to note that a more holistic picture requires interdisciplinary dialogue.

Historical Sketch

The concepts of health and disease were foundational to the ancient medical arts and bound up with distinct philosophical perspectives. To explain illness or symptoms of disease, as well as to cure the sick, pre-Socratic philosophers and ancient Greek physicians in the Hippocratic tradition (c. 400 B.C.E.) developed a basic explanation of health as balance (*isonomia*). The balance of the four humors—black and yellow bile, phlegm, and blood—in conjunction with environmental and temporal factors was central to the formalized model of health created by the Greek physician Galen (130–199 C.E.). A rudimentary nosology (classification of diseases) was developed around the imbalance of the humors.

Galen's humoral model persisted through the Middle Ages when it was augmented by Christian ideals of salvific suffering. Although the link between disease and sin was not a new development, moral dimensions of health and disease were described in terms of tests from God, punishment for sin, or demonic possession (Gunderman 2000). Toward the end of the Middle Ages, a new model was espoused by the physician-philosopher Paracelsus (Philippus Aureolus Theophrastus Bombastus von Hohenheim 1493–1541) indicating three elemental components (salt, mercury, and sulfur) as critical to healthy physiology. Paracelsus went on to claim that diseases were not simply internal imbalances, but rather resulted from autonomous entities "springing from the body" (Vichow 1981, p. 192). The ontologists—those thinkers who viewed diseases as actual entities—find the roots of their approach in the work of Paracelsus.

Modern concepts of health and disease (and the practice of scientific medicine itself) are grounded in Cartesian dualism. René Descartes (1596–1650) separated the mind and the body, and described the body as a set of parts working together according to mechanical rules. Because disease was the malfunctioning of the bodily machine, treatment consisted of diagnosing the malfunction and repairing the body, bringing it back to normal functioning (von Engelhardt 1995).

Over the next few centuries, the locus of disease shifted from the macroscopic to the microscopic, and eventually to the molecular. Contributions by the anatomists at the University of Padua—in particular Giovanni Morgagni (1682–1771)—opened discussion on pathophysiology and etiology through postmortem dissections of diseased organs. Marie Francis Xavier Bichat (1771–1802) explained the origins of disease in terms of histopathology—disease in tissues. On the cellular level, Rudolf Virchow (1821–1902) synthesized breakthroughs in bacteriology and microbiology and described *mycotic* diseases in terms of *ens morbi* and *causa morbi* (a being with a cause), and as a disruption in interrelated cellular *territories* which, in turn, compound and spread the disease process. With the rediscovery of Mendelian genetics in the late-nineteenth century, *inheritance factors* were singled out as disease entities that caused such disorders as Huntingdon's Disease and sickle cell anemia. Indeed sickle cell anemia was the first modern genetic disease identified as such by Linus Pauling.

In contrast to the ontologists were the nomino-physiologists, such as François-Joseph-Victor Broussais (1772–1838), who opposed the idea that diseases were actual entities. Such entity-based nosologies, he claimed, were not classifications of disease entities but rather were driven by a physician's instrumental and pragmatic need to diagnose or prognosticate. Claude Bernard (1813–1878) emphasized the need for clinical experimentation and observation in describing diseases. Through his diverse research projects, particularly studies of digestion, glycogen function, and vasoconstriction and dilation, Bernard developed physiological models that emphasized homeostasis and feedback loops in the regulation and maintenance of health. So too, the American physiologist Walter Cannon (1871–1945), in *The Wisdom of the Body* (1932), described health and disease in homeostatic terms.

Philosophical Trends

Philosophers of medicine and science began a more formal analysis of the concepts of health and disease during the first half of the twentieth century. The medical history and epistemology of Georges Canguilhem (1904–1995) and his student Michel Foucault (1926–1984) stimulated a renewed discussion of the normal and the pathological. Eventually a cannon of philosophical writings on the concepts of health and disease was formed during the period 1960 to 1981, a development that was driven in part by the birth and development of bioethics and its need for definitional precision for basic medical concepts (Caplan et al. 1981).

During the 1970s, a conceptual dichotomy in philosophy of medicine developed as new accounts of the status of disease took two tracks. First, reminiscent of the earliest philosophical constructions of disease, various versions of naturalism reemerged. Naturalistic accounts explained disease as deviations in natural form and function. As such, a disease was described as an entity or causal factor of that deviation independent of social norms or cultural values. This perspective is sometimes referred to as nonnormativism (Caplan 1988). Christopher Boorse (1975) presented the quintessential nonnormative position by referring to an objective biological framework that guides the identification and diagnosis of disease:

> [B]ehind this conceptual framework of medical practice stands an autonomous framework of medical theory, a body of doctrine that describes the functioning of a healthy body, classifies various deviations from such functioning as diseases, predicts their behavior under various forms of treatment, etc. This theoretical corpus looks in every way continuous with theory in biology and the other natural sciences, and I believe it to be value-free. (Boorse 1975, p. 55.)

In contrast, normativist philosophers point to the value-laden nature of disease constructions, eschewing the possibility that natural is definable and that diseases are value-free. These scholars directly counter the Boorsian model by pointing to research in philosophy and sociology of science that described science and medicine as social endeavors. Because of this social embeddedness, an autonomous and value-free framework of medico-biological theory does not exist independently of values. (Kuhn 1962, Longino 1990, Engelhardt 1981). Arthur Caplan, H. Tristam Engelhardt, and Joseph Margolis are among those who write a defense of moderate normativism. Caplan (1981) points out that, while some objective criteria for defining disease exist, nonnormativism as characterized by Boorse is fraught with conceptual inadequacies. Some conditions generally considered to be normal or natural (e.g., the common cold, dental plaque, acne, and others) are disvalued, while others considered to be abnormal may be valued (for example, dysfunctional gonads in a person who does not wish to reproduce). Margolis (1976) claimed that while certain biological functions may be conceived in universal terms, the actual concept necessarily reflects the state of the technology, social explanations, division of labor, and the environmental conditions of a given population. Engelhardt (1974) describes the pragmatic and value-laden nature of the concept of disease particularly in his historical exposition of the *disease* of masturbation.

The philosophical debate about the nature of somatic disease spills over into the analysis of mental health and disease. With the rise of scientific medicine, the prevailing model of psychiatric illness became biologically based. Mental illness was considered similar to other somatic diseases, rooted in a dysfunction, or even an *ens morbus*. This model was vigorously challenged by physician George Engel (1913–1999) as being overly reductionistic; he offered his own biopsychosocial model to account for the role of relationships and society in health and disease (Engel 1977). Thomas Szasz's *The Myth of Mental Illness* (1961) attacked the notion that mental illness was a disease of the brain or that mental illness existed at all. Szasz claimed that the notion of mental illness was a way to subjugate dissidents of the community's collective ethos or assuage sick individuals of their responsibilities.

In the early-twenty-first century, genetic technology and medicine as well as the results of the Human Genome Project added another level of complexity to analyses of health and disease. A greater understanding of epigenetics and the complexities of gene-environment interactions show it is difficult to identify the genetic causes of diseases that are outside the basic Mendelian framework. Nonetheless health and disease are increasingly described in genetic terms. Reification of genetic anomalies as being diseases has raised the very real possibility that all people are *diseased* in some way (Jüngst 2000).

Sociological Perspectives and the Medicalization of Deviance

Philosophical debates about health and disease as normative concepts grade into descriptive analyses of how society constructs, describes, and reacts to the realities of health, disease, and illness. Talcott Parsons (1902–1979) explained the concepts of health and illness as manifestations of certain role-types.

In framing the *sick role*, Parsons took the first step in describing illness as a form of deviant behavior legitimized by the medical institution (Bosk 1995). The sick role is characterized first by an exemption from social duties, exculpating patients for their illness. Parsons described the physician-patient relationship as analogous to the relationship between a child and parent in which the patient follows doctor's orders in a team effort directed toward the patient's wellness. Often this is a form of social control because a sick person needs to enlist the help of persons who are not sick and their *therapeutic agencies*.

Some social scientists have theorized the construction of disease emerges out of power structures, sanctioned under the guise of medical objectivity. Looking back in history, an early example of this dynamic was the description of drapetomania—a disease of slaves that caused them to try to run away. Physician Samuel Cartwright (1793–1868) presented an account of this disease and potential cures, which included, first, kind treatment, but later various forms of severe bondage and punishment. Since then, health and disease have sometimes been hijacked in the name of ideology or the *betterment of common good*. In hindsight these instances are obvious, for example, eugenics movements during the early-twentieth century in the United States and in Germany in which *diseased* individuals, their families, or their entire race were *treated* (Caplan 1992b). In contrast to these more egregious cases, some social scientists suggest more insidious forms of disease construction have occurred through the medicalization of deviant behavior.

Peter Conrad (1975, 2000) describes how hyperkinesis—now called attention deficit and hyperactivity disorder (ADHD)—became a disease. Conrad explains that, with the invention of the stimulant Ritalin and observation of its paradoxical effect on children, the manufacturer, CIBA, sought to market the compound to parents and teachers of unruly children. The *cure* preceded the *disease*. The administration of a drug that reigned in nonconformist children strengthened the status quo: educational systems not equipped to accommodate certain children and parents released from blame for their children's behavior. Similar examples can be found in feminist accounts of the social construction and medicalization of menopause and premenstrual syndrome (McCrea 1983, Richardson 1995).

Labeling theorists, such as Howard Becker (1928), describe the actions of *moral entrepreneurs* who create and enforce social rules. In medicine, moral entrepreneurs may be physicians who ascribe the label *diseased* to those who break with accepted conventions, thus suppressing or stripping them of opportunity, thereby expanding their own domain of professional influence (Becker 1963, Pfohl 1977, Bosk 1995).

As a result of labeling, stigma is often closely associated with disease. In certain cases, sick people remain closeted because of the stigma of their illness. Norma Ware (1992) offers the example of chronic fatigue syndrome. Delegitimation of the subjective experience of illness leads to further suffering arising from the stigma of the disorder, the alienation resulting from a decision to keep the illness secret, and the shame of being *wrong* in one's own definition of reality.

Broad Policy Implications

The ways in which the concepts of health and disease are framed have significant impact on health policy. In particular, defining what constitutes the appropriate level of medical care provided by a just society has been difficult to determine.

Several nosological frameworks driving insurance schedules and socialized coverage plans have been espoused over the years. Norman Daniels, in *Just Health Care* (1994), proposes a policy framework based not on definitions of disease or health but on *species-typical functioning*. Daniels proposes that normal functioning is an important baseline not because it is *natural*, but because it is a convenient point at which to determine what society should owe to its members. Indeed a consensus of what society ought to give to all its members has been elusive precisely because a common framework of health and disease has been impossible to construct.

Equally important to providing care and treatment of disease is the scientific quest to prevent and cure disease. Operational definitions of health and disease ground biomedical research priorities in government and private funding agencies. The National Institutes of Health (NIH) determine research priorities based on a broad range of criteria related to severity of diseases, epidemiological evidence, cost-benefit analyses, as well as projects that offer promises and opportunities, and interest groups/patient lobbying. Investment in research and development and biotechnology, as well as in allied fields of technology, rest on the social framework and disciplinary matrix within which technicians work. As such core concepts such as health and disease have a profound, albeit overlooked, influence on the trajectory of important advancements in technology.

The concepts of health and disease underlie decisions to fund basic bench research through clinical biomedical research and public health initiatives. Clearly a robust understanding of the complexities of these concepts is crucial for policymakers, clinicians, and patients alike.

HEAVY METALS

Heavy metals is a common toxicological term covering a number of metallic substances that acutely damage human beings and ecosystems, and whose atomic weights fall between and 64 and 201. Those responsible for the most injuries and deaths are lead, mercury, and cadmium. Others with toxic properties—for example zinc, beryllium, chromium, aluminum, bismuth, manganese, and copper—are frequently listed as *heavy*, but because their atomic weights fall below 64 are not chemically regarded as such. A term better-suited to all these substances might simply be *toxic*.

Another toxic material, arsenic, is often included among the heavy metals but chemists see arsenic as a semimetal because its chemical and physical properties are only partially metallic. Thus they advocate a separate classification for this substance that since the 1980s has been poisoning well water and damaging the health of hundreds of thousands of villagers in Bangladesh and West Bengal, India.

Origin and Issues

Metals leach into living systems from natural ore deposits. But by far the major sources of toxic entry are emissions and wastes from mining and smelting operations, manufacturing processes, power plant emissions, waste incinerators, and through such consumer items as fuel additives, dental amalgams, toys, paints, light bulbs, plumbing, electronic devices, even vaccines and herbal dietary supplements. Toxic metals are ubiquitous, persistent, and controversial, and because they destroy critical enzymes can be savage in their toxic effects.

Accordingly the regulation of these substances has taken many forms, from public health and consumer protection laws to measures that control air, land, and water contamination. International treaties are probably inevitable, since these metals disperse throughout the ecosphere, cross national boundaries, essentially never degrade, and accumulate to toxic concentrations in fruits, vegetables, farm animals, and seafood. The major practical approach to their control is capture, followed by impounding.

Heavy metals history is replete with stories of environmental injustice and regulatory lethargy. Children and developing fetuses are the most tragic victims, usually suffering from cancer and serious neural disorders such as Parkinsonism and mental retardation. Increasing bodies of evidence indicate that high toxic chemical levels also correlate geographically with high crime rates, raising important legal and ethical questions as to whether polluters should be liable for offenses that promote criminal behavior in persons exposed to metallic emissions.

State, local, and federal regulations over the last three decades of the twentieth century reduced public exposure to these substances. But localized incidents remain frequent in the early-twenty-first century and the legacy of past abuses poses persistent problems through the presence, for example, of industrial waste or Superfund sites that have not yet been cleaned up (or in technical jargon, *remediated*). The history of heavy metals toxicity is a particularly tragic one, marked by bitter conflicts over surreptitious dumping, disposal in areas populated by poor people, exposure to children, lack of equitable compensation of victims, and corporations that are unwilling or unable to pay for control and cleanup.

Mercury

One of the earliest, most heartrending modern instances of heavy metal poisoning was the disaster that occurred in Minamata, Japan, during the 1950s and 1960s when mercury was discharged from a plastics manufacturing plant into the waters of Minamata Bay. The metal, in the form of methyl mercury, accumulated in the bodies of fish that were the food staple for the thousands of persons who lived in that section of southwestern Japan. The pathological result was painful neural disorders that had distressing physiological, social, and psychological effects on the people of Minamata.

Mercury's largest single source is the combustion of coal in power plants, a problem that grows as global industrial economies expand. The challenge is enormous and international health and environmental advisory bodies have urged regulations that call for removal of 90 percent of mercury from such emissions. (Cadmium and lead are also significant emission components.)

Mercury regulation has been a controversial issue in the United States for several years, mainly over government attempts to amend the Clear Air Act in favor of less stringent standards for emissions. Relaxation of standards and regulations has always been under fierce debate in toxic metals regulation, but in the case of mercury, the underlying conflict has been more closely related to the government's market-based approach to regulation as opposed to regulatory procedures specific to conditions near emission sites. The regulatory hope among experts in toxic metals research and regulation is to construct an international treaty similar to the Kyoto protocol that was established to reduce carbon dioxide emissions from industrial operations and thus decrease global warming. In other words, if all industrial operations adhered to low to zero emission standards, environmentalists believe the world would be a much safer place.

In any case, the public and environmental agencies at all levels of government are now acutely aware of the dangers of mercury. Disposal from mining operations remain a problem throughout the world and disputes over health effects and liability generate headlines almost daily. Likewise mercury contamination in ocean fish such as tuna, mackerel, and salmon remains a constant concern. Mercury in dental amalgam was for years a major cause of concern, but due to intense public attention that issue has subsided in recent years.

Lead

Lead contamination is more widely recognized than mercury contamination but vigilance over its dangers has helped to establish broad measures to bring exposure under control. A metal widely used since early times and treasured as a decorative and culinary material in ancient Rome, lead's toxic problems have been known for centuries. Since the mid-twentieth century, thousands of children have suffered the effects of lead poisoning by ingesting or absorbing lead from toys, painted household items, playground soil, and refuse left after the demolition of homes and buildings.

But in the broader sense, it was the overall public health implications of lead in gasoline (in the form of tetraethyl lead) that caused most of the initial furor over the need to control it in the environment. The U.S. petroleum and auto industries successfully fought efforts to end its use. However when the auto industry began installing catalytic converters to comply with U.S. air pollution laws, testing determined that lead rendered the devices inactive. The auto industry had no alternative but to demand development of lead-free gasoline. Leaded gasoline, however, is still in use in many countries.

Lead from mining has always been an environmental and public health problem and remains so in the early-twenty-first century. A typical industrial example is emissions from the smelter at the Bunker Hill lead mine in

Pinehurst, Idaho, during the 1970s. For years fallout from the smelter contaminated the air in the area around Pinehurst. The Center for Disease Control (CDC) tested children in the area for blood-lead levels and found the highest amounts ever recorded in human beings.

On the whole, however, laws, regulations, and a high degree of watchfulness have brought the lead problem relatively under control, though lead poisoning incidents, especially in old housing, continue to be of concern, as do lead emissions from mining and smelting facilities around the world.

Cadmium and Chromium

Cadmium and chromium come from a variety of sources from cigarette smoke to smelting operations to increasingly voluminous waste from electronic devices. They enter living systems from alloys, pigments, batteries, metal coatings, electronic devices, mining operations, and industrial emissions. Cadmium especially affects the kidneys and lungs, but it also causes testicular damage, lung disease, and bone disease.

Chromium, for its part, is an essential nutrient in very small amounts. It is involved in manufacturing chrome-plated materials, tanned leather, dyes and pigments, and wood preservatives. It enters living things mainly through the air and underground water. Extended exposure to chromium can cause asthma, lung cancer, and ulcers.

Controversies

Chemists dislike the term heavy metals because of its inherent imprecision and often urge that it be abandoned. In 2002 the International Union of Pure and Applied Chemistry—the organization that sets the standards for chemistry's precise nomenclature—issued a technical report titled, "Heavy Metals—A Meaningless Term?" that reflected the frustration felt by the chemical community over the term's loose usage by those outside the field of basic chemistry. The term heavy metal, the report pointed out, "has even been applied to semimetals (metalloids) such as arsenic, presumably because of the hidden assumption that 'heaviness' and 'toxicity' are in some ways identical" (p. 796).

The report bemoaned what it called "the persistence of the term and its continuing use in literature, policy, and regulations" (p. 797). It stated,

> There is no similarity in properties between pure tin, which has low toxicity, and tributyltin oxide, which is highly toxic to oysters and dog whelks. Nor is there any similarity in properties between chromium in stainless steel, which is essentially nontoxic, and the chromate ion which has been associated with causing lung cancer. Thus, the tendency to group certain metals and their compounds together for toxicity assessment under the title 'heavy metals' must lead to fuzzy thinking and is another reason to abandon the term. (p. 799).

Ethical issues surrounding the heavy metals parallel those associated with harm caused by toxic substances in general. Tension always exists between producers of these substances and those exposed to them, often leading to tort damage claims and prolonged litigation. Those who believe industry should be held liable for injuries caused by toxic metal emissions have been turning for support to a relatively new legal theory known as the neurotoxity hypothesis. This hypothesis derives from neurochemical research that suggests that criminal behavior in individuals correlates with high levels of lead, manganese, and cadmium in the bodies of those individuals. Further research reinforcing such new insights could lead to changes in tort law that would impose stricter regulatory standards for these substances and more criminally related penalties for violators.

HEGEL, GEORG WILHELM FRIEDRICH

German philosopher Georg Wilhelm Friedrich Hegel (1770–1831), born in Stuttgart on August 27 and

Georg Wilhelm Friedrich Hegel, 1770–1831. The German philosopher and educator took all of knowledge as his domain and made original contributions to the understanding of history, law, logic, art, religion, and philosophy. *(The Library of Congress.)*

educated at the University of Tübingen, gained intellectual renown while teaching at the University of Berlin. A thoroughly systematic thinker, Hegel viewed philosophy, natural science, history, ethics, and religion as inherently connected in a whole that included difference while simultaneously transcending it. As a result, he presents the kind of comprehensive interpretation of science, technology, and ethics that is often implicit but seldom articulated in contemporary discussions, which, in light of Hegel, are challenged to move beyond particular case studies. Perhaps most famous for his *Phenomenology of Spirit* (1807), Hegel died suddenly on November 14 during a cholera epidemic.

Science and Technology in Hegel's System

For Hegel, the truths of the empirical (or special) sciences are justified only by the thinking at work in philosophy. Put another way, natural science occupies a middle point between sensation and philosophy. Just as sense experience needs science to grasp its deepest truths, so science requires philosophy.

The relationship between natural science and philosophy is best understood in terms of four modes of consciousness: sense-certainty, perception, understanding, and reason. The empirical sciences build on sense-certainty and perception to establish laws and theories. This move toward universality indicates that understanding is predominant in natural science. What the empirical sciences provide are nevertheless mere facts and concepts that are founded on fixed categories (for example, cause and effect, substance and accidents) that are accepted uncritically. Such a detailed explication of nature has a relative immediacy when viewed from the perspective of self-conscious reason and its characteristic philosophical thinking. It thus becomes the task of philosophy to give final meaning to what the sciences reveal by criticizing their inherent conflicts and contradictions on the way to establishing a unified synthesis in which these differences are preserved while being overcome. Ultimately, the empirical sciences are a necessary and integral phase in the development of consciousness and a crucial first step toward the rational unveiling of what Hegel calls Spirit in nature.

Hegel's view of technology emerges from his defense of the distinctly modern assertion that all knowing involves making. In accordance with this doctrine, Hegel maintains that human beings produce both themselves and their world. Individuals are only insofar as they are productive. In one's relationship with the natural world, such production manifests itself as work, a mediating activity pervaded by the tools one uses. Technology, therefore, emerges as formative for human beings insofar as it allows them to assert themselves over and against their physical environment. Though such is the case with even basic tools, it becomes most evident with the emergence of machines, the effectively self-reliant tools that deceive nature into working toward human ends. Whereas science aids in discovering the Spirit implicit in nature through observation, technology is the human way of actively manifesting Spirit in the natural world, which is continuously transformed through work.

Hegel's Influence

Hegel's initial influence rested with his ability to go beyond the distinction that his predecessor Immanuel Kant (1724–1804) made between phenomenal appearances (which are scientifically knowable) and things-in-themselves (which ground all phenomena, but remain unknowable in all respects other than their actual existence). Against Kant, Hegel argues that systematic philosophical reflection, in grasping the cognitive genesis of scientific knowledge and its contribution to self-consciousness, can indeed know reality in its entirety (that is, both phenomenal appearances and things-in-themselves), because there could not in principle be anything beyond such a synthetic whole.

The first generation of Hegel's followers nevertheless looked more to the practical implications of transcendence, thus proposing a further overcoming of Hegel himself that would make his philosophical synthesis, especially the notion of a self-consciousness that simultaneously makes the world and itself, into a lived reality. It was for this reason that Karl Marx (1818–1883) sought to turn Hegel right-side up and thereby place him on his feet (*The Holy Family*, 1845), not just to understand the world but to change it ("Theses on Feuerbach," 1845). Marx's critique centers around the plight of industrial workers and the alienation they experience in regard to the products of their labor, their work activity, and, above all, their humanity (*Economic and Philosophical Manuscripts*, 1844).

But it was another philosopher, Ernst Kapp (1808–1896), who took the technological implications of Hegel most seriously, and in doing so was the first to speak of a "philosophy of technology." Drawing on Hegel's theory of history, Kapp's materialism took historical evolution to be the result of humanity's various attempts to overcome the constraints of nature (*Vergleichende allgemeine Erdkunde*, 1845). Insofar as such an overcoming necessarily involves technological innovation, Kapp reflected extensively on the nature of tools, construing them as "organ projections" that essentially act as extensions of the human body (*Grundlinien einer Philosophie der Technik*, 1877).

The Master–Slave Dialectic

The historical and ethical import of Hegel's views on technology are best gleaned from his master–slave dialectic, a doctrine interpreted at length by Alexandre Kojève (1902–1968), whose post–World War II lectures, though idiosyncratic, proved influential. For Kojève history begins with the first battle that ends with a victorious master and a vanquished slave. In risking life for genuine human recognition, the master spurns a merely biological existence, thus triumphing over the slaves who, for fear of death, succumb to the master in order to preserve their lives. Through human conquest, the master achieves an independence that, at least for the time being, remains foreign to the slave. The slave works for the master, forced to struggle with an often recalcitrant nature in order to provide for the master's needs.

In spite of the seemingly unenviable position of the slaves, true human progress and genuine freedom would be impossible without them. Masters, freed from dealing with nature, live a life of leisure that consumes the products of nature without any compensatory replenishment. Slaves, by contrast, learn to confront nature, an imposition that obliges them to understand nature in order to control it. It is slaves, then, who develop science and technology and who, unlike masters, are the true creators. Only through such scientific and technological development is progress made and historical change enacted.

Furthermore, the path to true freedom finally becomes apparent as the freedom of the master ultimately reveals itself as false. Though a master achieves a measure of independence from the physical environment, this is an achievement that remains dependent on the activity of the slaves. Slaves, for their part, achieve scientific understanding and create technological innovations that clear the way for a genuine freedom by surmounting nature directly and becoming independent of the services of still other slaves.

Conclusion: The Ethical Dimension

The evolution of science and technology, for Hegel, has direct ethical implications. In marking desire as intrinsic to self-consciousness, Hegel maintains that real human satisfaction can be had only in and through the recognition of another self-conscious subject. Though the master sought such recognition in his relationship with the slave, slavish recognition is necessarily ungratifying insofar as it is given by a slave who is, by definition, less than fully human. Genuine human satisfaction, therefore, will be had only when the master–slave relationship comes to an end and the human beings involved recognize each other as equals.

This ethical ideal of reciprocal recognition is first envisioned by slaves who see how people can free themselves from their merely biological existence and thereby assert their dignity in a way other than the masterly domination of other human beings. Through scientific understanding and the technological mastery of nature, the master–slave relationship can be overcome, reciprocal recognition achieved, and genuine freedom finally won. For Kojève, such an occurrence will mark the end of history because the struggle for recognition, which is the principal cause of historical change, comes to an end.

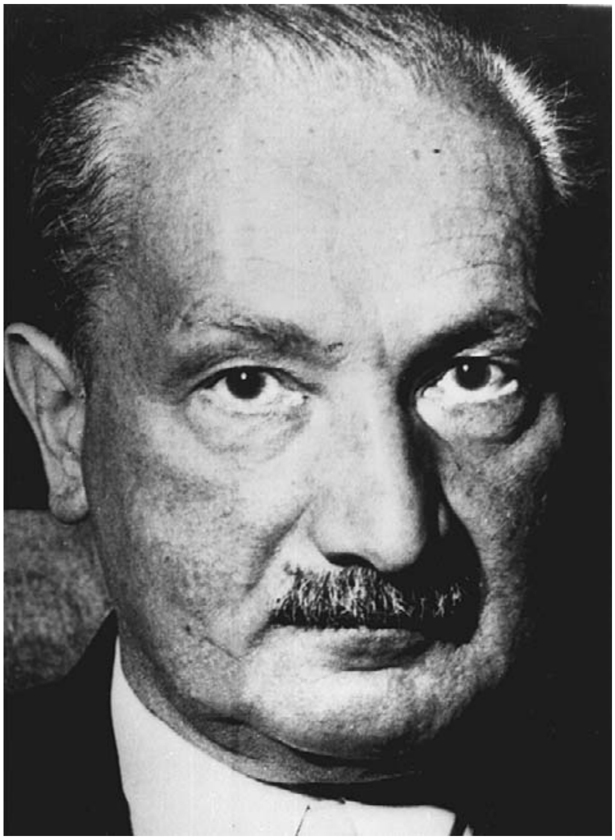
A careful summary of Hegel's *Phenomenlogy* that illuminates what is principally at stake in the text itself while locating Hegel more generally within the Western philosophical tradition.

HEIDEGGER, MARTIN

Martin Heidegger (1889–1976), who was born in Messkirch, Germany, on September 26 and died there on May 26, was among the most important thinkers of the twentieth century. His significance for science, technology, and ethics may be approached from four directions.

Theoretical Science and Practical Activities

Heidegger's first and still most important book, *Sein und Zeit* (1927; English trans. *Being and Time*, 1962), is a cornerstone of the existentialism that became prominent after World War II. The book's major terms—anxiety, resoluteness, everydayness, authenticity, concern, care,



Martin Heidegger, 1889–1976. The German philosopher has become widely regarded as the most original 20th century philosopher. Recent interpretations of his philosophy closely associate him with existentialism (despite his repudiation of such interpretations) and, controversially, with National Socialist (Nazi) politics. *(AP/Wide World Photos.)*

and the like—are concepts Heidegger helps make intellectually cogent. Albert Camus (1913–1960) and Jean-Paul Sartre (1905–1980) work on territory Heidegger opened up philosophically.

Heidegger's own goal, however, was not to outline a theory of human beings as radically insecure or irrationally committed, but to uncover the central openness of human beings to being as such. Humans are the entities for whom how to be is always an issue. This is true for everyone and not merely true generally or abstractly. Heidegger's goal is to clarify the question of being by working out what being is and how it matters for each human being.

Heidegger's analysis in *Being and Time* follows a path that begins with the significance of ordinary human concerns and concludes with the temporal meaning of being. The usual implicit meaning of being is that which is most fully or eternally present. As a result humans conceive all things as essentially static entities with fixed, general characteristics suitable for neutral measuring, spatially and temporally. People objectify even their own selves in this manner. The meaningful present, however, cannot exist apart from the ordinary worlds of significance into which people find themselves thrown. This richer temporality, not static presence, is the heart of being human, and the clue to being as such. There is a historical and temporal motion, indeed, a dizzying abyss beneath all presence.

The relation between theory and practice that Heidegger's analysis suggests has important implications for understanding scientific technology. Purely theoretical enterprises such as natural science or mathematics depend on views of time and space that flatten or narrow the rich meanings of being projected in the ordinary worlds of action and concern. Dealing with things as they are actually used is primary; theoretical and scientific analysis is secondary. The right time and place to use particular tools cannot be determined, for example, from the neutral coordinates of physics, but are inherent in use itself. Instead, physics abstracts from and narrows the richness of tools that do their jobs usefully in the appropriate place and time.

This narrowing does not mean, however, that what science discovers is false in its own realm. The relativism or inordinate human responsibility for meaning that is inseparable from Heidegger's understanding does not imply that everything is magically at human disposal. Rather, what natural science discovers may be correct, but humans must see how it is grounded on the broader truths of being and of human openness to being.

The History of Science

Many of the works of Heidegger and his followers include some notion that use, practice, and everyday concern precede the flattening on which modern science and technology are built. Indeed, this view has served as the basis for Heidegger's influence on academic studies in the history of science. Heidegger's teacher Edmund Husserl (1859–1938) and several of Heidegger's students or those he affected, such as Jacob Klein (1899–1978) and Alexander Koyré (1892–1964), made important contributions to the history of mathematics and science. Klein's *Greek Mathematical Thought and the Origin of Algebra* (1934) and Koyré's *Galileo Studies* (1939) may even be said to have transformed the field, because Heidegger's procedure, which influenced them, involved a relentless search for the experience and understanding at the heart of worn-out philosophical concepts commonly employed by academic history.

To grasp the existential origin of scientific concepts was to uncover their meaning, power, and range. Heidegger himself explored in various places the original Greek understanding of nature (*phusis*) and the changed understanding of nature and motion that differentiates Aristotelian and Newtonian physics. His 1936 lecture course "Die Frage nach dem Ding" (published in 1962; English trans. *What Is a Thing?* 1967) is especially cogent in this regard.

The Technology Question

Heidegger's most direct discussion of scientific technology is in his "Die Frage nach der Technik," delivered in early versions in the 1940s and published in 1954 (English trans. *The Question concerning Technology,* 1977). His analysis became a basic text for those worried about the power and dominance of contemporary technology. Both directly and indirectly it has influenced thinkers and activists (such as the German Greens) who in the name of the environment opposed growing industrialization and mechanization. Here and in other works, Heidegger's prescient sense of the importance of information science and life chemistry also connects his views to pressing controversies of the day.

Heidegger argues that the essence of technology is nothing technological, that is, that technology is not itself a tool or implement. Rather, the essence of technology involves the manner in which things first present themselves in the contemporary world, namely, as "standing reserve" to be manipulated or rearranged at will. Everything approaches humans as a source of energy, a human "resource," a matter to be organized. Lost in this scenario are the independence of things, their distinctive presence and shape, and the way in which they take place in a meaningful world they help to form. The simple bridge across a river allows the river to meander and stand forth in its own power; the dam that helps to generate electricity transforms this river into an implement interchangeable with other energy resources. Because people see themselves so generally as resources to be manipulated, they become alienated from their roots and traditions, and from the significance of birth and death. Technology sunders human beings from the lifetimes and the times of life that give individuals weight and direction.

Heidegger does not seek to solve the problem of technology directly or to overcome humanity's technological leveling. To do so would make his own effort one more link in the strangling technological chain. Rather, he tries to show that as the predominant presentation of beings today, technology itself must open to and be placed in being as such. The apparent technological annihilation of all other significance becomes a clue to the source of meaning generally. The results of uncovering this source cannot be predicted. But being and human openness to it can be addressed and discussed in the manner of *Being and Time*, or in the more direct yet more elusive way of some of Heidegger's work from the mid-1930s on, in which discussions of poetry and gods come to the fore.

The Nazi Question

Heidegger's work is tainted by his association with the Nazis. He joined the National Socialist Party when he became rector of Freiburg University in May 1933, whereupon he praised Adolf Hitler publicly. The intensity of his support subsequently diminished, and some remarks in his lectures may be read as opposition to the views of Nazi ideologues. Other remarks continued to defend the Nazis, however, and he remained a party member throughout World War II.

The important question for students of Heidegger and of technology is whether his support of the Nazis flows from his philosophical arguments or, rather, stems from personal idiosyncrasy or political naïveté. It would be difficult to take seriously a thinker whose discussions of what it is to be a human being were in no way linked to political actions and judgments; Heidegger's arguments do, in fact, display such a link. Heidegger's thought leads to immoderation and illiberalism because the standpoint from which he confronts issues is too encompassing to allow relevant ethical distinctions to matter or even become clear. Too many issues that to a responsible citizen or political leader involve significant differences between what is just and unjust look, from Heidegger's ontological point of view, to be the same. The substance of his understanding of human openness to being, moreover, with its emphasis on fate, authentic resolve, and the *Volk* (people), allows Heidegger to believe he has found essential links between his thought and the Nazis, and to accommodate his rhetoric to theirs.

It would be incorrect to claim that Heidegger's philosophical immoderation or basic concepts led him inevitably to support the Nazis or to approve all of Hitler's actions. The Nazis, he believed, ultimately failed to live up to what he called in 1935 "the inner truth and greatness of this movement." In the *Introduction to Metaphysics*, the version of 1935 lectures that he published in 1953, he described this "truth" and "greatness" as "the encounter between global technology and modern humanity. This same standpoint, however, led him not only (finally) to question the Nazis but to also treat the substance of Soviet Marxism, American democratic capitalism, and failed Nazism as essentially identical. The ethical and political immoderation to which Heidegger's view of technology can lead is strikingly captured not only in his political judgment but also in his identification of mechanized agriculture and the Holocaust: "Agriculture is now a motorized food industry, essentially the same as the manufacture of corpses in gas chambers and extermination camps, the same as the blockade and starvation of countries, the same as the manufacture of hydrogen bombs" (Polt 1999, p. 172, translating from Heidegger's "Das Ge-Stell").

Heidegger's thought cannot be reduced to his connection to the Nazis. His understanding of being and being human revitalized the study of philosophy by encouraging an encounter with the phenomena that the great works of Western thought have in view. His central concepts stimulated many to rethink the true sources of human freedom, excellence, and happiness. His view of scientific technology captures its breadth and centrality in a novel and still cogent manner. The paths he helped to open, however, can become closed by dogmatic application of his procedures. Heidegger's politics, moreover, encourage more than ordinary caution in dealing with his insights.

HINDU PERSPECTIVES

Hinduism is the oldest of the major world religions, and also apparently one of the most accepting of modern science and technology. It provides a central place to consciousness in its approach to reality, which explains why it has appealed both to scientists looking for a role of observers in physics and biology and also to those who have been critical of standard science for its emphasis on mechanistic explanations.

The origins of Hinduism are not found in a single individual, and its texts go back to antiquity in India. Within the tradition, it is called the Sanātana Dharma or Vedic Dharma (*sanātana* meaning eternal, *veda* meaning knowledge); the term Hindu originally referred to the inhabitants of the Indian subcontinent. The various sects of Hinduism take the Vedas (second millennium B.C.E., or perhaps a bit earlier), which are collections of hymns, to be their canonical texts. But the Vedas are difficult to understand, and for practical reasons, most Hindus rely on later texts such as the Upanishads, the Bhagavad Gītā, and the Epics (first millennium B.C.E.), Sūtras, Āgamas, Shāstras, Purānas (whose time frames range from centuries B.C.E. to texts as late as about 1000 C.E.) for guidance.

Hinduism takes phenomenal reality to be a projection of God (Brahman), who is both transcendent and immanent. In its transcendent form, Brahman is beyond any attributes; in its immanent form it may be visualized in many different ways, leading to a multiplicity of representations. The evolution of the universe is by laws (*rita*), yet sentient beings have freedom. The law of karma constrains ordinary action, but a realized person is free.

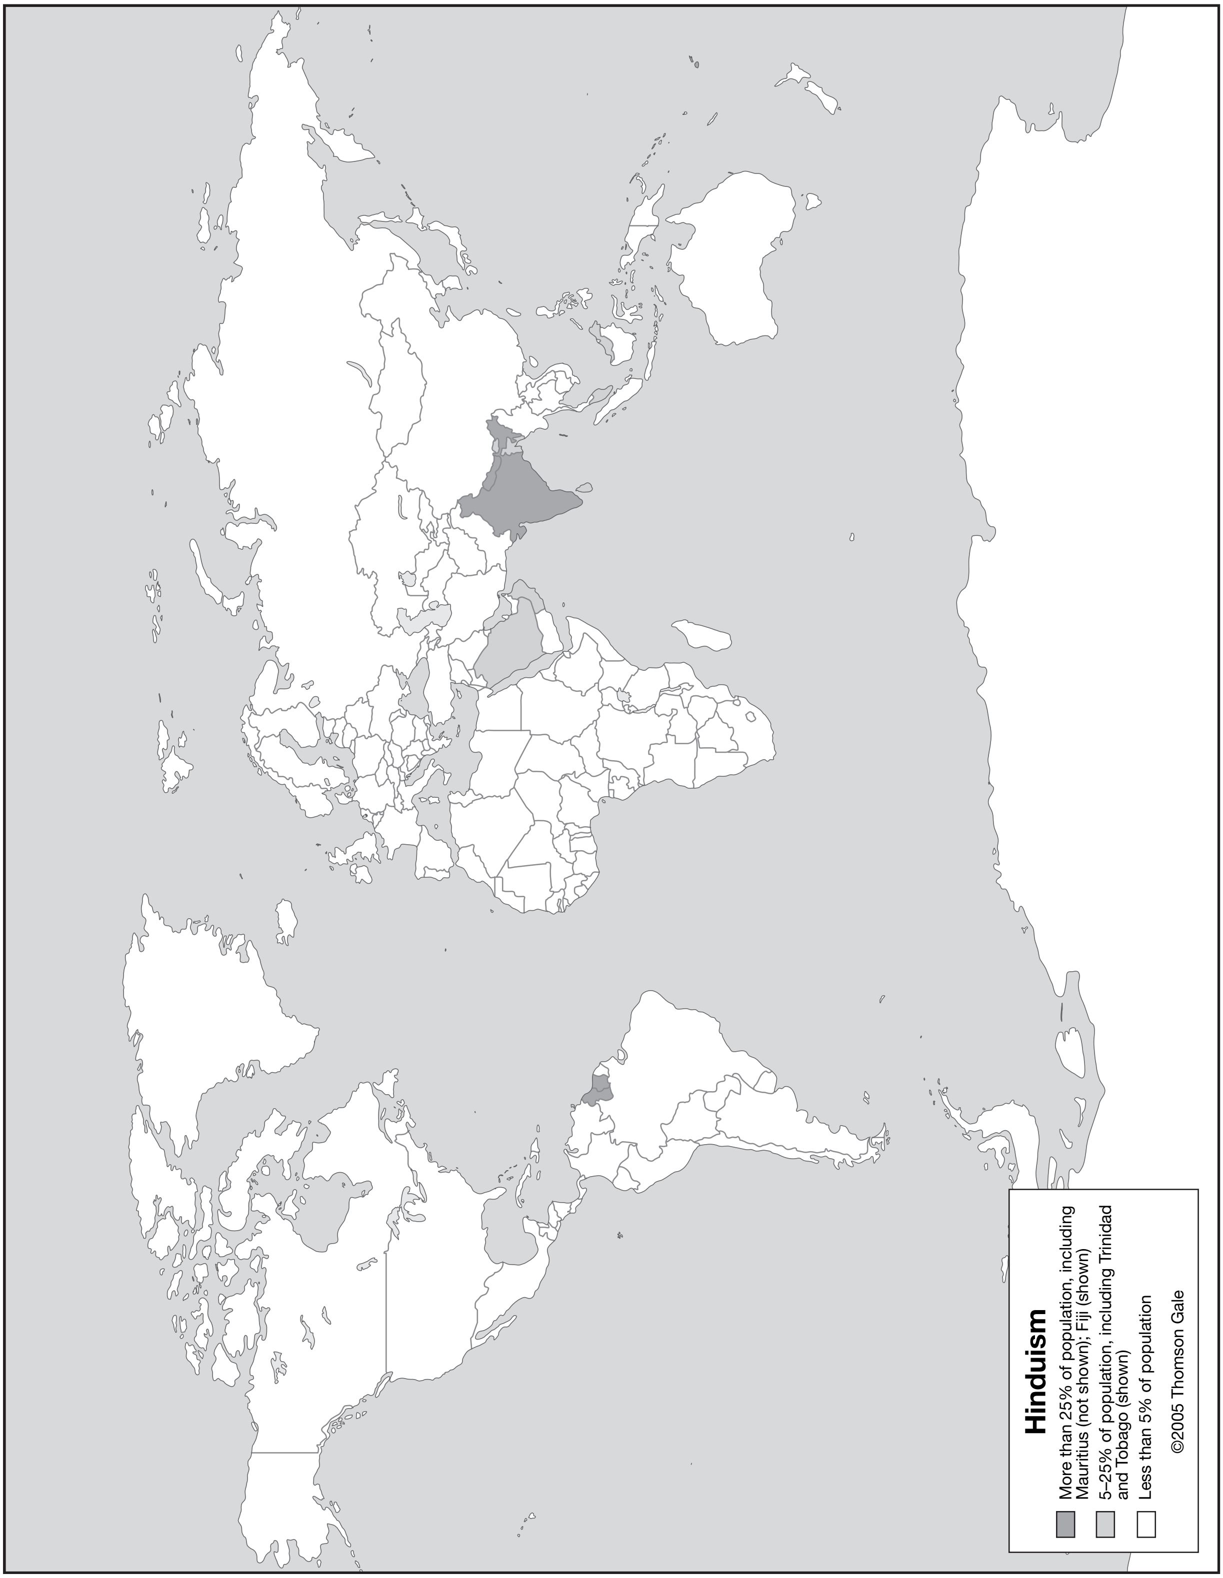
The Vedic texts claim that language cannot describe reality completely, although its mystery may be experienced fully. Knowledge is classified in two ways: the lower or dual; and the higher or unified. The lower knowledge, which describes the objective world, is obtained using logic and it is accessible by language. The higher knowledge concerns the experiencing self and is beyond ordinary language. The seemingly irreconcilable worlds of the material and the conscious are aspects of the same transcendental reality. Hinduism is supportive of all scientific exploration, believing that at its end one becomes aware of its limitations and the need to reach the mystery of the experiencing self. From a personal perspective, Hinduism is concerned with techniques that make self-transformation possible. Hinduism thus endorses both science and technology although not necessarily in their modern forms or for distinctly modern reasons.

Hinduism approaches the world in an ecological sense. Not only humans, but also animals, are conceived as sentient and, therefore, deserving of compassion. The Hindu approach to reality is through *jnāna* (intuitive understanding) that includes subjective and objective knowledge, value and fact, and consciousness and reality. *Jnāna* presupposes *jijnāsā,* a reaching out to understand, that leads to a spark of illumination. *Jnāna* requires the ethics of the individual as an indispensable condition for knowledge, which thus is not value free. Search for truth is a value orientation.

Historical Background

The history of early Hinduism is tied to the history of India. Its chronological time frame is provided by the archaeological record that has been traced, in an unbroken tradition, to about 8000 B.C.E. Prior to this are records of rock paintings believed to be considerably older. The earliest textual source is the Rigveda, which is a compilation of very ancient material. The astronomical references in the Vedic books recall events of the third or the fourth millennium B.C.E. and earlier. The recent discovery that Sarasvati, the preeminent river of the Rigvedic times, went dry around 1900 B.C.E. due to tectonic upheavals suggests that portions of the Rigveda were written prior to this epoch. According to traditional history, the Rigveda was written before 3100 B.C.E.

The other Vedic texts of the Yajurveda, the Sāmaveda, and the Atharvaveda borrow heavily from the Rigveda. The Brahmanas are prose works that describe



Hinduism

the Vedic ritual, and the Upanishads address philosophical issues. Ethical questions are directly addressed in the Sūtra literature, the Rāmāyana and the Mahābhārata, the Purānas, and the commentaries on these texts that have been written from time to time. Since the medieval times, the Bhagavad Gītā and the Rāmāyana have influenced millions, including Mahatma Gandhi.

Outside India, in the second millennium B.C.E., the ruling Mitannis in West Asia worshiped Vedic gods. The religion of Iran before Zoroastrianism was Vedic. Hindu religion spread to various countries in Southeast Asia in the first millennium B.C.E. and the largest Hindu temple in the world is found in Cambodia. In the twentieth century, Vedanta and Yoga have spread the popularity of Hinduism to Europe and North America.

Academic narratives of Hinduism emphasize issues related to social hierarchy, customs, and sectarian divisions around the worship of Vishnu, Shiva, and the Goddess. In reality, the social classes are not rigid, and most Hindus worship all the deities, although they might personally be more devoted to one or another. To understand why Hindus do not find it troubling to be devoted to more than one deity, it is necessary to examine the common thread of Vedic cosmology running through the tradition.

VEDIC COSMOLOGY. Briefly the Vedic texts present a tripartite and recursive view of the world. The universe is viewed as three regions of earth, space, and sky that in the human being are mirrored in the physical body, breath (*prāna*), and mind. The processes in these regions are connected as the consequence of a binding (*bandhu*) between various inner and outer phenomena. At one level, it means awareness that certain biological cycles, such as menstruation, have the same period as the moon. At another level, equations are postulated, such as the 360 bones of the infant (which fuse into the 206 bones of the adult) that correspond to the number of days in the civil year.

The connection between the outer and inner cosmos is seen most strikingly in the use of the number 108 in Indian religious and artistic expression. Elementary geometrical reasoning establishes that this number is the approximate distance from the earth to the sun and the moon in sun and moon diameters, respectively. The diameter of the sun is also approximately 108 times the diameter of the earth, but that fact is not likely to have been known to the Vedic sages. The number of dance poses given in the Nātya Shāstra is 108, as is the number of beads in a rosary. The *distance* between the body and the inner sun is also 108, which to span, symbolically, one uses 108 names of the deity in worship. The number of weak points in the body in Āyurveda, the Hindu medicine system, is 107, because in a chain 108 units long, the number of weak points would be one less.

The Vedas are primarily concerned about universal laws related to the inner self (*adhyātma vidyā*) that are true for all times. The Hindu experience is thus not contingent on a particular account of history, or an event that cannot be replicated. Complementing the Veda, which is the *heard* revelation (*shruti*), is the remembered tradition (*smriti*). As custom, *smriti* is considered appropriate for time and location and thus subject to change. This has allowed Hinduism to adapt to change over the millenniums.

VISHNU, SHIVA, AND THE GODDESS. Although the principles of Hinduism may appear very abstract, in practice Hindus relate to a personal deity much like followers of other religions. When viewed as the ethical principle, Brahman is Vishnu; as the inner Self, it is Shiva; and seen as the energy of Nature, it is the Goddess. Although at one level Vishnu and Shiva are the Preserver and the Destroyer; at another level, due to recursion, both Vishnu and Shiva, as well as the Goddess, are each the Creator, the Preserver, and the Destroyer. Furthermore each god has a goddess as consort, emphasizing the complementarity of the two. Shiva and the Goddess are also viewed as a single deity, as half of a whole, called Ardhanārīshvara, and Vishnu and Shiva as a single deity called Harihara.

Hinduism and Science

In Hinduism, the dividing line between objective sciences and *adhyātma vidyā* (spiritual knowledge) is the logical or linguistic paradox. Logical argument and rational proof using Nyāya is the way to obtain correct knowledge. But where paradox (*paroksha*) begins, one must let go of linguistic associations to experience paradox-free, deeper knowledge.

Nyāya's beginnings go back to the Vedic period, but its first systematic elucidation is Akshapāda Gotama's *Nyāya Sūtra*, dated to the third century B.C.E. Its text begins with the nature of doubt and the means of proof, and it considers the nature of self, body, senses, and their objects, cognition and mind.

The Nyāya system supposes that human beings are constructed to seek truth. Their minds are not empty slates; the very constitution of the mind provides some knowledge of the nature of the world. The four *pramānas* through which correct knowledge is acquired are *pratyaksha*, or direct perception; *anumāna*, or inference; *upamāna*, or analogy; and *shabda*, or verbal testimony. Four factors are involved in direct perception: the senses, their objects, the contact of the senses and the objects, and the cognition produced by this contact. The mind mediates between the self and the senses. When the mind is in contact with one sensory organ, it cannot be in contact with another. It is therefore said to be atomic in dimension. It is because of the nature of the mind that one's experiences are essentially linear, although quick succession of impressions may give the appearance of simultaneity.

The Nyāya attacks the Buddhist idea that no knowledge is certain by pointing out that this statement itself contradicts the claim by its certainty. One can check whether cognitions apply to reality by determining if they lead to successful action. Valid knowledge leads to successful action, unlike erroneous knowledge.

The evolution of the universe is ordained by cosmic law. Because it cannot arise out of nothing, the universe must be infinitely old. Because it must evolve, there are cycles of chaos and order or creation and destruction.

According to the atomic doctrine of Kanāda, there are nine classes of substances: ether, space, and time that are continuous; four elementary substances (or particles) called earth, air, water, and fire that are atomic; and two kinds of mind, one omnipresent and another that is the individual. The conscious subject is separate from the material reality but is, nevertheless, able to direct its own evolution.

The Mahābhārata and the Purānas address the question of creation. It is said that humans arose at the end of a chain, at the beginning of which were plants and various kind of animals. In Vedic evolution the urge to evolve into higher forms is taken to be inherent in nature. A system of evolution from inanimate to progressively higher life is a consequence of the different proportions of the three basic attributes of *sattva, rajas*, and *tamas*, which represent transparence, activity, and inertia, respectively. In its undeveloped state, cosmic matter has these qualities in equilibrium. As the world evolves, one or another of these becomes preponderant in different objects or beings, giving specific character to each.

Unlike the Abrahamic religions, whose eschatology is centered on the dead rising to the heavens, Hindu visions of the end of the world are naturalistic. For example, the Mahābhārata (Shānti Parva, Chapter 233) speaks of how a dozen suns will begin to burn when the time comes for universal dissolution a few billion years in the future. First all things mobile and immobile on Earth will disappear merging into the elements, making it, shorn of trees and plants, look as naked as a tortoise shell. Next Earth will melt, and then vaporize and become heat and wind. Then wind will be transformed into space, with its attribute of unheard or unuttered sound. Finally space will withdraw into Mind, ultimately merging into Consciousness, which is the origin of reality.

In Vedic discourse, the cognitive centers of the mind are called *devas*, deities or gods, or luminous loci. The Atharvaveda calls the human body the City of Devas. The number of devas is variously given, the most extravagant estimates are 3.3 million. All devas are taken to embody the same light of consciousness. The mind consists of discrete agents, although it retains a unity. Because each deva reflects primordial consciousness, one can access the mystery of consciousness through any of them.

When the cognitive centers nearer the sense-organs are viewed in anthropomorphic terms, they are called *rishis*, sages. The Yajurveda declares that seven sages reside within the body. The texts also divide the capacities of the mind into various dichotomies, such as high and low, left and right, and masculine and feminine.

MEDICINE. Āyurveda operates in the context that humanity's essential nature is the *ātman*, or Self, which is self-luminous, the source of all power and joy. Actions that aid in the manifestation of the divinity of the soul are beneficial and moral, and those that obstruct it are harmful and immoral. The Āyurvedic physician must help humans and nonhumans in their physical and mental health so that they can fulfill their quest for knowledge.

Āyurveda builds upon the tripartite Vedic approach to the world. Health is maintained through a balance between the three basic humors (*dosha*) of wind (*vāta*), fire (*pitta*), and water (*kapha*). Each of these humors has five varieties. Although literally meaning air, bile, and phlegm, the *doshas* stand for larger principles. The imbalance of these elements leads to illness. The predominance of one or the other leads to different psychological profiles. Charaka and Sushruta are two famous early physicians, and the beginnings of their compendiums have been dated to seventh century B.C.E.. According to Charaka, health and disease are not predetermined and life may be prolonged by human effort. For Sushruta, the purpose of medicine is to cure the diseases of the sick, protect the healthy, and prolong life. Indian surgery was quite advanced, even before 300 B.C.E.. The medical system tells much about the Indian approach to science. There was emphasis on observation and experimentation. The normal length of training appears to have been seven years. Before graduation, the students had to pass a test. Physicians were expected to learn through texts, direct observation, and inference. In addition, they attended meetings where knowledge was exchanged and were enjoined to obtain unusual remedies from herdsmen and forest-dwellers.

SCIENTIFIC IMAGINATION AND MODERN SCIENCE. A remarkable aspect of Indian literature is its scientific speculation. The epic Mahābhārata mentions embryo transplantation, multiple births from the same fetus, battle with extraterrestrials who are wearing airtight suits, and weapons that can destroy the world. The Rāmāyana mentions air travel. The medieval Bhāgavata Purāna has episodes describing how the passage of time can be different for different observers.

Conflict between science and religion has often arisen as a result of creation and end-of-the-world myths. Hindu views on these issues emerged from rational thought and are similar to some scientific views. Erwin Schrödinger, the cocreator of quantum theory, claimed to have been inspired by the Hindu mystical view of the identity of Brahman and the individual Self in his proposal of the quantum universal function that is a superposition of all possibilities. In fact, some philosophers of science see the evolution of quantum theory to be consistent with Vedānta. But because the bases for such beliefs in Hinduism and in modern science are quite different, it could also be argued that such relations are specious.

Hindu Ethics

The Vedas have many passages enjoining ethical behavior. The contemporary Hindu most often consults the Epics, Purānas, and the Bhagavad Gītā for such lessons. The Bhagavad Gītā is about the crisis facing Arjuna, hero of the Pandavas, as he confronts his relatives, the Kauravas, on the battlefield of Kurukshetra. Overcome by despair at the thought of killing his kinsmen in battle, Arjuna lays down his arms. But his charioteer Krishna, who is an incarnation of Vishnu, argues that Arjuna should do his duty and do battle. The human soul is not different from the universal soul and, thus, is immortal. When duties are performed without attachment to success or failure, one is not stained by action. Krishna teaches Arjuna the essence of *karma yoga* (yoga of works), *jnāna yoga* (yoga of knowledge), and *bhakti yoga* (yoga of devotion). He also teaches that the human being has a free will that permits him to make intelligent choices, which have a bearing on his karma. Using the battlefield of Kurukshetra as a symbol of life's struggles, the lessons of this text can be applied to everyday situations.

Elaboration of the social code is found in the Mahābhārata. The four great aims of human life are *dharma* or righteousness, *artha* or wealth, *kāma* or enjoyment, and *moksha* or spiritual liberation. Life runs through four stages: studentship, householdership, forest dwelling, and wandering ascetic. Society was divided into four classes: the teacher or *brahmin,* the warrior or *kshatriya,* the trader or *vaishya,* and the worker *shūdra.* These four were born from the head, the arms, the thighs, and the feet of *purusha,* the primal man. In reality, the aims of life run somewhat concurrently, and likewise, each individual, having the same *purusha* within, has attributes of each of the four classes.

Patanjali's Yoga Sūtra speaks of a system of eight limbs of which the first two emphasize moral and ethical preparation: moral restraint (*yama*), which includes to do no harm, truthfulness, to refrain from stealing, chastity, and to avoid envy; and discipline (*niyama*), which includes purity, contentment, asceticism, self-study, and devotion to the Lord. The remaining limbs prepare the individual for a mystical union with the Self: posture, breath control, sense withdrawal, concentration, meditation, and absorption. Thus ethical behavior is essential to prepare the individual to receive knowledge. This discipline connects the physical body to the energy sheath, which is the subtle body that envelops it.

Like the Yoga Sūtra, the law book of Gautama lists the following practices for a virtuous person: compassion for all beings, patience, contentedness, purity, earnest endeavor, good thoughts, freedom from greed, and freedom from envy.

Although its diverse texts point to corresponding diversity in practice, a common theme running in the various Hindu traditions is harmony in society and nature, necessitating obligations of different kinds. Humankind is enjoined with the stewardship of nature and a special responsibility towards animals that is symbolically represented in the veneration for the cow, the origins of which veneration rest in the central role of the animal in the economy of the village and because the Sanskrit for "cow" also means "Earth." These attitudes explain why vegetarianism is extolled in many Hindu communities.

PROSPECTS. Because Hinduism makes a distinction between higher and lower knowledge, it has no direct conflict with science, although it would take issue with technologies that do not promote social good. In the Hindu approach, logic and rationality is the means of obtaining outer knowledge that complements the inner science of the self. Hinduism does not contest scientific accounts of creation; in fact, its own accounts of creation and destruction are very similar. The appeal to a cycle of births helps the Hindu find order in events that might otherwise appear chaotic and unjust.

Hinduism recognizes that at one level all creatures are part of a food chain, in which the big fish eats the small. But this physical aspect of life represents the animal self. Hinduism's task is to raise the individual beyond the animal self to a state in which one appreciates the interconnectedness of reality and develops compassion for all beings. Nonviolence is lauded as the highest principle, with the acknowledgement that the real world has violence in it that reflects the level of the development of society.

Regarding the unborn, the Garbha Upanishad claims that the subtle body enters the embryo in the seventh month. Although Hindu law books condemn abortion, the early-twenty-first-century Hindu is likely to defer to the scientist in determining when the fetus is viable. Because the individual is not just the physical body but also the subtle body, cloning the physical body is not problematic. For similar reasons, Hindus are not opposed to stem cell research.

Because Hinduism acknowledges that animals are sentient like humans; it is opposed to the unnecessary medical testing of drugs and procedures on animals. Hindus have opposed genetic modification to crops in advanced countries with the major motivation of greater productivity, because it disrupts farming in the poorer countries and makes it likely that these farmers will become dependent on expensive patented seeds controlled by inaccessible corporations.

In medical practice, the Hindu approach stresses a holistic view to therapy that acknowledges connections between mind and body, which is part of the reason of the increasing popularity of Yoga and Ayurveda. But it is not clear yet to what extent these disciplines will be incorporated in mainstream medicine.

Many Hindus—and this included Mahatma Gandhi—are critical of those technologies that dehumanize the person, treating a human being as a mere cog in a machine, as happens to be the case in certain manufacturing processes. This is why Gandhi praised small-scale industry and urged for self-sufficiency in the village. Hindus believe that science and technology must be harnessed in a manner that furthers humanity's inherent quest for self-knowledge. Because individuals are defined not in isolation, but through their interactions with other persons, this quest cannot ignore the larger good of society, and requires ethical preparation on the part of the individual.

HIROSHIMA AND NAGASAKI

These two cities are etched in the collective consciousness of the world as scenes of utter destruction and inhumanity. The decision of President Harry S Truman to authorize the use of atomic bombs on the Japanese cities of Hiroshima and Nagasaki also remains one of the most contentious issues associated with the conduct of Allied forces in World War II.

Emotional Debates

The deep emotions that people feel toward this decision continue to resonate in American and Japanese life. These emotions were expressed in the reactions to the fiftieth-anniversary exhibitions about the dropping of the bomb at Hiroshima by the Smithsonian Institution's National Museum of American History and an exhibit in Hiroshima in 1995. Professional historians serving as museum curators prepared the Smithsonian exhibit. It was carefully vetted by a wider advisory group of American historians who represented varied views about the rationale and ethics of the American decision to use the atomic bomb. Yet when word leaked to members of Congress about the content of the exhibit, special hearings were held and a firestorm of controversy and publicity resulted in a complete redesign of the exhibit into a much more innocuous display of the *Enola Gay* bomber with a few selected images and commentary about the events of a half-century before.

A widely cited Gallup poll of the American public at the time found 85 percent approving of the use of the bomb on Japanese cities. Various public figures in Japan remonstrated about America's unwillingness to face fully the import of its actions, and public demonstrations occurred in both countries over this contentious exhibit. Yet in a similar manner, considerable controversy occurred in Japan over a new exhibit in Hiroshima on the eve of the fiftieth anniversary that highlighted Japanese aggression in the Pacific and suggested that some Japanese military units had committed war crimes in their prosecution of the war effort. Many Japanese public figures condemned the exhibit and called for its withdrawal.

What Happened

It is impossible from the vantage point of history to fully know what people in the United States and Japan knew, understood, surmised, and most importantly, felt, during the period when these momentous decisions were made. World War II by this point had seen more than 55 million deaths. By 1945 the Japanese military had lost 3 million men, including more than a million in the previous year. U.S. air forces dominated the skies of Japan, and bombers flew sorties in open daylight. More than a million Japanese civilians had been killed in air raids. Yet still the Japanese refused to surrender.

Across the Pacific plans were coming to life as men, materials, ships, communications systems, and so on were all being prepared for a momentous invasion of Japan that would involve in excess of a million troops in the initial assault in the south and another million in a second wave of assaults to the north. Intelligence sources indicated that the Japanese were massing troops all over key points in Japan and preparing to repel an invasion force they were sure was coming. American troops and their leaders who had studied the vicious fighting on Okinawa where U.S. marines suffered 67,000 casualties (about 35 percent of their total fighting force), including 7,700 dead, contemplated what it would be like to now try to take the Japanese homeland where a similarly high casualty rate might be anticipated. Naval personnel recalled the ferocious kamikaze attacks they had already endured and wondered how many thousands of more planes and pilots would be flung at their ships as they entered Japanese home waters and how many more U.S. ships would be sent to the bottom of the sea.

Oral accounts of major actors' thoughts, attitudes, convictions, actions, and beliefs after the fact is colored by those facts as well as the vicissitudes of public opinion such that these recollections may prove unreliable. Historians have amassed considerable written evidence that suggests that all of the following statements hold. Presidents Franklin Delano Roosevelt and Truman always believed the bomb could and should be used. The Soviet Union was already perceived as a major threat to world peace on the conclusion of hostilities against Japan, and containing the Soviet threat was paramount in the minds of America's senior policymakers. Estimations of casualties in the first (ninety-day-long) phase of the invasion of Japan varied widely from a low of 50,000 to a high of 250,000. The United States was willing to let the emperor remain on the throne—even though this was not communicated to the Japanese. Japan had made overtures to surrender through Russian and Swiss contacts as well as directly to General Douglas MacArthur's headquarters in January 1945. General Curtis LeMay, commander of the U.S.

strategic bomber forces in the Pacific, was determined to maximize air power effectiveness. The broken Japanese code indicated in July that the emperor was contemplating intervening with the Japanese military to broker a surrender. The United States had advance notice that the Soviets were entering the war against Japan in early August. The atomic bomb possessed a psychological effect well beyond its military effect and was clearly a weapon in a class by itself.

The atomic bomb was dropped on Hiroshima (population 285,000 civilians along with 43,000 soldiers) on August 6, 1945, at 8:15 A.M. local time. The immediate death toll according to estimates from a joint Japanese and American report issued in 1966 was greater than 70,000, including two American prisoners of war, with another 70,000 casualties. Of the city's 76,000 buildings, all but 6,000 were damaged and 48,000 were totally destroyed over an area of about eleven square kilometers. A total of almost 232,000 have died up to the present from disorders and problems linked to this event in Hiroshima, including children from 1945 dying from various cancers caused by the intense radiation.

The bomb dropped on Nagasaki (population 195,000) three days later killed some 36,000 Japanese outright, injured another 40,000, and caused about another 25,000 subsequent deaths due to burns and radiation exposure. By U.S. Army estimates, about 44 percent of the city was destroyed, the remainder being spared by the steep hills and topography of the city. Although Nagasaki was on the list of potential target cities, the selection of Nagasaki was "accidental" that day because clouds obscured the preferred target city of Kokura.

It is important to view the casualty figures in the context of the air war with Japan. The U.S. firebombing of Tokyo on March 9–10, 1945, resulted in more than 100,000 Japanese deaths in a twenty-four-hour period during which ground temperatures reached 1,100 degrees Celsius (the heat at the center of the atomic blasts by contrast briefly equaled that of the interior of the sun). Two subsequent air strikes against Tokyo resulted in more than half the city being completely destroyed by late May. What made the atomic bombs different was the devastation from one single bomb coupled with visual and nonvisual effects that dwarfed nonnuclear devices and long-term effects that could not even be predicted.

Postwar Assessments

The development of the atomic bomb was a major scientific and technical feat that employed at its peak 160,000 people and consumed two-fifths of the entire U.S. war budget while remaining hidden from members of Congress and even most senior military leaders, and prompted considerable angst and second-guessing on its moral appropriateness on the part of many of the scientists intimately connected with its birth.

One scientist, Joseph Rotblat, left the Manhattan Project because of his ethical concerns. Others self-organized and created a series of written documents that expressed their collective ethical and moral concerns about the bomb and its use. Captain Claude Eartherly, a pilot who flew the reconnaissance plane over Hiroshima but did not view the drop itself, later expressed regrets over his involvement and the American decision. This admission was seized on by the German philosopher Gunther Anders in a book called *Burning Conscience* and by advocacy groups to support arguments against both the use of nuclear weapons as well as the American decision to deploy them during the war. Eartherly became somewhat of a hero in communist countries and among "ban the bomb" groups. His wartime colleagues, including his commanding officer colonel Paul Tibbets who flew the B-29 that actually dropped the bomb, viewed Eartherly as a gambler, drunk, and publicity hound. (He spent his later years in a mental health facility.) Brigadier-General Tibbets expressed no regrets over his decision, although his service as deputy director of the U.S. military supply mission to India in the mid-1960s was cut short when the pro-Communist press in India labeled him as the "world's greatest killer."

A small panel of senior military, political, and scientific leaders made the final recommendation to President Truman after an intensive but brief consideration of various options. J. Robert Oppenheimer, lead science director for the project and a participant in these deliberations, later concluded that the military had kept civilians considerably in the dark about the actual state of affairs in the Pacific and the estimated impact of the proposed invasion of Japan.

Admiral William Leahy, Truman's chief of staff, believed throughout the process and after that use of the atomic bomb on two Japanese cities was completely unwarranted. He called for a return to warfare that excluded women, children, and other noncombatants. (The Allies, following the lead of the Japanese in China in the 1930s and the German firebombing of Coventry, England, in November 1940, regularly firebombed Axis cities causing massive civilian casualties on the grounds that this would hasten the end of the war.)

Justifications for the use of the atomic bomb against Japan flowed swiftly after its use, both from the White House and from military press releases. The U.S. public was also reassured that the latent results from this new weapon were modest. The *New York Times* headline of September 13, 1945, amazingly declared, "No Radioactivity in Hiroshima Ruin." Even in the earliest years, however, doubts about the necessity of the bomb as a military option to expedite the surrender of Japan were expressed by senior U.S. military leaders including Supreme Allied Commander Dwight D. Eisenhower, Chief of Staff General George Marshall, and General Henry "Hap" Arnold, commander of the Army Air Forces.

Historians in the ensuing decades have built an extensive, well-documented argument that a complex set of factors determined the decision with a principal facet, as expressed forcefully by Secretary of State James Byrnes, focused on containing the Soviet threat to the postwar world. Demonstrating the bomb against a real target would place the United States and Great Britain in a much more powerful negotiating position with Soviet leader Joseph Stalin at the end of the conflict.

While the necessity of the atomic bomb to end the war with Japan will continue to be debated, as Robert Jay Lifton and Greg Mitchell (1996) noted, "You cannot understand the twentieth century without Hiroshima" (p. xi). The Memorial Cenotaph in Hiroshima Peace Memorial Park declares, "Let all souls here rest in peace; for we shall not repeat the evil." Atomic bombs and the even more powerful thermonuclear weapons that have followed them have spawned a true human capability for omnicide—the wiping out of all life on the planet humans inhabit.

Walker, J. Samuel. (1997). *Prompt and Utter Destruction: Truman and the Use of Atomic Bombs against Japan*. Chapel Hill: University of North Carolina Press. Concisely argues that the decision to use the bomb was sound and wise militarily, politically, diplomatically, and morally.

HIV/AIDS

The human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS) has reached pandemic proportions and has presented a multiple-dimension challenge for science, technology, and ethics. In 2004 approximately 39.4 million people worldwide were infected with HIV/AIDS, among whom about 3.1 million died in that year, including about 510,000 children under age fifteen. The Joint United Nations Programme on HIV/AIDS/World Health Organization (UNAIDS/WHO) estimates that in that year 4.9 million new infections occurred. Impacts have been more severe in southern Africa, where about one-third of the deaths occurred in 2004 and where life expectancies have dropped by more than 20 years in some countries. HIV/AIDS increasingly affects women and children; nearly half of those infected worldwide are female, with even higher infection rates for women in Africa. Infected pregnant and nursing women can pass the disease to their babies.

Between 2001 and 2004 global funding for HIV/AIDS relief tripled to $6.1 billion, with resultant improvements in treatments and services; this figure includes estimates of funding from all sources, ranging from individuals and families to national and international efforts. Like infections, however, services are unevenly distributed, with the poor and stigmatized remaining underserved. Analyzing the ethics and politics of scientific, technological, and other responses is a contentious issue.

Historical Perspectives

It is useful to compare the HIV/AIDS pandemic with the Spanish influenza epidemic of 1917–1918, which also was promoted by the global transportation network at an earlier stage of its evolution. In a little less than two years the Spanish flu is estimated to have killed from 21 to 50 million persons worldwide in a population of approximately 1.8 billion. While HIV/AIDS has not yet killed as large a percentage of the world's population as the Spanish influenza epidemic, HIV/AIDS infections are not self-limiting and infection rates are expected to remain high unless effective prevention programs are developed and implemented.

Mirko Grmek (1990) provides an extensive history of the emergence and identification of HIV/AIDS. In the late 1970s the disease began to appear in the United States and Europe as physicians noticed unusual symptoms in members of homosexual communities in California and New York. Those patients presented with a variety of symptoms, such as pneumonia, mononucleosis, thrush, and Kaposi's sarcoma. Some were relative benign conditions, yet the patients went into a rapid decline, and their immune systems appeared to be compromised. The U.S. Centers for Disease Control announced the disease on June 5, 1981, but the disease was not named acquired immunodeficiency syndrome until the summer of 1982. Most of the early cases involved homosexuals, but other cases developed in intravenous drug users and then in heterosexual males, women, and patients with no history of drug use. The disease eventually was recognized in equatorial Africa, where cases might have appeared as early as 1962.

Scientists eventually identified "Patient Zero," a flight attendant who apparently was responsible for infecting a large number of the early patients in the United States. Spread of the disease thus took advantage of a global transportation network, establishing a pattern that was repeated on a much less dramatic scale with the severe acute respiratory syndrome (SARS) in 2002–2003 and poses an ongoing challenge to world health management. Patient Zero continued to engage in unprotected sexual activity long after being diagnosed, posing questions about responsibility to both patients and the medical community.

Science, Technology, and Responsibility

Since the early 1980s scientific research on HIV/AIDS has been involved in a series of controversies. For instance, immediately after the identification of AIDS researchers began to try to identify the cause. Priority in the 1983 identification of HIV as the infectious agent was claimed by both Robert Gallo at the National Cancer Institute in the United States and Luc Montagnier at the Institut Pasteur in France in what became a widely reported case of questionable scientific conduct. Even after the discovery of HIV a prominent researcher, Peter Duisberg, rejected it as the basic cause of AIDS and was accused of scientific irresponsibility.

HIV/AIDS research has divided scientists and has caused conflicts between scientists and the public about research strategies and priorities. Should the emphasis be on basic immunological science or on clinical treatments? Should treatment research be aimed at preventing human cell infection by HIV or attacking human cells that already are infected? More generally, what are the relative costs and benefits of spending money on HIV/AIDS research instead of on research into another disease, such as malaria or diarrhea? An estimated 300 million people are infected with malaria, among whom 1 to 1.5 million die annually. A fraction of the money spent on HIV/AIDS research and treatment would have a much greater impact on malaria, and the provision of safe supplies of public drinking water would cause a significant reduction in the over 1 million deaths each year from diarrhea.

Research, particularly drug testing, triggers further ethical questions. How much testing should be conducted before a potentially lifesaving drug is made available to the public? What rules apply when scientists conduct research in developing countries: the rules of the corporate home nation or the rules in the country where research is conducted? Are some policies, such as informed consent, so basic that they should apply anywhere in the world? Does consent always attach to the individual, or does it extend in some cases to communities with high infection rates? Should subjects and their communities participate in research design? How can information about research be explained effectively to people who are not familiar with scientific research and its implications? Can effective treatment be withheld for the purpose of advancing scientific understanding and the possibility of developing new drugs? How can participants be protected from or compensated for negative unintended consequences of research trials? What obligations do researchers have to provide short- and long-term health care to research subjects and their communities? How should societal needs for research be balanced against the rights of the individual? Vaccine research poses special problems because the subjects subsequently may test positive for HIV/AIDS.

FIGURE 1

Debate also continues over the relative merits of treatment and prevention. Is it better to ease suffering and prolong the lives of those already infected or to prevent new cases from occurring? Prevention will help only those who are not currently living with HIV/AIDS, whereas treatment is needed for the millions already infected to prolong lives, maintain family incomes, and promote general economic stability. Moreover, infected patients need relief from suffering

TABLE 1

Global Summary of the AIDS Epidemic, December 2004

Number of people living with HIV/AIDS in 2004	
Total	**39.4 million (35.9 – 44.3 million)**
Adults	37.2 million (33.8 – 41.7 million)
Women	17.6 million (16.3 – 19.5 million)
Children under 15 years	2.2 million (2.0 – 2.6 million)
People newly infected with HIV in 2004	
Total	**4.9 million (4.3 – 6.4 million)**
Adults	4.3 million (3.7 – 5.7 million)
Children under 15 years	640,000 (570,000 – 750,000)
AIDS deaths in 2004	
Total	**3.1 million (2.8 – 3.5 million)**
Adults	2.6 million (2.3 – 2.9 million)
Children under 15 years	510,000 (46,000 – 600,000)

The ranges around the estimates in this table define the boundaries within which the actual numbers lie, based on the best available information.

SOURCE: Marais et al. (2004), p. 1.

in addition to treatment to slow the progress of the disease. Should scarce human and financial resources be diverted from prevention and treatment to provide palliative care?

Additionally, some people see HIV/AIDS primarily as a behavioral problem; if the behavior changes, the problem will disappear. Controlling HIV/AIDS is about more than developing drugs and vaccines; social science also plays an important role. New drugs will not reach patients unless medical services and drug delivery systems in poor countries are improved. The public must be educated about both causes and treatment. Researchers should investigate reasons for stigma and develop strategies to reduce discrimination and protect the most vulnerable. Within the prevention camp some advocate abstinence as the only moral alternative, whereas others recognize the reality of sexual activity and believe it is more ethical to promote condom use to reduce infection. In such a complex scientific and technology context what is the proper mix of prevention, treatment, and care?

Social Responsibilities

The infectious nature of HIV/AIDS also raises questions about societal responsibilities to potential victims. Should doctors or health institutions inform others when a patient is diagnosed with HIV/AIDS? How should the need to prevent the spread of a deadly disease be balanced against a patient's right to privacy? Women may be particularly at risk from identification because their subordinate status in many places may subject them to social isolation or deprivation of home or property.

Society often discriminates against people infected with HIV/AIDS. Discrimination may be driven by fear of infection, and education should be provided so that people know that the disease is not spread through casual contact. The general stigma attached to homosexuals, drug users, and the poor also drives discrimination. UNAIDS attributes the lack of political will to deal with the pandemic in part to the high infection rates among "marginalized and stigmatized population groups such as women who sell sex, drug injectors and men who have sex with men."

HIV/AIDS exacerbates gender inequities. Women often lack both information about the disease and the power to refuse sex or demand that their sexual partners use condoms. Identification of affected women puts them at higher risk of stigmatization, expulsion from their families, and deprivation of property and employment. Poor women who lose their spouses to the disease may be unable to support their families. More than 2 million children are infected with HIV/AIDS. Millions of others live with infected family members or have been orphaned by the pandemic.

Earlier in the epidemic the high incidence of HIV/AIDS among American gay males juxtaposed prejudice against homosexuals with the increasing political influence of affluent gay men. The gay community effectively concentrated attention on the emerging disease; that resulted in the allocation of research dollars to develop new treatments. HIV/AIDS is now relatively controllable for those who can afford expensive antiretroviral treatments, but the epidemic continues to spiral out of control because millions of infected poor people cannot afford treatment. The needed antiretrovirals are too expensive for most HIV/AIDS patients, and 90 percent of those who need drugs cannot afford them; most of those patients live in sub-Saharan Africa.

Some countries, such as Brazil, have made antiretroviral drugs available for free or at low cost to poor people who need them. Such programs help current patients but may reduce incentives for future pharmaceutical research. Drug companies engage in research and development to make money; if developing countries can obtain drugs without paying market prices, profits will fall and pharmaceutical companies may be less likely to do research into diseases that occur primarily among the poor. Nevertheless, the World Trade Organization Agreement on Trade-Related Aspects of Intellectual Property Rights (TRIPS Agreement) allows an exception to intellectual property rights in special cases such as emergencies, and that provision has been used to give developing countries access to HIV/AIDS drugs.

Michael Specter maintains that treatment is not enough; only a vaccine can stem the pandemic, yet drug companies lack sufficient incentives to develop a vaccine. This constitutes a case of market failure requiring government intervention.

Pharmaceutical companies in affluent industrialized countries conduct most research on new drugs and vaccines. Do they have a corporate responsibility to spend money on public health problems that may not produce profits? Do their countries have a responsibility to protect the less developed world by providing direct assistance or incentives for drug research? The developed world may have a direct stake in stopping the pandemic to reduce economic and political destabilization in many poor countries.

HIV/AIDS constitutes a global health crisis, but those in greatest need of assistance live in the poorest countries or are among the poorest and most stigmatized members of more affluent societies and lack strong political support. The crisis affects more than individuals; families are disrupted, and societies destabilized: "AIDS is accomplishing a sweeping undoing of past human development advances, especially in southern Africa". The HIV/AIDS pandemic requires strategies to address problems from the individual level to the international level.

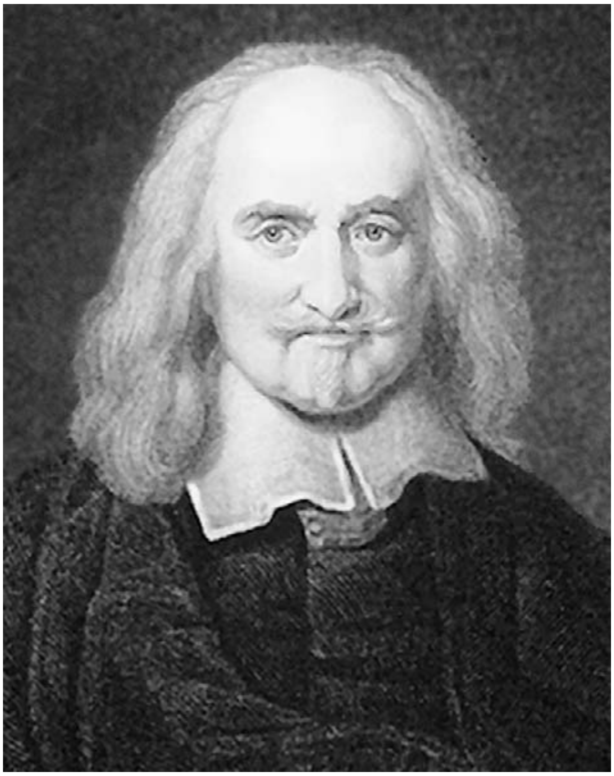
HOBBES, THOMAS

Thomas Hobbes (1588–1679) was born in Westport, England, on April 5, the son of a clergyman; he was a contemporary of Shakespeare. Hobbes developed a moral and political philosophy that was influenced greatly by geometry and the new sciences of the Enlightenment. After studying at Oxford University Hobbes became a tutor for the Cavendish family and escorted his charges on tours of the European continent. During those travels Hobbes became acquainted with science as it was being developed by Galileo Galilei (1564–1642), René Descartes (1596–1650), and Marin Mersenne (1548–1648), which he found more constructive than the political strife that characterized the English civil war (1639–1651).

Hobbes's political thought first was expounded at length in *The Elements of Law* (1640), which defended the monarchy, although on democratic grounds. He subsequently developed his arguments in *De cive* (1642), *De corpore* (1655), and *De homine* (1658), a trilogy on the state, physics, and anthropology in which Hobbes attempted to build a bridge between the new science and politics. His most widely read book both in his own day and up to the present has been *Leviathan* (1651). He also wrote a scientific dialogue, *Dialogus physicus* (1661), in response to the emerging experimental sciences and Robert Boyle's (1627–1691) work with air pumps. In 1666 Parliament nearly banned *Leviathan* as heretical, and Hobbes continually faced the threat of exile. He spent his later years composing a history of the English civil war and translating the *Odyssey* and *Iliad*. Hobbes died in Hardwick Hall near Chesterfield, England, on December 4.



Thomas Hobbes, 1588–1679. The English philosopher and political theorist was one of the central figures of British empiricism. His major work, *Leviathan,* expressed his principle of materialism and his concept of a social contract forming the basis of society. *(Archive Photos, Inc.)*

Moral and Political Philosophy

The avoidance of civil strife was one of the main intentions of Hobbes's work. His solution made him unpopular with both royalists and parliamentarians. Royalists argued that the king rules on the basis of natural or divine right; parliamentarians advocated democratic rule. Hobbes argued that the king should rule not by nature or divine commandment but because the sovereign is an artificial social construction fashioned by popular human reason motivated by the shared fear of violent death. It was the high probability of that fate in the state of war (or nature) that in earlier times had made life "solitary, poor, nasty, brutish, and short" (*Leviathan*, vol. I, p. 13). For Hobbes civil society is radically conventional because humans are not naturally social. People are compelled to form civil society by the laws of nature, understood as rational instructions on how to cooperate.

Hobbes argued for a subjectivist morality based on psychological egoism (all human action is selfishly motivated), with good and evil as names that signify appetites and aversions, especially those pertaining to self-preservation and peace. Social peace is possible because all people agree that it is good and are rational enough to cooperate. However, the plurality of tastes and definitions of good and evil means that a state of war will emerge quickly whenever the absolute authority of the sovereign is challenged.

Obedience even to arbitrary government is preferable to the state of war. The commonwealth is formed through social contracts, and the network of those contracts creates the Leviathan (from the Book of Job, meaning "King of the Proud"), or sovereign, which is an artificial "person" responsible for public welfare and social order. The sovereign could be a monarch, as Hobbes preferred, but it also could be a legislature or an assembly of all citizens. Hobbes's notion of the sovereign led to later contractarian philosophies, especially Jean-Jacques Rousseau's (1712–1778) ideal of the general will.

Fear of violent death thus brings humans to reason. In regard to the resulting self-regulating system of passions Hobbes constructed a political philosophy that foreshadowed liberal capitalism and its emphasis on individual rights and the primacy of material self-interest. However, his collectivist image of society comprising the body of the sovereign also has been interpreted as a forerunner of socialist thought. David Gauthier (1969, p. vi) sums up this duality: "Hobbes constructs a political theory which bases unlimited political authority on unlimited individualism." For Leo Strauss (1973) Hobbes marked the beginning of modern political philosophy (foreshadowed by Niccolò Machiavelli [1469–1527]) because he denounced aristocratic distinctions and virtues. He leveled all humans with his theory of natural equality and did not base morality on ideal virtues attainable, if at all, only by the few.

The Role of Science and Technology

A second basic intention in Hobbes's work was to put moral and political philosophy on a scientific basis. His civic science generally is regarded as being based on natural science in both method and material. Human thought and action are explained in mechanistic terms of matter in motion, and thus the laws governing political bodies can be derived from those governing physical bodies. Yet Hobbes held a compatibilist view that causal determination of human conduct is consistent with the freedom required for responsible moral agency.

Even though he worked briefly for the empiricist Francis Bacon (1561–1626), Hobbes was a rationalist who believed that science primarily meant geometry and the methodology of reasoning both from first principles, or causes, to effects and from effects to causes. The purpose of proper philosophy is universal assent attained through absolute certainty, and the first step in arriving at that certainty is an agreement to settle the definitions of words and their precise uses to avoid absurdities and disorder. Science is knowledge of the consequences of words established in that manner. Scholastic and religious reasoning breed controversy because they fail to define terms precisely.

Hobbes's political and natural philosophies are inseparable in the project of establishing consent on what is and how it can be known, thus leading to social order. Human will is the primary force of geometric proofs because humans determine original definitions. Geometry is an instance in which a diverse, subjective, and arbitrary human will has fashioned universal laws and truths by which all people can abide. Just as humans "make" the definitions in geometry (for example, "circle"), so too are the principles of politics (such as authority and justice) fabricated.

Strauss (1973), however, argues that modern natural science distorts Hobbes's moral and civic philosophy. The differences between the modern science of nature and human affairs outweigh the similarities. Indeed, in many places Hobbes stated that physical and political bodies are quite different. Furthermore, he did not take up science until he was forty years old, and he portrayed human nature as mutable and speech, reason, and sociality as products of free will. Vanity (the striving for absolute power) is a peculiarly human trait. Thus, Hobbes has a dualist philosophy (humans can will themselves out of nature) that is hidden by his monist (materialist-deterministic) metaphysics. Hobbes may wish to base his political theory on science because it progresses and produces real power, but a consistent scientific naturalism would ruin his moral philosophy.

The real basis of his philosophy was Hobbes's personal experience of human life. That experience actually has much in common with premodern science in that it proposes to disclose a teleology of human nature, even if a more debased teleology than argued for by the ancients. For that reason, "it can never, in spite of all the temptations of natural science, fall completely into the danger of abstraction from moral life and neglect of moral difference" (Strauss 1973, p. 29). It retains its moral basis precisely because it is not founded on modern science but instead on firsthand experience of humanity. As evidence for his claim Strauss points to the introduction of *Leviathan*, which states that one need not be trained in the physical sciences to formulate the right theory of human nature.

In another account Strauss (1965) argues that Hobbes posited two determinants of human willing—fear of violent death and the pursuit of domination over things—and that this underpins the distinction between the aims of politics and those of natural science. For Hobbes science is the methodical search for causes; in contrast, religion is the unmethodical search for causes. The purpose of science is the conquest of nature to make life more comfortable. It arises from human striving for power and honor, but that inexhaustible urge ensures that what is at stake is not the enjoyment of the object that is desired. Instead, the attainment of objects is only a means to more power: "the end becomes a means, the means becomes an end" (Strauss 1965, p. 89). Even if it is not properly based on science, Hobbes's politics is the foundation of modern technology.

The Politics of Knowledge: Hobbes versus Boyle

Strauss argued that the content of Hobbes's natural science obfuscates his political philosophy. Steven Shapin and Simon Schaffer (1985), however, argue that Hobbes's political theory holds true for the process of science. Both Strauss and Shapin and Schaffer see Hobbes as making constructivism and artifice superior to nature. Strauss uses this to purify Hobbes's politics of natural science; Shapin and Schaffer use it to justify Hobbes's insight that the two are inextricably connected in a single process: "Knowledge as much as the state, is the product of human actions" (Shapin and Schaffer 1985, p. 344).

Contrasting the philosophies of Hobbes and Robert Boyle, Shapin and Schaffer highlight the dynamics of the period when the modern relationship between scientific knowledge and the polity was being formed. The dispute between Hobbes and Boyle can be cast as different notions of what counts as science and legitimate knowledge. Hobbes's science was based on geometry and the deduction of irrefutable (moral and epistemic) truths from distinct first principles. Boyle proposed an experimental science that would be based on empirical observations made by a group with special training. Hobbes attacked this on epistemic grounds, claiming that the "facts" derived from sensory experience are mere "seeming or fancy" because they are too private.

However, this objection to Boyle's science is also moral. Both Boyle and Hobbes offered solutions to the problem of order in terms of ways to produce agreement and consent. Boyle attempted to remove natural philosophy from the "contentious link with civic philosophy" (Shapin and Schaffer 1985, p. 21). Hobbes attempted to erect a philosophy "that allowed no boundaries between the natural, the human, and the social, and which allowed for no dissent within it" (Shapin and Schaffer 1985, p. 21). Boyle's knowledge is produced among a community of experts, and that creates differences in the larger body politic, destroying natural equality, universal assent, and social order. Moreover, Boyle's scientific community allows for dissent about causes within its borders, which Hobbes found to be both a threat to civic order and a sign that it was not a true philosophy. Hobbes saw in Boyle's science the same socially corrosive element that exists in traditional monarchism and religion. The laboratory is a divisive and dangerous form of elitism pretending to a nonartificial hierarchy.

Arguing that "solutions to the problem of knowledge are solutions to the problem of social order," Shapin and Schaffer use the notion of "intellectual space" to distinguish Hobbes from Boyle (Shapin and Schaffer 1985, p. 332). For Hobbes philosophy is not the exclusive domain of professionals. He considered its intellectual space public because its purpose is the establishment of peace and order. In this regard natural science and civic science are the same. In Boyle's experimental science, however, there is a special place for doing natural philosophy—the laboratory—and access to it is quasi-open. In principle anyone could witness the goings-on in that space, but in practice it "was restricted to those who gave their assent to the legitimacy of the game being played within its confines" (Shapin and Schaffer 1985, p. 336). Boyle separates the study of nature, or objects, from the study of human affairs, or subjects. The existence of a separate community producing and legitimating knowledge was anathema to Hobbes, who argued that the philosopher's task was to establish peace and that this separate group threatened civic order. Bruno Latour playfully summed up his interpretation of Hobbes's reaction to Boyle: "we are going to have to put up with this new clique of scholars who are going to start challenging everyone's authority in the name of Nature by invoking wholly fabricated laboratory events!" (Latour 1993, p. 20).

For Hobbes philosophical and political spaces need masters who determine right knowledge and right conduct for all, thus constraining opportunities for interpretation and controversy. A chain is fastened from the lips of the sovereign to the ears of the people. This alleviates the problem of "seeing double" that occurs when loyalties are divided between different professional groups or different personal interpretations of events. Shapin and Schaffer claim that "Hobbes's philosophical truth was to be generated and sustained by absolutism" (p. 339). This was strictly opposed to Boyle's notion of intellectual space because the foundation of knowledge was considered to be free will. Truth claims are verified by free acts of witnessing. Boyle saw the experimental community neither as tyranny nor as democracy but as a group regulated by conventions of selectively restricted access. The experimental community gained such wide support because it offered solutions to practical problems and because its members presented it as a model of the ideal polity. Nonetheless, this does not deny the fact "that there is a power-structure to truth and a truth-structure to power" (Wolin 1990, p. 12).

In the end Shapin and Schaffer conclude that "Hobbes was right" (p. 344) in the sense that Hobbes's instrumentalism or social constructivism better explains science, society, and their relationship than does Boyle's realism. Knowledge, like society, is conventional and artifactual, and scientists do not produce objective truth claims. Shapin and Schaffer probably exaggerated their instrumentalism to call attention to the increasingly problematic aspects of the "boundary-conventions" that distinguish science from politics. Their main point is that the solution to problems of knowledge is always political in that it requires the establishment of conventions of interaction and rules for determining legitimacy and because the knowledge this community produces becomes an integral part of political action.

Boyle and the experimentalism of the Royal Society "won" not because they reflected nature objectively but because their use of rhetoric garnered the most political power. Even though Hobbes was the first modern mediator between science and society, historians have purified Hobbes of science and Boyle of politics, reinforcing the idea that the two realms are naturally distinct. Shapin and Schaffer work to expose the intellectual and historical roots of that distinction, which increasingly is being questioned on the basis of expanding democracy rather than, as with Strauss, on the basis of a reaffirmation of nature.

Argues that Hobbes modernized despotism by founding it on scientific theorization but that he continues a chain of despotism from Plato, through medieval monarchs, to Popper's scientific social engineers.

HOLOCAUST

The word *holocaust* is derived from the biblical Greek term *holocauston*, meaning a "burnt offering" made in sacrifice to God. The term came to be widely used in the early 1970s to refer to the mass extermination of the Jews in the gas chambers of an organized system of death camps initiated by German dictator Adolf Hitler (1889–1945) and the Nazi Party during World War II. In the 1980s, some scholars argued that the word holocaust imputed more meaning to the event than it deserved and began calling it the *Shoah*, a Hebrew term referring to a time of desolation. The connotations of the latter have come to color even the meaning of the former.

In World War II nearly 30 million people died in combat or as random civilian victims of war. History is filled with wars and massacres, but genocide is something else. While the Turkish attempt to eliminate the Armenians (c. 1915) may be an earlier example of genocide, the Holocaust has come to be described as the archetypal example. Genocide is a systematic, state-sponsored, bureaucratically organized attempt to eliminate an entire people (usually identified in "racial," ethnic, or religious terms) from the face of the earth, not for any strategic military or political advantage but simply because they exist. The Nazi attack on the Jews was not an attempt to eliminate a foreign enemy but its own Jewish citizens first and then all the Jews in Europe. While others were also made victims in the death camps (such as the mentally retarded, homosexuals, and communists), the Jews and Gypsies were the only two peoples targeted for *total* annihilation. Thousands of Gypsies and 6 million Jews were murdered. A third of the world's Jews and two-thirds of Europe's Jews died in the Holocaust.

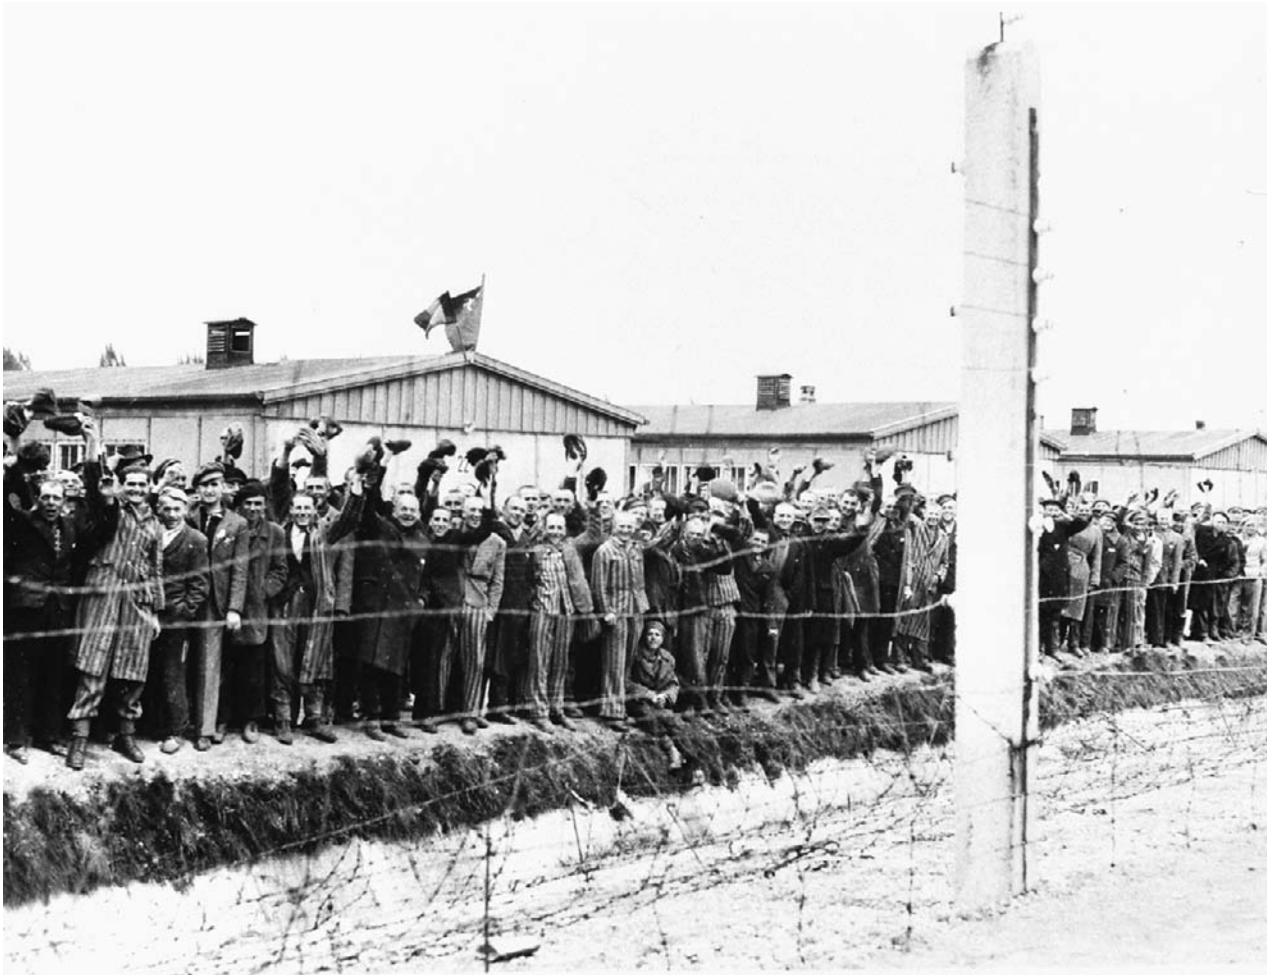
In the Nazi genocidal project, science was used to provide a biological theory of race that offered ideological justification for genocidal public policies of racial purity, and technology was used to provide the most efficient means to carry out these policies.

Science

The Nazis used English naturalist Charles Darwin's (1809–1882) biological theory of evolution to justify their program of genocide. Darwin posited the evolutionary differentiation of species as the product of "natural selection" in which only those organisms most successful in adapting themselves to a particular ecological niche survive to reproduce themselves and so shape the gene pool. This law of competition came to be known as the "survival of the fittest," meaning the survival of those most successful at adaptation.

In the nineteenth century this scientific theory was transformed into a political ideology known as "social Darwinism" by metaphorically extending Darwin's biological theory into the realm of society. In this way social phenomena such as class conflict or the conflict between nations were imagined to operate by the same laws of "natural selection." It seemed only "natural" to the Nazis to conclude that the ascendancy of the Nazi German nation-state was the outcome of a biological process in which the fittest race had survived to dominate all others, proving the superiority of the Aryan race. The greatest threat to this evolutionary outcome was, in their view, racial pollution—the biological mixing with "inferior races" that would weaken the purity of Aryan blood.

As Robert Jay Lifton (1986) noted, the death camps were viewed as public health projects in which the Jews were considered a cancerous growth on the body of the Aryan race, threatening its organic health (i.e., racial purity), and so had to be cut out in order to restore the body to health. It was no accident that physicians were required to fill the role of those who selected some victims for the work camps while sending others directly to the gas chambers. The doctor, as an elite scientifically trained professional, gave an aura of "scientific" legitimacy to the



Survivors of a concentration camp line up along a wire fence in Dachau, Germany. Many are still wearing the striped uniform of the camp. *(AP/Wide World Photos.)*

entire genocidal enterprise, and the "scientific theory" of racial purity gave the doctors a rationalization that allowed them to think of killing as a form of healing.

The Nazis had to ideologically twist science to justify their genocidal actions. Biologically all human beings are capable of interbreeding and therefore constitute a single species: There is only one human race. The Nazi "theory" of races was an ideological myth. Moreover, Darwin's theory suggested that it was genetic diversity not genetic uniformity that promoted survival. Finally, "survival of the fittest" had descriptive rather than normative status in Darwin's theory.

Technology

A technological civilization is one shaped by bureaucracies of technical experts who organize society to accomplish all its tasks using the most efficient solutions that science can discover. Richard Rubenstein (1975) notes that the turning point in the Nazi genocidal program occurred in reaction to Kristallnacht (The Night of Broken Glass, November 9–10, 1938), when Heinrich Himmler (1900–1945), head of the Gestapo, the German secret police, rejected and suppressed the further use of mob violence that been promoted by Joseph Goebbels (1897–1945), German minister of propaganda. Himmler recognized that the only way to efficiently organize mass death was to remove the element of personal emotion and replace it with the cool and efficient operations of the impersonal techno-bureaucratic procedures that typified the death camps.

As the Holocaust well demonstrates, techno-bureaucratic organization is impervious to ethical considerations, because bureaucracy separates ends and means. When persons choose both ends and means they feel the connection in their experience out of which a sense of personal responsibility can emerge. But in a bureaucracy, those higher up are viewed as being in a better position to choose the ends than the technical experts, lower down in the hierarchy, who are charged with developing the means to accomplish them. The Nazi doctors who did the selections in the death camps saw themselves as mere cogs in a complex bureaucratic machine. Even if one refused to participate that would change nothing. Like a replaceable part, one doctor would simply be substituted for by another, more accommodating one. These doctors did not feel responsible because the victims were dead long before they ever got to the camps, declared so by those higher up in the bureaucracy who alone had the authority and responsibility. Indeed, the Nuremberg war-crimes trials that followed World War II (1945–1949) demonstrated the prevalence of this logic in the repeated defense of those accused who plead non-responsibility because they were "just following orders."

Ethics after the Holocaust

The Nuremberg trials, by identifying "crimes against humanity" for prosecution, represent an initial attempt to think globally about ethics. Indeed, the horror of the atrocities of World War II sent a global moral shock through the human race that led to the creation of the first global ethic in history. For the movement for human rights arose in response to the trauma of the Holocaust and the other atrocities of World War II. This movement culminated in the formation of the United Nations (UN) in 1946 and the adoption of the Universal Declaration of Human Rights by the UN in 1948. The preamble to the declaration recalls the "barbarous acts which have outraged the conscience of mankind," preparing the way for the declaration's main body, which strongly affirms the unity of humanity. Consequently this document stands against all ideologies that would divide humanity, racially or otherwise, in order to claim the world and its resources for some superior *volk*—as the Nazis attempted to do.

Unlike the technical and esoteric language of most academic treatises on ethics, human rights language is a language that has spontaneously taken root in cross-cultural public discourse. The language of human rights has become embedded in the language of politics and international relations. Even if, in many cases, the political use of this language is hypocritical, still that is the homage that vice pays to virtue, which means that human rights can be used as a measuring rod for cross-cultural social and political criticism.

Moreover, in the aftermath of World War II, a plethora of both governmental and nongovernmental organizations committed to preserving and protecting the rights of all human beings across all religions and cultures has emerged, deeply influencing global social policies. Such organizations include the UN itself, especially its Commission on Human Rights and its various subcommissions, as well as the International Court of Justice and regional conventions on human rights in Western Europe, the United States, and Africa. Then there are the governmental offices of individual nations that monitor each other for rights violations and use this information to political advantage. (Motivations of self-interest aside, this political game does keep the pressure on to observe human rights.) Finally, there are nongovernmental voluntary associations committed to human rights such as Amnesty International, the Anti-Slavery Society, and the International Committee of the Red Cross as well as religious organizations, labor organizations, and professional associations.

In the last quarter of the twentieth century and into the twenty-first, the Holocaust or Shoah has become a symbol for the universal call to conscience and responsibility on behalf of the human dignity and human rights of all. In this context the rhetoric of the Holocaust and of human rights, as one might expect, has often become politicized and sometimes trivialized. And yet the moral climate of human history has been unarguably changed by the language of "human rights" and "human dignity" evolving into the global moral language of accountability and by the Holocaust becoming a powerful symbol of everything that would violate such dignity and rights.

HOMOSEXUALITY DEBATE

Homosexuality has been a subject of scientific study for many years. Much of the research has focused on whether homosexuality is a product of biology or psychological conditioning. That nature-nurture question often has entered into ethical and political debates about homosexuality. For example, in the early 1990s two studies were released that indicated that homosexuality may be biological. One study identified distinctive neural structures in homosexual men (LeVay 1993). The other correlated a genetic marker with male homosexuality (Hamer and Copeland 1994).

Those studies received significant media attention because they seemed to strike at the heart of the political debate about gay rights. Opponents of gay rights had argued that homosexuality is a choice and that homosexuals seek "special rights" for a deviant and destructive lifestyle. Consequently, gay rights advocates began to argue that the studies mentioned above showed that homosexuality is not a choice but an innate biological characteristic worthy of constitutional protection.

Early Studies of Homosexuality

These debates about homosexuality date back to the mid-nineteenth century, when Karl Heinrich Ulrichs (1825–1895), a German jurist, attempted to theorize homosexuality as a biological condition. Ulrichs believed that the embryo contains female and male "germs" and that as an embryo develops, one of the germs becomes dominant, producing either male or female sexual organs. These sexed germs, he argued, also produce the sex drive, and thus it is possible for the body of one sex to possess the sex drive of the other. Because Ulrichs was a jurist, not a scientist, his primary concern was to secure the civil rights of homosexuals, and he believed a biological theory would facilitate his efforts (Brookey 2002).

Shortly after Ulrichs introduced his theories, they were incorporated into the work of the neurologist Richard von Krafft-Ebing (1840–1902). Krafft-Ebing defined homosexuality as a predetermined sexual attraction brought about by either genetic or situational factors. *Situational homosexuality*, according to Krafft-Ebing, occurred when men were precluded from sexual intercourse with women or masturbated. He characterized situational homosexuality as an inherited condition that existed as the lingering residue of an animalistic bisexuality that would die out slowly in the process of evolutionary advancement (Brookey 2002). Krafft-Ebing's theories were influential for many years but would be eclipsed when Sigmund Freud introduced his own theories on human sexuality.

Freud argued that children are born into an innate state of bisexuality, but as they develop, this bisexual energy is directed into heterosexuality. However, if a child does not develop proper relationships with his or her parents, sexual development may be arrested and homosexuality can result. Freud did not believe that homosexuality is always the product of psychological pathology. Consequently, he regarded efforts to change homosexuals into heterosexuals with great pessimism (Lewes 1988).

Modern Theories

After World War II American psychoanalysts reinterpreted Freud's theories, particularly those regarding homosexuality. The psychologist Sandor Rado (1890–1972) led that effort when he rejected Freud's theory of innate bisexuality. Rado argued that bisexuality does not exist, rejected the possibility of biological homosexuality, and argued that homosexuality can only be a product of mental pathology. He claimed that homosexuality is a mental pathology and that the possibility for change is much greater than Freud supposed. Edmund Bergler (1889–1962) was a Freudian who advocated psychoanalytic therapy and claimed to have converted homosexuals. Bergler was also an active opponent of the early gay rights movement, and he often testified in government hearings that homosexuals should be precluded from public service.

The psychoanalytic position on homosexuality remained unchallenged until Alfred Kinsey (1894–1956) began publishing his research on human sexuality. Kinsey's work indicated that human sexuality is much more varied and fluid than psychoanalytic theories supposed. Rado's dismissal of bisexuality was challenged by Kinsey's empirical findings, which indicated that a significant number of adults had sexual experiences with persons of both sexes. Consequently, Kinsey's work also challenged psychoanalytic beliefs about homosexual pathology because it recognized that homosexuality was practiced by a variety of individuals and did not treat homosexuals as a distinct or deviant class. The psychiatrist Evelyn Hooker (1907–1996) also challenged many psychoanalytic assumptions about homosexuality. Specifically, Hooker's research concluded that many homosexuals did not suffer from severe mental disturbances and that homosexuals were just as diverse in their behavior and psychological profiles as heterosexuals were.

Kinsey's and Hooker's research established doubt in the psychiatric community about the pathology of homosexuality, and in 1973 the American Psychiatric Association (APA) voted to remove homosexuality from its list of mental diseases. That decision reflected suspicion of psychoanalytic approaches and concern about the use of behavior modification conversion therapy. Many psychoanalysts protested the decision, and *ego-dystonic homosexuality,* a condition experienced by homosexuals who wanted to change their sexual orientation, remained on the list so that therapists could continue to practice conversion therapy. Even that exception, however, was eliminated in 1997 when the APA determined that psychological therapies cannot cure homosexuality.

Judicial Decisions and Ethical Issues

The publication of LeVay's and Hamer's studies has renewed interest in biological explanations of homosexuality. Although gay rights advocates thought that research would yield political advantages, arguments about the biological basis of homosexuality did not acquire legal traction. A biological argument was presented to the Supreme Court in the 1995 hearing on Colorado's Amendment 2, an anti–gay rights initiative. Although the Court ruled against the initiative, the evidence demonstrating a biological basis for homosexuality was not mentioned in its decision (Keen and Goldberg 1998). In addition, the biological argument did not figure in the Court's 2003 decision to strike down state anti-sodomy laws.

Apart from the legal question, there are ethical concerns about the use of biological research to treat homosexuality (Murphy 1997). Would a "homosexual" gene lead to a genetic test for homosexual predisposition? Would couples choose to abort a fetus that tested positive for this genetic predisposition? Could homosexuals seek genetic therapy in order to change their sexual orientation? Could homosexuals be compelled to submit to that therapy? Currently, these ethical questions are moot because additional research has not verified Hamer's and LeVay's research conclusively. Both the legal and the scientific debates about homosexuality have not been resolved.

HORMESIS

Hormesis is a dose-response phenomenon in which a low dose of a toxin has the opposite effect on a biological system than a high dose of the same toxin. It is generally characterized as toxic effects that are beneficial at low doses and harmful at high doses. There is some ambiguity in the more precise definition of the term, however, because some speak strictly of low-dose stimulation of biological endpoints (for example, immune system strengthening), whereas others also use it to refer to low-dose inhibition of biological endpoints (such as tumor formation). Hormesis has long been marginalized in medical and environmental fields. A growing body of evidence suggesting hormetic effects across a wide range of biological organisms and systems, however, has brought increased credibility to the topic. The implications of hormesis are potentially huge, especially in terms of risk assessment policies and research paradigms. Skepticism and controversy persist surrounding the future status and impacts of hormesis as new research, aided by advanced technologies, yields uncertainty and more questions than answers.

History

Ideas similar to hormesis have been vaguely formulated for centuries, including Hippocrates' saying that "likes are cured by likes," Paracelsus's notion that "the dose makes the poison," and Friedrich Nietzsche's famous remark that "what does not destroy me makes me stronger." Hugo Schulz, a German pharmacologist who observed that small doses of poisons stimulated the growth of yeast, was the first to systematically describe hormesis in 1888. Rudolph Arndt, a German physician, found similar results in his research on the effects of low doses of drugs on animals. Arndt claimed that toxins in general produced stimulation of biological endpoints such as growth or fertility at low doses, which became known as the Arndt-Schulz law. It lost credibility in the 1920s and 1930s, however, because Arndt was an adherent of homeopathy (Kaiser 2003). Founded by Samuel Hahnemann (1755–1843), homeopathy parallels hormesis in two respects, namely the idea that likes cure likes (symptoms produced by toxic doses can be cured by a remedy prepared from the same substance) and the theory of infinitesimals, which stated that the more dilute a substance is the more potent it can become. The marginalization of Arndt's work meant that hormesis research did not receive federal funding during the formative years of toxicological development.

C. M. Southam and J. Erlich first coined the term hormesis in 1943 in research that showed an antifungal substance had stimulatory effects on fungi when administered in low doses. The term derives from a Greek root meaning to excite, indicating the ability of small amounts of dangerous substances to excite an organism's defense systems, thereby making it healthier than it would be otherwise. Hormetic effects have since been observed in organisms ranging from humans and rats to water fleas and various plants. Yet outside of low-level ionizing radiation studies (the field in which the concept of hormesis is best developed), these observations went largely unexamined and were usually treated as aberrant data.

Edward Calabrese and Linda Baldwin (2001) synthesized these disparate findings in the toxicology literature. They also found that hormetic dose-response curves outnumbered curves showing no effect at the lowest doses by 2.5 to 1 (2003). This coupled with older, extensive literature on the beneficial effects of minute doses of ionizing radiation for animals (Luckey 1980, 1991) sparked increased interest in hormesis. In 1990 a group of scientists representing several federal agencies, the private sector, and academia launched a program of analyses and workshops called Biological Effects of Low Level Exposure (BELLE) and a newsletter devoted to low-dose toxicology. The U.S. National Research Council (NRC) has sponsored research on radiation hormesis. Researchers in Japan note that victims from the World War II nuclear attacks, if they were sufficiently distant from the blast site, have lower death rates than peers not exposed to the radiation. Researchers at Johns Hopkins University found that tens of thousands of U.S. Navy shipyard workers exposed to radiation in the 1960s and 1970s have fewer cancers than nonexposed workers (Boice 2001). Others have found evidence that lung cancer rates are lowest in areas with the highest levels of radon.

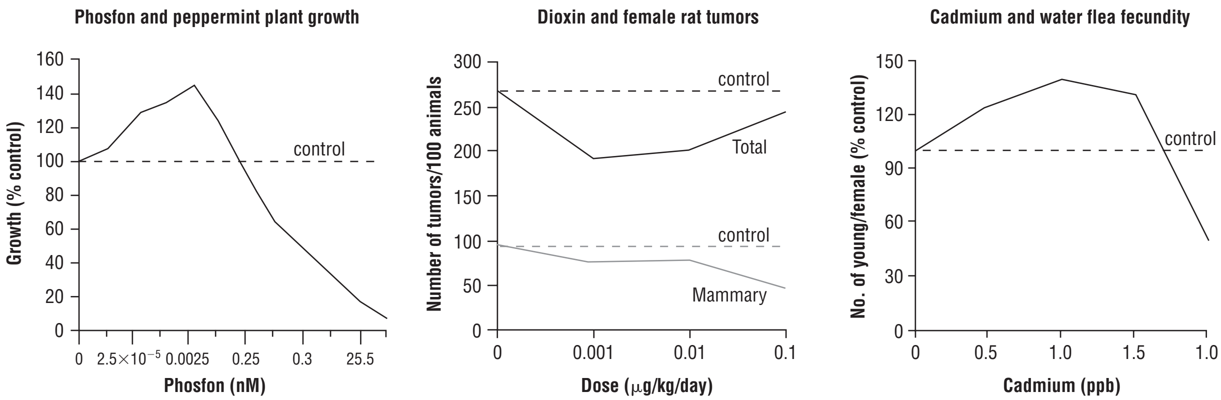
Explanation and Implications

The biological mechanisms underlying the details of hormesis are still poorly understood. In general hormesis is a manifestation of homeostasis, the fundamental property of living organisms to maintain internal conditions that are in a state of (dynamic) equilibrium. Biological systems, even at the molecular level, have adaptive responses to stress that can trigger a variety of effects including increased cellular repair, beneficial apoptosis (programmed cell death), and increased immunological strength (Stebbing 1982). For example, the cellular damage caused by exercise in the short-term stimulates beneficial long-term effects because certain physiological mechanisms overcompensate, thus making the body stronger. Caloric restriction has also been proposed as a hormetic phenomenon. Some researchers have found that low levels of dioxin reduce the occurrence of tumors in rats, low levels of cadmium increase water flea fecundity, and low levels of phosfon (a herbicide) stimulate peppermint plant growth (Kaiser 2003). These results show up as biphasic dose-response curves shaped like a *J* or an inverted *U* (see Figure 1). Such dose-response curves are not unique to hormesis, however, because they are found especially in studies of endocrine disruptors that have no beneficial effects at any dose.

When referring to nutrients, hormesis is rather straightforward. Iron, for example, is necessary for transporting oxygen throughout the body, but too much iron is poisonous. The largest scientific and political implications from hormesis come from research that shows beneficial effects from small doses of chemicals long believed to be toxic at any level, such as dioxin and certain pesticides. For example, heavy metals such as mercury spur synthesis of proteins that remove toxic metals from circulation and may prevent some DNA damage caused by free radicals. Because the relationship between dose and effect is the fundamental concept of toxicology, these kinds of results may bring about radical changes in environmental and medical sciences and regulatory practices.

FIGURE 1

The Puzzle of Hormesis



SOURCE: Kaiser (2003), p. 377

Low doses of phosfon, a herbicide, caused plants to grow better (left); small amounts of dioxin, a carcinogen, reduced tumors in rats (center); and a little cadmium, a toxic metal, caused water fleas to produce more young (right). The effects were reversed at higher doses.

Indeed some suggest that hormesis marks a revolution in toxicology, pharmacology, and risk assessment. The dominant environmental risk assessment model is twofold. For carcinogens, regulatory agencies use a linear, nonthreshold dose-response model that assumes no safe level of exposure. For noncarcinogens, regulatory agencies assume there is a threshold dose, below which there is no risk of harm. Both risk assessment models are riddled with assumptions due to extrapolations from high-dose laboratory experiments to the low doses characteristic of human exposure. Calabrese (2004) argues that the resulting uncertainty has led to a protectionist public health paradigm with stringent environmental standards that often come at high costs.

He claims that these two dose-response models erroneously calculate public health standards, poorly communicate risks to the public, lead to exorbitant cleanup costs, and provide the wrong cues about how to prioritize investments in the environment. Hormesis provides an alternative risk assessment model that harmonizes policies on carcinogens and noncarcinogens, eliminates the need to extrapolate data, and places environmental risk assessment on the same solid empirical grounding as health insurance and other forms of risk estimates. He also claims that hormesis has important implications for clinical medicine. It can improve the selection of dosages and help medical researchers avoid situations in which declining concentrations of drugs in the body (toward the end of treatment, for example) may actually stimulate the microbes or tumors they are intended to eliminate.

Clearly hormesis could radically alter environmental and biomedical practices. For certain carcinogens, for example, the benefits of hormesis may occur at levels higher than the recommended safe doses for humans. It could also change the way scientists perceive and measure risk. But major changes are not likely to occur swiftly. Beneficial hormetic effects differ by individual and are still poorly characterized, and military or industrial interests may compromise the integrity of some hormesis research. Furthermore much of the research done on hormesis has focused too narrowly on single endpoints such as cancer while ignoring others. This may mean that harmful effects at low doses are not registered. Regulators must understand complex interactive effects, which greatly increase the costs of research (Renner 2003). Most importantly Calabrese fails to consider the price paid for eliminating unverifiable extrapolations. Low-dose testing requires long-term experiments with much larger sample sizes than current risk assessment models, because at low doses small signal-to-noise ratios require researchers to collect more data in order to obtain acceptable confidence intervals. The long time periods required for such research are not suited to the needs of decision makers.

As Gary Marchant (2001) argues, the refusal by U.S. Environmental Protection Agency (EPA) regulators to consider the health benefits of ozone in their 1997 revision of air quality standards provides lessons for the regulatory implications of hormesis. First, regulatory agencies are highly resistant to considering hormesis because it is a nonintuitive phenomenon that departs from traditional toxicology assumptions. Second, scientific evidence for hormesis is severely scrutinized, which makes credibility difficult to achieve. Third, judicial review may be an effective mechanism for forcing regulatory agencies to consider hormesis.

The accumulation of scientific data and advances in the techniques of molecular biology have brought the phenomenon of hormesis and the attendant controversies once again to the forefront of science and society. Hormesis carries great economic, environmental, and public health implications, but conclusive data are hard to obtain because of the large sample sizes needed and ethical restrictions on human subjects research. Hormesis supports the argument put forth by Bruno Latour (1998) that science, rather than clearing away societal controversies, actually increases uncertainty. Continued research may resolve conflicts but it may just as well add new uncertainties to those currently generated by extrapolation in risk assessment models.

HUMAN CLONING

Human cloning, which occurs naturally but rarely with the birth of identical twins, became a technological possibility with the development of the technique of somatic cell nuclear transfer (SCNT) to clone the first mammal in 1996. As a result of this scientific advance, the prospect of human cloning quickly became a hotly debated ethical issue. As the debate developed it also became common to distinguish reproductive cloning from therapeutic cloning, each being subject to slightly different ethical assessments.

History and Science

Cloning (from the Greek word *klon*, a twig or slip) is a natural process of asexual reproduction found in many plants and some animals. When strawberry plants send out runners that set roots and turn into new plants, this is an example of a plant naturally cloning itself. Even artificial cloning is not entirely new. For hundreds of years gardeners have taken slips (small shoots or twigs cut from plants) and rooted them to produce new plants in a process that could also be described as cloning. Then in the 1970s scientists began experiments in artificial cloning with frogs and toads, and subsequently with other animal embryos. But it was not until the successful SCNT cloning of the sheep "Dolly," performed in 1996 and formally announced in February 1997 by the Roslin Institute in Scotland, that it became clear something similar might be possible with mammals.

Mammals have two kinds of cells: somatic cells (many of which can reproduce themselves by clonelike division, but only themselves and not a whole organism) and sex cells (which come in two forms, ovum in females and sperm in males). The SCNT process works as follows: The nucleus is removed from a somatic cell of either a female or a male. An unfertilized ovum is taken from a female and has its nucleus removed and then replaced with the somatic cell nucleus. The resulting ovum with a somatic cell nucleus is then stimulated and implanted in a female womb to grow to term. The resulting offspring is genetically identical to the individual that was the source of the original somatic nucleus.

The technology of cloning is thought to be feasible in many mammalian species, including humans. As of 2005, successes in cloning of many species have been achieved. But neither the cloning of primates nor of humans has been successful as yet. Human somatic cell nuclear transfer, if successful in producing offspring, would not be "duplication" because identical genomes do *not* produce identical phenotypes. Nevertheless, Korean scientists have used cloning technology to produce cloned embryos, and subsequent experiments have furthered such technologies, which are aimed at producing embryonic stem cells for research and therapeutic purposes.

The science and technologies of cloning remain in their infancy. Pharmaceutical companies have not expressed great interest in trying to work to clone people because they see much bigger markets in the cloning of animals and cells. Efforts to create a human clone have been limited largely to groups outside the mainstream of science and medicine, and no one knows for sure whether stem cells derived from cloned human embryos really will prove useful as a way to cure diabetes, liver failure, Parkinson's disease, spinal cord injuries, or any other disease or ailment.

Ethical Concerns

It is easy to see why there is so much interest in and concern about human cloning. There is seemingly no end to the parade of people who issue press releases proclaiming that they are close to success in cloning a human baby. And there is certainly a simple fascination with the technical possibility. Proponents of cloning have also suggested it might serve as a new, unusual, but perhaps efficacious treatment for infertility, enabling those unable to pass genes to future generations to do so in a way that is at least analogous to the familial linkage of twins. And, they point out, scientists have created animal clones and at least a small number of human cloned embryos with hardly any oversight or public accountability.

Dolly, the cloned sheep. The result of an experiment by Scottish embryologist Ian Wilmut, Dolly was the first cloned adult mammal. *(Archive Photos, Inc.)*

There are grave risks, however, to any resulting offspring: Mammalian cloning, through the SCNT process, has resulted in the birth of hundreds of organisms. But significantly more nuclear-transfer-generated embryos fail during pregnancy than would fail in sexual reproduction, and a substantial majority of cloned animals who have survived to birth have had some significant birth defect. For these and related reasons President Bill Clinton in 1997 issued a moratorium banning the use of federal funds for human cloning, a position subsequently endorsed by the National Bioethics Advisory Commission.

And for some who believe that any human embryo is a person from the moment of its creation, the fight over human cloning is a fight both about what constitutes membership in the human community and about the morality of abortion. Many opponents of abortion hope that if they can gain legal recognition for cloned human embryos they can then move on to get legal standing for any human embryo or fetus.

One such person is U.S. President George W. Bush. A few months after hearings at the United Nations in

TABLE 1

Chronology of Key Early Events in the Human Cloning Discussion

1932	Aldous Huxley publishes *Brave New World*, including the "Bokanovsky Process" for producing cloned children.
1938	German embryologist Hans Spemann publishes *Embryonic Development and Induction*, in which he speculates about the possibility that the nuclei of fully differentiated cells may be able to initiate normal development in enucleated egg cells.
1952	U.S. embryologists Robert Briggs and Thomas J. King first successfully transfer nuclei from early embryonic cells of leopard frogs to enucleated leopard frog eggs.
1960s and 1970s	British developmental biologist John Gurdon makes further advances in cloning frogs. Debates about the implications of cloning begin.
1966	U.S. biologist Joshua Lederberg publishes an article in *The American Naturalist* titled "Experimental Genetics and Human Evolution," in which he speculates on the implications of cloning humans.
1971	U.S. geneticist James D. Watson testifies before Congress on the subject of human cloning.
July 25, 1978	The birth of Louise Brown, the first baby conceived through in vitro fertilization (IVF), shows that human birth is possible from eggs fertilized outside the body and then implanted in the womb.
1994	The National Institutes of Health Human Embryo Research Panel issues a report that deemed research involving nuclear transplantation, without transfer of the resulting cloned embryo to a uterus, as one type of research acceptable for federal support.
1996	In the U.S. the Dickey Amendment is enacted, which prohibits federal funding to create human embryos for research purposes and research that destroys or discards human embryos.
July 5, 1996	Cloned sheep "Dolly," named after the country singer Dolly Parton, was born using somatic cell nuclear transfer (SCNT).
Feb. 1997	Ian Wilmut et al. (Roslin Institute), "Viable Offspring Derived from Fetal and Adult Mammalian Cells," *Nature*, vol. 385 (27 February), pp. 810–811, announces the birth of Dolly.
March 1997	President Bill Clinton issues moratorium banning the use of federal funds for human cloning, and asks the National Bioethics Advisory Commission (NBAC, also sometimes called the National Bioethics Advisory Board) to analyze the ethical issues involved. It issues its report in June 1997.
August 1997	Clinton Administration proposes legislation banning human cloning for at least five years, in order to give the NBAC sufficient time for reflection.
Sept. 1997	Thousands of U.S. scientists voluntarily commit to a five-year moratorium on human cloning.
Jan. 1998	Nineteen European countries ban human cloning. Dr. Richard Seed, a Chicago physicist, announces plans to clone a human being. U.S. Food and Drug Administration claims authority to regulate human cloning, making it a violation of federal law to attempt cloning without FDA approval.
Nov. 6, 1998	University of Wisconsin biologist James Thomson and Johns Hopkins biologist John Gearhart announce the isolation of human embryonic stem cells, sparking increased interest in therapeutic cloning.
Aug. 2000	President Bill Clinton announces new guidelines for the federal funding of embryo research, but in early 2001 President George W. Bush places them under review before they are implemented.
Nov. 2000	Japan outlaws human reproductive cloning.
July 2001	The U.S. House of Representatives passes the Human Cloning Prohibition Act to outlaw both reproductive and therapeutic cloning, but the bill dies in the Senate.
Nov. 2001	Scientists at Advanced Cell Technology make unverified reports of the first cloned human embryos.
Dec. 2001	Britain outlaws human reproductive cloning.
Feb. 2002	United Nations begins consideration of a world-wide ban on human cloning.
July 2002	The U.S. President's Council on Bioethics issues its report *Human Cloning and Human Dignity: An Ethical Inquiry*.
Sep. 2002	California becomes the first state to pass a law legalizing therapeutic cloning.
Dec. 2002	The Raelians make the unsubstantiated announcement that they successfully cloned a human being.
March 2004	Korean scientists announce they have used SCNT to clone human blastospheres.
June 2004	United Nations Conference on Human Cloning.

SOURCE: Courtesy of Carl Mitcham and Adam Briggle.

February 2002, Bush announced in a speech from the White House's Rose Garden that he favored a ban on all forms of human cloning, including the cloning of human embryos for the purpose of stem cell research (Bush 2002).

Bush warned that in our zeal to find benefits and cures we could also "travel without an ethical compass into a world we could live to regret." Throughout the rest of his speech were salted words and phrases such as "products," "design," "manufacturing," "engineered to custom specifications." Bush was concerned that cloning would lead to the literal manufacture of human beings. A few months later, on July 10, the President's Council on Bioethics issued a report concluding that moral concerns about human cloning were sufficient to warrant a complete ban on using cloning to make people and a moratorium of at least four years on using cloning for research purposes.

Bush was hardly acting alone in sounding the tocsin of moral concern about the dangers of cloning. He was simply the most prominent among a long list of conservatives, pro-lifers, and neoconservatives, along with a small number of neo-green thinkers, who saw cloning in general as holding the seeds of the degradation of humanity.

Reproductive Cloning

So is there a strong case against human cloning? Reproductive cloning raises the question: Would it be unethical for anyone to try to clone a human being today or at any point in the future? Those who oppose human cloning point to the repugnance of a style of reproduction with such profound potential for vanity, arguing that the freedom of children and the nature of the family are in danger.

There is little debate concerning the claim of most scientists and ethicists that it would be irresponsible and morally wrong to try to use cloning to make a human being anytime soon. The experience of using cloning to make sheep, cows, pigs, and mice has made it abundantly clear that cloning is dangerous. There is real risk of death for the clone and a high risk of disability, and there are also very real risks for the surrogate mother who carries cloned fetuses to term. Without better safety data from animals, including primates, there is no ethical justification for trying to clone a human being.

But safety, while a very real concern, is not a concern about cloning per se. Presume that cloning were to someday prove safe. Would it still be ethically wrong to use it to make people? Any answer that pins the dangers for early prospective clones on something other than mere physical harms novel to the cloning process can become diffused in two conceptual problems:

- one is attempting to protect future potential persons against harms that might be inflicted by their very existence, and
- societies around the world have indicated that they believe that the early cloning experiments will breach a natural barrier that is moral in character, taking humans into a realm of self-engineering that vastly exceeds any prior experiments with new reproductive technology.

Laws that would regulate the birth of a clone are philosophically difficult in part because they traverse complex jurisprudential ground: protecting an as-yet-nonexistent life against reproductive dangers, in a Western world that, in statutory and case law at least, seems to favor reproductive autonomy.

Many people seem inclined to put those philosophical issues, nonetheless, into a position of primacy in the human cloning debate, including President Bush and his chief bioethical adviser, Leon R. Kass. But the case against cloning when safety is taken out of the equation is a more difficult case to make than that which pivots upon safety alone. This is true whether one considers merely reproductive cloning or cloning for the sake of embryonic-based stem cell therapies.

One such argument against cloning people is that it is wrong to manufacture people. But cloning human beings is no more manufacturing them than using test-tube baby technology or artificial insemination or even neonatal intensive care. No one feels any less human for having been born in a neonatal unit or delivered by forceps or started up in a petri dish. Clones would be no less people with free will and human dignity than any other person.

Or would they? Some contend that cloning is wrong because everyone is entitled to their own unique genetic endowment. This too is not a strong argument because identical twins and triplets already exist and do quite well despite the existence of another person with the exact same genes. Even if one is worried that parents will try to manipulate or force the clone to behave or develop in certain ways, it has to be said that this is precisely what parents do with their children all the time whether they have a genetic tie to them or not. Should laws against cloning reach into social preferences about how children should be raised that are not enshrined in law?

Therapeutic Cloning

Even if the case against human reproduction by means of cloning is not as strong as it may initially appear, there remains the separate issue of human therapeutic cloning. Therapeutic cloning is not intended to create another human being. It employs SCNT to use the results for other purposes. Is it moral to create cloned human embryos simply to destroy them for the purposes of obtaining stem cells to use in medical research or for other potential uses?

Those who oppose the use of cloned embryos for research or therapeutic purposes do so on the basis of two arguments. First, they may oppose therapeutic human cloning weakly, on the grounds that the cloned embryos are potential human life and as such deserve respect. The opposition here is weak only insofar as it need not entail an opposition without compromise. Second, they may oppose therapeutic human cloning more strongly, on the grounds that embryos have the status of human beings from the moment of conception. Here this opposition is more likely to be one that resists any compromise.

In response to the stronger opposition the fact remains that left in a dish in a lab a cloned human embryo has no potential for personhood unless one assumes the voluntarism of highly trained specialists and of women with empty wombs. Even then such embryos are only dubiously embryonic in that their potential to develop in a human uterus has been anything but established, and their differences from "ordinary" embryos—whether or not one considers such embryos to be persons—have been shown to be abundant and significant. So it is not self-evident that it is immoral to make and destroy cloned embryos on the grounds that this is the same as killing a human being.

Assessment

National debates and those at the United Nations on whether or not to ban human cloning, either outright or merely for reproductive purposes, remain significant venues for science, technology, and ethics interactions. On the one hand, there may be considerable public policy difficulties in implementing any restrictions on reproductive cloning that does not also limit therapeutic cloning, because the initial SCNT technology (or some future technique of a related sort) would be the same for both purposes. On the other hand, it may be that reproductive cloning will remain morally unacceptable simply because it will always be too dangerous or too risky for the future offspring.

At the same time the irony may be that cloned human embryos, which arguably lack true personhood, will remain the best source for stem cells for research and therapeutic uses—uses that may enable humans to respond more effectively to dangers and risks from illness, disease, and injury. Yet because of the potential value of human stem cell research there are also active programs to develop ways to create such cells without involving human embryos. That there might be a technological fix for the moral divide between those in favor and those opposed to stem cell research remains a distinct possibility.

Either way, those who argue about the moral status of human clones and the processes that produce them represent the widest variety of perspectives—in what may almost be called the "kitchen sink" of bioethical debates, involving as they do as many obvious issues about cloning as one could conjecture, as well as a number of subtle issues that depend on careful science and good public policy. On the positive side are proponents such as Michael Fumento (2003) who see human cloning as part of a wave of historically unprecedented benefit and power. On the negative side are critics such as Francis Fukuyama (2002) who see threats to the very nature of humanity. How well society handles human cloning will demonstrate not only how it handles one of its most extreme and extraordinary cases of conflict in medicine, but also how prepared it is for a world in which different kinds of personhood and parenthood may become as ubiquitous as new kinds of food and transportation.

HUMAN GENOME ORGANIZATION

The Human Genome Organization (HUGO) is an international society of elected members with an interest in the scientific, commercial, and societal impacts of research on the human genome. HUGO should not be confused with the Human Genome Project (HGP), a U.S. program founded in 1990 and funded by both the U.S. Department of Energy and the National Institutes of Health. HUGO serves as a vehicle for the international coordination of human genome research.

A group of forty-two scientists founded HUGO in September 1988 after a discussion spurred by molecular biologist and Nobel laureate Sydney Brenner (b. 1927) began in April of that year. In the same year the Department of Energy and the National Institutes of Health signed a memorandum of understanding to cooperate in support of human genomic research. An eighteen-member executive council leads the organization, but the complete membership forms a general assembly with ultimate control of the organization. Members of the organization also serve on a number of committees on particular topics, such as ethics and intellectual property rights. New members are elected annually after receiving nominations endorsed by at least five previous or current members.

The purposes of HUGO are to assist the international coordination of research on the human genome, coordinate and facilitate the exchange of data and biomaterials relevant to human genome research, and encourage public debate and provide information and advice on the scientific, ethical, social, legal, and commercial implications of human genome projects (McKusick 1989).

The HUGO Council and its committees have released a number of statements concerning societal impacts, including statements on patenting, cloning, gene therapy, and benefit sharing. In 1996 the HUGO Council approved the first of those statements: "Statement on the Principled Conduct of Genetics Research," which was written by the ethics committee the previous year (Human Genome Organization 1995). The statement includes a general set of recommendations to address concerns about genetic discrimination, information access, and genetic reductionism, among other issues. The recommendations broadly urge the scientific community to meet those concerns through self-oversight and better training.

In statements on patenting in 1995, 1997, and 2000 HUGO argued that expressed sequence tags (ESTs) and single nucleotide polymorphisms (SNPs) do not merit patent protection without detailed knowledge of the biological function of the sequence in question. This position contrasts with patent laws in the United States and Europe, which allow the patenting of those sequences. HUGO argues that the sequences can be found easily with modern genetics computing but that patent seekers cannot determine the utility of a sequence without doing much more research. HUGO believes that granting patents on ESTs or SNPs prematurely creates disincentives for genetics research.

With regard to cloning HUGO has suggested that no one should attempt reproductive cloning of a human by means of somatic cell nuclear transfer but that basic research using that technique or other cloning techniques and therapeutic cloning should be pursued (Human Genome Organization 1999). However, HUGO also has suggested that embryos should not be created for the purpose of genetic research.

HUGO's statement on gene therapy in 2001 supported the pursuit of somatic gene therapy with strong safeguards, including public oversight and review (HUGO Ethics Committee 2001). The appropriateness of germline therapy that would affect a patient's descendants should be discussed widely. The draft stresses the need for public involvement in setting the limits and ethical principles that should guide gene therapy.

HUGO provides an avenue for the scientific community to communicate its position on the ethical and societal implications of biotechnology research. The organization's international membership includes many preeminent researchers in the field. However, membership is voluntary and the organization has no ability to sanction members or enforce its policies. Its contributions to discussions of the ethical and societal implications of human genome research have been minimal. The organization has not made those issues an important part of its mission.

HUMANISM

Humanism is a philosophy and way of life (a lifestance) based on empathy, reason, and experience. To humanists, empathy—which is the starting point for compassion and social action—is a product of human nature: the fact that humans are highly developed social animals. Reason is a product of human intelligence that, when combined with experience, leads to the scientific method. And humanists regard the scientific method as the only reliable tool for both acquiring and validating the knowledge necessary to realize the aims of human compassion. To the twentieth-century philosopher Bertrand Russell, the whole concept could be summed up this way: "The good life is one inspired by love and guided by knowledge" (Russell 1957, p. 56).

Given this premise, humanism is an essentially pro-science outlook. And because science becomes socially beneficial primarily through technology, humanists tend to be supportive of technology. Nevertheless, because empathic concerns are basic to humanism, and consequently to humanist ethics, any technology that proves itself more harmful than good in regard to humanity and living nature will be challenged by humanists. This is why humanists have been active in efforts to protect the environment, outlaw certain weapons, ensure product safety, minimize negative social impacts evident in widespread technologies, and so on.

On the other hand, because of the humanist focus on science as the primary means of knowing, there is no place for supernatural belief in humanist thought. Humanism is a completely naturalistic and nontheistic worldview. As such, it leaves humanists with the recognition that humanity alone must take responsibility for making the world better. Along these lines, Humanist Manifesto II (1973) states: "No deity will save us; we must save ourselves." Therefore humanists tend to be relatively fearless in the face of admonitions against scientific hubris and dire warnings that given technologies will allow humans to "play god." In the humanist view, science and technology are tools that allow humans to take charge of their lives, protect themselves from diseases and other dangers, and generally improve the human condition. Therefore, emerging technologies of great promise have tended to be welcomed by humanists rather than feared.

The roots of the humanist worldview are complex, so much so that this background is most clearly understood when pursued as three separate histories: that of the word *humanism*, the ideas of humanism, and the organized humanist movement.

The Word

The Roman grammarian Aulus Gellius, who flourished circa 160 C.E., noted (in *Noctes Atticae* [Attic nights] the dual usage of the Latin *humanitas* (humanity). One usage was comparable to the Greek concept of *philanthropia* and indicated an attitude of general benevolence or humanitarian sympathies, while the other was comparable to the Greek *paideia* and indicated the achievement of being humanized (*humanissimi*) through acquired learning in the liberal arts. Because this latter usage was seen as a capability that separated humans from animals—giving humans the power of independent judgment—it had been favored by the Roman orator and philosopher Cicero (106–43 B.C.E.) and the Roman scholar Varro (116–27 B.C.E.) as a civilizing force.

Such an autonomous, cultured view of life fell largely out of fashion during the Middle Ages, replaced by a notion that human beings were defined players within set hierarchies of the cosmic order, as maintained by the authority of the church, the empire, and the feudal system. But as a few cities and communes gained political independence in the fourteenth century, intellectual independence followed. And with it came a revival of the ancient Greco-Roman spirit. This took the form of a Renaissance literary and philosophic movement of scholars calling themselves *humanists*. Through a revival of classical letters and a focus on the humanities, Renaissance humanists promoted religious tolerance, worldly ethics, a sense of history, and an interest in nature. In the latter case, what had begun as a revival of humane letters became an impetus for the advancement of science, thus broadening humanism's meaning. Additional broadening occurred as humanist ideas came to be advocated not only by Roman Catholics but also by Protestants, Jews, and nonreligious skeptics.

During the subsequent period of the Enlightenment the term was little used. But in 1853 a democratic organization appeared in England, calling itself the Humanistic Religious Association of London and declaring emancipation "from the ancient compulsory dogmas, myths and ceremonies borrowed of old from Asia and still pervading the ruling churches of our age." Around the same time, in France, the pioneer sociologist Auguste Comte (1798–1857) formulated a "religion of humanity" out of his science-oriented, nontheistic philosophy of positivism.

In 1867 a group of radical Unitarians and freethinkers in the United States formed the Free Religious Association and eventually, by the end of the century, many came to propound what they called *humanistic theism*—essentially a mix of the most liberal Unitarianism, Universalism, and Reformed Judaism of the time together with freethought critiques of more traditional faith. Among the radical Unitarians was Edward Howard Griggs who in 1899 wrote a popular book, *The New Humanism: Studies in Personal and Social Development,* advocating science (particularly Darwinism), "the Greek ideal," Christian spirituality, and social change (including women's rights). These positions were all rolled into an idea for a new religion that would "teach the divinity of common things" and proclaim "the infinite significance of humanity." Another radical Unitarian was the Reverend Frank Carlton Doan, whose 1909 *Religion and the Modern Mind* set forth a more inner-directed, psychological humanism that promoted meditative self-awareness as the starting point for social progress.

Throughout the first three decades of the twentieth century, Irving Babbitt (1865–1933), Paul Elmer More (1864–1937), and Norman Foerster (1887–1972) developed what has been variously termed academic humanism, literary humanism, and the new humanism. This reactionary outlook called for a return to a classics-based education, declared the humanities superior to science, proclaimed human beings superior to nature, and advanced a puritanical morality of decorum. Vestiges of this viewpoint remain in the early twenty-first century among some specialists in the humanities (who sometimes term themselves humanists), often expressed through a distrust of science and technology.

Among philosophers, F. C. S. Schiller in England published *Humanism: Philosophical Essays* in 1903 and *Studies in Humanism* in 1907, advocating a subjectivist form of pragmatism. Later, Jean-Paul Sartre (1905–1980) developed an existential humanism and Jacques Maritain (1882–1973) a theocentric Catholic humanism drawing on the thought of Thomas Aquinas. There have even been both Marxists and Social Darwinists who have taken the humanist label.

While many or all of the above have been regarded as representing different types of humanism, it would be more correct to understand them as different usages of the same word. From this perspective, it is possible to see the current usage of the term humanism as more or less serendipitous and possessing largely superficial rather than substantive connections to the ideas of those who had used the word earlier. The origin of current usage is as follows.

During World War I, the American Unitarian minister John H. Dietrich (1878–1957), having doubts concerning his earlier Christian convictions, adopted a naturalistic, pro-science, ethical worldview linked to a progressive social outlook. But he had no name for this combination of ideas until he read a 1915 article by a positivist, Frederick M. Gould, published in a magazine of the British Ethical Societies. Gould used the term humanism to express a belief and trust in human effort. This was somewhat different from the Renaissance usage already familiar to Dietrich—which suggested that the word could be adapted to his own nontheistic form of Unitarianism. So Dietrich began using it.

Independently, in 1916, another American Unitarian minister, Curtis W. Reese, arrived at similar conclusions. His term of choice, however, was *the religion of democracy*. He argued that democratic religion is human centered in contrast with the authoritarianism of theocratic religion. Edwin H. Wilson, in his 1995 book, *The Genesis of a Humanist Manifesto,* tells how the two men met in 1917 at the annual Western Unitarian Conference: "While Reese was speaking . . . on 'The Religion of Democracy,' Dietrich pointed out: 'What you are calling the religion of democracy, I am calling humanism.' It was a momentous convergence of minds—and at that moment, a movement was launched" (pp. 7–8).

The Ideas

In *The Philosophy of Humanism* (1997), Corliss Lamont sees a number of historic ideas, trends, and movements as converging over time to create contemporary humanist thought: these being empirical science, ancient and modern philosophies of materialism and naturalism, free thought, liberal religion, democracy and civil liberties, Renaissance humanism, and literature and the arts—in other words, most of the Western intellectual tradition. There are similar trends in the histories of non-Western cultures, together with cross-pollination with the West, so Lamont also draws attention to relevant intellectual traditions in China, India, and the Middle East. This sort of approach, however, can be accused of creating a pedigree out of ancestors adopted for their compatibility.

Therefore, William F. Schulz, in his 2002 book, *Making the Manifesto,* focuses on more proximate antecedents: nineteenth-century science, the impact of Charles Darwin (1809–1882) and Sigmund Freud (1856–1939), cultural anthropology and the higher criticism of the Bible, free thought and religious modernism, progressivism and the social gospel, and the philosophies of pragmatism and critical realism. Nevertheless, because humanism is not the sum of these things, and because it continues to evolve, it is best described less in terms of its origins and more in terms of what it is: a worldview with the following features.

Humanism's epistemology is derived from the Instrumentalism (the view that the abstract concept of "truth" is best replaced by the more empirical concept of a "warranted assertion") of the American educator and philosopher John Dewey (1859–1952). Metaphysically it is naturalistic (the view that the universe is natural and there is no supernatural). Its worldly ethic is essentially altruistic but because of the humanist commitment to reason, it also involves elements of the Utilitarianism of the English philosopher John Stuart Mill (1806–1873), which holds that acts are good only to the extent that they have practical social benefits that can be rationally decided. Thus humanist ethics are situational (changing with situations) in a context of compassion as well as egoistically consequentialist (taking consequences into account from the standpoint of enlightened self-interest). In the social and political realm this dichotomy reveals itself in a recognition of the inherent conflict between individual liberty and social responsibility, leading to the conclusion that moral dilemmas are real and a necessary part of life and law. Democratic values—including social justice, the enfranchisement of the disenfranchised, and the open society—are central to humanism as an expression of the Golden Rule (do to others as you would have them do to you), which is itself a formula derived from the human capacity for empathy. In matters of personal self-development toward a meaningful life, humanism has been informed by Bertrand Russell's *The Conquest of Happiness* (1930).

The Movement

In 1876 the Society for Ethical Culture was founded by Felix Adler, a Reform Jew who was active in the Free Religious Association. Ethical Culture was a new religion that promoted ethical behavior and social service—deed above creed—with its values derived from neo-Kantian principles. By around 1950, however, the various Ethical Culture societies in the United States and England had evolved Adler's philosophy into humanism or had come to understand it as such. As a result, the American Ethical Union became one of the founding member organizations of the International Humanist and Ethical Union (IHEU), the world coalition of humanists.

In 1916 Reese and Dietrich began preaching humanist ideas from the pulpits of their Unitarian churches. Slowly humanism spread among Unitarians, aided by the creation of the Humanist Fellowship at the University of Chicago in 1927 and the founding of the *New Humanist* magazine one year later. In 1929 the Unitarian minister Charles Francis Potter left the denomination to found the independent First Humanist Society of New York, a church that would eventually count among its members Albert Einstein and Helen Keller.

Meanwhile in India in 1925 Periyar launched Self-Respect, a humanist political and social reform movement devoted to human rights and opposed to the caste system. Openly nontheistic and critical of Hindu and other religious beliefs, it was and remains a proponent of scientific and technological development.

A Humanist Manifesto, published in the *New Humanist* in 1933, was the first major document to lay down the basic principles of humanism. It was signed by prominent academic philosophers (including Dewey), clerics (Ethical Culture, Jewish, Unitarian, and Universalist), educators, journalists, scientists, and social reformers.

In 1941 a number of the manifesto signers founded the American Humanist Association and its magazine, the *Humanist.* Both continue into the twenty-first century, and the organization has counted among its presidents the Nobel Prize–winning geneticist Herman J. Muller and the science popularizer Isaac Asimov.

Following World War II a number of humanist organizations sprung up in Europe, India, and elsewhere. This international growth led to the founding of the IHEU in 1952 at a humanist conclave in Amsterdam chaired by the English biologist Julian Huxley. In the early 2000s the IHEU indirectly represents millions of humanists worldwide in national and local organizations on six continents.

In his 1957 book, *New Bottles for New Wine,* Huxley coined the term *transhumanism* out of a recognition that humanity "*is* in point of fact determining the future direction of evolution on this earth" and therefore a term is needed to signify "man remaining man, but transcending himself, by realizing new possibilities of and for his human nature" (pp. 14, 17). Huxley's word has been taken up by futurist-oriented humanists engaged in exploring the possibilities of radical improvements in the human condition and human capabilities through the likes of cyber-, bio-, and nanotechnology. To foster dialogue and advance this pursuit, the World Transhumanist Association was founded in 1998. Since then a growing number of people have been calling themselves transhumanists.

HUMANITARIAN SCIENCE AND TECHNOLOGY

Humanitarian was first applied to organizations such as the International Red Cross/Crescent, founded in 1864 by the Swiss philanthropist Jean-Henri Dunant (1828–1910), in response to his experience with wounded soldiers at the Battle of Solferino, Italy, in 1859. From the beginning the term was thus allied with an ethical vision for the use of science and technology (initially in the form of medicine) to benefit human beings who may have previously been harmed by technology (at first in the form of military weapons).

Background

Humanitarianism is an ethical vision closely associated with the creation of the social sciences. During the nineteenth century, modern natural science began to explore social phenomena, in part to deal with the challenges presented by new human powers over the natural world. Industrial technologies created urban centers that needed better management for the benefit of the human beings who lived in them, not as members of some political or religious or ethnic group but simply as human beings, who could also be scientifically studied as such. Public health and public engineering is for the benefit of all, although the "all" was in the first instance understood within a national context.

Humanitarianism thus aims to extend compassion beyond traditional family or village limits, especially through the utilization of science broadly construed. Although this may appear to have been simply a secular version of Christian missionary work—especially since humanitarian organizations often attracted voluntary contributions from believers—the increasing number of middle-class persons involved in providing relief for the victims of warfare and the improvement of urban slums constituted a historically unique social movement (Morehead 1999).

The larger background is that the early-1800s gave science and technology major roles in the construction, organization, and maintenance of both nation-state and colonial empire. First in England and France and later in the United States, centers of raw materials extraction and industrial production also created an exploited working class. Witnessing the living conditions of these people, humanitarian scientists and engineers often responded to alleviate such situations as best they could through technical improvements. After 1830 in Lille, France, humanitarian physicians studied and denounced the deplorable conditions of working class people in order to improve their health and living conditions (Gerard 1999). In 1838 German-born naturalist Robert Schomburgk sought to use his knowledge to reduce the enforced slavery of Indians in British Guiana by establishing a political boundary in harmony with their natural territory (Riviere 1998). Indeed in the 1800s humanitarian science, by emphasizing the unity of all peoples as human beings in the eyes of science, was a significant contributor to abolitionist movements throughout the world.

Across the turn of the nineteenth to twentieth century, international conflicts and natural disasters affecting large populations further spurred efforts to utilize science, technology, and medicine to ameliorate the conditions of wounded and displaced peoples. The Franco-Prussian War (1870–1971), the Ohio and Mississippi River floods (1884), the Spanish-American War (1898), the San Francisco earthquake (1906), and World War I (1914–1918) all provided major tests for the International Red Cross and related humanitarian agencies. The continued involvement of scientists and engineers in humanitarianism was reflected in scientist and inventor Alfred Nobel's creation of the Nobel Prizes at his death in 1896; the first Peace Prize was awarded to Dunant in 1901.

The twentieth century witnessed the further institutionalization of humanitarian activities related to science and technology in labor movements, public health work (including family planning), and immigrant settlement and education (which often emphasized technical education). Finally in response to the horrible uses of science in World War II (1939–1945), especially in the death camps of Nazi Germany, humanitarianism led to adoption of the Universal Declaration of Human Rights (1948), which stipulates "the right freely . . . to share in scientific advancement and its benefits" (Article 27).

Some argue that all science and technology are inherently humanitarian in their basic orientation, which was the view of both early modern scientists and proponents of the Enlightenment. Over the course of the modern period, however, it became increasingly recognized not just by socialists that special efforts are often needed to protect science and technology from dehumanizing distortions caused by economic or political interests. Efforts to liberate the benefits of science and technology from pernicious influences have taken place in national and international regulatory agencies, which may in many instances be styled humanitarian. Especially during the last half of the century humanitarian science and technology were further encouraged by four interrelated phenomena: the consumer movement, the environmental movement, the alternative technology movement, and public interest science.

Engineers especially also have been major contributors to international development work. For instance, the idea for the U.S. Peace Corps originated in 1960 with civil engineer Maurice Albertson, who was also intimately involved in its creation.

However, by the last quarter of the century, disaster and refugee relief had taken on characteristics that exceeded the capacities of many traditional humanitarian organizations. The end of the Cold War (1989) and the subsequent rise of genocide and terrorism as an international threat promoted humanitarian missions by the armed forces, which relied heavily on engineering skills. Increasingly humanitarian action involved scientific and technological developments in psychological counseling, high-tech monitoring (of military movements or weather), and the use of specially designed equipment (mobile power plants, water purification systems, and more). But a further response was the creation of new kinds of not-for-profit and non-governmental organizations oriented toward humanitarian action as part of an emerging international civil society. The failures and inadequacies of post-Cold War ideology of humanitarianism have also been subject to extensive criticism (see, for example, Rieff 2002).

Science and Engineering without Borders

Humanitarian science and technology may be related to what Carl Mitcham (2003) has termed *idealistic activism* among scientists and engineers, as illustrated by organizations such as International Pugwash (founded 1957) and the Union of Concerned Scientists (founded 1969). Among a diverse collection of related organizations seeking to build bridges between humanitarianism and scientific technology are the Responsible Care initiative of the American Chemistry Council and the International Network of Engineers and Scientists for Global Responsibility (INES). Responsible Care, founded in 1988, is a voluntary program to improve environmental health and safety in the chemical and related industries, especially in developing countries. INES, founded at a 1991 international congress in Berlin, is an association of more than ninety organizations in fifty countries promoting the involvement of technical professionals in humanitarian and peace development activities.

In 1971, however, humanitarian science and engineering activism took a new turn with the formation of *Médecins sans Frontières* (MSF or Doctors without Borders). MSF, which has become the largest non-governmental relief agency in the world, grew out of dissatisfaction with the inability of the Red Cross/Crescent to react independently of national government controls, and its tendency to remain within safe boundaries. The idealistic physicians of MSF pioneered new ways to bring medical science and technology to people in crisis and to speak out against human rights abuses. Since its founding, MSF has responded to needs resulting from earthquakes, hurricanes, war, and famine in Central America, Africa, Russia, the Balkans, and the Middle East (Tanguy 1999).

Inspired by MSF, other science and engineering organizations followed suit. Examples include *Avaition sans Frontières* (1980), providing air deployment for humanitarian projects, and ORBIS ophtalmologists (1982), providing preventive and surgical eye care to poor communities throughout the world. In the early-1990s, there also emerged independently a number of groups going under some form of the name Engineers without Borders: *Ingénieurs Sans Frontières—Ingénieurs Assistance Internationale* (Belgium), *Ingeniería sin fronteras* (Spain), *Ingenièrer unden Graenser* (Denmark), *Ingenjörer och Naturvetare utan Gräser-Sverige* (Sweden), *Ingegnería Senza Frontiere* (Italy), and others. In 2003 these groups organized Engineers Without Borders—International as a network to promote "humanitarian engineering . . . for a better world." The process has also led to educational programs in humanitarian engineering, efforts that parallel others in public health and nutrition science, and policy programs that seek comprehensive, interdisciplinary understandings of humanitarian crises.

Undoubtedly one of the personal inspirations for engineering without borders efforts was the life and work of mechanical engineer Fred Cuny (1944–1995). Following relief work in Biafra (1969), Cuny sought to bring his engineering skills to bear in earthquake disasters in Central America (1971 and 1976), Sudan (1985), Iraq (1991), Somalia (1992), Sarajevo (1993–1994), and Chechnya (where he was assassinated). Cuny's book *Disasters and Development* (1983) outlines what became known as the *Cuny approach*, an effort to respond to disasters not just by returning people to their predisaster state, but as opportunities to help them improve their lives beyond what otherwise might have been possible.

Defining the Field

Although subject to continuing debate, the basic dimensions of humanitarian science and technology may be summarized as follows. While advances in science and technology have benefited many persons, they have also often increased rich–poor divides, to which specific organizations have tried to respond. Among these, many emphasize science and engineering expertise. Humanitarian science and technology projects, typically operated on a not-for-profit basis, aim either to provide fundamental needs (such as food, water, shelter, and clothing) when these are missing or inadequate in the developing world, or higher-level needs for underserved communities in the developed world.

In contrast to corporations, which aim for relatively near-term profit, and governments, which fund in light of election cycles and constituent dependencies, humanitarian projects are of longer-term importance for society as a whole. Humanitarian science and engineering ideally engage local communities in direct participation in determining project needs and directions. Additionally they seek strategies, designs, and technologies that promote both the sustainability of natural systems and cultural traditions.

HUMANIZATION AND DEHUMANIZATION

To humanize is to engage with the human. In many instances this involves actions or constructions to accommodate the limits or needs of human beings, as in the "humanization of science and technology." While science and technology have themselves been extolled as humanizing the world, they have also been criticized as in need of humanization—that is, as dehumanizing. Indeed, it is the negative concept that is in more common use and has emerged to play important roles in at least four areas: psychology, theology, art, and social criticism.

Psychology, Theology, and Art

In social psychology dehumanization is defined as the process by which one person or group views others as not worthy of humane treatment. The dehumanization of enemies is common in personal conflict, civil strife, and warfare—and in the case of large-scale warfare perhaps even unavoidable. Extreme dehumanization leads to crimes against humanity and acts of genocide such as the Holocaust, where even technicians and other "innocent" German citizens were culpable in the dehumanization of victims. There are two types of dehumanizing agents here: those who actually commit the crimes and those who passively conform and silently witness them. In both cases, the act of characterizing others as less than human may serve as a coping mechanism to dampen the psychological effects of mass cruelty. The use of dehumanizing names to disparage others is not confined to extreme or fringe situations, however. Such disparaging language can also be found in mainstream elements of society including laws, magazine articles, and scientific journals (Brennan 1995). Research in conflict resolution and peace studies promotes techniques for the rehumanization of enemies (Stein 1996).

Psychological analyses of dehumanization have described it as a process by which individuals or groups project their own faults onto opponents. Dehumanization in this sense is thus a generalization of the scapegoat phenomenon (Girard 1986), which plays an important role in Christian theology. Moreover, in part because of the Enlightenment claims for the humanizing character of science and technology as opposed to the dehumanizing character of religion, religious and theological discussions have developed extended arguments for religion as a humanizing factor in human affairs. For example, Barbara Rumscheidt (1998) argues that the development of socially engaged Christian faith communities can counteract the dehumanizing effects of globalizing capitalism.

Two specific religious contexts in which the question of humanization has taken form are in Marxist-Christian dialogues and liberation theology. In both these cases the problematic of scientific and technological development is also important. For example, the roots of liberation theology stem in part from industrial development in Latin America, which benefited some but marginalized and impoverished others. Subsequent ecclesiastical developments addressed the question of how economic and technological modernization can promote genuine human progress for all.

José Ortega y Gasset (1925) used the concept of dehumanization to characterize art in the early twentieth century, which by abandoning traditions of romanticism and realism, deformed reality and shattered its merely human aspect. In avant garde art, all that is real, natural, and human is purged in favor of purely artistic elements—which, for Ortega, is actually a good thing. Dehumanization in this context is an aristocratic revolt against the industrial massification of culture, an effort to break through to a higher form of civilization, anticipating subsequent notions of post- and transhumanization.

Criticizing Science and Technology

Ortega was also one of the first philosophers to address both the humanizing and dehumanizing aspects of technology. For Ortega technology is an integral part of being human, but by overwhelming human beings with means to transform the world modern technology can undermine the more central human attributes of imagination and intentionality. As if reflecting Ortega's notion, social criticism of science and technology has tended to bemoan both unrealized possibilities and popular acquiescence to inertial trajectories in technoscientific development. Indeed, according to Carl Mitcham (1984), the question of humanization is one of the most broad and synthetic themes in the critical examination of technology. In what ways, and to what extent, do science and technology promote or obstruct human well being? In terms of the individual, this is an ethical question; in terms of social institutions it is a political one.

Three key arguments for science and technology as humanizing forces are as follows. First, science is a natural expansion of human knowledge that promotes material progress as well as intellectual and spiritual fulfillment. This dual humanizing quality of science was famously portrayed by novelist C.P. Snow's "two cultures" argument, in which scientific intellectuals are viewed as more humane than their literary intellectual counterparts.

Second, science has a normative structure that reciprocally reinforces democratic principles and practices, according to sociologist Robert Merton, scientist Michael Polanyi, philosopher Karl Popper, and others. Since the Enlightenment, the structures of the republic of science have often been presented as models for civil society.

Third, technology humanizes by freeing human beings from disease and other burdens of nature. Economist Julian Simon, for instance, has been an outspoken advocate of the view that technology has increased human prosperity and well-being and will continue to do so as long as humans are allowed to freely develop and deploy it. A collateral argument is that computers and artificial intelligence humanize not just nature by placing it under human control but the world of artifice as well by overcoming the limits of machines and making them more human-like.

In opposition there are also three key arguments for science and technology as dehumanizing forces. First, scientific knowledge is said to alienate humans from the natural, organic, or lived experience. Behaviorist psychology and rational actor theories in the social sciences reduce humans to bundles of calculations and reactions. More generally, Edmund Husserl, in analyzing how the sciences interact with the "life world," warned that modern science arose on the basis of a great forgetting of the immediate, which played out in a parallel amnesia in the human sciences (Rajan 1997).

Second, technology creates an artificial world that is even more burdensome than nature. Some versions of this argument lament the spiritual disease and the feelings of anomie and powerlessness engendered by the modern, Western world (for example, Montagu and Matson 1983, Ryan 1972). Technology has increased the tempo of life to a frantic pace and the massification of production processes and media images produce the foreboding by Ralph Waldo Emerson that "Things are in the saddle,/And ride mankind." Indeed social theorist Jacques Ellul argues that technique has shifted from success in the material world toward a broad spectrum of human activities from education to politics, art, and even ethics—each of which it transforms into a technical process aiming at some form of efficiency. For radical educational theorist Paulo Freire (1970), such dehumanization becomes perfected when it is welcomed rather than shunned, and rehumanizing begins by raising consciousness of one's less-than-human existence.

Third, the conquest of nature and the transformation of the social world leads to the conquest of human nature—and thereby its destruction. This argument, as advanced, for instance, by the literary scholar, novelist, and lay theologian C.S. Lewis, has been revised and deepened by, among others, intellectual historian John Hoberman and science policy philosopher Leon Kass. For Hoberman (1992), the use of drugs to enhance performance raises fundamental issues about the structure of human activity and the connection between performance and effort. For Kass, "Human nature itself lies on the operating table, ready for alteration, for eugenic and neuropsychic 'enhancement,' for wholesale redesign" (2002, p. 4). What is most disturbing about this situation, which was foreshadowed in Aldous Huxley's *Brave New World* (1932), is not the lack of freedom or equality, but the dehumanization and degradation of people who choose "nothing humanly richer or higher"—a fate that may emerge in regimes of individualist democratic consumerism more than totalitarian control.

Assessment

As this third critique of technology demonstrates, judgments of both humanization and dehumanization are necessarily based on visions of human nature. They are related to notions of humanism that likewise involve assessments of the character and influence of science and technology. As such, the concepts of humanization and dehumanization fail as primary ethical concepts for the judgment of science and technology, although they often figure in popular discussions as summary presentations of more fundamental views.

Cultural and philosophical visions of human nature can even create fundamentally opposed understandings of humanization and dehumanization. For example, some philosophical anthropologies envision humans as radically circumscribed by the limits of mortality and futility. From this perspective, dehumanization may occur when such limits are drastically altered or surpassed. Other treatments of human nature characterize humans as self-making beings with unbounded potentialities. From this perspective, the imposition or voluntary submission to certain limits could be regarded as dehumanizing acts.

HUMAN NATURE

Many ethical judgments make appeals to human nature either as their foundation or as their standard. In the strongest case ethics is argued to be based on human nature; in other instances actions are proscribed if they fail to respect human nature or are recommended because they are said to be in harmony with human nature. Human nature is also an object of scientific investigation, raising questions related to both process and product: whether scientific investigation is undertaken in ways that respect human nature and whether the results of such investigations can contribute to the understanding of human nature in an ethically relevant sense. After a brief review of theories of human nature, the focus in this entry will be on the final question: the extent to which scientific knowledge of human beings can contribute to understanding or assessing these theories, especially in their role as foundations for ethics.

Theories of Human Nature in History

According to Leslie Stevenson (2004), theories of human nature entail theories about the world, human beings, what might be wrong with human beings, and how anything that is wrong might be corrected. Even those who deny any essential human nature in favor of a historical or cultural construction of human nature have views about what kinds of things human beings are and their place in the world. However, with regard to explicit theories of human nature, premodern theories generally viewed humans as properly subordinate to a larger order so that even though people on occasion rebel against that order (by means of what the Greeks calls *hubris* and the Bible calls sin), they are called upon to learn to control such rebellion by means of ethical or religious practices. By contrast, modern theories tend to see human beings as unjustly limited by the larger order and thus encouraged to overcome those limitations, often by means of science or technology.

More specifically, for Plato, in a famous analogy from the *Republic* (p. 437b ff.), the human soul is presented as being composed of three parts: appetite, reason, and spiritedness. Lack of order results whenever appetite or spiritedness predominates and steps outside the guidance provided by reason. In a similar manner, for Aristotle in *Nicomachean Ethics* (vol. I, p. v), human lives can be oriented toward pleasure, politics, or knowledge, but the perfection of human nature resides with rationality in both practice and theory. Thomas Aquinas (1224–1274) further develops this perspective by arguing that the lawful order of nature is manifest in human nature (in a form he terms natural law) in aspirations to life, affective sociability, and the rational pursuit of both politics and science. Although the Jewish, Christian, and Islamic views of human nature seek in some measure to subordinate rationality to faith in revelation, that faith, like reason, ultimately places boundaries on appetitive, political, and even scientific activities. Structurally similar views can be found in the Asian religious and philosophical traditions associated with Hinduism and Buddhism.

More typically modern theories such as those of Thomas Hobbes (1588–1679) and John Locke (1632–1704), even when they offer a materialist and mechanistic analysis of the workings of human nature, argue that humans are improperly constrained by the state of nature. In Hobbes's frequently cited description, the state of nature is one in which human life is "solitary, poor, nasty, brutish, and short" (*Leviathan,* vol. I, p. 13), a condition from which human beings justly seek any means of escape. This notion that people are unjustly constrained by the human condition is repeated and developed in philosophies as diverse as those of Jean-Jacques Rousseau (1712–1778), Immanuel Kant (1724–1804), Georg Hegel (1770–1831), and Karl Marx (1818–1883). According to Rousseau, for instance, "Man is born free, but everywhere is in chains" (*Social Contract,* vol. I, p. 1). The psychological theory of Sigmund Freud, with its distinction between id, ego, and superego, reverses Plato's theory by suggesting the primacy of id or appetite over both individual self (ego) and social restraint (superego).

Three Basic Approaches to Human Nature

What can science contribute to the assessment or criticism of these diverse theories of human nature? One scientific debate concerns the relative influences of nature and nurture in human affairs. Another focuses on degrees of rationality or nonrationality in human decision and action. Among the most fundamental questions is that concerning whether there is something—a rational or transrational mind or soul—that cannot be accounted for by the same material causes that govern all other things in the natural world.

Materialism (or physicalism) is the position that the physical world is self-contained or closed so that the physical world can be explained only through physical causes and effects. In considering human nature, a materialist would say that human beings must be explained as purely material mechanisms, as physical bodies governed exclusively by physical causes. Consequently, the human mind should be understood as an activity of the physical brain. All the thinking, feeling, and willing of the conscious self must be determined totally by the body, particularly the brain and nervous system.

Against such a materialist view of human nature a dualist would argue that mind is not fully reducible to body, that the mind can act as an immaterial cause on the material brain. An interactionist dualist would agree that the mind depends on the brain as its necessary but not sufficient condition. Thus, if some part of the brain is damaged or ceases to function normally, this can interfere with mental activity. Still, as long as the mind is supported by normal brain activity, the mind can exert its independent power over the brain. When people act through conscious thinking and willing, they use their immaterial minds to control their material brains. A religious believer might go further and claim that the immaterial mind was created by an immaterial God, and thus the mind or soul is supernatural. This supernatural character of the soul could render it immortal so that the human soul could survive the death of the human body.

There are, then, at least three fundamentally distinct views of human nature that are based on three views of the relationship between mind and body. The materialist believes that the mind has no immaterial power to act on the body. The interactionist believes that the immaterial mind interacts with a material body. The supernaturalist believes that the immaterial mind is supernatural and immortal. Each of these views implies more general perspectives on human beings and their place in nature.

Traditional Arguments for Interactionism

These conflicting views run throughout the history of natural science from Socrates to the present. In Plato's *Phaedo* (pp. 96a–100a) Socrates (470–399 B.C.E.) talks with his friends while awaiting execution. He recounts that as a young man he thought that a scientific investigation of nature would explain the causes of everything. He hoped to explain the physical causes of all things coming into being and passing away, including the causes of animal life and the causes of human thinking in the brain. He became frustrated when he found that a complete science of nature as governed by physical causes was beyond his grasp. To explain the world, Socrates insists, it is necessary to understand both physical causes and mental causes. For example, to explain why Socrates is sitting here awaiting his execution, one might describe the physical mechanisms in his body—the bones, muscles, ligaments, and so on—that control his movement. However, although these physical causes are necessary in explaining why he is sitting here, they are not sufficient. It is also necessary to explain how Socrates made up his mind to accept his punishment because this mental decision controls his physical body.

Socrates appeals to a person's ordinary experience of making up his or her mind and then freely choosing to act according to that conscious mental decision; this leads people to think that the mind has a power to act that changes the physical causes of the body. Holding oneself and others morally and legally responsible for their conduct assumes that freedom of thought and choice. People do not hold nonhuman animals or human children morally responsible for their behavior because it is assumed that they lack the moral freedom that is attained only by the development of rational choice in normal human adults through learning and habituation. If human conduct were fully determined by physical causes in the body, it would be impossible to hold people morally or legally responsible for their conduct.

From ancient Greece to the present this kind of Socratic thinking has led many scientists, philosophers, and theologians to conclude that human nature is characterized by a complex interaction of mind and body, mental causes and physical causes. The human mind acts upon the human body, or the mind exerts an immaterial power that is not reducible to the material causes of the body.

Modern Arguments for Materialism

Socrates was responding to a materialist or physicalist tendency that would become a strong tradition in Western science. That materialist tradition gained great power during the scientific revolution of the sixteenth and seventeenth centuries. Proponents of the new science saw the universe as a mechanism that could be explained by mechanical laws working through purely physical causes. It seemed that much of human nature could be explained similarly without invoking an immaterial soul.

Hobbes saw nature as matter in motion governed by laws of motion such as those discovered by Galileo (1564–1642). Animal life, then, including human life, is "but a motion of limbs." "For what is the heart, but a spring; and the nerves, but so many strings; and the joints, but so many wheels, giving motion to the whole body" (*Leviathan*, Introduction). Animal motion is driven mechanically by selfish passions that goad animals to seek pleasure and avoid pain. Although human beings are moved by some of the same selfish passions, humans are unique in their capacity for reason and speech. However, even this uniquely human intellectual activity can be understood mechanistically as the computational manipulation of informational symbols (*Leviathan*, vol. I, p. 5). The soul or mind cannot be immaterial. It must be the activity of the material body. This must be so if one accepts the claim of natural science that everything in the universe is matter in motion. Because of his materialism Hobbes was denounced by religious and political leaders as a morally corrupting teacher of hedonism, egoism, and atheism.

Hobbes's materialist science of the soul seemed to be confirmed by Thomas Willis's (1621–1675) studies of the brain. Working in England at the same time as Hobbes, Willis compared the anatomy of the human brain with that of other animal brains and combined experiments on brains with medical observations of brain-damaged patients to develop what he called "neurology." He reached five broad conclusions. First, all mental experience arises from the motion of "animal spirits" undergoing chemical changes in the brain. Second, different parts of the brain have different functions. Third, the human brain resembles other animal brains, particularly those of monkeys and apes. Fourth, this science of neurology could be used by medical doctors to cure diseases of the brain through the use of drugs that would alter the chemistry of the brain. Fifth, all this supports the general view of the "mechanical philosophy" of the seventeenth century that the human body and brain are both machines explainable by mechanical laws.

Although Willis was mistaken about many details, his broad conclusions are supported by modern neuroscience. What Willis called animal spirits can be understood as electrical and chemical signaling between neurons. Willis's observation that the brain has specialized functions has been elaborated by studies of the ways neurons are organized into modular networks with distinct functions. Willis's claim that the human brain resembles the brains of other animals can be explained by evolutionary biology. His hope that drugs could cure the diseases of the soul seems to have been fulfilled by modern psychopharmacology in its use of drugs to treat mental disorders and enhance mental function. Finally, Willis's mechanistic account of the mind has been elaborated with computer models of the mind as an information-processing system.

It may appear, then, that the science of the human brain initiated by Willis proves Hobbes's materialist view of the soul. However, Willis was not a strict materialist because he believed that his science showed the existence of two souls. The "sensitive soul" found in all animals was purely material and therefore vulnerable to physical diseases. In contrast, the "rational soul" found only in humans was immaterial and immortal, although it depended on the sensitive soul. Thus, Willis's account of human nature was interactionist in that he thought the material brain and the immaterial soul mutually influence each other. He was also a supernaturalist in that he thought the immaterial soul was created by God to be immortal.

In the early twenty-first century some scientists, such as James Watson (2003), Edward O. Wilson (1998), and Steven Pinker (2002), argue that natural science sustains a purely materialist view of human nature and refutes any belief in the human soul as immaterial or immortal. Those scientists dismiss belief in an immaterial soul as an unscientific superstition. However, other scientists, such as Wilder Penfield (1978) and John Eccles (1994), defend Willis's interactionist view of the mind as an immaterial cause that can act on the brain. Eccles, a Nobel Prize–winning neuroscientist, has argued that modern neuroscience is compatible with belief in the self-conscious mind as an immaterial power for thinking and choosing.

Ethical Implications

What difference do these debates over the science of mind-brain interaction make for an understanding of human nature and morality? Those who argue for an immaterial soul agree with Socrates that the capacity of the mind to act outside the laws of physical nature is necessary for moral freedom. They warn against scientific materialism as a denial of free will that would make it impossible to hold people morally responsible for their conduct. They also warn that a materialistic view of human nature would promote a Hobbesian hedonism in which people would see themselves as animals moved by selfish passions with no spiritual capacity for rising above their material interests. To explain the soul as merely biochemical activity in the brain would seem to deprive human life of any unique moral dignity. Moreover, if scientific materialism teaches that human nature has only limited dignity above the rest of nature and if the ultimate end of modern science is the conquest of nature, people may be tempted to use the technological power of science to alter human nature itself in ways that would be dehumanizing.

The history of eugenics illustrates the potentially corrupting effects of a materialist view of human nature. The Judeo-Christian view of human beings as having been created in God's image with immortal souls has supported the moral principle of the special sanctity of human life. However, by the end of the nineteenth century modern science, particularly Darwinian science, had persuaded many people that human beings are merely highly evolved animals and that they do not have immaterial or supernatural souls that set them above the rest of animal nature.

If human beings are products of an evolutionary process governed by survival of the fittest, it seemed that reproductive fitness would be the only moral value coming from nature. Proponents of eugenics argued that human beings should be bred just as other animals are to improve the genetic quality of the species. As a result many state governments in the United States passed laws that forced individuals regarded as genetically inferior to be sterilized so that they could not reproduce. In Nazi Germany, Adolf Hitler (1889–1945) used policies of eugenics, euthanasia, and genocide to eliminate people whom he identified as belonging to inferior races. Some historians, such as Richard Weikart (2004), have explained the horrors of eugenics and Nazism as having been caused partly by the influence of Darwinian materialism in devaluing human life.

Other philosophers such as Peter Singer (2001) have argued that because religious belief in the sanctity of human life has been refuted by scientific materialism, people may be morally justified in euthanizing infants born with severe deformities. Some posthumanist or transhumanist proponents of biotechnology see no moral limit on the power to use science to redesign human beings, perhaps even to the point of abolishing human nature itself. All this seems to confirm the fears of many people that modern science, insofar as it promotes a materialist view of human nature, subverts traditional morality.

At the same time some scientific reasoning about the human mind may support traditional morality by showing how it is rooted in the brain. In *The Descent of Man* (1871) Charles Darwin (1809–1882) argued that a natural moral sense was implanted in human nature by evolutionary history. As naturally social animals, human beings evolved to have a natural sense of right and wrong that would support social cooperation on the basis of ties of kinship and reciprocity. To reinforce this cooperative behavior they were endowed with emotional propensities to moral emotions such as love, guilt, and indignation and also were endowed with the intellectual capacity to formulate social norms of cooperation rooted in those moral emotions.

Some neuroscientists have found that moral experience depends on the moral emotions sustained by the emotional control centers of the brain and on the moral reasoning carried out in the prefrontal cortex of the brain. If these parts of the brain are not functioning normally, people cannot act as moral beings. For example, psychopathic criminals apparently have an abnormality in their brain circuitry that prevents them from feeling the moral emotions that support the moral conduct of normal human beings. Such scientific research suggests that morality is part of the biological nature of human beings.

HUMAN RIGHTS

At first glance human rights might seem to have little relevance for science, but this is not the case. Science is dependent on respect for human rights, particularly freedom of thought and freedom of speech. In many countries, however, the human rights and academic freedoms of scientists are violated by government or by groups that enjoy government support. Science can play an important role in helping to protect and promote human rights. In addition, international human rights law recognizes a substantive right to the freedom necessary for scientific research and a right to have access to the benefits of scientific progress. Yet in some circumstances scientists and health professionals have contributed to human rights violations.

Human Rights

What then are human rights? Rights in moral philosophy and political theory are understood as justified claims. A right is an entitlement of a person or group to some good, service, or liberty. As entitlements, rights differ from ideals, guidelines, or acts of charity. A right creates correlative obligations or duties to secure or not interfere with the enjoyment of that entitlement.

Human rights are a special class of rights, the rights one has by virtue of being a human being. Human rights are predicated on the recognition of the intrinsic value and worth of all human beings. As such, human rights are considered to be universal, vested equally in all persons regardless of their gender, race, nationality, economic status, or social position. Cumulatively human rights represent the minimum conditions for a decent society.

Contemporary twenty-first century conceptions of human rights were formulated at the end of World War II. The Universal Declaration of Human Rights (Universal Declaration), adopted without dissent by the U.N. General Assembly on December 10, 1948, represents an international consensus regarding the core rights and freedoms necessary to realize the inherent dignity and rights of all members of the human family. The Preamble to the Universal Declaration proclaimed "a common standard of achievement for all peoples and nations." As a declaration of the General Assembly, the Universal Declaration does not have direct legal force, but in the past fifty-six years it has become recognized as international common law. Moreover a series of international and regional human rights instruments based on the Universal Declaration are legally binding on countries that ratify them and thus become state parties bound by their provisions.

Many of the rights and standards set out in the Universal Declaration and other human rights instruments are essential to the conduct of science. Science is a worldwide enterprise requiring freedom of thought, communication, and travel, and the freedom to pursue professional activities without interference. The International Covenant on Civil and Political Rights, to which the United States is a state party, recognizes the following rights relevant for scientific inquiry:

- The right of everyone to freedom of thought (article 18);
- The right to hold opinions without interference and the right to freedom of expression, including the right to seek, receive, and impart information and ideas of all kinds, regardless of frontiers, through any media (article 19);
- The right to freedom of association with others (article 22);
- The right to liberty and security of person (article 9);
- The right to liberty of movement and freedom to choose one's residence and to be free to leave any country, including one's own (article 12);
- The right not to be subjected to medical or scientific experimentation without consent (article 6).

Provisions of other international human rights instruments also have important effects on the progress of science. The Universal Declaration includes the following additional rights that have counterpart provisions in the International Covenant on Economic, Social and Cultural Rights to which over 140 countries, but not the United States, are state parties:

- The right to education, including free and compulsory primary education, with technical and professional education generally available and higher education equally accessible to all on the basis of merit (article 26);
- The right to share in scientific advancement and its the benefits (article 27a);
- The right of everyone to the protection of the moral and material interests resulting from any scientific, literary, or artistic production of which he is the author (article 27b).

Protection of Scientists' Rights

Like other members of society, scientists are vested with basic human rights. Those rights are, however, violated in some countries. Scientists are persecuted for their work, for the expression of their opinions or beliefs, and for their peaceful efforts to oppose human rights violations or promote political change. The independent thinking and international connections of members of the scientific community can sometimes seem threatening to repressive or ideologically rigid governments. Scientific reverence for truth, reliance on empirically verifiable facts and measurable data, open dissemination and communication beyond national borders, and universality of discourse and goals by their very nature challenge some regimes.

This potential vulnerability has led scientists in some countries to form networks to protect the international human rights of members of the scientific community and scientific organizations. The Science and Human Rights Program of the American Association for the Advancement of Science (AAAS) is one such organization. Working with AAAS members and affiliated professional societies, the Program conducts casework on behalf of scientists, engineers, and health professionals whose human rights have been violated; prepares statements and reports; convenes meetings on human rights issues of special concern to scientists; organizes humanitarian and fact-finding missions; and assists other scientific organizations with cases and issues of special importance to the scientific community. The Program focuses its individual casework on three main areas: (a) violations of scientific freedom and the professional rights of scientists, engineers, health professionals, students in any of these fields, scientific organizations, and professional groups representing their interests; (b) violations of the human rights of scientists not directly related to the conduct of science, and (c) participation by scientists in practices that infringe on the human rights of others.

Initiated in 1993, the AAAS Human Rights Action Network uses electronic mail to inform AAAS members and other subscribers of cases and developments deserving special attention, and to coordinate the efforts of scientists to appeal to governments on behalf of their colleagues whose human rights are being violated. The network builds on the long-standing tradition of letter writing as an effective means of reminding governments that their transgressions have not gone unnoticed.

Science in the Service of Human Rights

Scientists have unique skills that can help promote and protect the human rights of all people. Scientific applications to human rights involve both utilizing scientific expertise and taking methodologies developed for other purposes and adapting them for human rights uses.

Human rights work requires accurate documentation of violations. Governmental authorities and the general public may be skeptical of reports of human rights violations. In some cases governments may deny that abuses have taken place in their country. Scientific methodologies can help establish the credibility of those who publicize violations and try to bring about change or institute legal action on behalf of victims. Scientifically based methods of data collection, storage, and analysis are particularly necessary when dealing with large volumes of data on human rights violations typical of truth commissions and tribunals. Adaptations of information management technologies for human rights have included specialized research and survey designs, interviewing techniques, database designs, controlled vocabulary structures for database processing, and analytic strategies for quantitative data analysis.

As human rights workers increase their use of electronic media for data storage and electronic communication, they become increasingly vulnerable to a variety of electronic attacks. Cryptographic applications enable human rights groups to secure their information against surveillance, ensure that their communications cannot be faked, and even hide their communications in digital images or sound files.

In the early-twenty-first century, extrajudicial executions and *disappearances* continue to occur in perhaps fifty countries. Independent forensic investigations can be crucial in determining the cause and manner of suspicious death and in proving whether a victim was tortured. Often the judiciary in these countries is reluctant to investigate killings perpetrated by the army or police or other regular security forces, special units outside of the normal chain of military command, paramilitary units, *death squads* sanctioned by the government, or armed groups opposed to the government. To respond to these blatant violations of human rights, forensic pathologists have investigated individual incidents of suspicious deaths by conducting initial and second autopsies, observing official inquests into deaths in detention, and assisting court-ordered investigations of suspicious deaths. In addition, teams of forensic anthropologists exhume mass graves to document murders of groups and communities.

Rights to Scientific Freedom and Access to the Benefits of Science

International human rights law recognizes a substantive right to the freedom necessary for scientific research and a right to have access to the benefits of scientific progress. Building on a parallel provision of the Universal

Declaration, Article 15 of the International Covenant on Economic, Social and Cultural Rights (ICESCR) specifies that state parties "undertake to respect the freedom indispensable for scientific research and creative activity" (Article 15[3]). This article also instructs states parties to "recognize the right of everyone" both "to enjoy the benefits of scientific progress and its applications" (Article 15[1][b]) and "to benefit from the protection of the moral and material interests resulting from any scientific, literary or artistic production of which he is the author" (Article 15[1][c]). To achieve these goals, the text mandates that states parties undertake a series of steps, including "those necessary for the conservation, the development and the diffusion of science and culture" (Article 15[1][c]). More specifically, states parties make the commitment to "recognize the benefits to be derived from the encouragement and development of international contacts and cooperation in the scientific and cultural fields" Article 15[4].

A government can best show respect for the freedom indispensable for scientific research and creative activity by adhering to basic human rights norms recognized in the Universal Declaration and the International Covenant on Civil and Political Rights. In addition, the pursuit of science requires an environment that supports the freedom to pursue scientific research in accordance with ethical and professional standards without undue interference. Conversely the freedom to undertake scientific research and creative activity implies a need for scientific responsibility and self-regulation. Scientific societies in many developed countries have adopted codes of professional ethics in pursuit of these goals. Many of these codes, however, are primarily concerned with the ethics of individual conduct and do not place the scientific enterprise in a broad social context.

Protection against Human Rights Abuses

Much has been written about the challenges posed by science and technology to human rights and human dignity. In the years since the publication of Jacques Ellul's pioneering work *The Technological Society* (1964), for instance, an increasing number of thinkers have called attention to the potential of technology to diminish human dignity and to erode moral values. While the vast majority of health professionals and scientists have sought to be faithful to ethical values, some have been tempted or forced to facilitate harmful practices. Health professionals have been implicated in torture and other cruel and degrading treatment (Amnesty International French Medical Commission and Marange 1989). Psychiatric institutions have been misused to incarcerate political dissidents. Scientists have developed chemical and biological weapons for regimes that intended to use them on their own populations.

The Universal Declaration on the Human Genome and Human Rights, prepared by UNESCO and then adopted by the U.N. General Assembly in 1999 is an example of an initiative that addresses the potential impact of a new technology on human rights and dignity. It emphasizes that genetic research and applications should fully respect human dignity, freedom, and rights and prohibits all forms of discrimination based on genetic characteristics. The declaration affirms the principle of freedom or research related to the genome (Article 12b), but with the caveat that researchers respect principles of caution, intellectual honesty, and integrity (Article 13). The document assigns responsibility to states to take appropriate measures to foster the intellectual and material conditions that promote freedom in the conduct of research on the human genome and safeguard respect for human rights in the process (Articles 14–16). The declaration further recommends that benefits from advances in biology, genetics and medicine, concerning the genome, should be made available to all (Article 12a).

Human cloning constitutes another issue. In October 2003, the U.N. General Assembly considered a treaty to ban human cloning. Delegates agreed that the treaty should prohibit reproductive cloning, the creation of cloned embryos to produce babies, but they deadlocked on the issue of whether the prohibition should extend to "therapeutic" or "research" cloning. Nor could they agree on going forward with a treaty that only addressed reproductive cloning. Confronted with this disagreement, the General Assembly voted to delay discussion of the treaty until its 2005 session (Aschwanden 2003).

HUMAN SUBJECTS RESEARCH

In the field of ethical issues in scientific research, the two most controversial topics concern involve the use of humans as research subjects and the use of nonhuman animals as research subjects. Each of those debates goes back over a hundred years, to the final decades of the nineteenth century, and thus has a substantial literature that has developed a sophisticated level of discussion. This article will briefly summarize the history of the field first, and then explain some of the regulations that have resulted, and close with identifying some of the most important future issues.

Historical Developments

By 1900 there was ample evidence of an appreciation in the medical and scientific communities of the ethical issues that would have to be resolved before a person was used as a subject in experiments. In Prussia a ministerial directive issued in 1900 restricted research to the use of persons who could benefit from the research, who were told in advance of the risks of participation, and who gave their consent. This was in response to well-known experiments with the leprosy bacillus on unwitting subjects in Prussia around that time.

At around the same time in Cuba, United States General Walter Reed (1851–1902) conducted yellow fever studies but required that both soldiers and civilians volunteer first, be informed of the risks (including the risk of death), and sign a consent form. The form was written in both English and Spanish. This is said to have been the first use of a signed consent form and also could be considered the first example of ethical international research informed by cultural competence. Reed's caution was a response to an experiment in Italy in which five persons were infected with yellow fever without being told and an initial experiment in Cuba by two colleagues of Reed who intentionally infected themselves that led to the death of one of them.

In light of the degree of awareness shown at the beginning of the century, it is surprising that by mid-century some of the most barbaric things ever done in the name of science would come to pass. A combination of factors contributed to that decline in standards, including racism and anti-Semitism, exacerbated by nationalism and xenophobia; those problematic social elements were long established but were pushed to extremes by World War II.

Three examples of well-known and frequently cited unethical research involving human subjects occurred in the middle third of the twentieth century. The Tuskegee experiments, observing the consequences of untreated syphilis in American blacks, began in 1932, when there was no effective treatment, but continued until 1972, long after the discovery of penicillin. The research done by Nazi doctors was by far the most brutal and murderous. Those experiments included testing the limits of human endurance up to and including death from causes such as bullet and knife wounds; decompression at high altitudes, which was tested by putting people in decompression chambers and measuring when their lungs burst; and hypothermia, which was tested by keeping subjects immersed in ice water. Japanese experiments in the notorious unit 731 were just as grievous as the Nazi experiments, though less well known. The thalidomide tragedy revealed the importance of the oversight of drug trials and the recognition of the problems of self-policing by pharmaceutical companies that have a financial investment at stake. That experience propelled the U.S. congressional hearings known as the Kefauver hearings.

Ethically disturbing human experiments were done well after that period. Two examples in the United States were performed on institutionalized populations: testing gamma globulin treatment of hepatitis after infecting children at the Willowbrook State School in Willowbrook, New York, and tracing differences of rejection of live cancer cells in subjects after injecting those cells into people at the Jewish Chronic Disease Hospital in Brooklyn, New York without explaining what was in the injections. These were among twenty-two experiments described by Henry K. Beecher in an influential paper published in the *New England Journal of Medicine* in 1966, "Ethics and Clinical Research."

There are many ironies in this history. For example, the most brutal and murderous research was done in Germany, the country that had promulgated the first modern code for ethical research. Then the country that provided all the judges and all the lawyers at the Nuremberg Trial of Physicians (1946) that led to the Nuremberg Code (1947) acted as if the code did not apply to its citizens in the years after World War II. This history of the field seems to show that some of the lessons need to be learned and relearned periodically and that only revelations of scandals and abuses have the power to restrain research.

Regulations

The last third of the twentieth century saw the codification of many of the lessons that had been learned and left a number of areas of great import that are still very much disputed. Several of those lessons have been accepted widely and codified into U.S. and international law.

In 1964 the original Declaration of Helsinki was passed by the World Medical Association. It reiterated the famous first line of the Nuremberg Code, stating that the voluntary consent of the human subject is absolutely essential, though it still left it up to the researcher to decide what to say, how much to disclose, and how to document the informed consent process. It has been revised and strengthened a number of times, most recently in 2000. The most important difference from U.S. regulations involves placebo controls, which generally are encouraged in the United States (especially by the Food and Drug Administration) and discouraged (though not forbidden) in the Declaration of Helsinki.

As a result of the public reaction to the Tuskegee experiments in 1974, the U.S. Congress authorized the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research. The National Commission resulted in the publication of the Belmont Report (1979) and the issuance of federal regulations in 1981 known as 45 CFR 46. Those regulations led to the requirement of prior review of research protocols by independent committees known as Institutional Review Boards (IRBs). This was modeled on prior peer review, which had been required at the National Institutes of Health (NIH) since 1965 and for all NIH-sponsored research since 1966. The basic protections of the regulations (outlined in subpart A) were consolidated into "the Common Rule" in 1991 and adopted by sixteen federal agencies.

IRB oversight, in contrast to peer review, required that there be at least one nonscientist, one community member, and should not be either all men or all women. Although many people still have concerns about the real independence one can expect in light of the fact that most of the members of the committees are usually employees at the same institution where the research is being done, it was an important innovation.

Before approving a proposed research protocol, the IRB must ascertain that the research is scientifically valid (the goals are worthwhile and achievable by the methods proposed) and that the risks to the subjects are kept to a minimum and are justified by the potential benefits to be gained. It also must determine that the selection of subjects has been equitable (no groups are excluded without good reason) and that the subjects have been recruited without any deception or coercion, that the confidentiality of the subjects has been adequately protected, that the subjects have been fully informed about the risks and have given voluntary consent that has been documented, that proper steps have been taken to ensure that the subjects understand all the information they have been given, and that they understand that they can withdraw from the research at any time. The IRB is also responsible for monitoring the research and has the power to stop any study that is dangerous to the participants, a task often assigned to a separate Data and Safety Monitoring Board (DSMB).

An IRB has the responsibility to ensure the voluntary participation of the research subjects as well as their safety. Thus, IRBs often focus on the informed consent form that will be given to potential subjects to ensure that the risks are portrayed realistically and not underplayed and that there is no misleading of the subjects about the likelihood of benefit. Terms such as *the doctor*, *medicine*, and *therapy* can be used by researchers without any intent to deceive yet can be read by subjects as meaning that they are enrolled in an experiment whose purpose is to help them rather than to improve the understanding of a drug or disease process. This is referred to as the therapeutic misconception. The same concern for language has made some IRBs to suggest using the term "participants" instead of "subjects" as a reminder to the researcher that she is seeking the cooperation of well informed volunteers, not passive recruits who don't ask questions. The regulations also require that extra attention be paid before any members of certain groups of persons known as vulnerable populations are used. These groups include children, the mentally handicapped or mentally ill, prisoners, pregnant women, and fetuses.

Ironically, since the 1990s there has been recognition in the United States by the Food and Drug Administration that drugs have been tested disproportionately on white men too frequently and that it would be scientifically helpful to have more studies with women, minorities, and children to test for variations in effectiveness and safety. However, the history of abuse probably has made researchers hesitant to enroll persons in these categories, not to mention the distrust that members of these groups might feel after the historical record at Tuskegee, Willowbrook, and the Jewish Chronic Disease Hospital.

All government funded research with human subjects is required to be reviewed by an IRB. This includes the behavioral and social sciences as well as biomedical sciences. Many of the same ethical issues arise, though the potential harms may be of a psychological nature, such as risk to privacy or to self-image, rather than a physical one. A concern that may occur with greater frequency in psychology is that fully informing a subject of the nature of the research could bias the answers the subject gives. Thus researchers will seek to reveal less of the purpose of the study than would be the case in medical research. This type of purposeful deception will have to be justified to the IRB, and assurances that any risks to the subjects are minimal. Assessing this kind of risk is difficult, as seen in the fact that the highly innovative and influential milgram experiments conducted in the 1960s are deemed controversial by some commentators to this day. The primary harm to the subjects was a loss of self-esteem as they reflected on their own willingness to submit to the orders of an authority figure and inflict pain on strangers. But it would not have been possible to do the experiment had the consent process told them in advance that the strangers in apparent pain were only actors. An honest debriefing, with counseling if necessary, may help to alleviate possible harms in cases where some initial deception cannot be avoided.

This also brings up the question of non-government funded research. Much pharmaceutical research and research on medical devices is funded by the FDA, and so falls under the common rule. But beyond government funding sources, there is currently no review needed in the U.S. for privately funded research. Should private enterprise, from marketing research to genetics and biotechnology, be unencumbered by regulations whose intent is to ensure the safety of citizens? Should civil rights and human rights be allowed to set restrictions on private companies in cases where there is, as yet, little risk identified? When one pictures marketing questionnaires, it is easy to be swayed towards a libertarian distrust of unnecessary and intrusive government regulations. But when one considers the potential profits from genetics and biotechnology research, there may be more reason to consider preemptive regulation, such as already exists with state commissions in many European Union countries concerning IVF.

Future Issues

Soon after the Belmont Report the Council for the International Organization of Medical Sciences (CIOMS) produced a report on the special issues that occur in international research. The beginning years of the twenty-first century have seen growth in funding for international research. Although some of this increase in funding could be due to economic globalization and the lessening of national identity for multinational corporations, there may be more ominous motivations. For example, funding sources for pharmaceutical research are often in first world countries such as the United States, the United Kingdom, France, Germany, Belgium, and Switzerland. However, when an even larger proportion of research in is done developing nations, it could be because of lax regulations (including ethical regulations) in the developing world.

A second topic that inevitably will grow in importance is the range of new research resulting from the Human Genome Project. That project was completed in less time than originally planned and has provided an enormous amount of raw data with which biologists hope to map a deeper understanding of normal development and pathogenesis. However, all genetic information has ethically complex properties, such as providing information about the relatives of research subjects as well as about the persons who volunteered to be involved in the research.

Another challenging ethical issue unique to genetics is the possibility of curing a disease by means of germline gene therapy, removing the disease from human history but at the risk of altering the human genome. Similarly, genetic interventions have the potential to blur the intuitive distinction between medical treatment for an illness or dysfunction and enhancement of traits which a person may find unsatisfactory yet fall within the normal range of human beings. Either way we are on the cusp of gaining the knowledge of the human genome that would allow genetic engineering with the purpose of improving the race (using Nazi terminology, creating a new master race). Might we soon enter a phase of deliberate evolution, or worse, develop into two sub-species, the feral and the enhanced?

The third topic of concern is stem cell research and the related issue of human cloning. Advances in invitro fertilization (IVF) and other assisted reproduction technologies (ARTs) have made the possibility of human cloning real. Many species of mammals already have been cloned, and it may be only a matter of time before a human is cloned. Although some people have argued that this should be considered an alternative technique for infertile couples to have a child, it has been outlawed in many countries as threatening the dignity inherent in the uniqueness of each life.

Stem cell research, which would find its best source of human embryonic stem cells in the excess embryos created by IVF programs, also has been opposed by critics who believe it violates the respect owed to human embryos or treats them as means rather than ends. However, attempts at broad bans have been less successful than with cloning for a number of reasons: The therapeutic potential could benefit many more people, and the majority of scholars and researchers in both ethics and developmental biology believe that there is a fundamental moral difference between a preimplantation embryo and an embryo or fetus that has been implanted successfully in a human womb.

Beyond issues related to transnational experimentation, genetics, and stem cells research, one might suggest that as the scientific and technological enterprise advances, all people become the subjects of scientific research. Mike Martin and Roland Schinzinger (1996) have argued for understanding engineering as a form of social experimentation. But even more broadly, the increasing use of medicines that often create therapeutic dependencies, unregulated uses of IVF and frozen embryos, and the popularization of plastic surgeries and advanced prosthetics all point toward people treating themselves (not just scientists treating people) as human subjects in scientifically based actions the full outcomes of which remain uncertain.

HUME, DAVID

David Hume (1711–1776) is one of the most influential philosophers of the modern period. He was born in Edinburgh, Scotland, on April 26. His first and most

David Hume, 1711–1776. The Scottish philosopher developed a philosophy of "mitigated skepticism," which remains a viable alternative to the systems of rationalism, empiricism, and idealism. (*© Corbis.*)

important work, *A Treatise of Human Nature* (published in two installments in 1739 and 1740, before Hume turned thirty years old), was supplemented in later life by *Essays, Moral and Political* (two volumes, 1741–1742), *An Enquiry Concerning Human Understanding* (1748), and *An Enquiry Concerning the Principles of Morals* (1751). The latter two books restate in more accessible form the arguments of the *Treatise*. He also wrote a six-volume history of England (1754–1762) and *Dialogues Concerning Natural Religion*, published posthumously in 1779. Hume, who died in Edinburgh on August 26, applied what he considered the experimental method of science to an examination of ideas and morals, thereby developing an ethics that bases moral judgments on feelings. Because emotivism is so frequently assumed in the contemporary West, to read Hume can be an exercise in cultural self-understanding.

Empiricism

Hume begin his *Treatise* arguing that human knowledge is limited to sense-experience. The contents of sense-experience can be distinguished into impressions and ideas. Impressions, which include all sensations and passions, are more forceful and lively than ideas, which are "the faint images of these in thinking and reasoning" (Hume 1888 [1739–1740], p. 1). Ideas are thus epistemologically inferior to impressions, and the secondary status that Hume gives them remains characteristic of popular denigrations of their relative impotence. This distinction also suggests that the logical analysis of conceptual relations is less important than the knowledge of matters of fact.

Hume further distinguishes between the simple and complex. Simple impressions and ideas, such as the seeing or imagining of a particular shade of red, admit of neither distinction nor separation. Complex impressions and ideas, such as the seeing or imagining of an apple, can be analyzed into their component parts. Whereas all simple ideas are derived from and exactly represent simple impressions, many complex ideas are not, and so their veracity must be called into question. In *Enquiry Concerning Human Understanding*, Hume remarks, "When we entertain, therefore, any suspicion that a philosophical term is employed without any meaning or idea (as is but too frequent) we need but enquire, from what impression is that supposed idea derived? And if it be impossible to assign any, this will serve to confirm our suspicion" (Hume 1894 [1748], p. 22). Something like this view is often employed when people appeal to science in rejecting ideas of God or the soul.

But the most famous subject of Hume's criticism is the relation of cause and effect. Philosophers and scientists traditionally believed that to know something fully requires knowledge of the cause on which it depends. For Hume, such knowledge is impossible. Although the causal relationship provides the basis for all reasonings concerning matters of fact, all such reasoning is quite contingent. This is because one can always imagine, without contradiction, the contrary of every matter of fact (e.g., "the sun will not rise tomorrow" neither is nor implies a contradiction). For Hume, the causal relationship between any two objects is based strictly on experience, and all that experience establishes concerning causal relationships is that the cause is prior in time and contiguous to its effect. Experience cannot establish a necessary connection between cause and effect, because one can imagine without contradiction a case in which the cause does not produce its usual effect (e.g., one can imagine that a cue ball violently strikes another billiard ball and then, instead of causing the billiard ball to move, the cue ball bounces off it in some random direction). The reason why a person might mistakenly infer that there is something in the cause that necessarily produces its effect is because past experiences have habituated the person to think in this way (see *Treatise*, Book

I, Part III; first *Enquiry*, secs. IV–V). In thus arguing that humans have no direct impression of anything more than spatial and temporal contiguity, Hume sees himself extending empirical science. At the same time, he reduces science's epistemic power by depriving it of any deep knowledge about what lies beyond experience.

Theory of Morals

Hume's argument with regard to morals is similar. For Hume, moral distinctions are derived from feelings of pleasure and pain of a special sort, and not—as held by many Western philosophers since Socrates—from reason. Working from the empiricist principle that the mind is essentially passive, Hume argues that reason by itself can never prevent or produce any action or affection. Because morals concerns actions and affections, it cannot be based on reason.

Reason can influence human conduct in only two ways. First, reason can inform a person of the existence of something that is the proper object of a passion, and thereby excite it. Second, reason can deliberate about means to an end that a person already desires. But should reason be in error in either of these areas (for instance., by mistaking an unpleasant object for one that is pleasant, or by mistakenly selecting the wrong means to a desired end), it is not a moral but an intellectual failing. As a final point, Hume argues for a distinction between facts and values. According to Hume, one cannot infer conclusions about what *ought to* or *ought not* be the case based on premises of what *is* or *is not* (see *Treatise*, Book III, Part I, sec. 1).

Because moral distinctions are not based on reason, Hume infers that they are based on sentiments that are felt by what he calls a "moral sense." When a person describes an action, sentiment, or character as virtuous or vicious, it is because its view causes a pleasure or pain of a particular kind. Hume is well aware that not all pleasures and pains lead to moral judgments (for example, the pleasure of drinking good wine). Rather, it is "only when a character is considered in general, without reference to our particular interest, that it causes such a feeling or sentiment, as denominates it morally good or evil" (Hume 1888 [1739–1740], p. 472). Finally, Hume argues that even though moral distinctions are based on feelings, this does not lead to moral relativism. This is because the general moral principles and the moral sense faculty that recognizes them are common to all human beings.

Influence

As indicated, Hume's view that the source of moral approval and disapproval is not reason but the sentiments that are felt has been widely influential. In the twentieth century this view was restated as the emotive theory of ethics. According to A. J. Ayer's *Language, Truth, and Logic* (1936), once statements of the form "*X* is wrong" are distilled of their factual components, they merely evince the speaker's moral disapproval, for example, "Boo *X!*"

In contemporary times, such a view is often deployed against anyone who attempts to make ethical criticisms of science or technology, with the claim that critics are simply stating their own personal preferences. Abandoning Hume's belief in a moral sense faculty common to all humans as itself unjustified by empirical science, it is argued that in a pluralistic society, with many different sentiments and preferences, scientists and engineers should be at liberty to research or invent as they see fit—with perhaps the sole proviso that they do not materially harm other persons. Whether or to what extent this is an adequate ethics for science and technology is a question that Hume's philosophy obliges us to ponder.

HUSSERL, EDMUND

Born in Prossnitz, Moravia (now Prostêjov, Czech Republic) on April 8, Edmund Husserl (1859–1938) inaugurated the phenomenological movement in philosophy. Trained as a mathematician at Vienna, where he received his Ph.D. in 1883, Husserl began studying philosophy in 1884 under Franz Brentano (1838–1917) and went on to teach in the philosophy faculties at Halle an der Saale, Göttingen, and Freiburg. His most notable works—*Logical Investigations*, *Ideas* (Volumes I, II, and III), *Cartesian Meditations*, and *The Crisis of European Sciences and Transcendental Phenomenology*—seek a philosophical grounding for mathematics, logic, and science by analyzing the intentional or essential structures of consciousness in its relation to objects in the world relations between subjectivity and objectivity. After his death on April 26 in Freiburg, a substantial body of posthumously published work extended his account of subjectivity and its correlative world into the domain of intersubjective experience, and the development of an ethical system that exhorts a fully rational human existence in which all persons repeatedly justify their beliefs and actions.

The fundamental method of phenomenology is the "reduction," which entails suspending the philosopher's own participation in our natural beliefs about the world. Not a denial of the external world, the reduction simply neutralizes dogmatic assumptions about experience in order to examine more closely experience and its objects just as they are given; hence, phenomenology calls itself a "presuppositionless" enterprise.

Husserl's most overtly relevant work for science, technology, and ethics, *The Crisis* (1936), argues that science and technology constitute a nonneutral transformation of life rather than a simple neutral extension of ahistorical human concerns. Neither pro– nor anti–science and technology, Husserl's *Crisis* suspends the typically modern commitment to science in order to disclose and examine the repercussions of those unreflectively accepted scientific presuppositions and practices that transform the prescientific life-world of human experience. Husserl values the way science tests and retests experience, thereby contributing to a fuller sense of objectivity than everyday judging. In their great success, however, science and technology create "fact-minded" citizens blinded by promises of objectivity and control. In their narrow view of reason as mere calculation, science and technology consider themselves value neutral and thus exempt from responsibly advising about how to make difficult decisions arising from the means

Edmund Husserl, 1859–1938. The German philosopher is considered the father of phenomenology, one of the most important trends in 20th-century philosophy. *(The Granger Collection, New York.)*

they produce. Moreover, one could argue, science and technology evolve in rarefied discourses unavailable to most citizens and beyond democratic control. Followers of Husserl thus are able to argue that humankind's historical circumstance marks a crisis in which science and technology develop independently of value questions and democratic voice, yet are unreflectively and passively received and deployed.

To philosophers of technology, however, Husserl's corrective measure in the form of a relentless search by the subject for a fuller sense of evidence to justify beliefs and actions often appears to be a formal, abstract quest for ideal essences. Ethical discussions of science and technology thus often disregard Husserl's phenomenology. Husserl's protégé, Martin Heidegger (1889–1976), for example, believes Husserl's emphasis on cognition lands him squarely in the path of human technological domination of the world. The phenomenological reduction, Heidegger argues, "reduces" the world to human "intentional" activities and sacrifices world independence to consciousness's drive to explain and predict experience with absolute certainty. American pragmatist philosopher Larry A. Hickman (2001) argues that privileging conscious reflection and increased objectivity over lived experience renders phenomenological inquiry a private enterprise tied to "ideal essences." Unable to reconfigure its ideals, Hickman finds phenomenology incapable of a providing a viable program for the reform of technology. And the American post-phenomenologist Don Ihde (1990) reiterates Heideggerian and pragmatist criticisms. Because Husserl neglected the inseparability of sense-extending technologies from scientific discovery, Ihde argues he never reached beyond an intimation of a philosophy of technology.

Yet Husserl's contribution to the philosophy of technology can be found in these criticized notions intentionality and objectivity, which form the basis of his ethics of a self-conscious community founded on intuitionally fulfilled beliefs and actions, and provide the basis for a critical assessment of technology. For Husserl, consciousness, in its very nature as activity, is intentional. In its care for and interest in the world, consciousness transcends itself. Always outside of itself, a subject experiences the world in a public and intersubjective rather than private and solipsistic way. Intuitional fulfillment denotes the correlation of a subject's intentional anticipations with the evidence found in experience. When experience does not confirm a subject's anticipation, the intention goes "unfulfilled" and demands that the subject revise prior beliefs, thus achieving a degree of objectivity. When experience confirms a subject's anticipation, the intention gets "fulfilled," again achieving a degree of objectivity. Because Husserl advocates self-critique and reflection as a lifelong task, even fulfilled intentions require further experiential confirmation over time and across subjects. Rather than a fixed ideal, objectivity remains open to reconfiguration according to experiential evidence given in the fluxing relation between subject and world.

An interesting instance of the kind of self-critical agency that Husserl advocates can be found in the life of the Polish scientist Joseph Rotblat (b. 1908), who worked on the atomic bomb. Rotblat initially justified his participation by reasoning that only Allied bomb development would counter potential German development. After the German defeat, Rotblat reflected on the standard attitude of the scientists working on the project—many of whom believed it was not their job to advise about how the atomic bomb should be used—leading him to leave the project before the first testing and use of the bomb. Rotblat resolved to henceforth carefully choose each of his future projects, accepting only assignments he judged of definite benefit for humanity. Rotblat's revised outlook on his career as a scientist follows in the spirit of Husserl's ethics based on a subject's vow to live a life guided by a repeated and critical evaluation of beliefs. Rotblat's decision to withstand the heedless activity that Husserl believes characterizes the contemporary relation to science and technology exemplifies the self-reflection and self-responsibility for which Husserl argues when he exhorts subjects to continuously assess their experiences.

Aldous Huxley, 1894–1963. The novels, short stories, and essays of the English author Huxley explore crucial questions of science, religion, and philosophy.

HUXLEY, ALDOUS

Aldous Leonard Huxley (1894–1963) was a British writer best known for his 1932 novel *Brave New World,* which portrays the dehumanizing aspects of scientific and technological progress. Born in Godalming, Surrey, England on July 26, Huxley's poor eyesight kept him from an early goal of becoming a scientist. After attending Oxford University and achieving fame as the author of several novels, in 1937 Huxley moved to California, where he became a screenwriter. Later he experimented with psychedelic drugs and incorporated mysticism into his work. Huxley died from throat cancer in Hollywood on November 22.

A moralist, social satirist, and interdisciplinary intellectual, in *The Perennial Philosophy* (1942) Huxley sought to identify the origin of being, prior to the fragmentation of experience into diverse languages, religions, and systems of knowledge. In the present age, however, he realized that reconnecting with such a foundation would involve reconciling humanity to the social and spiritual consequences brought about by science and technology (Murray 2002). To this end, Huxley often used literature to advance the causes of social sanity and personal enlightenment. Three themes are central to this life-long project: relations between literature and science; science, technology, and the abuse of power in emerging mass societies; and the potential for science and technology to enrich or corrode human nature.

Science and Literature

Huxley believed it was crucial to connect science and literature. Indeed, his novel *Point Counter Point* (1928) has been described as an "application of the theory of relativity to the art of fiction" (Deery 1996, p. 31). But he also felt it mistaken to define literary theory as a progressive, systematic, and verifiable body of knowledge employing the scientific method.

Huxley sought to reclaim a unified human experience by achieving the proper balance between different forms of knowledge. In this respect, he was the intellectual descendant of the debates about science and humanism held between his grandfather, Thomas Henry Huxley (1825–1895), and his great uncle, Matthew Arnold (1822–1888). The issue was particularly impelling because the secularization of society placed a great burden on literature to uphold the humanist tradition just when scientific discoveries were undermining traditional understandings of the world and the human place within it.

Huxley also saw literature as a vehicle for critiquing the social and moral consequences of scientific progress. The seriousness with which Huxley took up this task distinguished him from contemporaries, most of whom distanced themselves from social criticism. He held that "one of the prime duties of the twentieth-century artist is to draw attention to the evil ends for which a morally neutral science is being used" (Deery 1996, p. 25).

Science, Technology, and Power

Huxley believed that the "most profoundly important sociological factor of modern times [is] the growth of technology and what may be called the technicization of every aspect of human life" (1978, p. 18). Indeed, it was Huxley who caused Jacques Ellul's *The Technological Society* to be translated into English in 1964. Although he portrayed the relationship between science, technology, and social control in *Brave New World,* Huxley also examined the issue in essays such as "Science, Liberty and Peace" (1946), where he argued that science and technology tend to perpetuate and intensify inequalities and threaten peace and freedom. Mass production and mass media are used by the few to manipulate and control the many, as the rationalization of society reduces citizens to mere cogs in the machine. Huxley also recommended that scientists boycott harmful work and take action to foster positive scientific research. In *Brave New World Revisited* (1958), he argued that individual liberties must be protected from abuses of power.

This issue also dominates Huxley's last novel, *Island* (1962), which portrays a utopian society. It is a small, self-sustaining community removed from the pernicious effects of industrialization and the materialistic mindset of a scientific culture. Education, tranquility, and spirituality take the place of indoctrination, consumerism, and carnality portrayed in *Brave New World*. Multi-parent families and disciplined sexual practice replace machines and artificial stimulation. It is a society characterized by the pursuit of personal fulfillment and selfless care for the community. Although technology is not dominant, *Island* is not a pre-modern utopia. Its technologies serve community and spiritual flourishing rather than social power and personal distraction.

Science, Technology, and Human Nature

The difference between the drug "soma," in *Brave New World* and "moksha," in *Island* raises a basic question in Huxley's work and suggests the connections between his work and later developments in biomedical technology. Whereas soma flattens and attenuates human experience, moksha enhances and enlightens it, posing the question of what it means to be truly human. In fact, many of the central themes of Huxley's work (love, family, mortality, happiness, authenticity, consciousness, and the human spirit) highlight this basic issue. Huxley was aware that technoscience, especially biomedical science, could fundamentally alter these aspects of life.

There is disagreement about whether the *Brave New World* scenario of a dehumanized, or post-human, future is a likely consequence of biomedical technologies such as psychotropic drugs and germline engineering. Some argue that as long as individuals freely choose these technologies, there is no threat to human dignity (Blackford 2004). Others claim that human nature itself is under threat, even if these technologies are adopted within a liberal democratic system (Kass 2004). Hard, top-down attempts to control human behavior are not the only threats; there are also soft, bottom-up threats that appeal to the lowest common denominators in human desire.

Huxley also considers the dehumanizing potentials of scientific and technological change in other works. In *Point Counter Point*, he argues that liberal democracies and autocracies share a common faith in the powers of science and technology to deliver human happiness. Realizing that this happiness is oftentimes shallow and inauthentic, the protagonist in the novel proclaims that the only difference is "whether we shall go to hell by communist express train or capitalist racing motor car" (p. 414). In *Antic Hay* (1923), Huxley lampooned a decadent society of lost souls searching for meaning and true happiness, but only on the surface of the latest fads. In *Ape and Essence* (1948), he warned of the catastrophes that can result from humanity's hubristic search for knowledge and control of nature. He also satirized the scientific quest for immortality in *After Many a Summer Dies the Swan* (1939).

Huxley's most telling interpretation of the proper use of technology to enhance rather than corrupt human nature comes from his two books about psychedelic drugs, *The Doors of Perception* (1954) and *Heaven and Hell* (1956). These works present a philosophy of the prudent use of technology as an aid in the search for truth, goodness, and beauty, which Huxley believed to be the purpose of human life. Drugs can assist someone in this search, but he warned that they must be used cautiously. They are not an excuse to forgo the responsibilities that come with freedom. Rather, "Ethical and cognitive effort is needed if the experience is to go forward from this one-shot experience to permanent enlightenment" (Deery 1996, p. 109). As John the Savage remarked in *Brave New World,* experience has to "cost" us—it has to be difficult—if it is going to be truly meaningful.

Huxley was not opposed to new developments in science and technology. His message is that these developments must be guided by moral inquiry and held to the standards of individual dignity and enlightenment as well as social sanity and peace. They must further be directed and adopted by a free and well-educated populous, and not forced by the hand of technocrats or the mantras of mass society. As his utopian *Island* illustrates, this will mean science and technology play much smaller roles in human life, not because they are inherently nefarious, but rather because they can only go so far in assisting the good life. It is a thin line, after all, between enhancing the human soul and erasing it.

HYPERTEXT

Hypertext is a way to organize information in a digital format that makes use of traditional text structures (words, sentences, pages, articles or chapters, books, and libraries) as enhanced by the multiple linkages (words to words, words to sentences, sentences to sentences, sentences to pages, pages to pages, pages to chapters, and so on) possible in cyberspace. When hypertexts further employ graphics, images, audio, and video, they become hypermedia. By both enhancing and subverting traditional assumptions about the linear reading of a text (i.e., word after word, sentence after sentence, page after page) hypertexts also both expand ethical reflection and create ethical issues related to access, the implications of linking choices, and more.

Structures and Opportunities

The architecture of information in the digital context consists of three basic elements: nodes, links, and anchors. In hypertext, information is distributed in building units called nodes. Nodes store a large amount of information, anything from a printed page to an entire book. Nodes can include text, graphics, images, and sounds (hypermedia). They are connected by links; a link between two nodes allows the reader to switch from one to another.

Anchors allow readers or users to determine whether a link exists and if so, to access it.. The reader can switch from one informational unit to another by clicking an anchor zone. Anchor zones are identifiable by some kind of emphasis; they may be a different color than other text, cause changes in the shape of the cursor, appear as icons, and so on, and usually give an indication of the link destination.

With these three basic construction elements, among others, designers can build simple and reduced hypertextual organizations, as well as large, complex ones. Well-designed hypertextual organizations are of great help in translating information to the computer screen. If providers of digital support were limited to using traditional methods of information dissemination, such as print matter, the efficiency and value of that support would be severely reduced.

Providing information through hypertext creates different ways of reading. Readers have more paths open to them because nodes offer a variety of links. Sequential or traditional reading does not allow such multiplicity. Thus hypertextual reading is termed *navigation*.

Historical Development

Vannevar Bush presented a precursor to modern hypertext technology in "As We May Think" (1945). Using the technology available at that time, Bush proposed the Memex, a device that could present independent documents in much the same way that memory works, jumping from one to another. In 1965 Theodor (Ted) H. Nelson coined the term *hypertext* and discussed the *Docuverse*, a universe composed of a range of documents, including international literary works. He argued that one should be able to navigate through all the documents and their interrelated fragments and parts. The very same year J. C. R. Licklider published *Libraries of the Future*.

These ideas and concepts could not be realized until devices to implement them were created. Douglas Engelbart, for example, not only proposed theoretical concepts but played a key role in inventing devices which are now integral parts of the modern computer, including the mouse, computer windows, and other graphic interfaces.

Hypertext is the result of technological achievements in hardware and software as well as the creativity of authors who experimented with different structures. Hypertext requires communication networks, computers, authoring tools, and browsers that allow readers to see the hypertext on the computer screen and interact with it. Hypertext also requires continued exploration of the possibilities in this new information framework.

Developers, designers, and inventors have achieved major technological advances in this nascent field. Among them are Tim Berners-Lee's invention of the World Wide Web (www, the largest and best-known hypertextual construct) and HyperText Markup Language (HTML); Peter Brown's development of the first software guide for hypertext production in personal computers, accessible to computer users of all levels of expertise; and Bill Atkinson's design of the HyperCard for Macintosh, which uses the programming language HyperTalk.

Achievements and Ethics

Information on the www is like an unbound book. Any author can add to the work by using a link. Readers navigate through this information and each binds the material into an individual *book* composed of different authors' pages. Boundaries that define the notions of intellectual property are difficult to maintain and traditional methods of protecting copyrights are becoming obsolete. New legal and cultural tools are needed to deal with such changes.

The Wiki Wiki Web is an example of a hypertext construct based on the unrestricted access of users. Each user contributes to the collective work and decides where to create links. There are no webmasters or any central control. Each reader is an author and has the power to eliminate or change the contributions of others. Individual responsibility and self-control and a sense of collaboration on a collective work are guiding forces in these activities, one of which is the continuous creation of the online Wikipedia. Robert McHenry (2004), however, has challenged the quality of this "faith-based encyclopedia."

Hypertext technology allows virtually unrestricted linking of information nodes. Links to information that is clearly related to the subject matter of a particular text are certainly acceptable. But when the destination of a link is not visible, or when readers are diverted to a destination despite their intent to go elsewhere, ethical issues arise.

Likewise decisions to link to certain materials or web sites and not to others, while understandable and arguably defensible, could result in the marginalization of groups with less scientific or social prestige and power. The need to discriminate among the vast amount of information available on the Internet could lead to *cherry-picking* sources of information and experts in fields, thus virtually excluding access to other sources and experts. This situation raises the potential for what has been called *a balkanization of the global village* by Marshall Van Alstyne and Erik Brynjolfsson.

Transcending the barriers of traditional text is certainly an achievement with positive implications that are still being explored. However the potential misuse of hypertext technology or the unforeseen negative results of its use are causes for concern and thoughtful examination.

I

IBERO-AMERICAN PERSPECTIVES

To introduce a Spanish- and Portuguese-speaking perspective on science, technology, and ethics is difficult and somewhat artificial. From the beginning it must be acknowledged that Spain and Portugal on the Iberian Peninsula of Europe together with the more than twenty Spanish- and Portuguese-speaking countries that can be identified in the Americas compose a heterogeneous group. In many respects differences outweigh similarities. Nevertheless, the differences are perhaps no greater than those present in other large-scale linguistic or cultural perspectives such as are represented by Africa, China, or India. Provided that this introduction is not taken as a substitute for more particular assessments of the situations in Argentina, Brazil, Chile, Colombia, Cuba, Ecuador, Guatemala, Mexico, Peru, Portugal, Spain, and Venezuela (to mention only a dozen of the most populous countries), it may serve to highlight some modest commonalities that do in fact exist.

Context

Understanding relations between science, technology, and ethics in the Ibero-American countries requires some appreciation of the historical relations between Spain and Portugal on the Iberian peninsula and those countries in the Americas that emerged from Iberian colonization. The sixteenth and seventeenth century Iberian colonizations of the Americas brought with them ideals of the Counter Reformation rather than the ideals of liberalism the practice of exclusion that were more characteristic of English colonialism. From the very beginning, there was thus little enthusiasm for science and technology in themselves, and even considerable skepticism regarding their benefits. The local cultures that emerged in the eighteenth century and then sought independence in the nineteenth century adopted a sense of being on the periphery that was reinforced, especially in Spain, by its sense of separation from Europe and then the loss of its last major possessions to the United States in Spanish-American War of 1898.

Subsequent early twentieth century attempts by Latin American countries to modernize and become players in international affairs had to struggle with the increasing influence of the United States and continuing marginalization in the mother countries of Spain and Portugal. Virtually all Ibero-American countries were also afflicted until the 1970s with civil wars and economic difficulties. The last decades of the twentieth century were then characterized by attempts to recover cultural roots and establish regional identities, often through ambitious political projects of international cooperation and development such as the Alliance for Progress (which was proposed by American president John Fitzgerald Kennedy [1917–1963] in 1961 but petered out by the late 1960s), or through more modest academic projects, including the formation of regional networks promoting scientific education and research. The failures of major development programs to achieve their stated goals, and the difficulties that emerging cadres of scientists and engineers had in securing adequate employment in their home countries, nevertheless sponsored an ongoing sense of skepticism and dissatisfaction with scientific and technological initiatives.

Against such a background it is thus appropriate to review in slightly more detail various indicators concerning the role of science and technology in various Ibero-American situations. This will be followed by an assessment of social and academic attitudes toward science and technology, including those manifested in Latin American social thought. Finally it will be appropriate to comment on the reception and development of science, technology, and society (STS) studies in the region, and to review recent initiatives to promote a proper regional reflection on the social meaning of science and technology.

Science and Technology in Ibero-American Countries

Until the latter decades of the twentieth century, the role of scientific research and technological development (R&D) in Ibero-American countries can be encapsulated in a well-known phrase from Miguel de Unamuno y Jugo (1864–1936): "¡Qué inventen ellos!" (Let others invent!). Unamuno was one of the leading members of the "Generation of 1898," the year that Spain lost the last of its major colonies, and a philosopher who struggled to come to a new self-understanding of what it meant to be Spanish. Unamuno's manifesto was to make a virtue of history: Spain should not compete with others in science and technology, but seek a non-technical identity in its cultural traditions. Although Unamuno himself was adamantly opposed to the traditionalists who made up the base for Francisco Franco (1892–1975) during the Spanish Civil War (1936–1939), the fascist triumph can be interpreted as an initial victory for such an ideology. Only in the 1950s did this victory evolve into a kind of technocratic development that, after Franco's death in 1975, could serve as a foundation for major scientific and technological change. (Changes of a comparable character took place in Portugal after the death of António de Oliveira Salazar [1889–1970].)

The increasing social and political belief in a link between economic development and technoscience that characterized the last half of the Franco regime was also reflected in Latin America in emerging public policies for the promotion of R&D. It was especially at the exhaustion of the development model known as "industrialization by import substitution" during the 1980s, when a large number of national science and technology organizations were created, that many governments began to recognize a need to support their science and technology systems. The loss of a dream of self-sufficiency in the midst of globalization was coincident with the diffusion of new discussions of innovation. The new discourse has nevertheless brought its own worries, especially a tendency to subsume science policies under economic policies—a view that at the beginning of the twenty-first century serves as the guiding principle for the reorganization of R&D in many Latin American countries. In such a context, economics trumps science—as well as ethics.

Yet good intentions have seldom equaled actions. In the decade of the 2000s, it has remained the case that only around 0.5 percent of the gross domestic product (GDP) is allocated to R&D in most Latin American countries. Because there is little privately supported higher education, universities absorb the major portion of public R&D funding; there is no significant demand for R&D in the private sector. In spite of public declarations and formal documents, Unamuno's spirit remains strong. Indeed, with regard to science and technology, the inequality of Latin America in relation to other regions is even more pronounced than the much better known economic inequalities. This is well documented by a wide variety of indicators: funding, active researchers, science students, scientific publications, patents, and more.

Relevant data is available on the Ibero-American and Inter-American Network on Science and Technology Indicators Website (www.ricyt.org), as well at regular United Nations Educational, Scientific, and Cultural Organization (UNESCO) and Organisation for Economic Co-operation and Development (OECD) publications on the state of science and technology throughout the world. For example, while in developed countries about fifty percent of the student-age population pursues some level of higher education, in Latin American this number is below twenty percent. This is after a doubling of university graduates during the 1990s. From this scarce percentage, in 1997 only eleven percent were graduates in mathematics, science, or engineering. It is against this scarcity and imbalance that the efforts of research groups in Brazil, Colombia, Cuba, Mexico, and Venezuela must be appraised.

A certain imbalance among these countries must also be recognized. Over seventy percent of Latin American scientific researchers are concentrated in three countries: Argentina, Brazil, and Mexico. While some countries, such as Brazil and Cuba, are making a strong economic and political effort to promote R&D, others, such as Peru and El Salvador, were not even investing 0.1 percent of their GDP in science and technology as of the late 1990s. The situation in Spain and Portugal is also distinctive. Particularly since joining the European Union, Spain and Portugal have worked to reach European standards with regard to science, technology, and innovation indicators. Although they have yet to match the general European standards, especially in relation to their weak public funding and poor investment from the private sector, their indicators are significantly better than those of most Latin American countries. For example, publications from Spain included in the Science Citation Index (around 25,000 in year 2000) were almost as great as those from all of Latin America (around 28,000 in the same year)—but still far below a single North American country such as Canada (with 38,000 in 2000).

Clearly much work remains to raise the profile of science and technology in all the Ibero-American countries. Mere awareness of the problem is not enough. Instead, decisive steps are required from many social actors in order to promote science and technology and to develop their economic potential. At some level, such work will rest on an ethical assessment of the value of science and technology that does not ignore their potential dangers. Indeed, the issues concerning relationships between science, technology, and development have been themes of critical social reflection in Latin America—a tradition of reflection that is in the process of being modified by the regional emergence of STS studies.

Latin American Social Thought

Relevant in the present context is the evolution of a distinctive school of Latin American social thought on science and technology, especially as reflected in a number of thinkers concerned with both the foundations of science and regional political change. Although the most significant of these were born and based in Argentina, they had a much wider influence during the 1970s and since. What follows is a brief review of the work of three representatives of this school.

OSCAR VARSAVSKY. Oscar Varsavsky (1920–1976) was an Argentinean mathematician and physicist who was also one of the most politically engaged scientists of his generation. He developed a criticism of what he called "scientism," particularly in Latin America: that is, the ideological attitude often assumed in science in which scientists focus their professional interest on their own careers, adopting them to the patterns operative in leading foreign scientific centers, thus developing an external dependence while ignoring immediate social needs and the political meanings of their work. According to Varsavsky, it is a prevailing obsession for quantitative methods and an illusion of freedom in research that obscures the scientists' dependency on capitalist economic forces and market laws.

Adopting a relativist viewpoint, Varsavsky held that there is more than one way to do science and technology. There are different styles in science and technology, linked to different national projects and eventually to different social values. Varsavsky thus developed a normative criticism of contemporary science, rejecting the linear model of innovation as dependent on basic science—a science policy ideology that became very influential in Latin America during the 1970s. In a more positive vein, Varsavsky argued for a new style in science and technology in Latin America: a science for the people or, better, a science from the people, providing the region with a certain scientific and technological autonomy, and linked to a style of society that he called *socialismo nacional creativo* (creative national socialism).

JORGE SÁBATO. Jorge Alberto Sábato (1924–1983) was an Argentinean metallurgist and self-educated physicist who had an important role as the promoter of research in the Argentine Atomic Energy Commission. He was also influential in the creation of the Physics Institute in Bariloche, Argentina. A sharp and lucid thinker, Sábato had a strong influence from the 1960s concerning the way to conceptualize scientific and technological development in Latin America. His most widely cited contribution is his 1968 paper "La ciencia y la tecnología en el desarrollo de América Latina" (Science and technology in the development of Latin America), coauthored with Natalio Botana. In this paper he introduces the metaphor of the triangle of scientific and technological development, whose three vertices are government, the production sector, and the knowledge-generation sector. This has come to be known as the "Sábato triangle," which he used as a heuristic tool for analyzing problems posed by the lack of innovation in the periphery.

According to Sábato, it is the weak connections between those three vertices, in contrast to the situation in developed countries where they constitute a system, that explains the weakness of innovation capacities in Latin America and its technological dependency. These ideas were contrary to the then-prevalent linear model of innovation, and clearly anticipated forthcoming theories on systems of innovation.

AMÍLCAR HERRERA. Amílcar Herrera (1920–1995) was an Argentinean geologist and eldest, but also longest-lived, of the three the thinkers under review. His main book, *América Latina: Ciencia y tecnología en el* *desarrollo de la sociedad* (1970), an edited volume that included Sábato's 1968 paper, outlines his primary intellectual orientation: developing a Latin American view about the problems of underdevelopment and their relation to science and technology. Immediately afterward, his *Ciencia, tecnología y desarrollo social: ciencia y política en América Latina* (Science, technology, and social development: science and politics in Latin America, 1971), critically analyzed the social and historical context of science and science policy in the Latin American region. It is in this second volume that Herrera, adopting a structural and contextual approach, introduced a now widely used distinction between explicit and implicit science policies. An explicit science policy is the one that can be found in standard formal documents, a modernizing and progressive policy in accordance to universal ideals. The implicit science policy is the one really at work, characteristically at the service of the ruling social classes.

Herrera also criticized the use of conventional socioeconomic indicators for development in Latin America, and argued in favor of an orientation of the scientific and technological capacities toward proper regional problems such as those of undernourishment, misery, and ignorance. Finally, shortly before his death, his *Las nuevas tecnologías y el futuro de América Latina: Riesgo y oportunidad* (New technologies and the future of Latin America: risk and chance, 1994) proposed a strategy for scientific and technological development appropriate to the Latin American countries and sensitive to the type of society to be pursued.

Of course, none of these authors considered himself a STS scholar. They were simply critical scientists interested in the social realities of Latin America, as connected to science, technology, and innovation, and as such they anticipated some of the ideas that could subsequently find a home in STS scholarship. Indeed, they created a social thought tradition that has molded the later reception of STS authors and ideas.

Moreover, they are not alone in the movement of Latin American social thought on science and technology. Others who deserve mention are the Chilean Fernando Fajnzylber (who focused his work in the study of the relationship between economic development and inequity) and the Venezuelan Marcel Roche (founder of the journal *Interciencia* and promoter of science studies in his country). Still others have also made lively contributions to STS research, in countries such as Brazil, Colombia, Cuba, and Uruguay.

The tradition of Latin American social thought was not, however, particularly influential in promoting an ethical assessment of science and technology in relation to developments in either Spain or Portugal. In Spain one primary influence was the work of José Ortega y Gasset (1883–1955) who, as a member of the "Generation of 1927" (the generation associated with the second Republic), criticized the views of Unamuno. Ortega's *Meditación de la técnica* (1939) provided a positive but critical analysis of technology as central to human life. Another influential philosopher of Spanish origin, Juan David García Bacca (1901–1992), who spent most of his adult life in Ecuador, Mexico, and Venezuela, adopted an even more positivist perspective that virtually ignored any negative political implications of scientific and technological progress. More recently the critical phenomenological analyses of the Venezuelan Ernesto Mayz Vallenilla on the tendencies of technology to be transformed into what he terms a meta-technology have also had some limited influence.

STS in Ibero-American Countries

It is within the previously noted contexts that STS studies—as the basic framework within which discussions of science, technology, and ethics have been manifest—have emerged in Spain, Portugal, and Latin America. Before turning to this emergence, however, it is necessary to provide some commentary on the underlying interpretation of science studies in these countries.

In Spanish- and Portuguese-speaking countries there is a certain ambiguity concerning how to interpret and translate the English acronym "STS." Some translate it as "science and technology studies" (*estudios sobre ciencia y tecnología*); others take it to stand for "science, technology, and society" (*ciencia, tecnología, y sociedad*). The well-known distinction between the two STS subcultures—an academic subculture focused on the study of technoscientific change as a social process, and the social factors that might be rendered responsible for shaping such a change, versus an activist subculture focused on the social and environmental effects of technoscientific products, upon their educational, ethical, or political aspects—is repeated in the Ibero-American perspective. But this repetition is a weak one, and the fact is that in Latin America especially the two approaches have tended to merge even when the interpretation of STS as "ciencia, tecnología, and sociedad" predominates.

The STS subcultures, whether disciplinary or activist, originated in the late 1960s and the early 1970s in the United States and the United Kingdom, and from there were transferred to other industrialized countries mostly in continental Europe. It was during the 1980s and 1990s that STS penetrated the academic and educational institutions of more peripheral European countries, such as Spain or Portugal, and other peripheral regions, such as Latin America. In Spain, Colombia, and Cuba, it was only in the late 1980s that such things as social constructivism, technology assessment, gender issues in scientific research, along with new trends in science education, began to be pursued. The academic and institutional consolidation of STS, however, did not reach the region until the 1990s, and even then in a slow and hesitant way that has continued into the twenty-first century.

There are nevertheless some exceptions worth mentioning, both in research and education. With regard to research, a number of groups linked to universities have had some important results. Examples include

- the STS postgraduate program and research group organized by José Sanmartín in the University of Valencia, which started the first formal STS education program in Spain in the 1980s;
- the group led by Mario Albornoz at the Ibero-American Science and Technology Indicators Network (RICYT) in Buenos Aires, which gathers scholars from many Latin American countries;
- the Hebe Vessuri group at the Venezuelan Institute of Scientific Research (IVIC) in Caracas, with its tradition of collaboration with UNESCO;
- the team arranged by Javier Echeverría and Emilio Muñoz at the STS Department, Spanish Research Council, Madrid;
- the scholars gathering around Renato Dagnino in the University of Campinas, near Sao Paulo in Brazil;
- the research group linked to Maria Eduarda Gonçalves and José Luís Garcia at the Institute of Social Sciences at the University of Lisbon;
- the network of Jorge Núñez, Director of Postgraduate Studies, Havana University, Cuba;
- the research group led by León Olivé and Rosaura Ruiz in the National Autonomous University of Mexico (UNAM), hosting many editing and teaching STS activities.

Not included in this list are other important researchers who have made no less significant contributions in countries such as Colombia (Mauricio Nieto, Carlos Osorio) and Uruguay (Judith Sutz, Rodrigo Arocena).

With regard to education, STS has been making a strong impact on the Spanish secondary school system and on higher education in Cuba since the mid-1990s. More modest impacts are to be found in Mexican secondary education, where a certain implementation of STS content has taken place in natural sciences subjects and is underway in technological education. There are also a number of particular universities where STS research groups have flourished when linked to diverse graduate or postgraduate programs (see above). However, these are rather exceptions to the general rule of slow consolidation of a regional STS scholarship.

The case of Cuba is worth special note. After the end of the Cold War, reforms in Cuba began also to affect education. Under the title of "Social problems of science and technology," the content of STS experienced an impressive expansion in the Cuban system of higher education. STS largely replaced the previously obligatory study of Marxism, and so is now taught as part of practically all university degrees. It constitutes a compulsory examination for Ph.D. candidates and for any scholar applying for promotion within the faculty system.

Discourse Transfer Issues

STS and related discussions of science, technology, and ethics can be understood as cultural constructs. Such discourses arose initially in more economically and technologically developed countries in response to certain social demands. These demands included calls for alterations in the academic image of science, desires to increase scientific literacy among non-scientist citizens, needs for reforms in science education, political efforts to extend public control over technological change, concerns for social accountability related to science and technology policies, and more. Discussions of the professional ethical responsibilities of scientists and engineers and efforts to enhance the responsible conduct of scientific research were especially associated with the intensified interactions between science, technology, economics, and politics. The transfer of such discourses to the more peripheral Ibero-American countries, despite the differences that exist among them, has confronted a number of common problems.

First, an obvious but important fact is that many of the social demands out of which STS originally emerged in the Anglo-American center of scientific and technological advance in the 1960s did not exist until much more recently in Spain, Portugal, or Latin America. With no significant interest in the classic sociology of science, one should not expect there to be much interest in the sociology of scientific knowledge and related analyses of the academic status of science. Where large sections of the population are illiterate, it is unlikely that there will be desires to increase scientific literacy. Without democracy, it would be nonsensical to argue for an extension of democracy into the regulation of science and technology.

Second, the constitution of a critical mass of STS scholars in every country requires an established research infrastructure in the natural and social sciences. It depends on reasonable input and output indicators in those fields, as well as institutional structures for facilitating interdisciplinary research. Unfortunately, in Ibero-American countries there has traditionally been an important lack in both respects. At the same time, the creation of small national groups of STS scholars, who could be put together and form a critical mass in the region as a whole, has faced serious difficulties because of severe restrictions on academic support and communication.

Finally, third, there has been an excessive peripheral focusing on the English-speaking center. Spanish STS scholars, for example, tend to read STS literature in English, produced by American, British, Dutch, or French authors. They thus largely ignore what their cultural neighbors are doing in Colombia, Venezuela, or even Portugal.

Fortunately, the situation in Ibero-American countries is changing. The effort of a number of international governmental organizations, such as UNESCO, the Programa Iberoamericano de Ciencia y Tecnología para el Desarrollo (CYTED), and the Organización de Estados Iberoamericanos (OEI), as well as some national science teachers associations (such as those in Chile or the Brazil), are promoting research and breaking down communication barriers. Traditionally isolated local universities and research centers are increasingly cooperating to promote STS throughout the region. This will undoubtedly stimulate discussions of science, technology, and ethics, as well.

Recent Initiatives

Two significant recent examples of recent initiatives are the creation of an Ibero-American STS Thematic Network and the promotion of a number of university Science, Technology, Society, and Innovation (STS&I) chairs, in both cases as initiatives of the OEI—an intergovernmental organization that depends on the ministries of education of the Spanish- and Portuguese-speaking Latin American countries, plus Spain and Portugal.

The Ibero-American STS Thematic Network gathers STS scholars from some fifteen countries in the region, focusing their work around typical STS subjects such as science and gender, social impact indicators for R&D activities, or ethical aspects of new technologies. The central goal of this network is to stimulate an endogenous STS scholarship in the Ibero-American region, while promoting a constructive dialogue with the international forefront in the field. Among the tools that are already in use are the support of STS publications (in Spanish and Portuguese), electronic diffusion and distance learning courses, and the sponsoring of STS conferences and meetings in the region (see http://www.oei.es/cts.htm).

The network draws applications to the fields of science education, communication, and management. For example, in the field of science and technology management, the OEI has made use of network resources and included a STS orientation in Science Administration courses that have been organized since 1998. These courses are addressed to young high officials of the Latin American ministries of science (or whatever ministry holds science policy competencies) as well as national organizations responsible for science policy in the region. The inclusion of STS content in these courses, comprising fifteen to thirty percent of the lecture time, has been well received.

As to the research guidelines of this initiative, its critical focus has been the urgent need to promote economic development in the region and a central place for science and technology in such a process. According to this view and reflecting the critical tradition of Latin American thought, a social critique of science should be compatible with the encouragement of science and science policies. In more practical terms, policy, ethics, and history-based applied analyses, often assuming the form of interdisciplinary studies, have taken precedence over theory-oriented and disciplinary stances. "Science, technology, and society" has dominated over "science and technology studies."

The creation of STS+I Chairs in Ibero-America exhibits similar tendencies. STS+I chairs are an OEI initiative in collaboration with national science and technology agencies, and in some cases ministries of education. Basically, the idea underlying STS+I Chairs is to constitute networks of universities (both public and private) that, duly supported by other public organizations, will be able to strengthen particular lines or research and education (linked to STS and innovation issues), thus making better use of the potentialities of participant institutions. To date, chairs have been established in El Salvador (September 2000), Argentina-Uruguay (April 2001), Colombia (September 2001), Cuba (November 2001), Costa Rica (July 2002), Panama (April 2003), Mexico (May 2003), and Peru (June 2003).

The organizational model is different in each case, respecting each country's characteristics (with a strong or weak national differentiation, with one or another higher education system, etc.). But basically a STS+I chair is constituted by a named professorship with supplementary funds to support education and research activities. What unifies the various STS+I chairs is the attempt to promote a dialogue between the scientific and humanistic cultures, as well as the social projection of scientific knowledge generated in the university by means of teaching seminars and other initiatives of knowledge diffusion, as well as the support of research. The general idea is the creation of a common working ground for higher education and research institutions, a common space conceived for sharing and rationalizing human and material resources. Not only banks and corporations, but also education and research institutions, need to establish alliances and common projects in order to be competitive and make an optimal use of their potentialities.

STS+I Studies

The STS+I acronym emphasizes the particular perspective in which STS studies are being developed in the Ibero-American region, receiving international STS scholarship and adapting it to the tradition of critical thought on science and public policy represented by Varsavsky, Sábato, and Herrera. The STS+I perspective also tries to cope with the two major challenges of the so-called knowledge society, as seen from a regional perspective: the appropriation of such knowledge by the production sector, and its appropriation by the civil society.

A pragmatic approach to the region's sensibilities is perhaps the best way to characterize these fields and their interrelation in the present geographic and cultural context. On the one hand, in the STS field, through the study of academic themes such as science and gender, science education, or engineering ethics, the goal is to achieve an understanding of the relationships between science and technology in their social context in order to promote social interests for scientific issues, scientific and technological literacy, and public participation in public policies related to science and technology. On the other hand, in the innovation field, through the study of themes such as university-corporation relationships, national systems of innovation, and technological management, the goal is to understand institutional and socioeconomic conditions underlying the phenomenon of innovation in order to support innovation and the creation of innovation systems in countries of the region. The great challenge and novelty of the STS+I approach has been the combination of these lines of work in a common framework of interdisciplinary reflection, with a strong practical or policy orientation.

"Society" and "innovation" are the key terms of the so-called "Declaration of Santo Domingo," from a regional summit on science and technology held in March 1999 as a preparatory meeting of the World Congress on Science, arranged by UNESCO and the International Council of Scientific Unions (ICSU) and held in Budapest in June-July 1999. It is not by chance that these two points were also emphasized in the final declaration of the Third Ibero-American Course for Science and Technology Administrators, held also in March 1999 in Bogota, Colombia, which gathered participants from twelve Latin American countries.

In fact, in the contemporary world, and especially in Latin America, these two goals—to open science and technology systems to social sensitivities and public participation, and to reorient these systems toward economic development—are not only compatible but mutually interdependent. Technological innovation, the process that begins with the organized creation of an idea and concludes with the social diffusion of its material realization, requires social support and participation for its feasibility and consolidation. Just as a country with half its population in poverty cannot pretend to be internationally competitive or to enjoy sustainable economic development, the consolidation of such growth and competitiveness requires public interest, democratic support, and confidence in institutions among all the citizens. Moreover, from the perspective of the periphery, technological innovation is necessary for national economic competitiveness and also for the creation of the material conditions that make possible, among other things, the modernization of political and administrative structures and the generation of a participatory culture.

Acknowledgment

Although only the author is responsible of any omissions or mistakes, this article draws on a number of experiences and personal communications involving the STS Network of the OEI. Due credit must be given to the Network scholars who provided many clues and much information. Particularly helpful have been Elsa

Beatriz Acevedo (Colombia), Rodrigo Arocena (Uruguay), Renato Dagnino (Brazil), José Luis Luján (Spain), Jorge Núñez (Cuba), and Sara Rietti (Argentina).

ILLICH, IVAN

Most well known as a 1970s social critic of the technologies of schooling, development, and health, Ivan Illich (1926–2002) was born in Vienna, Austria, on September 4, and died in Bremen, Germany, on December 2. In the 1980s Illich shifted from social criticism to cultural archeology, that is, an effort to expose *modern certainties* or assumptions, in order to provide an ethical perspective on the ways technology has transformed human experience in the late twentieth and early twenty-first centuries.

Ivan Illich, 1926-2002. Theologian, educator, and social critic Illich sought bridges between cultures and explored the bases of people's views of history and reality. *(The Library of Congress.)*

Early Years and the Centro Intercultural de Documentación

Illich was born in Vienna, of French and Serbo-Croatian descent. During World War II he was in some danger because of the Jewish heritage on his mother's side. After the war he undertook studies in science, philosophy, theology, and history; was ordained a Catholic priest; and in the 1950s was posted to the United States, where he became a protégé of the conservative Cardinal Spellman, head of the New York archdiocese. There he acted as a pastor to Puerto Rican immigrants, and as a result of sympathies with their plight, was appointed Vice-Rector of the recently established Catholic University of Puerto Rico. His work in Puerto Rico galvanized an emerging criticism of policies promoting economic and technological development, and led him in the 1960s to establish the Centro Intercultural de Documentación (CIDOC) in Cuernavaca, Mexico, as an institutional base for the exploration of alternatives. CIDOC became a locus for visits by many dissatisfied with technosocial trends and the inspiration for a generation of social critics, from Paul Goodman (1911–1972) to Paolo Frerire (1921–1997). Accused by the Vatican of thereby becoming a scandal to the Church, Illich resigned his institutional ministry, although he was never laicized or married.

It was from CIDOC that Illich published his most widely read books: *Deschooling Society* (1971), *Tools for Conviviality* (1973), and *Medical Nemesis* (1976). In each case Illich identified what he termed the phenomenon of *counterproductivity*: that is, the pursuit of a technical process to the point where it undermines its original goals. The system of public schooling, originally conceived to advance learning, had become an impediment to real education. Advanced technological tools were at odds with autonomous human development and the culture of friendship, in the name of which they were often invented. High-tech health care was making people sick. Iatrogenic illnesses, that is, illnesses caused by physicians—as when patients have negative reactions to drugs, are harmed by diagnostic x-ray treatments, or are otherwise misdiagnosed and mistreated—had, he argued, become a counterproductive epidemic.

The correct response, for Illich, was to learn to practice a more disciplined and limited use of science and technology, and to invent alternative, especially low-scale, technologies. In many instances, however, the practice of such an ethical imperative was made difficult by what Illich termed *radical monopolies*: Although no car manufacturer has a monopoly on the automobile market, cars themselves have a overwhelming monopoly on roads so as to crowd out pedestrians and bicycles.

Living His Theory: After CIDOC

Practicing what he preached, and fearing that CIDOC itself might become counterproductive, Illich closed the center in 1976. He divided up its accumulated assets equally among all those who worked there, from the teachers to the gardeners, and became for the remainder of his life an itinerant scholar. During this period he held posts as visiting professor at a number of universities, from the University of California at Berkeley and the United Nations University in Tokyo to Pennsylvania State University and the University of Bremen, Germany. Two early collections from these years—*Toward a History of Needs* (1978) and *Shadow Work* (1981)—stress counterproductivity in the economics of scarcity, or the presumption that economies function to remedy scarcities rather than to promote community sharing of available goods. Technoeconomic progress was, Illich argued, actually undermining society and culture, the possibilities for friendship and solidarity, and specifically increasing the gap between the rich and the poor both within developed countries and between developed and developing countries.

Toward a History of Needs also hints at a new project in historical archeology that takes its first full-bodied shape in *Gender* (1982), an attempt to recover those social experiences of female/male complementary obscured by the modern economic regime of sex. *H_2O and the Waters of Forgetfulness* (1985) explores the possibility of a history of *stuff*. *ABC: The Alphabetization of the Popular Mind* (1988) carries historical archeology forward into the area of literacy, as does *In the Vineyard of the Text* (1993). Both examine how the techniques of reading transform human beings' experience of themselves and each other, thus inviting contemporary consumers of automobiles and computers to consider that they might not be wholly unaffected users of neutral technologies. Modern technology, for Illich, tends to emerge from and then reinforce a distinctive ethos, the recognition of which is best appreciated by investigations into the moral environments of previous techniques.

In the 1980s Illich became afflicted by a mascular tumor for which, again in accord with his beliefs, he refused high-tech medical treatment. Although he was in increasing pain during the last two decades of his life, he sought to practice what he understood as the traditional arts of suffering, and continued to develop his ideas. He was in his last years especially critical of the notions of "environmental responsibility" and what he saw as the new ideology of "life." Calls for environmental responsibility were, he argued, often just another excuse for advancing technological management of the world, and even the Christian pro-life movement gave too much ground to science insofar as it defined human life in terms of a molecular-biological genesis that cannot be directly experienced. What was at work in history was a counterproductivity writ large that he often described with a Latin phrase, *corruptio optimi que est pessima*, the corruption of the best is the worst. Just as the sweetest flowers, when they rot, smell worse than weeds, scientific and technological attempts to better the human condition, not to mention Christian efforts to institutionalize the friendship of charity, ultimately undermine their own ends.

Illich's criticism itself often was criticized as being overstated and polemical—too much a radical, anarchistic prophesy to be taken seriously. Many of his specific historical claims seemed exaggerated to more sober historians, and he was sometimes unfair to those who questioned his ideas. Yet popular recognition of counterproductivities in government regulation were an ironic echo of Illich's more sweeping analyses. And precisely because of his efforts to live friendship as a fundamental human good, he remained until his death at a friend's home in Bremen, Germany, a charismatic figure who continued to influence cultural criticism and to inspire students seeking alternatives to the standard paths of worldly success.

IMMATERIALIZATION

SEE *Dematerialization and Immatrialization*.

INCREMENTALISM

In its most generic form, incrementalism is a normative theory of problem solving and decision making. Incrementalist strategies favor small-scale changes, monitoring, flexible positions, and decentralized organization. Incrementalists have been inspired by the epistemology of Karl Popper (1902–1994) and the economic views of Friedrich Hayek (1899–1992). These connections tie the theory of incremental development to controversies over democratic versus totalitarian forms of government and over socialist versus capitalist economic systems. Incrementalist principles thus have wide application but are explored particularly in the search for solutions to social problems and more specifically in the effort to intelligently control technology.

Basic Arguments

As a means of addressing social problems, Robert Dahl and Charles Lindblom give incrementalism a clear standing relative to other approaches.

> Incrementalism is a method of social action that takes existing reality as one alternative and compares the probable gains and losses of closely related alternatives by making relatively small adjustments in existing reality, or making larger adjustments about whose consequences approximately as much is known as about the consequences of existing reality, or both. Where small increments will clearly not achieve desired goals, the consequences of large increments are not fully known, and existing reality is clearly undesirable, incrementalism may have to give way to a calculated risk. Thus scientific methods, incrementalism, and calculated risks are on a continuum of policy methods. (Dahl and Lindblom 1953, p. 82)

Incrementalism is here conceived as one of several processes that facilitate rational calculation by reducing sources of complexity. By emphasizing alternatives that differ from existing reality by only small degrees, prediction of consequences is improved, identification of causes is made possible, reversibility of decisions is maintained, and the cost of altering organizational hierarchies is avoided.

David Braybrooke and Charles Lindblom (1963) develop these views by criticizing deductive systems, welfare functions, and other synoptic models (including Bayesian methods) that achieve quantitative rigor by assuming that options and states of the world can be exhaustively and exclusively specified. Such models are too formal, centralized, and idealistic to apply to practical decision making. By laying out two intersecting axes, one for degree of knowledge (low to high) and one for size of proposed change (small to large), four quadrants of decision making are established (Figure 1). Incrementalist strategies flourish in the quadrant defined by small changes in the context of low degrees of knowledge. The strategy of *disjointed incrementalism* proceeds through partisan mutual adjustment by which agreements are negotiated among individuals with no need of an overarching design. Lindblom's classic statements (1959, 1979) characterize incrementalism as *muddling through* (a term delivered to incrementalists via Popper's critique of its denigration by Karl Mannheim [1940]). These statements often present a more extreme form of incrementalism, no longer merely one of several alternatives (including calculated risk) but rather as the only viable approach to resolving social problems.

For David Collingridge, incremental advances are prudent where consequences of choice are unclear. Such is the case in the emergence of new technologies, and here incrementalist concepts provide a framework for controlling technological development. Collingridge's early work (1980, 1982) attacks the Bayesian account of decision making and articulates the role of flexibility and corrigibility in decision making. In particular the

FIGURE 1

Bayesian model is blind to the fact that earlier choices, prescribed by the model, may serve to prevent the adoption of new, better options at a later date. Yet one should choose such that one's future flexibility is not precluded by current choices. The art of choosing options that maintain flexibility thus becomes the cornerstone of Collingridge's theory of decision making and technology control. Controlling technology depends upon two factors, the ability to anticipate undesirable consequences and the ability to avoid such consequences once predicted, but this generates the *dilemma of control.*

> Attempting to control a technology is difficult, and not rarely impossible, because during its early stages, when it can be controlled, not enough can be known about its harmful social consequences to warrant controlling its development; but by the time these consequences are apparent, control has become costly and slow. (Collingridge 1980, p. 19)

This dilemma, which has sometimes been termed the *Collingridge dilemma,* can be resolved either by improving predictability or by increasing controllability. Efforts to improve predictive reliability in the context of infant technologies are absolutely hopeless on Collingridge's view, so resolution occurs only by focusing on the control issue. The manner in which technologies become resistant to change must be understood. Entrenchment occurs because technologies become intertwined so that changing one requires changing many, thus making change costly and slow, if even possible. The solution is to develop technologies in ways that avoid rigidity and maintain flexibility. This may be achieved by implementing corrigible technologies whose flaws can be detected quickly and corrected easily. Continuous monitoring with the aim of finding error is thus imperative. Decisions that keep future options open should always be favored. Collingridge's later work (1992) provides close analyses of several contemporary technologies. These analyses show that the cost of inevitable mistakes can be further reduced through decentralized decision making and non-hierarchical organizational structures. Significantly concern about the unpredictability of technology is no longer limited to the emergence of *new* technologies. The inevitability of error and of predictive unreliability are seen as general conditions of human existence. "We are indeed poor naked creatures . . . People have to make choices under great adversity, where the levels of uncertainty seem bottomless" (Collingridge 1992, p. 3). Like Lindblom, Collingridge's later work takes a more extreme view of the nature and promise of incrementalism.

Additional support for incrementalist principles can be found in the work of Joseph Morone and Edward Woodhouse (1986) where the aim is to explain the *infrequency* of technological disasters. Several strategies facilitate intelligent control of technology, one of which is to "Be actively prepared to learn from error, rather than naively expecting to analyze risks in advance or passively waiting for feedback to emerge" (Morone and Woodhouse 1986, p. 160). In the realm of business operations, James Quinn (1980) concludes that, while most companies have formal planning structures, formal planning has little to do with effective operations. Major strategic decision making occurs outside of the formal planning process. Managers maintain flexibility and avoid premature decisions, delay action as long as feasible to increase feedback and communication, and promote interactive learning. So incremental development may account for successful business management as well as technology development per se.

Theory and Criticism

As indicated, incrementalist thinking emphasizes flexibility and responsiveness, values with roots in the philosophy of Popper and the economic theory of Hayek. Popper's epistemology (1972) emphasizes the inevitability of error and the necessity of devising effective means for learning from mistakes. This is achieved by maximizing opportunities for feedback via experience, especially by subjecting proposals to critical tests and by continuously reshaping ideas in the face of failed predictions. Hayek (1960) opposes the concentration of power in the hands of the few and top-down management via pre-planned, large-scale solutions. Rather he argues that market activity conveys information so as to exploit knowledge distributed throughout society, which results in a bottom-up problem solving. Even effective social institutions can arise by means of decentralized action. These concepts of decentralized decision making, continuous expectation of error, and iterative improvement through active exploitation of mistakes resonate throughout incrementalist thinking.

In respect to criticisms of incrementalism, Collingridge (1992) identifies two categories: critiques that point to successful, non-incremental development and critiques that point to unsuccessful incremental change. Ian Lustick (1980), for instance, argues that non-incremental approaches are superior in achieving safety in nuclear power. Other examples of this type include Paul Schulman (1975, 1980) and Jennifer Hochschild (1984). By contrast, incrementalism is also criticized as too plodding to resolve certain social problems. Sometimes radical innovations are called for in response to radical socioeconomic contingencies. Problems whose severity has quantitative measures, such as air pollution, prove that small-scale change allows desirable goals to gradually slip further away. Or threshold and *sleeper* effects may occur in which large unpredictable changes result from small steps (Dryzek 1987; Mushkat 1987).

A related worry concerns the extent to which incrementalism is too extreme in its distrust of prediction and knowledge. This distrust may derive from concerns expressed by Adam Ferguson and Baron de Montesquieu, and later echoed by Hayek, over the unanticipated consequences that attend all technological innovations. In its extreme forms, incrementalism justifies limiting technological or social programs on the basis of general unpredictability and inadequate knowledge. Nevertheless more than mere inevitability of error is required to justify restricted development. The fact that unexpected consequences, even undesired consequences, will occur fails to make the case. What is needed is some assurance that the magnitude of the unexpected, undesirable consequences will outweigh the magnitude of the expected, desirable consequences. For this, substantial and reliable predictability is required.

Collingridge admits, for example, that not all resources can be committed to maintaining flexibility and that corrigibility and monitoring have costs. These costs must be weighed against that of making an error. Yet if predictability is forsaken, such *error costs* cannot be accurately estimated (Croy 1996). By granting accurate estimation of error costs, Collingridge's case assumes predictive reliability and lapses into inconsistency.

Incrementalism has also been criticized for insensitivity to the political process, both in the attempt to develop technology and to solve social problems. Collingridge has been admonished for not recognizing that determining what counts as an error or mistake is essentially a politically driven judgment (Johnston 1984), and more recent work on incrementalist theory takes pains to deal with the deleterious effect of special interest groups on incremental development (Hayes 2001). In each case, political process complicates the speedy responsiveness to error so crucial for flexibility.

Critiques such as these reveal the connection between incrementalism and controversies surrounding attempts at social progress, particularly those that pit utopian reform against incremental development. Popper's distinction between piecemeal social engineering and utopian engineering paves the way for this connection and for the wide reach of incrementalist concepts. When taken in its less extreme form as one problem solving strategy among many, one that is warranted or not by the nature of the problem confronted, incrementalism withstands critical scrutiny, provides a helpful methodological tool in the quest for improving society, and stimulates questions about the nature of social reform.

INDIAN PERSPECTIVES

India (along with China and Egypt) is home to one of the oldest and perhaps the most continuous cultural tradition on the earth. Although it occupies only 2.4 percent of the global land area, it is home to fifteen percent of the population, and by 2050 is projected to be the most populous country in the world. India spends approximately six billion dollars every year on science and technology; science and technology have been central to the country's development since its independence in 1947, while themselves being subject to distinctive assessments and adaptations.

Historical and Cultural Context

Knowledge enjoys sacred stature in Indian culture and civilization. Saraswati, the goddess of knowledge, occupies a place of pride in the Hindu pantheon, while India's much-reviled caste system accorded the highest social status to Brahmins, whose profession was to create and disseminate knowledge. Ancient India's sometimes contested scientific contributions—including theories of gravity, the age of the universe, modern numerals, trigonometry, and the conception of zero—were often first described in religious scriptures. Utilitarian and empirical observations about agriculture and medicine that survived generations were often couched in idioms and expressions with religious connotations. Even during Mughal rule (1526–1707), respect for Indian mathematics was instrumental in its spread to places as far as Central Asia, Spain, and North Africa (Teresi 2002).

Respect for knowledge workers—scientists and doctors—turned to awe during British rule, when science as practiced in Europe took hold through the Geological, Botanical, and Trigonometric Surveys established through the efforts of the Asiatic Society (founded 1784). Although the first voices of dissent—notably of the philosopher Ananda Kentish Coomaraswamy (1877–1947), poet and literature Nobel laureate Sir Rabindranath Tagore (1861–1941), and the father of India's freedom struggle, Mohandas Karamchand Gandhi (1869–1948)—against this surrender to Western science were voiced as early as 1905, they had to wait till the 1970s and 1980s to gain traction through democratic people's movements.

When India became independent after two hundred years of British rule, Gandhi anointed Jawaharlal Nehru (1889–1964) the country's first prime minister. While

Nehru was popular in his own right and received three overwhelming electoral mandates following his appointment in 1947, his elevation to the highest office—although a foregone conclusion—was a curious one.

It was curious because Nehru's and Gandhi's visions of independent India could not have been more different. Nehru's vision of India was that of a highly industrialized and progressive economy where dams, laboratories, industrial facilities, and mechanization would be revered as "temples of modern India" (Nehru 1958, p. 3). Gandhi's vision, conscious of India's predominantly rural base, focused on the rural village as the central element of development and opposed all products of science and technology that displaced human labor. Few, however, shared Gandhi's economic views in the Congress party, and a desire to undertake rapid (state-sponsored) industrialization was articulated as early as 1931 (Chandra, Mukherjee, and Mukherjee 1999).

To Nehru's credit, then, goes the rapid growth of India's industrial infrastructure, the creation of the Council of Scientific and Industrial Research (CSIR), the world's largest chain of publicly-funded research laboratories, the founding of the Indian Institutes of Technology, the country's nuclear and space research programs, and most importantly, the faith that "science alone . . . could solve . . . problems of hunger and poverty, of insanitation and illiteracy, of superstition and deadening custom and tradition, of vast resources running to waste, of a rich country inhabited by starving people" (Gopal 1972, p. 807).

Nehru's investment in science and technology produced the Green Revolution, which is arguably the first significant achievement of mainstream Indian science. India's Green Revolution refers to the enormous improvement in agricultural productivity the nation achieved starting mid-1960s. Thanks to Green Revolution's introduction of a high-yield variety of seeds, fertilizers, and scientific agricultural practices, India's production of food grains increased by thirty-five percent between 1967 and 1970. India, which imported 10.3 million tons of food grains in 1966, had food grain reserves of 128.8 million tons in 1984 and exported 4.8 million tons of food grains in 2001 (Chandra et al. 1999).

While its ecological legacy is sometimes disparaged, the Green Revolution vindicated Nehru's "temples of modern India" and established their legitimacy as effective instruments of development. These institutions have since notched several accomplishments, including supercomputers in response to technology denial from the United States; the production, launch, and utilization of satellite technology; processes to produce raw materials for fuels and textile fibers; and a cheap but effective telecommunication network (Parthasarathi 2003).

Yet academics complain that scientific work accomplished entirely in India is yet to win a Nobel Prize, and the number of peer-reviewed papers decreased by almost twenty percent between 1980 and 2000, even as the number of universities and research institutions almost doubled and funding grew seventeen times (Balaram 2002). Further, corporate innovation and science-based entrepreneurship, notwithstanding several promising efforts, has been limited in scope and success (Turaga 2000). At the same time, China, South Korea, Brazil, and Israel have registered impressive growth, leaving critics to suggest that mainstream Indian science is of a mediocre quality.

Technocracy versus People's Science

Even so, the rapid advent of globalization has dulled dissent and absolute devotion to the technocrat was witnessed as late as 2002, when the renowned missile scientist A. P. J. Abdul Kalam (b. 1931) became independent India's eleventh president. Although elected indirectly, Kalam's nomination received a landslide vote, nationwide support, and near fanatical endorsement from India's educated middle class.

Kalam's disheveled long hair, soft-spoken demeanor, and spartan lifestyle (a bachelor, he lived in a one-bedroom government apartment until he became president) reinforced stereotypes of scholarship and suggested integrity uncommon to recent Indian public life. Kalam became a national icon and household name following India's May 1998 nuclear tests, of which he was the widely recognized scientific architect. What fired the imagination of the nation's educated, however, were Kalam's dreams of a *developed* India constructed through the apolitical pursuit of science and technology as an entirely objective and value-free activity (Kalam 2002).

In sharp contrast to Kalam is the articulate activist Sunita Narain, chairperson of the New Delhi-based radical environmental advocacy group Centre for Science and Environment. Narain has marshaled scientific research, data, and opinion to create immensely popular media campaigns for clean air, water, and food that have eventually influenced public policy. Narain commands enough influence for *India Today*, a leading Indian newsmagazine, to list her as one of India's fifty most powerful and influential citizens in 2004. However, "development is not a road" for Narain, who is severely critical of India's scientific, political, and social establishment (Narain 2003).

The lopsided battle being fought at the crossroads of these conflicting definitions of *development* constitutes a central theme in the emerging interdisciplinary field of Science, Technology, and Society (STS) studies in India. The stronger side in this battle is the statist version of science promoted by the likes of Kalam, whose vision of development is sanitized, crystalline, and sees power plants, dams, roads, factories, and software firms as both instruments and milestones in the quest for India's development. The rapidly growing ranks of the country's educated middle class see in Kalam an unprecedented opportunity to achieve this vision.

Cast against this powerful technocracy is a motley crowd of academics, environmentalists, and social critics with diverse but strong intellectual views. These are people who agitate against dams because of their inhumane consequences on marginalized tribal groups, picket government offices to protest power plants in protected forests, and advocate indigenous, small-scale technologies to harvest water and energy. Not half as focused or strong resource-wise as the statist agenda, these constituents of civil society have covered ground using imaginative ideas, rich rhetoric, moral leadership, articulate spokespersons, and successful grassroots political action.

Critics also question why a developing country like India should invest in supercomputers, satellites, and atomic energy, especially when more Indians sleep hungry than elsewhere in the world, one in three is illiterate and subsists on less than a dollar a day, infant mortality is at sixty-eight per one thousand births, nearly half of all Indian children are malnourished, access to affordable drugs is heterogeneous and available to every other Indian in the best of communities, and only twenty-eight percent of India's population has access to improved sanitation (United Nations 2003, pp. 237–339). That the Indian discourse of ethics in science and technology should raise these questions indicates that Nehru's "temples of modern India" have not been successful enough.

According to critics, the Nehruvian model was never suited to address these problems in the first place and instead has aggravated them. The Booker Prize-winning author Arundhati Roy, for example, estimates that the 3,600 dams India has built have "displaced maybe up to 56 million people" from their farms and livelihoods to the growing ranks of the urban poor (Roy 2001, p. 10). Things would have been different in Gandhi's village-based economy, they argue. Gandhi, however, was not alone critiquing the application of science and technology in the Indian context.

The Swadeshi Movement

The role and effects of modern science on Indian traditions, people, and society was intensively debated as early as 1905, during the *Swadeshi* (local, native, indigenous) Movement, when "the boycott of foreign goods . . . met with the greatest visible success at the practical and popular level" (Chandra, Mukherjee, Mukherjee, et al. 1989, p. 129). Although Swadeshi was a political movement belonging to the larger freedom struggle, "it was accompanied by an efflorescence of cultural debates . . . around the civilizational question of science and state" (Visvanathan 1987, p. 15).

Coomaraswamy was a leading figure in this debate; he was concerned that, lacking concerted effort, India's great craft traditions and art cultures would be lost to modern science. Intermediate technologists such as the British civil servant and founder of the Indian National Congress, Allan Octavian Hume (1829–1912), appreciated, if reluctantly, the rationality of traditional technologies but questioned their viability against the "onslaught of modernity, capitalism, and imperialism" (Visvanathan 1987, p. 17). If intermediate technologists exhorted blending both medieval and modern technological traditions to facilitate meaningful industrialization, Tagore was convinced that the two cultures could converse only after the differences between them were first recognized. It was to facilitate such studies that Tagore created Visva-Bharati University at Santiniketan in eastern India in 1925.

Most of these Swadeshi arguments, however, have gone unaddressed and modern India would disappoint Coomaraswamy, Hume, and Tagore. India's current and future economic growth rests on exporting software services, rendered by engineers educated at institutions (for example, the Indian Institutes of Technology) built with the support of Western universities. Curricula at such universities rarely include STS studies or the traditional technologies that Coomaraswamy wanted to preserve. Globalization and liberalization have relentlessly destroyed Indian communities practicing traditional agriculture and medicine, art, and handicrafts. Although governmental and voluntary initiatives seek to preserve the few remaining bastions of India's cultural traditions, they are a far cry from the "gene pools of an alternative imagination which had to be sustained and eventually made available to the West" (Visvanathan 1987, p. 16).

Future Prospects

Not all is lost, however, and there is cause for optimism in contemporary India. One heartening illustration is the pioneering work of Sulabh International, which has worked with local governments, communities, and vendors to develop a low-cost, environmentally sustainable, and socially acceptable sanitation system for both rural and urban communities. In the past thirty-five years, Sulabh has created fifty thousand jobs through its one million latrine units that have served over ten million people. Similar efforts by several voluntary outfits, people's science movements, and public-spirited initiatives have helped achieve social equity, improved literacy, and better and affordable public health care (United Nations 2003, p. 105).

Even the mainstream scientific establishment is better engaging traditional and indigenous knowledge systems. In the mid-1990s, CSIR successfully contested and overturned a U.S. patent on the use of turmeric powder to heal wounds. The U.S. Patent and Trademark Office upheld CSIR's claims that turmeric has been used in India for centuries and its medical properties are well ingrained in Indian folklore.

Indian scientific agencies have since aggressively espoused the intellectual property rights of India's indigenous communities and encourage research, development, and commercialization of traditional knowledge. Fundamentally, however, India has made a decisive shift towards the Western scientific and technological traditions to derive the same economic and human development benefits realized by developed nations. Thus, when CSIR succeeded in overturning the turmeric patent, it chose to project the victory as the best possible evidence of the integrity, transparency, and objectivity of the international patenting regime, which India began conforming to completely starting 2005.

India is, however, yet to embrace STS concepts such as risk assessment, informed consent, engineering ethics, right to information, and transparency to the extent they are ingrained in the practice of science in the developed West. This will change with economic and technological development, which is occurring rapidly, as well as grassroots people's movements. A greater impetus, however, might come from Western collaborators, who are increasingly using India's modern infrastructure, engineering talent, and large population to cheaply develop products, design cars and factories, and conduct clinical research (Turaga 2003). Illustrating this growing trend is a 2001 controversy involving Johns Hopkins University and a cancer hospital in southern India, where some patients participating in a clinical trial were not informed of the new drug's consequences (Bidwai 2001).

The foremost of Indian polity and society's concerns for the future relate to advancing the quality of its people's economic status, health care, and education. Science and technology are now widely accepted as important to such development. This unquestioning acceptance has been tempered to some extent with grassroots activism and people's movements, which have their origin in India's successful practice of and absolute commitment to democracy. Further, India's globalization will enable the quick assimilation in its public policy of Western principles shaping scientific and technological progress. Thus, the relationship between India—one of the world's most profound civilizations—and science, technology, and ethics will be shaped by two important trends that differ in size and methods, but have goals that share some philosophical similarity.

INDIGENOUS PEOPLES' PERSPECTIVES

The term *indigenous* is used to refer to the original inhabitants in a region. With regard to human populations, this term can be politically ambiguous, but the concept is still helpful in referring to small-scale societies with distinct languages, mythic narratives, sacred places, and kinship systems. Located on all the major continents (except Antarctica) as well as the Pacific Ocean areas, more than 500 million peoples are considered indigenous. In many contemporary settings these native societies are so marginalized within their nation-state settings and so subject to the extractive exploitation of multinational corporations that their existence is threatened. In these traditional societies the distinctive activities of understanding nature, the technology of subsistence, and an ethics of balance are not separate from one another. Rather, in diverse ways in these different native settings, the interactive relationships of knowing, producing, and thinking about behavior constitute coherent social wholes that can be called worldviews. Indigenous worldviews change over time, yet they also manifest symbols shared with the larger human community in rituals and myths that bind the quest for personal identity, the spirit of community, and ways of knowing the cosmos.

The term *lifeway* is used here to indicate this cultural integration of thought, production, and distribution among indigenous societies. These diverse and integrated perspectives of native peoples have often been dismissed as animism, or *failed epistemologies*, that posited a vitality or life force within the world that entered into all technological activities and ethical considerations. From a social science perspective, no such life force could be measured or consistently observed, and, thus, the worldviews, ethics, and technologies of native peoples were seen as too limited for attention by modern urban societies. However in the early-twenty-first century, the philosophical subtlety and social creativity evident in such native technologies as astronomical and ethnobotanical knowledge, healing therapies, cosmological narratives, and aesthetics of performance evident in ritual performances and rock art petroglyphs (rock incisions) and pictographs (applied paint) are being reassessed.

Approaches to Indigenous Peoples

Early encounters by Western Europeans with indigenous peoples were generally interpreted in the context of the Bible. When indigenous peoples manifested empirical knowledge, productive technology, or disciplined behavior, observers judged the achievements to be God-given and their genesis related to Western scriptures. Thus a naïve view of native peoples as prelapsarian, or living in the original innocence of the edenic paradise, gave rise to a romantic view of indigenous peoples as *noble savages*. From a similar but negative biblical perspective, indigenous peoples, their arts, and their activities were seen as spawned by the devil and deprived of the divine grace of the Western civilized arts. Thus any striking architecture, such as the mounds of the river valleys of Ohio or the Mesoamerican pyramids, was attributed to *lost* biblical tribes, or prehistoric Caucasian influences from Viking navigators or Irish monks. Lacking a coherent social science, early encounter-period European views dismissed as childlike the petroglyphs and pictographs of indigenous peoples. Thus the lyrical hunting scenes in the cave art of Zimbabwe, Botswana, and South Africa, or the numinous presences manifest in the cave art of Australian indigenous peoples was largely interpreted as psychological projection, sympathetic hunting magic, or primitive aesthetic. For indigenous peoples, however, these varied forms of symbolic expression symbolically made present their commitments to place, the numinous forces in local regions, and often their knowledge base regarding animals, plants, land, and weather.

Beginning with the sixteenth-century early modern period, new intellectual perspectives in Western Europe associated with critical, skeptical thought allowed for innovative views of indigenous lifeways. Influenced by the *Jesuit Relations* (1632–1673) as well as limited exchanges with Brazilian native peoples, Michel Montaigne (1533–1592) rejected the idea of native peoples as morally depraved and favorably compared the reported cannibalism of indigenous peoples with the savage brutality of the religious wars of Europe of his

Petroglyphs. These images had deep cultural and religious significance for the societies that created them. *(Field Mark Publications.)*

day. Baron de La Brède et de Montesquieu (1689–1755) in *The Spirit of the Laws* (1748) proposed that the spirit of native societies also resulted in laws, political structures, and social decorum.

By the early-twentieth century, the philosopher Lucien Levy-Bruhl (1857–1939) proposed that indigenous worldviews emerged from a prelogical mentality, intellectually different than the rational, logical Western mind, characterized by *mystical participation* in a pervasive life force (Levy-Bruhl 1923, 1985). His thesis is sharply questioned for projecting a universal mindset on very different peoples, but his emphasis on a cultural logic brought to descriptions of the world is now widely accepted. For native peoples, their perception, knowledge, and explanation of the world relates to their immediate technological-environmental circumstances as well as their linguistic and ideological heritage.

Franz Boas (1858–1942) emphasized *cultural relativity* and oriented a new generation of anthropologists to investigate the knowledge, technologies, and ethics of indigenous peoples as whole systems, or cultures. The anthropologist Claude Levi-Strauss (b. 1908), in *The Savage Mind* (1962), observed that the science and technology of native peoples follows from a mental structure evident in mythologies in which perception and attention to the natural world gradually lead to a cultural world. From a religious perspective, Mircea Eliade (1907–1986) proposed in the 1950s that indigenous peoples embodied technologies and ways of living that were based on seasonal and cosmological cycles rather than linear, historical understandings of reality.

Faced with the description of native North American peoples as the *first ecologists,* scientists in the 1980s questioned the roles of indigenous peoples in the extinction of large mammals, which occurred when native peoples were believed to have migrated to the American hemisphere (Martin and Klein 1984). The scientific understanding of indigenous knowledge continues into the present often including the voices of indigenous elders, artists, and intellectuals who seriously challenge the extinction theory. Acknowledging the roles of native hunters in mammoth and mastodon die-off evident in Clovis and Folsom spear-point technologies, they propose broader considerations of both anthropogenic and natural causes such as climatic change, disease pathogens, and fire (Deloria 1995, Wong 2001).

Indigenous Perspectives

Indigenous perspectives suggest that the art of knowing, or science, and the forces of production, or technology, as well as the sense of appropriate behavior, or ethics, weave together social and cosmological values. That is, knowledge of the world, tools for work, and reflection on one's behavior are properties of persons who are actively engaged with a living environment. Human persons interact with a world alive with dynamic forces that are powerful persons watchful of human behavior. Science, technology, and ethics are not transmitted in traditional thought as ways of controlling nature but primarily as modes of interaction with these other-than-human persons. Indigenous science results from maturing attention to nature as beings-in-the-world having capacities to interact with humans in person-to-person exchanges.

Technology is a way of creating the world, in relation to a task, that a person comes to gradually and internally as much as productively and externally. Ethics among indigenous peoples embodies a cultural relationship with specific places and forms of life in a local region that matures as the person ages. Through ritual and performance arts, such as rock art, basketry, canoe making, beading, and habitat construction, indigenous people express personal and social identity. These coherent, integrated activities place the human person in relation to powerful other-than-human spirit beings that inhabit the cosmos. Thus the personal subjectivity of humans, in indigenous perspectives, is brought to fruition through intersubjectivity with the world of animate forces. Paraphrasing the observations of Thomas Berry (1988), the weave of indigenous science, technology, and ethics is evident in their recognition that the universe is not a collection of objects, but a communion of subjects.

The social and cosmological basis of science, technology, and ethics within indigenous thought stands in sharp contrast to nonnative, European, Western, Marxist, capitalist, or other current globalization views. Broadly speaking, in modern standpoints technology has been identified as technical or mechanical manipulation of inert matter related to work as production. Ethics, following this paradigm, comes before action as intentional thought brought to fruition in activity. In all three acts, namely, science as knowing, technology as work, and ethics as intention, the human is central. The contemporary global ethos associated with urban, industrial societies is wholly anthropocentric. In the indigenous perspective the roles of science, technology, and ethics are integrated into the formation of persons and communities (Ingold 2000). Science, technology, and ethics are not simply anthropocentric acts that psychologically orient individuals and communities inward as the source of ultimate value. Rather indigenous perspectives foster an anthropocosmic orientation in which the living world is central, and the human seeks to balance inner identity and meaning in relation to a holistic outer world.

Indigenous intellectual knowledge exemplified in such inventions as the canoe, the bow and arrow, ritual ceremonies of seasonal renewal, and shamanistic therapies all involve complex interactions of place, spirit persons, and symbolic language. Coupled with the striking traditional environmental knowledge evident, for example, in the extraction and blending of plants to produce the ritual hallucinogen, ayahuasca, they affirm the prowess of science and technology among indigenous peoples. Rarely, however, have observers determined that material, human, and spiritual worlds are separated by the indigenous ethics implicate in those inventions. Becoming an authentic human in indigenous views involves relationship with and treatment of the natural world-as-person. Knowing and using the world implicates one's own body, social setting, and larger cosmological forces.

One Example from the Yekuana Peoples of South America

Among the Yekuana peoples of Venezuela traditional environmental knowledge gives rise to technical skills that foster an ethics, constructed in relation to mythological stories, for progressing gradually into mature personhood. Technical developments, such as the press for extracting yucca, the large circular community houses, as well as forms of social life are considered to have come from the culture hero, Wanadi; whereas all the troublesome, corruptible, dangerous aspects of nature and human life come from Odosha. The complex stories of the birth of Odosha from Wanadi's afterbirth, which was improperly buried, and the consequent yearnings and desires embedded within the natural world serve to teach Yekuana traditional environmental ethics. Each individual Yekuana participates in both the cosmic struggle of Wanadi and Odosha, as well as in the creative presence of Wanadi, for example, in the knowledge, skill, and intention of making yucca presses and especially baskets.

The Yekuana have developed a complex set of ethical teachings connecting the emergence of designs for baskets, the materials for making baskets, and limits on collecting those materials. Set within mythological stories of Wanadi and Odosha, the tense and ambiguous weave of the actual human condition is likened to those cosmological webs of relationships. Among the Yekuana the pragmatic use and location of grasses and roots for basket making are hedged with ethical warnings of the allure of those spirit beings who inhabit the grasses as well as the danger of inappropriate and unlimited use.

The knowledge of these grasses, the technical skills used in weaving them into baskets, and the complex of stories associated with their presence in the region are also directly related to personal maturing and social status (Guss 1989).

These complex cosmological stories braid cognitive-intellectual and affective-emotional realms of human experience into a learned and embodied practice of restraint. In effect, the weaving of baskets among the Yekuana is considered an aesthetic and contemplative skill in which individuals mature in their self-realization of society and bioregion. Thus Yekuana ethics springs from an inherent knowledge of limits with regard to natural consumption.

Conclusion

Indigenous knowledge is traditional in that it informs technical means not as a separate ethical mode but as the cosmological weave of storied knowledge, natural materials, and a respect for beings-in-the-world that limits consumption. No doubt ethical teachings emerged among indigenous peoples because there were those who overstepped cultural boundaries. The examples given here are not descriptive of all individuals within any one particular native community, nor of the diverse ways of knowing, embodying technical skills, and implementing ethical teachings among indigenous peoples. Yet there are shared indigenous perspectives, or *family resemblances*, embodied in science, technology, and ethics as ways of living that arise from the mutual dialogues of body, society, and place in the larger cosmological whole.

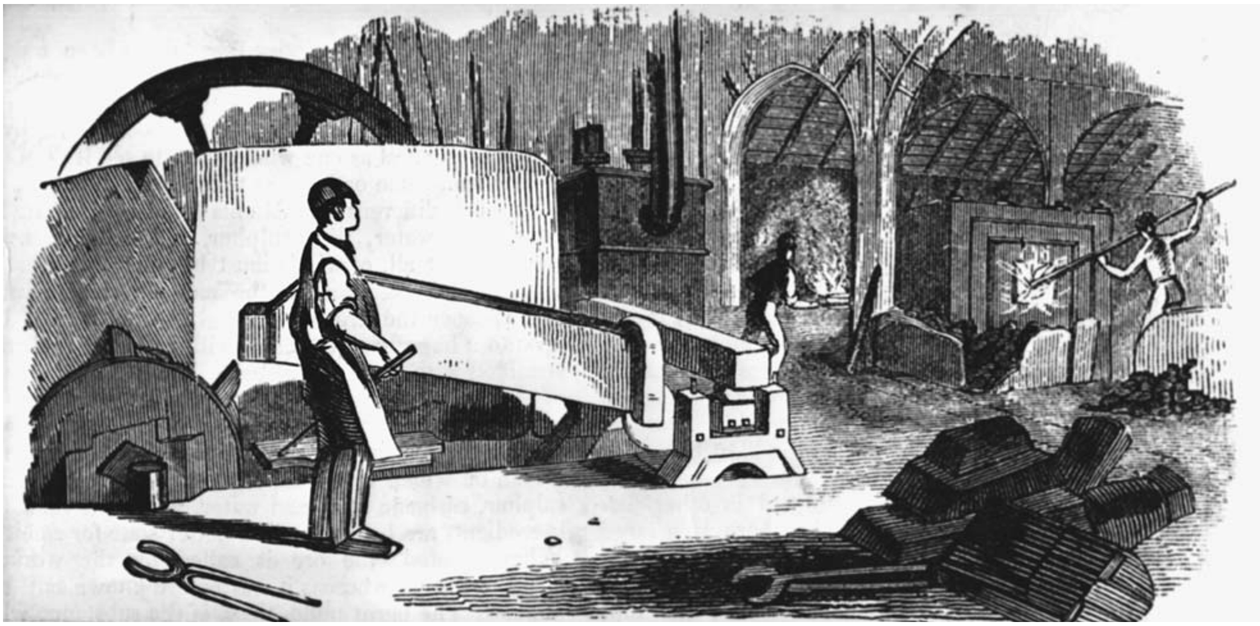
INDUSTRIAL REVOLUTION

The concept of an industrial revolution denotes an economic transition in which the means of production become increasingly specialized, mechanized, and organized. This process uses technology, in some association with science, to create large increases in the productive capacity of an economy, which in turn eventually transforms society as a whole. Industrial revolution is less violent or dramatic than political revolution and has roots that extend into the preindustrial agrarian past as well as consequences that continue to influence distant places and times. Great Britain inaugurated the Industrial Revolution in the late eighteenth century, and other nations have undergone similar revolutions in



A puddling furnace. Iron production was the first pillar of the Industrial Revolution. *(Hulton Archive/Getty Images.)*

subsequent years, continuing to the present. This process may be described as a single ongoing Industrial Revolution or as a series of separate revolutions that influence one another. Either way, the Industrial Revolution is without question one of the most important transformations in human history, and it is best understood through an appreciation of its complex origins, its evolution and spread, and its ethical and political influences.

Historical Origins

Most human societies have passed through several broadly defined stages marked by major turning points or revolutions. The transition from nomadic hunting and gathering to settled agriculture (farming and herding) that first occurred in the Near East is often called the Neolithic revolution. By enabling humans to live in one area, grow more numerous, and produce sufficient food surpluses to support nonfarming vocations such as artisanship and soldiery, the Neolithic revolution laid the groundwork for the next stage in societal evolution, the urban revolution. Human history is largely the history of cities and nations, and the gathering of populations into concentrated areas is responsible for many political, cultural, technological, scientific, and other developments. The Industrial Revolution is a third major societal transition point that follows and was made possible by the first two revolutions.

An industrial revolution requires a confluence of favorable labor, capital, technological, and ideological conditions. One vital component of industrialization is a populous labor supply that receives support from an agricultural sector capable of feeding it, and that possesses the necessary skills and discipline for manufacturing work. Capital is vital for covering the start-up and operating expenses that accompany new industrial endeavors, such as the purchase of land, facilities, and machinery; the preparation of stock on hand; the establishment of accounts receivable; and salary payments. Industrialization also depends on technological developments in manufacturing, power generation and transmission, transportation, and raw materials processing. Finally, an industrial revolution is facilitated by the development of political and philosophical ideologies that justify or mandate human organization and control over the natural environment. After many centuries of heterogeneous worldwide population growth, economic development, and technological advancement, all of these conditions converged for the first time in eighteenth-century Great Britain.

The Original Industrial Revolution

A variety of conditions caused Britain to experience moderate economic and manufacturing growth in the early eighteenth century, but these factors produced the greatest effects after 1760. By the 1780s, the British Empire's population, mechanization, and productive output were dramatically expanding. The term "Industrial Revolution" was first formulated by British historian Arnold Toynbee (1884), who considered this period of industrial and technological change more historically significant than political events such as the French Revolution.

Some of the preconditions of the British Industrial Revolution span or even predate the eighteenth century. New agricultural practices, such as the enclosures policies that brought more land under development, Jethro Tull's mechanical drill for sowing seed (c. 1701), Lord Townshend's four-year crop rotation system, advances in animal breeding, and the cultivation of the potato in Ireland, made possible a period of steady population growth. This population included a large supply of available laborers who started to concentrate in towns or cities.

Prior to the existence of large manufacturing establishments, Great Britain fostered a rich craft tradition that provided technological infrastructure and a substantial pool of skilled labor. Farmers comprised more than 90 percent of the preindustrial population, but artisans played a vital economic role. Indeed, while specialized artisans often congregated in cities, many farmers themselves practiced diverse craft trades or produced domestic manufactures in the evening or during winter months, serving as a vast pool of potential labor. This labor was increasingly tapped by enterprising merchants through the putting-out system, which involved the coordination of decentralized part-time laborers and led to regional specialization and the promotion of markets and towns. Early manufacturing networks introduced organizational, managerial, and business strategies that fostered the division of labor, specialization, and greater cooperation between workers or firms.

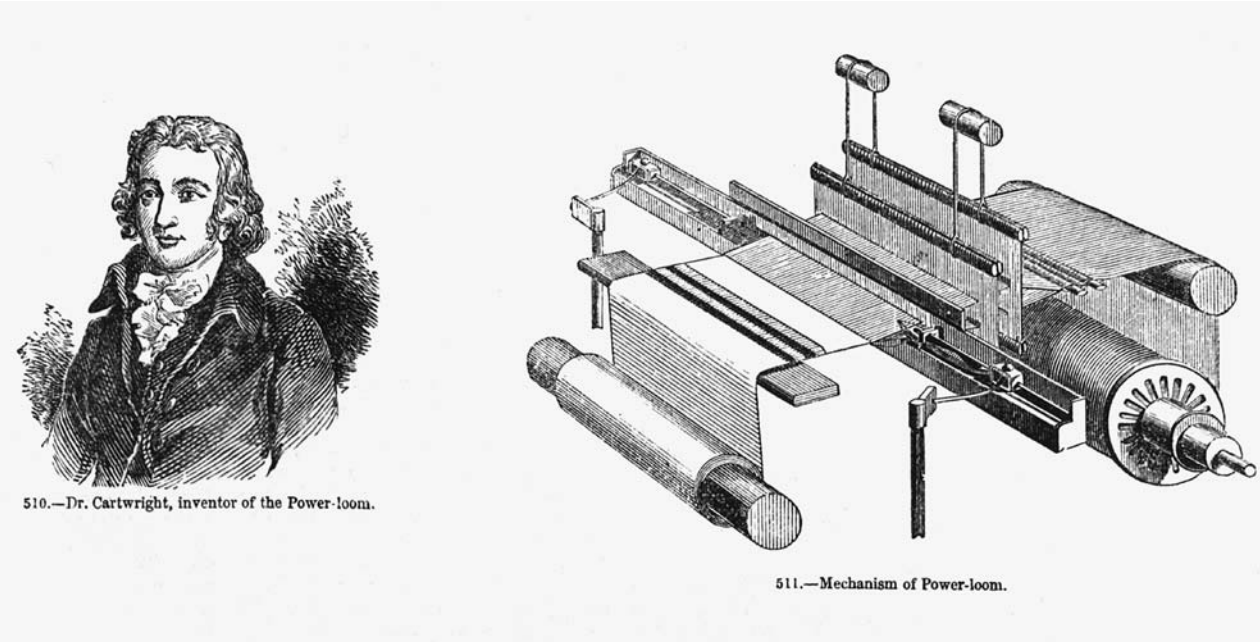
Great Britain also benefited from a convergence of advantageous economic, environmental, and technical factors. It possessed ample supplies of natural resources such as waterpower and coal, and its efficient transportation networks, including turnpike roads and water transport, further aided development. The commanding British navy and merchant network facilitated the shipment of raw materials to the mother country and carried British products to distant colonies or foreign markets. Described as a "nation of shopkeepers," Britain was founded on commerce, and its many merchants and middlemen fostered the spread of the market and funded manufacturing endeavors. Investment capital could also be raised and distributed through an advanced banking system and institutions such as the London Stock Exchange, and favorable regulatory policies (especially in comparison with European practices) enabled British manufacturers to practice their trades with a minimum of government interference. Two hundred years of British economic growth produced a relatively high level of prosperity, a widespread market economy, and a large potential demand for manufactured goods. And because the Industrial Revolution first took place within a capitalist economy, the pursuit of private profit drove the technological and industrial transformation.

What made it possible to take advantage of this confluence in material factors was the contemporary development of new ideals about how human beings could best realize their humanity. A sense of human beings as having the right to dominate the nonhuman world through technology, which had been emerging within a Christian theological framework in Europe, was given new secular articulation by, for instance, Francis Bacon (1561–1626) and his followers. Bacon's ethical vision of "the conquest of nature" for the "relief of man's estate" both justified and encouraged those activities that merged historical changes into a revolution in human industrial activity.

The takeoff of the British Industrial Revolution arose when several key productive sectors used new technologies to increase quantities of low-priced manufactured goods, change employment patterns, and expand technological networks that aided technical innovation and adoption. As the first nation to industrialize, Britain could not receive capital or technological aid from others. Fortunately, the technological challenges of the early Industrial Revolution were relatively simple and were certainly addressable via decentralized and informal experimentation and tinkering.

Iron production was the first technology to influence the British Industrial Revolution, in conjunction with developments in coal processing. Prior to the eighteenth century, British iron production had been increasingly limited by scarce supplies of wood, which was used to make charcoal. Coal was unusable in blast furnaces for various reasons, but in 1709 Abraham Darby discovered that coke, a burnable substance produced from coal, could be used. Technical barriers and quality control issues proved very limiting until 1760, at which point the British iron industry rapidly expanded.

Steam engines served as a second pillar of the Industrial Revolution and had close ties to coal mining and iron production. The Newcomen steam engine, invented by Thomas Newcomen in 1712, was a bulky and inefficient apparatus requiring enormous quantities of coal fuel. These limitations did not deter coal mine operators, who used it to pump water from deep mine shafts. Steam engines also became increasingly important for the iron industry, where they pumped water for water-powered bellows beginning in 1742, drove air



Dr. Edmund Cartwright (left), the inventor of the power loom (right). The textile industry was the third pillar of the Industrial Revolution. *(© Hulton Getty/Liaison Agency.)*

bellows a few years later, and then directly pumped air into furnaces after 1776 via the far more efficient Boulton-Watt steam engine (produced by James Watt and Matthew Boulton). Steam engines freed blast furnaces from the restrictions of water power and were used in different types of factories by the early 1780s.

The third and most visible British technology was the textile industry, which became increasingly mechanized throughout the eighteenth century as self-acting machinery replaced hand manufactures. The weaving process underwent steady productivity increases from early inventions such as the 1733 hand loom and flying shuttle, which caused weaving to outpace yarn production and create yarn shortages. The situation was corrected by subsequent inventions that automated the spinning process, such as James Hargreaves's spinning jenny (c. 1764) and Richard Arkwright's 1769 water frame. Samuel Crompton's 1779 spinning mule combined aspects of earlier spinning technologies and enabled yarn production to outpace weaving technology. This in turn inspired Edmund Cartwright to make a powered weaving loom in 1785. In addition to this technological escalation, the imposition of new organizational schemes in increasingly large textile factories greatly facilitated productivity increases as well as more exacting standards for the production of uniform thread and woven products.

As a result of these industrial developments, relatively high-quality and inexpensive British goods seized control of the home market and led to enormous increases in the demand for manufactured goods and in the standard of living. Mass production (a term first introduced to describe early-twentieth-century industrialization in the United States) helped inspire mass consumption. In addition to the large and steady domestic market, British goods also dominated many overseas markets, aided by Great Britain's colonization efforts, powerful navy, and aggressive merchant network. Great Britain also spurred industry through wartime purchases.

Britain appreciated the benefits it incurred from its sizable technological lead and attempted to guard and maintain this advantage through mercantile policies and the strict prohibition of technology transfer. Of course, other nations attempted to compete with Britain, which led to industrial espionage, the emigration of British technicians, and industrialization in other nations.

Waves of Industrialization

Although Britain led the world in industrial growth through the 1830s, the Industrial Revolution soon spread to other countries. A second wave of industrialization took place from the 1810s to the 1870s in Belgium, France, Germany, and the United States; and a third wave swept through Russia, Japan, Sweden, Italy, and other nations in the decades surrounding 1900. Latecomer nations have several advantages over industrial

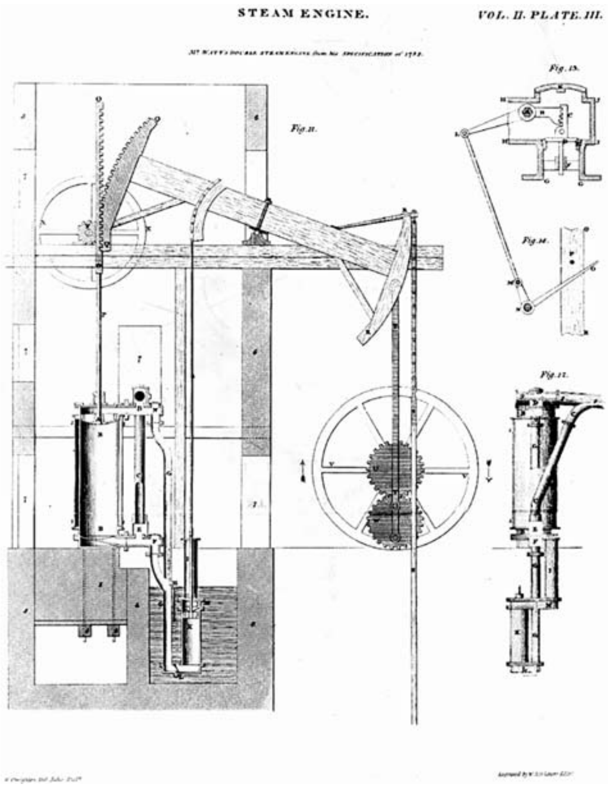


Diagram of the Watt steam engine. The steam engine is seen as the second pillar of the Industrial Revolution. *(The Library of Congress.)*

pioneers: Governments recognize the advantages of industrialization and develop supportive policies; investment capital is often available from individuals or institutions in more advanced economies; and technological expertise can often be borrowed or appropriated from the industrial powers. In addition to the iron, coal, and textile industries, railroads emerged as a fundamental technology of later industrialization. The Industrial Revolution continued to catalyze changes in technological development, managerial and labor organization strategies, economic policy, and consumer behavior.

As with the British example, the nations in the second wave of industrialization experienced long periods of gradual population growth fostered by agricultural improvements, economic and commercial expansion, and technological development that promoted a rapid industrial takeoff. Despite an overall manufacturing output that, as late as the 1780s, was not that far behind Britain, French industrialization was hindered by strong conservative craft and agrarian traditions and setbacks from the French Revolution and Napoleonic Era. France's mid-nineteenth-century growth was driven by widespread rural industry and thriving local markets, and was greatly aided by new government policies and the creation of institutions to collect and distribute investment capital.

Also in the mid-nineteenth century, the Prussian government took an active role in the sponsorship and funding of large-scale industry, and a close family of German banks offered capital and advice to support new industrial ventures. German industrialization truly began after the 1871 unification of the German states, but powerful agricultural interests successfully protected agrarian subsidies at the expense of the industrialists well into the 1890s. German industry also pioneered the inclusion of research laboratories as a well-funded and influential component of manufacturing endeavors, strengthening the link between science and technology.

Finally, industrialization in the United States was hampered by its small, sparse, and rural population; the lack of a strong economy or banking system; and competition from British goods. Many of these inhibiting factors had been reduced or removed by the mid-nineteenth century, and industrialization was aided in the United States by booming population growth, plentiful natural resources, increased access to investment capital, and the import and modification of technologies from Britain.

The end of the nineteenth century introduced an array of new technological products such as chemicals, bicycles, automobiles, and electrical networks; new methods of mass production and factory mechanization; dramatic increases in the quantity of capital required to launch new manufacturing endeavors; and the corresponding development of new capital-raising strategies such as large-scale stock subscriptions and direct government subsidies. Russia and Japan were the two largest economies to industrialize during this third wave of the Industrial Revolution, following Russia's abolition of serfdom and Japan's increasing degree of interaction with foreign nations. Both governments directly and unhesitatingly supported industrialization by running pilot companies, raising taxes or requesting foreign loans to produce investment capital, and establishing pro-industry policies. During the twentieth century the Industrial Revolution continued to evolve and spread to new regions such as China and India.

Indeed, as a result of post–World War II developments in automation, cybernation, and computerization, people began to speak of a second industrial revolution originating in the United States and spreading to other parts of the world. The phenomenon of globalization, which depends on advances in transportation and communication, could also be described as an extension of the industrialization that began in eighteenth-century Great Britain.

Ethics and Politics

The Industrial Revolution affected everyone and everything on the globe, starting with irrevocable alterations to societal development. Individuals and families increasingly left behind their rural agrarian life to gather in urban centers that offered increased access to a staggering variety of jobs, services, and goods, at the cost of health risks and a very different way of life. While the increased productivity of industrialization generally led to rising standards of living and increased consumption, societies became highly stratified and the newly created wealth and luxury items were not shared equally.

Industrial laborers often endured horrible working conditions, such as bad air quality, deafening noise, poor lighting, cramped conditions, lack of sanitation and resultant disease, repetitive work, and dangerous equipment that could cause mutilation and death. Industrialization also imposed a new system of managerial regulation, increased discipline, and the removal of skilled laborers' privileges. When laborers resented or resisted new workplace policies, employers considered them lazy and responded by structuring wages in a manner that forced employees to work long hours at a rapid pace in order to earn a living. This often resulted in the employment of entire families, especially in the textile industry. Unskilled workers frequently lived under the constant threat of unemployment, and even when they were employed their living conditions were often squalid.

The Industrial Revolution may have most affected the lives of women and children. Although advocates of industrialization asserted that contemporary children worked long hours on the farm, children working in factories routinely endured truly nightmarish work environments. Labor laws and other responses to unpleasant child labor conditions gradually shifted the focus of childhood from productivity to education. And although industrialization often forced women to work under horrible conditions for less pay than their male counterparts, this was sometimes mitigated by new opportunities for employed women, such as freedom from the toil or drudgery of farm labor, increased personal and economic freedom, and exposure to urban influences. The Industrial Revolution steadily pushed work out of the family setting and redefined gender and child roles.

These changes inspired extensive commentary from contemporary participants, particularly when the impacts were experienced for the first time in Great Britain. Romantic poets such as William Blake (1757–1827), Victorian novelists such as Charles Dickens (1812–1870), and socialist philosophers such as Friedrich Engels (1820–1895) approached this problem from different perspectives but were united in their association of industrialization with corruption, exploitation, poverty, and other social evils that primarily affected members of the laboring classes. Responses to industrialization included the Luddites' destruction of textile machinery as a means of protesting technological displacement of workers; the promotion of socialist ideals by philosophers such as Engels and Karl Marx (1818–1883); and efforts by Edwin Chadwick (1800–1890) to use the public health movement to establish scientific and technological principles for the improvement of housing and sanitation systems. But on balance, especially under the influence of such ameliorative initiatives, industrialization also clearly improved the material qualities of human life. Versions of these initiatives have been manifested and criticized in other industrializing nations, and debates over the positive and negative impacts continue into the present.

The Industrial Revolution also permanently altered the global power balance. The earliest industrializing nations exerted a substantial and lasting economic and military influence on the nonindustrial world. The growth of industrial economies and trade networks often promoted deindustrialization in less advanced countries that had previously benefited from the sale of handicrafts or other goods. Most nineteenth-century industrial powers practiced imperialism and colonialism, which yielded new supplies of raw materials and new markets and propagated capitalist and Western values throughout the world. In addition, the Industrial Revolution inspired many governments to shift their political philosophy from laissez-faire policies that favored traditional landed interests to proactive social and economic reforms.

Finally, the Industrial Revolution produced previously unimaginable effects on the human–environment relationship. The Industrial Revolution removed many barriers to population growth and accelerated the ability of farmers to produce food more efficiently, leading to an ever-increasing world population. And by increasing fuel use, the supply and demand of manufactured goods, and the scope of extractive tools and machinery, industrialization led to astronomical levels of raw material harvesting and ensuing environmental consequences such as deforestation and air and water pollution. At the same time, the Industrial Revolution firmly connected the scientific tradition to technological development, leading to increased industrial research and development, new standards of education, superior scientific equipment, government funding of science, and renewed support for the increase of human knowledge.

BIBLIOGRAPHY

Ashton, T. S. (1997). *The Industrial Revolution, 1760–1830,* rev. edition, with a new preface and bibliography by Pat Hudson. Oxford: Oxford University Press. This concise study focuses on the beneficial and progress-oriented aspects of the Industrial Revolution, with emphases upon innovation and the revolution's historical context.

Breunig, Charles, and Matthew Levinger. (2002). *The Revolutionary Era, 1789–1850,* 3rd edition. New York: Norton. Offers a general overview of the industrial revolution as well as a contextual study of relevant trends and events in contemporary Europe.

Diamond, Jared. (1999). *Guns, Germs, and Steel: The Fates of Human Societies.* New York: Norton. This expansive work explores the geographical, environmental, and demographic factors that caused human civilizations to develop differently. While it does not explicitly discuss the Industrial Revolution, its explanation of the Neolithic and urban revolutions provide interesting background and a global perspective.

Hobsbawm, Eric. (1962). *The Age of Revolution: Europe, 1789–1848.* London: Weidenfeld and Nicolson. This survey work adopts an economic approach to European history that is sympathetic to workers and the labor movement. Hobsbawm explores the causes and impacts of the industrial revolution at length and also discusses other European events in the same era.

Hobsbawm, Eric. (1999). *Industry and Empire: From 1750 to the Present Day,* revised and updated with Chris Wrigley. New York: New Press. This detailed study explores the political, social, and economic history of the industrial revolution (extending into the late twentieth century), primarily from a Western perspective.

Hughes, Thomas P. (1989). *The American Genesis: A Century of Invention and Technological Enthusiasm, 1870–1970.* New York: Viking. Praises the achievements of technological creativity in the United States during the second wave of industrialization as equivalent in significance to those of the Renaissance.

Landes, David S. (2003). *The Unbound Prometheus: Technical Change and Industrial Development in Western Europe from 1750 to the Present,* 2nd edition. Cambridge, UK: Cambridge University Press. Classic and detailed analysis of the economic and societal causes and impacts of the first industrial revolution, emphasizing the importance of technological enhancements to productive potential and the associated enrollment of natural, human, and financial resources.

Mokyr, Joel. (1990). *The Lever of Riches.* New York: Oxford University Press. A historical approach to technological creativity, exploring the many factors that give some nations innovative advantages over others, as well as the economic and social impacts of creativity.

Pacey, Arnold. (1990). *Technology in World Civilization: A Thousand-Year History.* Cambridge, MA: MIT Press. A global approach to the history of technology, concisely highlighting the impact of technology transfers and industrial development upon different civilizations' economies and societies.

Simon, Julian L., ed. (1995). *The State Of Humanity.* Oxford: Blackwell. Collects fifty-eight original articles arguing that industrialization has created across-the-board material benefits for all segments of society.

Toynbee, Arnold. (1884). *Lectures on The Industrial Revolution in England.* London: Rivingtons. First use of the phrase "industrial revolution" to describe the great industrial and economic changes faced by great Britain at the end of the eighteenth century.

INFORMATION

Science, technology, and ethics are all forms of information that depend *on* information to work. Furthermore there exist sciences, technologies, and ethics *of* information. To disentangle some of the main relations among these aspects of information, it is helpful to start with a simple example.

Monday morning. John turns the ignition key of his car, but nothing happens: The engine does not even cough. Not surprisingly the low-battery indicator is flashing. After a few more unsuccessful attempts, John calls the garage and explains that, last night, his wife had forgotten to turn off the car's lights—this is a lie, John did but is too ashamed to admit it—and now the battery is dead. John is told that the car's operation manual explains how to use jumper cables to start the engine. Luckily his neighbor has everything John needs. He follows the instructions, starts the car, and drives to the office.

This everyday example illustrates the many ways in which people understand one of their most important resources: information. The information galaxy is vast, and this entry will explore only two main areas: information as content and information as communication. The reader interested in knowing more about the philosophical analysis of the concept should consult the work of Jaakko Hintikka and Patrick Suppes (1970), Philip P. Hanson (1990), and Fred I. Dretske (1999).

Information as Content

It is common to think of information as consisting of *data* (Floridi 2005). An intuitive way of grasping the notion of data is to imagine an answer without a question. Ultimately data may be described as relational differences: a 0 instead of a 1; a red light flashing; a high or low charge in a battery.

To become information, data need to be *well-formed* and *meaningful*. Well-formed means that data are clustered together correctly, according to the rules (syntax) of the chosen language or code. For example, the operation manual from the example above shows the batteries of two cars placed one next to, not one on top of, the other. Meaningful indicates that the data must also comply with the meanings (semantics) of the chosen language or code. So the operation manual contains illustrations that are immediately recognizable.

When meaningful and well-formed data are used to talk about the world and describe it, the result is *semantic content* (Bar-Hillel and Carnap 1953, Bar-Hillel 1964). Semantic content has a twofold function. Like a pair of pincers, it picks up from or about a situation, a fact, or a state of affairs *f*, and models or describes *f*. *The battery is dead* carves and extracts this piece of information—that the battery of the car is dead—and uses it to model reality into a semantic world in which the battery is dead. Whether the work done by the specific pair of pincers is satisfactory depends on the resource *f* (realism) and on the purpose for which the pincers are being used (teleologism). Realistically *the battery is dead* is true. Teleologically it is successful given the goal of communicating to the garage the nature of the problem. *The battery is dead* would be realistically false and teleologically unsatisfactory if it were used, for instance, to provide an example of something being deceased.

INFORMATION AS TRUE SEMANTIC CONTENT. *True semantic content* is perhaps the most common sense in which information can be understood (Floridi 2005). It is also one of the most important ways, since information as true semantic content is a necessary condition for knowledge. Some elaboration of this concept is in order. First the data that constitute information allow or invite certain constructs and resist or impede others. Data in this respect work as *constraining affordances*. Second the data are never accessed and elaborated independently of a *level of abstraction* (LoA). An LoA is like an interface that establishes the scope and type of data that will be available as a resource for the generation of information (Floridi and Sanders 2004). *The battery is what provides electricity to the car* is a typical example of information elaborated at a driver's LoA. An engineer's LoA may output something like *a 12-volt lead-acid battery is made up of six cells, each cell producing approximately 2.1 volts*, and an economist's LoA may suggest that *a good quality car battery will cost between $50 and $100 and, if properly maintained, it should last five years or more*. Data as constraining affordances—answers waiting for the relevant questions—are transformed into information by being processed semantically at a given LoA (alternatively the right question is associated to the right data at a given LoA).

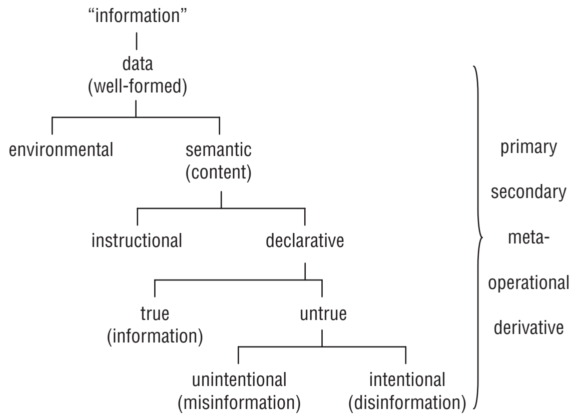
Once information is available, knowledge can be built in terms of *justified* or *explained information*, thus providing the basis of any further scientific investigation. One knows that the battery is dead not by merely guessing correctly, but because one sees the red light of the low-battery indicator flashing and perceives that the engine does not start. The fact that data count as *resources* for information, and hence for knowledge, rather than *sources*, provides a constructionist argument against any representationalist theory that interprets knowledge as a sort of picture of the world.

An instance of *misinformation* arises when some semantic content is false (untrue) (Fox 1983). If the source of the misinformation is aware that the semantic content is false, one may speak of *disinformation*, for example *my wife left the lights on*. Disinformation and misinformation are ethically censurable but may be successful teleologically: If one tells the mechanic that one's wife left the lights on last night, the mechanic will still be able to provide the right advice. Likewise information may fail to be teleologically successful; just imagine telling the mechanic that one's car is out of order.

INSTRUCTIONAL INFORMATION. True semantic content is not the only type of information. The operation manual, for example, also provides *instructional information*, either imperatively—in the form of a recipe: First do this, then do that—or conditionally—in the form of some inferential procedure: If such and such is the case do this, otherwise do that. Instructional information is not about *f* and does not model *f*: It constitutes or instantiates f, that is, it is supposed to make *f* happen. The printed score of a musical composition or the digital files of a program are typical cases of instructional information. The latter clearly has a semantic side. And semantic and instructional information may be joined in performative contexts, such as christening a vessel—for example, "this ship is now called *HMS The Informer*"—or programming—for example, when declaring the type of a variable. Finally the two types of information may come together in magic spells, where

FIGURE 1

The Taxonomy of Information



SOURCE: Courtesy of Luciano Floridi.

The figure illustrates how some of the main types of information may be related into a tree-like structure.

semantic modeling is confused with instructional power and control. Yet, as a test, one should recall that instructional information does not qualify alethically (from *aletheia,* the Greek word for truth). In the example, it would be silly to ask whether *only use batteries with the same-rated voltage* is true or false.

ENVIRONMENTAL INFORMATION. When John turned the ignition key, the low-battery indicator flashed. He translated the flashing into (a) semantic information: The battery is dead; and (b) instructional information: The battery needs to be charged or replaced. However the flashing of the indicator is actually an example of *environmental information*.

Environmental information may be described as *natural data:* It requires two systems *a* and *b* to be coupled in such a way that *a* being (of type, or in state) *F* is correlated to *b* being (of type, or in state) G, thus carrying to the observer the information that *b* is G (Jon Barwise and Jerry Seligman provide a similar analysis based on Dretske 1999). The correlation is usually *nomical* (it follows some law). It may be engineered—as in the case of the low-battery indicator (*a*) whose flashing (*F*) is triggered by, and hence is informative about, the battery (*b*) being dead (G). Or it may be natural, as when litmus—a coloring matter from lichens—is used as an acid-alkali indicator (litmus turns red in acid solutions and blue in alkaline solutions). Other typical examples include the correlation between fingerprints and personal identification, or between the age of a plant and its growth rings.

One may be so used to equating the low-battery indicator flashing with the information (that is, meaning) that the battery is dead as to find it hard to distinguish sufficiently between environmental and semantic information. However it is important to remember that environmental information may require or involve no semantics at all. It may consist of correlated data understood as mere differences or constraining affordances. Plants (e.g., a sunflower), animals (e.g., an amoeba) and mechanisms (e.g., a photocell) are certainly capable of making practical use of environmental information even in the absence of any (semantic processing of) meaningful data. Figure 1 summarizes the main distinctions introduced so far.

FIVE TYPES OF INFORMATION. More detail may now be added. First it should be emphasized that the actual *format, medium,* and *language* in which information is encoded is often irrelevant. The same semantic, instructional, and environmental information may be analog or digital, printed on paper or viewed on a screen, or in English or some other language. Second thus far it has been implicitly assumed that *primary* information is the central issue: things like the low-battery indicator flashing, or the words *the battery is dead* spoken over the phone. But remember how John discovered that the battery was dead. The engine failed to make any of the usual noises. Likewise in Sir Arthur Conan Doyle's *Silver Blaze* (1892), Sherlock Holmes solves the case by noting something that has escaped everybody else's attention, the unusual silence of the dog. Clearly silence may be very informative. This is a peculiarity of information: Its absence may also be informative. When it is, the difference may be explained by speaking of *secondary information*.

Apart from secondary information, three other typologies are worth some explanation since they are quite common (the terminology is still far from being standard or fixed, but see Floridi 1999b). *Metainformation* is information about the nature of information. "*The battery is dead is encoded in English'' is a simple example*. *Operational information* is information about the dynamics of information. Suppose the car has a yellow light that, when flashing, indicates the entire system that checks that the electronic components of the car is malfunctioning. The fact that the light is off indicates that the low-battery indicator is working properly, thus confirming that the battery is indeed dead. Finally *derivative information* is information that can be extracted from any form of information whenever the latter is used as a source in search of patterns, clues, or inferential evidence, namely for comparative and quantitative analyses. From a credit card bill concerning the purchase of gasoline, one may derive information about the cardholder's whereabouts at a given time.

Information as Communication

Also important is the concept of information as communication, as in the sense of a transmitted message (Cherry 1978). Some features of information are intuitively quantitative. Information can be *encoded, stored*, and *transmitted*. One also expects it to be *additive* (information *a* + information *b* = information *a* + *b*) and *non-negative*. Similar properties of information are investigated by the *mathematical theory of communication* (MTC, also known as *information theory;* for an accessible introduction, see Jones 1979).

MTC was developed by Claude E. Shannon (Shannon and Weaver 1998 [1949]) with the primary aim of devising efficient ways of encoding and transferring data. Its two fundamental problems are the ultimate level of data compression (how small can a message be, given the same amount of information to be encoded?) and the ultimate rate of data transmission (how fast can data be transmitted over a channel?). To understand this approach, consider the telephone call to the garage.

The telephone communication with the mechanic is a specific case of a general communication model. The model is described in Figure 2.

John is the *informer*, the mechanic is the *informee*, *the battery is dead* is the message (*the informant*), there is a coding and decoding procedure through a language (English), a channel of communication (the telephone system), and some possible noise. Informer and informee share the same background knowledge about the collection of usable symbols (the *alphabet*).

MTC treats information as only a selection of symbols from a set of possible symbols, so a simple way of grasping how MTC quantifies *raw information* is by considering the number of yes/no questions required to guess what the informer is communicating. When a fair coin is tossed, one question is sufficient to guess whether the outcome is heads (*h*) or tails (*t*). Therefore a binary source, like a coin, is said to produce one bit of information. A two-fair-coins system produces four ordered outputs: <*h*, *h*, *h*, *t*, *t*, *h*, *t*, *t*> and therefore requires two questions, each output containing two bits of information, and so on. In the example, the low-battery indicator is also a binary device: If it works properly, it either flashes or it does not, exactly like a tossed coin. And since it is more unlikely that it flashes, when it does, the red light is very informative. More generally the lower the probability of *p* the more informative the occurrence of *p* is (unfortunately this leads to the paradoxical view that a contradiction—which has probability 0—is the most informative of all contents, unless one maintains that, to qualify as information, *p* needs to be true [Floridi 2004]).

Before the coin is tossed, the informee does not *know* which symbol the device will actually produce, so it is in a state of *data deficit* equal to 1 (Shannon's *uncertainty*). Once the coin has been tossed, the system produces an amount of raw information that is a function of the possible outputs, in this case two equiprobable symbols, and equal to the data deficit that it removes. The reasoning applies equally well to the letters used in your telephone conversation with the mechanic.

The analysis can be generalized. Call the number of possible symbols *N*. For *N* = 1, the amount of information produced by a unary device is 0. For *N* = 2, by producing an equiprobable symbol, the device delivers one unit of information. And for *N* = 4, by producing an equiprobable symbol, the device delivers the sum of the amount of information provided by coin *A* plus the amount of information provided by coin *B*, that is two units of information. Given an alphabet of *N* equiprobable symbols, it is possible to rephrase some examples more precisely by using the following equation: log 2 (*N*) = bits of information per symbol.

Things are made more complicated by the fact that real coins are always *biased*, and so are low-battery indicators. Likewise in John's conversation with the mechanic a word like *batter* will make *y* as the next letter almost certain. To calculate how much information a biased device produces, one must rely on the frequency of the occurrences of symbols in a finite series of occurrences, or on their probabilities, if the occurrences are supposed to go on indefinitely. Once probabilities are taken into account, the previous equation becomes Shannon's formula (where *H* = uncertainty, what has been called above data deficit):

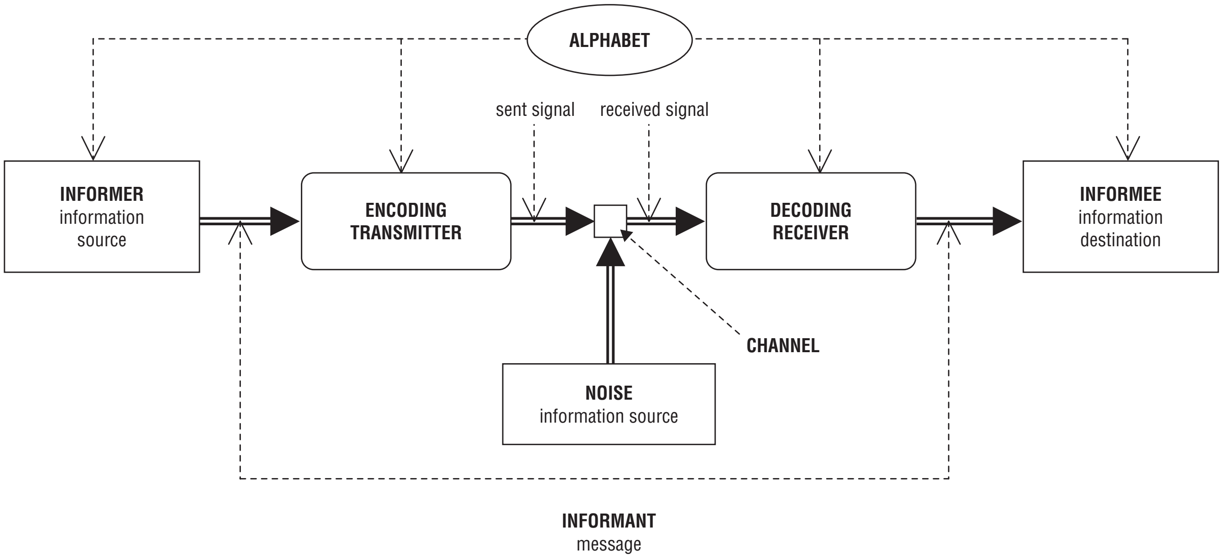
$$H = -\sum_{i=1}^{N} P_i \log P_i (\text{bits per symbol})$$

The quantitative approach just outlined plays a fundamental role in coding theory, hence in cryptography, and in data storage and transmission techniques, which are based on the same principles and concepts. Two of them are so important as to deserve a brief explanation: *redundancy* and noise.

Redundancy refers to the difference between the physical representation of a message and the mathematical representation of the same message that uses no more bits than necessary. It is basically what can be taken away from a message without loss in

FIGURE 2

The Communication Model



SOURCE: Courtesy of Luciano Floridi.

The figure illustrates the main elements and their relations in the communication model according to Shannon's approach.

communication. John's statement that his wife was responsible for the dead battery was redundant.

Compression procedures work by reducing data redundancy, but redundancy is not always a bad thing, for it can help to counteract *equivocation* (data sent but never received) and noise (received but unwanted data, like some interference). A message + noise contains more data than the original message by itself, but the aim of a communication process is *fidelity*, the accurate transfer of the original message from sender to receiver, not data increase. The informee is more likely to reconstruct a message correctly at the end of the transmission if some degree of redundancy counterbalances the inevitable noise and equivocation introduced by the physical process of communication and the environment. This is why, over the phone, John said that *the battery is dead* and that *the lights were left on last night*. It was the *by whom* that was uselessly redundant.

MTC is not a theory of information in the ordinary sense of the word. The term raw information has been used to stress the fact that in MTC information has an entirely technical meaning. Two equiprobable *yeses* contain the same quantity of raw information, regardless of whether their corresponding questions are *Is the battery dead?* or *Is your wife missing?* Likewise if one knows that a device could send with equal probabilities either this whole encyclopedia or just a quote for its price, by receiving one or the other message one would receive very different quantities of data bytes but only one bit of raw information. Since MTC is a theory of information without meaning, and since information – meaning = data, *mathematical theory of data communication* is a far more appropriate description than *information theory*.

MTC deals not with semantic information itself but with messages constituted by uninterpreted symbols encoded in well-formed strings of signals, so it is commonly described as a study of information at the *syntactic* level. This generates some confusion because one may think the syntactic versus semantic dichotomy to be exhaustive. Clearly MTC can be applied in information and communication technologies (ICT) successfully because computers are syntactical devices. It is often through MTC that information becomes a central concept and topic of research in disciplines like chemistry, biology, physics, cognitive science, neuroscience, the philosophy of information (Floridi 2002, Floridi 2004a), and computer ethics (Floridi 1999a).

INFORMATION ETHICS

Information ethics is a field of applied ethics that addresses the uses and abuses of information, information technology, and information systems for personal, professional, and public decision making. For example, is it okay to download someone else's intellectual property like pictures or music? Should librarians ever remove controversial books from the shelves or monitor users' Internet searching? Should a scientist post the genome for the Ebola virus on the Internet?

Information ethics provides a framework for critical reflection on the creation, control, and use of information. It raises questions about information ownership and access to intellectual property, the rights of people to read and to explore the World Wide Web as they choose. Information ethicists explore and evaluate the development of moral values, the creation of new power structures, information myths, and the resolution of ethical conflicts in the information society (Capurro 2001). If bioethics addresses living systems, then information ethics similarly covers information systems. Where bioethics evolved from medical ethics after World War II to engage the broader implications of societal changes such as informed consent and reproductive rights, information ethics grew out of the professional ethics traditions of librarians and early information professionals in order to describe and evaluate the competing interests that sought to control the information assets of a high-tech society (Smith 1997). Like other areas of applied ethics in science and technology, information ethics focuses on social responsibility and the meaning of humanity in relation to machines.

Built from the codes and commitments of professional librarians to protect the right to read, fight censorship, protect patron privacy, assure confidentiality of library records, and provide service for everyone, information ethics has extended these traditions into cyberspace. The term information ethics first appeared in the literature of library and information science in the late 1980's (Hauptman) alongside other terms such as information technology ethics, cataloging ethics, and archival ethics. In the next few years, information ethics grew to encompass dilemmas facing librarians and information professionals (Mason, Mason, and Culnan 1995) as they introduced new information and communications technologies (ICTs) to public, academic, and special libraries and also into publishing, healthcare, and the new information industry.

Today information ethics encompasses a wide range of issues involving the creation, acquisition, organization, management, translation, duplication, storage, retrieval, and any other processes involving printed or digital texts, graphics, voice, and video. Information ethics can address any issue relating to the *Information Society* or the *Knowledge Economy*. As a field of applied ethics, it draws upon historical and philosophical insights (Floridi 1999) in order to describe current problems such as bridging the digital divide and to craft normative solutions for personal and professional conduct and for public policy (Tavani 2003).

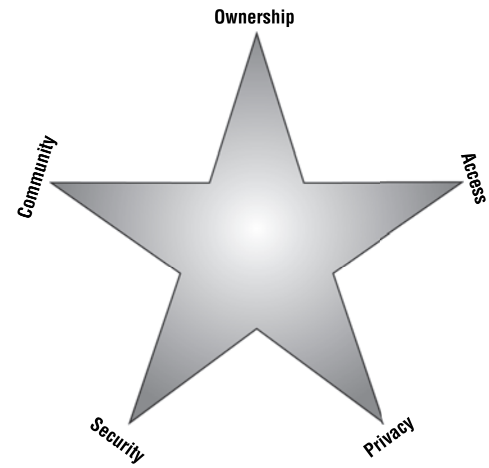
The Historical Context

In the mid-fifteenth century, Johannes Gutenberg's invention of the movable type printing press altered the parameters of information access and control and began to change the world. Widespread dissemination of printed information helped to change the balance of power in Europe, notably contributing to the sixteenth-century Protestant Reformation, disruptions to the political power of the Roman Catholic Church, and the rise of the nation-state.

In the mid-twentieth century, Claude Shannon (1948) and others developed elegant mathematical theories that made modern information technologies possible while other advances, such as the development of the atomic bomb, made the risks and rewards of widespread scientific and technological knowledge more significant and more visible in everyday life. Since then the increasing volume of digitized information and the exponential improvements in digital processing, storage, and communication have again altered the landscape of information access and control.

FIGURE 1

Five Themes in Information Ethics



SOURCE: Adapted from Smith, Martha. (2001). "Global Information Justice: Rights, Responsibilities, and Caring Connections." *Library Trends* 49 (3): 525, figure 6.

The COAPS star suggests the potential both for overlap and conflict amongst five infoethical themes.

Alongside the technological advances that have occurred since the mid-twentieth century, formal consideration of the uses and abuses of information began even before it was designated information ethics, or *infoethics*. The UN General Assembly raised many infoethical themes in the Universal Declaration of Human Rights (1948) including information access (Article 19), intellectual property (Article 27), privacy (Article 12), security (Articles 17 and 27), community (Article 27), and education (Article 26). Since then, the role of information in government, healthcare, and business, and concerns about the uses of that information, have continued to fuel public policy debates. The UN Educational, Scientific and Cultural Organization (UNESCO) uses the term information ethics to focus attention on global problems ranging from literacy, including cell phone access in the developing world, the need to protect local cultures and languages from the dominance of English on the Internet, and the ramifications of expanding databases of genetic information.

In the last fifteen years, information ethics has also evolved within and beyond its early professional and academic communities. Its academic vitality is evident in the formation of scholarly associations such as the International Society for Ethics and Information Technology (INSEIT), scholarly websites such as the International

TABLE 1

Most Challenged Books, 2002

Title and Author	Sexual Content	Offensive Language	Unsuitable to Age	Wizardry, Occult	Racism	Insensitivity	Violence	Disobedience
Harry Potter series, J.K. Rowling A young wizard studies magic and battles evil.				✓				
Alice series, Phyllis Reynolds Naylor Alice searches for a female role model.	✓	✓	✓					
The Chocolate War, Robert Cormier Jerry challenges the high school power structure.		✓	✓					
I Know Why the Caged Bird Sings, Maya Angelou Autobiography of an African American poet.	✓	✓	✓		✓		✓	
Taming the Star Runner, S. E. Hinton A talented, urban punk exiled to a farm.		✓						
Captain Underpants, Dav Pilkey Comic battles with Dr. Diaper and talking toilets.			✓			✓		✓
The Adventures of Huckleberry Finn, Mark Twain Classic novel of a boy's journey down the Mississippi.		✓			✓	✓		
Bridge to Terabithia, Katherine Paterson Friends reign in a fantasy kingdom in the woods.	✓	✓		✓

Book challenges illustrate the ethical tension between freedom of information and other values.

Center for Info Ethics (ICIE), and journals such as *The Information Society* (1981), *Journal of Information Ethics* (1992), *Science and Engineering Ethics* (1995), *Ethics and Information Technology* (1999), and *International Review of Information Ethics* (2004). The growing number of books and journal articles that address ethics in academic and professional literature indicates the expanding recognition of and participation in the field.

Key Ethical Themes

From the perspective of information ethics, there are five important themes to be considered: *community*, *ownership*, *access*, *privacy*, and *security* (COAPS; see Figure 1). As a framework, the COAPS themes help to guide ethical analysis and aid the discovery of underlying conflicts, as illustrated by ethical questions that have emerged since the mid-twentieth century.

Does the anonymity of the web encourage or detract from *community* formation online?

Who *owns* e-mail messages on a corporate e-mail server, and who can read them?

Do patients have a right of *access* to information about a terminal illness?

Do libraries and librarians have an obligation to protect the *privacy* of patron records?

Does personal *security* warrant the widespread use of surveillance cameras in public places?

Community

In an 1813 letter, Thomas Jefferson distinguished goods that are lessened and ideas that are multiplied when shared:

> He who receives an idea from me, receives instruction himself without lessening mine; as he who lights his taper at mine receives light without darkening me.

The distinction has become increasingly salient over time. Future creative work builds on past creative work. All branches of science have flourished since the Royal Society of London first published the *Philosophical Transactions* in 1765, establishing a creative commons of scientific work for scrutiny, criticism, and derivation.

TABLE 2

Post 9/11 U.S. Government Legislation and Programs

Legislation or Program Name	Summary
Terrorism Information Awareness Program (TIA)	.. "search[ing] for indications of terrorist activities in vast quantities of data."
Uniting and Strengthening America by Providing Appropriate Tools Required to Intercept and Obstruct Terrorism Act of 2001 (USA PATRIOT)	Grants law enforcement broad rights of search and surveillance with limited judicial oversight.
Computer Assisted Passenger Pre-screening System II (CAPPS II)	Focused on identifying and computing risk score for airline passengers.

SOURCE: Defense Advanced Research Program Agency (DARPA), http://www.darpa.mil; Electronic Privacy Information Center (EPIC), http://www.epic.org; American Civil Liberties Union (ACLU), http://www.aclu.org.

Legislation and government programs illustrate the ethical tensions that arise between the search for security and the desire for privacy.

While ideas on paper may be expensive to reproduce and awkward to distribute, they have demonstrated great power. Creativity requires a balance of access, to make future creative work possible, and control to make creative work worthwhile. The U.S. Constitution, Article 1, Section 8, establishes such a balance by granting inventors limited-term, exclusive rights to exploit their inventions, in exchange for full disclosure for the benefit of future inventors. Lawrence Lessig (2001) has written and spoken extensively about the intellectual and creative commons. In 2002, Lessig and others founded Creative Commons (http://www.creativecommons.org), "devoted to expanding the range of creative work available for others to build upon and share."

For software, the *open source* movement, described by Eric Raymond (1999), encourages community and collaboration by requiring programmers to share software source code and to allow the creation of derivative works. The widely deployed Linux operating system and Apache web server demonstrate the multiplicative benefits of a creative software commons.

Ownership

Modern technology, practice, and law allow tight control over the communication of and access to ideas, threatening the creative commons and future creative works. For example, while Charles Dickens's *Oliver Twist* (1837) exists in the public domain, *digital rights management technology* allows a publisher to prevent a buyer from sharing, copying, or printing the e-book version, a level of control that becomes more significant when fewer printed copies of a work exist. In practice, librarians balance owning paper journals against licensing electronic journals. Web-based, electronic journals offer economy and powerful access capabilities but also carry the risk of complete loss when the license expires. In law, the United States has extended the period of copyright protection, once fourteen years after publication, to seventy years after the author's death, seriously restricting the creation of derivative works.

The Internet hosts a dynamic evolution of morals, ethics, and laws related to information ownership and use. Freed from the limitations of identity, distance, and substance, Internet users have not always transplanted their behavioral norms directly from the *real* to the *virtual world*. Individuals and legislators face novel situations when the concept of theft is separated from both physical location and physical loss. Peer-to-peer file-sharing networks allow complete strangers to share perfect copies of digitized songs across vast distances while a presumed anonymity frees them from social constraints they might feel off-line.

Access

The First Amendment to the U.S. Constitution prohibits Congress from making laws "abridging the freedom of speech or of the press." The Universal Declaration of Human Rights, Article 19, begins "Everyone has the right to freedom of opinion and expression." These declarations codify ethical principles that recognize the value of expressing multiple points of view.

But freedom of speech, while widely recognized as a fundamental right, remains controversial in detail and execution. Because members of a pluralistic society may hold different values, there are frequent conflicts about what information should be publicly available and what information should not be. The American Library Association (ALA) Code of Ethics states, "We uphold the principles of intellectual freedom and resist all efforts to censor library resources." That commitment conflicts with the values of those who challenge the availability of some books in school and public libraries. The ALA Office for Intellectual Freedom reports over 6,000 book challenges (that is, " an attempt to remove or restrict materials, based upon the objections of a person or group") between 1990

Popular books and films frequently draw on infoethical dilemmas for dramatic conflict.

and 2000. Table 1 lists the most frequently challenged books of 2002 and the reasons for the challenge.

Privacy and Security

Competing values and interests in public policy and government activities also lead to ethical tensions. Terrorist attacks, whether in Madrid, London, Tel Aviv, Kashmir, Tokyo, or New York, place governments in unfamiliar ethical territories as they develop responses in the form of new laws, policies, and programs that are in turn subject to the critical appraisal of civil liberties and human rights groups. James Moor (1998) describes such circumstances in terms of *conceptual muddles* and *policy vacuums* that arise when new situations (such as terrorism) and emerging capabilities (data mining) lead to new behaviors (widespread surveillance) with concomitant ethical questions of whether familiar concepts (privacy) apply and whether the new behaviors are acceptable. Table 2 presents a selection of U.S. government actions that have raised serious ethical dilemmas of privacy versus security and that illustrate an ongoing struggle between secrecy and accountability.

To the extent that such programs occur in secrecy, they leave their scope, policies, methods, activities, and even underlying data insulated from review and criticism. They leave the participants unaccountable outside their bailiwicks. As Joseph Pulitzer observed,

> There is not a crime, there is not a dodge, there is not a trick, there is not a swindle, there is not a vice which does not live by secrecy. (Brin 1998)

While secrecy does not presuppose malicious intent, it reduces the opportunity for accountability and opens the door for individual and institutional misuse of information.

Information professionals face dilemmas when balancing their ethical and legal obligations. For example, the USA PATRIOT Act grants law enforcement agencies broad rights to examine the records of library patrons. The ALA Privacy Toolkit describes privacy as "essential to the exercise of free speech, free thought, and free association" and urges libraries to adopt routine patron privacy and record retention policies in support of the library mission. At the same time, library policies may conflict with fulfilling the surveillance mission of law enforcement agencies.

Government responses to terrorism provide the opportunity for both practical and philosophical consideration. Practically it is reasonable to consider how much these actions enhance security, how much they impinge upon privacy, and what are the relative weights to be applied on either side of the equation. Philosophically it is valuable to ponder how government efforts to ensure security conflict with guaranteed civil rights.

Information Ethics in Popular Culture

Fiction and films frequently illustrate information ethical dilemmas, illuminating significant points that may not be apparent in everyday life. The entertainment value of emphasizing particular dilemmas and their consequences in fictional settings does not reduce the value of ethical exploration by way of popular culture.

Machines have long mimicked and extended human physical capabilities. But a physical aid such as a snow shovel presents few consequential dilemmas and appears only infrequently as the dramatic centerpiece of a film or book. At the other extreme, information technologies mimic and extend the human mind—popularly regarded as the essence of being human. The role of self-aware creations in fiction and film has increased as information and information technology permeate everyday life. Consider the Terminator (1984, 1991, 2003) and Matrix (1999, 2003, 2003) trilogies which project the ethical dilemmas that arise when the roles of information processing machines conflict with the needs, even the survival, of human society. Table 3 lists examples of films and fiction that highlight infoethical dilemmas drawn from the COAPS framework.

Professional Ethics

Ethical dilemmas also arise in the course of professional activities. When individuals adopt professional roles, they assume obligations beyond and sometimes in conflict with their personal beliefs. Librarians who order

TABLE 4

Professional Codes of Ethics—A Sample

Professional Organization	Of Particular Note

only books and materials supporting their political views about capital punishment are not exercising their professional obligations to build balanced collections and to provide services for a diverse, multicultural public. *Professional neutrality* refers to the commitment to separate professional obligations and personal beliefs.

Many professional groups have developed formal statements to guide decision making and behavior in situations common to their professions. These are often called *codes of ethics* to reflect their deliberate and conscious origins. Table 4 presents a sample of professional organizations with published ethical codes in fields related to the use of information.

Ethical decision making is neither straightforward nor predictable. Codes provide public statements of ideals and intentions. However they are only the starting point for decision making in professional activities. Codes cannot foresee every situation, yet professionalism often calls for decision making and action in unclear situations. Such ambiguity can require a delicate balancing act among stakeholder beliefs and priorities, the demands of professional obligations, and short-term, long-term, and unintended consequences.

Future Prospects for Information Ethics

The published literature of information ethics intertwines with other areas of applied ethics such as computer ethics, cyberethics, journalism, communications, and media ethics, image ethics, Internet ethics, engineering ethics, and business ethics, reflecting its broad philosophical underpinnings and practical applications far beyond academia. Information ethics contributes to society when it addresses problems that affect the quality of life. Looming ethical questions may seem to arise more from science fiction than science and technology, but science fiction quickly becomes everyday fact. For example, witness the confluence of technology, biology, and national security in the increasing use of biometric identification methods. Looking forward to future technologies and ethical debates:

Will single-issue, virtual *communities* focused on abortion or animal rights, for example, reduce the tolerance for other points of view?

What new business models will arise if intellectual property *ownership* withers in the face of unstoppable copying?

Who will have *access* to the research information about cloning a human?

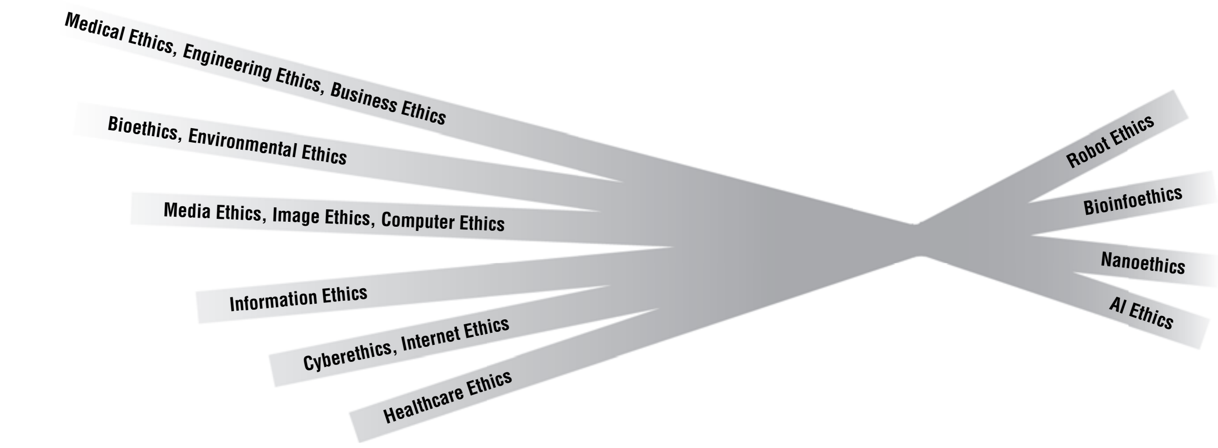
Will the *privacy* rights of consumers be renegotiable with every credit card transaction?

After the poliovirus has been successfully synthesized from its constituent chemical building blocks, does publishing the gene sequences for deadly viruses on the Internet pose a threat to worldwide *security?*

The future is arriving quickly in the emerging field of *bioinfoethics*. It signals a fresh arena for exploration using the combined insights of bioethics and information ethics. It encompasses recent discussions of reproductive ethics, genetics ethics, healthcare ethics, and computer ethics. Bioinfoethics promises to shape

FIGURE 2

Future Infoethics—Arising from Many Domains



SOURCE: Courtesy of Ed Elrod and Martha Smith.

Infoethics embraces many ethical domains. It provides a rich foundation for evaluating the ethics of emerging technologies and practices.

personal decisions, professional practice, and public policy. Beyond that, new infoethical domains will continue to emerge wherever new technologies and practices raise new dilemmas that might include applications of robots, nanotechnology, and artificial intelligence. Figure 2 illustrates the contributions of many, diverse domains of ethical analysis to bioinfoethics and to other emerging ethical domains in the future.

An Icelandic genetic mapping project illustrates such a bioinfoethical dilemma. With parliamentary approval, a private company has begun collecting and analyzing genealogical, medical, and genetic data about the people of Iceland in the hope of uncovering diseases with genetic bases and then developing profitable new drugs to treat those diseases. Such research holds the potential for immense medical benefit and immense privacy intrusion. Genetic mapping is likely to become more widespread, thereby expanding the relevance of the bioinfoethical debate.

The COAPS framework (Figure 1) suggests bioinfoethical questions about such a database. How should *communities* organize and negotiate to assure that the use and benefits of genetic databases best reflect the community interests? Should *ownership* of the genetic and medical data lie with the individuals or the company? What financial benefits accrue to the individuals if they do *own* the data? Should there be widespread *access* to the data to maximize the scientific benefit? Does one-way identity coding sufficiently protect individual *privacy* when the records carry other medically relevant but potentially traceable information? What *security* procedures are demanded for the centralized accumulation of immense amounts of personal and medical data? The Association of Icelanders for Ethics in Science and Medicine (Mannvernd) maintains a broad collection of information about genetic practices and the corresponding ethical considerations.

The Icelandic genetic database represents the leading edge of converging medical, social, government, and information technology practices. The associated bioinfoethical dilemmas explore frontiers of emerging ethical debates and demonstrate the relevance of information ethics to everyone.

INFORMATION OVERLOAD

First comprehensively treated by the futurologist Alvin Toffler (1970), *information overload* refers to excessive flows and amounts of data or information that can lead to detrimental computational, physical, psychological, and social effects. For the vast majority of human history, information was scarce and its production, dissemination, and retrieval were nearly unqualified goods that could improve culture, develop commerce, and promote personal autonomy. The advance of information and communication technologies especially since World War II has transformed this scarcity into an abundance. For example, Peter Lyman and Hal Varian (2003) estimated that print, film, magnetic, and optical storage media produced roughly five exabytes of new information in 2002, equivalent to the information that could be stored in 37,000 libraries the size of the Library of Congress. This doubled the amount of new information that had been stored just three years earlier. The glut of information takes several forms and raises many concerns. Indeed it is ironic that information technologies, envisioned by many of their progenitors as devices for organizing information, improving understanding, and boosting productivity often also contribute to disorders, inefficiencies, and confusion.

Causes and Types

Technology, the free-market, and democracy have nearly erased the limits that once caused only the most important information to be published and distributed. Computers, cell phones, the Internet, optical cables, and wireless and satellite transmissions are just a few key technologies fueling the information age. People have become increasingly dependent on such technologies in both their professional and private lives, making information overload nearly unavoidable. The ease and low cost of online publishing and electronic mailing swells the amount of available information, including irrelevant and low quality information.

Information overload occurs in several forms. The term is frequently used in computer theory when so much information has entered an information-processing system that the system cannot easily, if at all, process it. This is usually due to hardware or software limitations, and the idea parallels findings by psychologists that cognitive constraints limit human capacities to process information. Information overload has also been utilized by cognitive scientists in their explanations of intelligent activity. One example is Herbert Simon's concept of *near decomposability* (where short-run behavior of components is independent of other components in the same system). An organism's visual subsystem, for example, can suffer from information overload, while the overall organism does not. In turn, the overall organism can suffer information overload, because it may lack the architectural structure to manage the information gathered and transmitted by each of its subsystems. Another more general concept useful in describing information overload is the decline in the *signal-to-noise* ratio, which denotes the proportion of useful information to all information present in some particular context.

Information overload is commonly experienced in the workplace, especially by managers and government officials who must synthesize growing streams of data. Academics and others who perform research are also negatively impacted by excessive flows of information that make it hard to discern high from low quality knowledge. Finally, information overload is a general experience shared by citizens in developed nations, where streams of information from a variety of media are unavoidable in daily life. Human beings have limited cognitive capacities to store and render information meaningful, and the blitz of information made available by modern technology can easily overwhelm these capacities. Spam, unsolicited commercial bulk E-mail, and its attendant aggravations and lawsuits highlight one specific instance of the personal and social ramifications of information overload.

Effects and Responses

Although information overload in computers can cause technical and social problems, its most detrimental effects usually occur when individual humans must cope with excess information. Indeed Toffler summarized one of the most pernicious effects with his term *information anxiety*. Richard Saul Wurman (1989) explains that, "Information anxiety is produced by the ever-widening gap between what we understand and what we think we should understand. Information anxiety is the black hole between data and knowledge. It happens when information doesn't tell us what we want or need to know" (p. 222). Showing the close connection between information overload and the overwhelming speed of modern social change, Wurman warns that information anxiety limits people to being only seekers of knowledge, because there is no time to reflect on the meaning of that knowledge for one's life. Many people become so obsessive in this quest that they experience what some have called an *information addiction* (Reuters 1997).

The printing press and its many unintended social consequences are often cited as precursors to such ethical implications of increased information. The sociologist Georg Simmel pointed to information overload in several of his studies. For example, he noted that some city dwellers developed the habit of hardly noticing individuals when moving through a crowd. In the 1960s, James G. Miller researched the psycho-pathological effects of information overload, and Karl Deutsch described information overload as a disease of cities that limits freedom as well as efficient communication and transport. In his 1986 *Overload and Boredom*, the sociologist Orrin E. Klapp argued that the second law of thermodynamics applies to information and culture as well as energy: The greater a social system's information and culture output the greater the system's disorganization in the form of information overload. This yields noise, banality, alienation, despair, anxiety, disenchantment, anomie, feelings of illegitimacy, and absurdity. Boredom results not from the absence of stimulation, but by its excess and repetition. Irrational or poor decisions can also result from information overload. Indeed, some researchers in choice behavior argue that too much choice can be a bad thing (Schwartz 2004).

Walter Kerr (1962) argued that modern societies erode pleasure because the information made available nearly anywhere (now via cell phones and portable computers) enables work to impinge on leisure time. On the positive side, this can improve work and enhance communication with loved ones. In a similar vein, some research suggests that children exposed to computer-enriched environments develop higher-order thinking abilities to a significantly greater degree than those not so exposed (Hopson 2001). Finally, recent philosophers (such as Braybrooke 1998) have conceptualized social information overload as a central element in the logic and processes of social change more generally.

A 1996 survey conducted by Reuters is just one of many reports investigating the effect of information overload. Surveying more than 1,000 managers, this report found that increasing numbers of people suffer ill health due to the stress of information overload and important decisions are delayed by excessive information. David Lewis proposed the term *Information Fatigue Syndrome* for the symptoms uncovered in this report, including poor decision making, difficulties in remembering, reduced attention span, and stress. Nearly half of those surveyed predicted that the Internet would play a primary role in aggravating the problem further. Yet in a follow-up report two years later, researchers at Reuters found that only 19 percent of respondents felt the Internet was making the situation worse, while nearly half felt it was improving the situation. More broadly, this report concluded that the age of information overload is waning, because although some economies were still struggling with it (for example, Southeast Asia), others (such as the United States, Japan, and Western Europe) were beginning to overcome it.

Timely, relevant, and accurate information is crucial for much of the government and many sectors of the economy (although opinions on the degree to which information is important for different tasks vary across the globe). So, if the solution is not to simply tune out, how are the problems posed by information overload resolved? Solutions can be categorized under the broad heading of information management. Entities implementing information management policies (according to the 1998 Reuters report) experienced marked increases in productivity and decision-making capability. Information management in this context connotes methods for evaluating, prioritizing, and processing information (for example, the ranking operations performed by many search engines). Technology (especially e-mail and the Internet) is increasingly regarded as enabling information management rather than exacerbating information overload. Work practices are being adapted to use information technologies more effectively and businesses increasingly rely on a single, trusted source of comprehensive information in order to improve efficiency.

Perhaps a computer-neural interface will be developed to improve cognitive abilities to process and store information, but will this necessarily enhance the capacity to understand and control nature and society? One conundrum raised by the issue of information overload is that infinitely increasing both information and the capacity to use that information does not guarantee better decisions leading to desired outcomes. After all, information is often irrelevant, either because people are simply set in their ways, or natural and social systems are too unpredictable, or people's ability to act is somehow restrained. What is required, then, is not just skill in prioritizing information, but an understanding of when information is not needed. These cases do not point to insoluble problems. Instead they raise a more appropriate question most eloquently stated by T. S. Eliot (1952) in *The Rock:* "Where is the wisdom lost in knowledge and where is the knowledge lost in information?"

INFORMATION SOCIETY

The term *information society* refers to a set of developments in the global human environment that began during the last quarter of the twentieth century. These developments entailed increasingly intensive use of technologies of information and communication, from desktop computers and a plethora of sensing and "smart" devices to mobile telephony and portable handheld electronics, all progressively interconnected. In a cursory sense, an information society is simply one heavily dependent on these technologies for human interactions and transactions, though no clear threshold exists for classifying a society as informational at any particular stage of technological development. In a more important and complex sense, an information society is one in which use of various technologies has produced or is producing substantial change in the ways people live, learn, work, socialize, and govern themselves.

A New Context for Ethics

As societies around the globe integrate various technologies into economic, social, educational, personal, and governmental practices, the resulting changes create new contexts for ethics in the mundane sense of the customary guidelines for their engagement. The altered context involves new linkages among individuals and

A palm pilot. These hand-held computers are one of the products of the Information Society. (*© SIE Prouductions/Corbis.*)

organizations, along with transformations in the identity and structure of human collectivities. One hallmark is decentralization in some forms of control and decision making. In economic transactions, this involves reduced reliance on hierarchical structures in favor of more distributed, flexible, horizontal links among organizations able to communicate and coordinate with less centralization. At the same time that certain organizational structures are becoming less centralized, possibilities for the collection of highly centralized data about citizens and their activities are expanding. This means that increasingly centralized bodies of information about citizens are available both to government and to the new forms of decentralized organizations in economic and other realms.

In the social arena, such changes involve more flexible, complex patterns of association with decreased dependence on physical proximity or identification with well-bounded groups or communities. One extreme gives rise to self-organizing groups and associations that may be temporary in nature. Another is the direct exchange among individuals of digitized artifacts such as moving or still photography, music, books, or other narratives in the presence of little or no coordinating authorities and brokers.

The trend toward information societies is sometimes described in terms of the replacement of industrial-age human structures with *networks*. These networks involve adaptable, flexible, complex communication and interactions with many points of intersection. One of the classic descriptions of the information society is the trilogy of books by Manuel Castells collectively entitled *The Information Age: Economy, Society, and Culture* (1996, 1998, 1999). An earlier and widely influential statement that anticipated some of the developments of the information society is Daniel Bell's *The Coming of Post-Industrial Society* (1973).

Origins of the Information Society

Several factors contributed to the trend toward the information society. The intellectual threads of the information society can be traced back as far as Gottfried Wilhelm Leibnitz (1646–1716), who in the seventeenth century postulated a machine that might manipulate mathematical representations of human thought. More concretely, it was the rapid technological innovation by twentieth century corporations and universities that resulted in the production of a stream of fast, inexpensive, portable computing and communication technologies. These innovations began with the development of digital computers from the 1940s through the 1960s. Following establishment of digital computing as a field, progressive miniaturization from the 1970s through the 1990s promoted the design of smaller and more powerful information and communication devices.

Another interpretation traces the technological origins of the information society back to the industrial revolution. James Beniger (1986) argues that the demands for control and management of information associated with industrial activity and socioeconomic structure paved the way for the eventual rise of the information society.

A second economic factor contributing to information society trends was a wave of privatization of previously state-dominated media in many countries during the last two decades of the twentieth century. Both the technological developments and the restructuring of media-state relations fed economic globalization. Intensified economic and financial linkages among nations through corporate multinationalism and national trade policies created tighter interdependencies among societies and provided for means of cultural and social change. These developments were concentrated in the Americas, Europe, Australia, and non-authoritarian Asian nations. In many societies with authoritarian governments, such as Saudi Arabia and China, various government policies limited the deployment of information technologies.

Ethical Issues in the Information Society

Most technological innovations, beginning with the first use of tools made of stone or bone, have permitted humans to engage in new kinds of actions and to restructure relationships with one another. These altered actions and relationships raise important questions of ethics, social order, and governance. Which new possibilities for human agency and for restructuring of societies are desirable? How should such questions be decided—by individuals, by markets, by states, by religious institutions? Technologies of the information society precipitated many such questions. For instance, access to the technological infrastructure of the information society is highly unequal across nations and across groups and among individuals within nations, raising the possibility that information societies will be exclusionary. Additionally, the digitization and centralization of information and the density of interconnections among people allow for far greater possibilities of privacy violations by other individuals, corporations, and governments in information societies than in industrial ones. One of the most important ethical issues in information societies involves challenges to traditional conceptions of information ownership, which in earlier periods was defined partly by practical constraints on its replication and exchange.

Because cultures are sustained and altered by communication and the preservation of certain artifacts and information, information society changes create cultural mixing and shifts. Especially controversial is the transfer of Euro-American cultural norms and practices to non-Euro-American societies. Even within Euro-American societies, debates about the regulation of speech that were once largely settled matters have been revisited, due to the vastly increased capacity for people to communicate material or ideas that were previously limited by such simple constraints as cost.

It is difficult to predict how far trends toward information societies will extend. It is important to observe that the rise of industrial societies in the nineteenth and twentieth centuries did not bring about the cessation of agricultural activities or the end of agrarian ways of life. Instead they produced a shift in the locus of human activity for many people in many societies. Similarly, the rise of the information society will not entail the end of industrial activity or the termination of industrial-age social structures, cultural practices, and economics, but rather a transition to altered human arrangements across this spectrum.

INFORMED CONSENT

Informed consent is an individual's voluntary agreement, based on adequate understanding of relevant facts, to permit some type of intervention by a second party. This term is most commonly used in medical contexts to refer to individuals' agreements to undergo medical treatment or to participate in research. In most cases, informed consent is required both ethically and legally prior to the commencement of treatment or enrollment in research.

Recent History

The ethical and legal mandate for informed consent as understood in the early twenty-first century was not established until the latter half of the twentieth century. Before that time, a paternalistic paradigm governed the relationship between patient and health care provider. However, driven by landmark cases, revelations of abuse, and a changing professional ethic, there has been a shift toward patient autonomy and away from physician paternalism. The establishment of a requirement for informed consent occurred independently but concurrently in the two contexts of medical treatment and research with human subjects.

MEDICAL TREATMENT. U.S. courts first recognized the need for patients to give consent for medical treatment in *Schloendorff* v. *Society of New York Hospital* in 1914. It was not until *Salgo* v. *Leland Stanford, Jr. University Board of Trustees* in 1957, however, that the additional provision requiring physicians to give patients information relevant to their treatment decisions was established. This requirement for physician disclosure was expanded, developed, and solidified by *Natanson* v. *Kline* (1960), *Mitchell* v. *Robinson* (1960) and *Canterbury* v. *Spence* (1972). These precedents were then incorporated into statements by the Judicial Council of the American Medical Association (AMA) in 1981 and the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research in 1982. The need to obtain patients' informed consent has since been incorporated into the medical practice guidelines of numerous national and international organizations of medical professionals.

RESEARCH SUBJECTS. The evolution of informed consent in research with human subjects was spurred not by legal decisions but by public and professional reaction to several cases in which people were used as research subjects without their knowledge or permission. The Nuremberg Code of 1947 established general guidelines for human subjects research in response to the revelation of the Nazi medical experiments, stating that the informed and voluntary consent of subjects was "absolutely essential." In an effort to create more specific ethical guidelines for research, the World Medical Association (WMA) adopted the first version of the Declaration of Helsinki in 1964, which also held the subjects' informed consent to be a necessary element of ethical research.

In 1966, Henry K. Beecher published an article in the *New England Journal of Medicine* identifying twenty-two ethically problematic studies involving human subjects, including studies at the Jewish Chronic Disease Hospital and Willowbrook State Hospital. Beecher concluded that patients must give informed and voluntary consent before participating in research. The uncovering of the Tuskegee syphilis study that took place between 1932 and 1972 brought widespread attention to violations of the rights of human subjects. In the Tuskegee case, poor and uneducated African American men were enrolled in a study of the progression of untreated syphilis without their knowledge or consent. At least partially in response to these abuses, The Belmont Report, published in 1978, and finally the federal Common Rule (45 CFR 46) in 1991 incorporated the requirement for informed consent into United States regulation.

PHILOSOPHICAL FOUNDATIONS. The moral requirement for informed consent can be grounded in both deontological and consequentialist ethical theory. Immanuel Kant (1724–1804) held that moral worth is based upon the ability to reason and that the ability to reason must be respected by others. Rational choices are expressions of the ability to reason and so have intrinsic value. As a result, people have obligations to make rational choices and others are obligated to respect those choices. Giving (or refusing to give) informed consent is a form of rational choice and so therefore has intrinsic value within a Kantian deontological framework.

The value of informed consent can also be derived from consequentialist ethical theory. Consequentialists hold that something is good if it produces good outcomes. In most cases, people know their own goals and values better than anyone else, and therefore are in the best position to decide how to promote their own good. Even though people may, on occasion, be mistaken about what is good for them, they benefit overall from exercising self-determination. As a result, the best outcomes are brought about when people make decisions for themselves. The requirement for informed consent is one way to protect and encourage self-determination and therefore to bring about good consequences.

Five Elements of Informed Consent

There are at least five necessary elements of informed consent: disclosure, understanding, capacity or competency, voluntariness, and assent. These elements can take different forms in research and treatment contexts and can entail various ethical and legal standards.

DISCLOSURE. Informed consent can only be given if the person consenting is adequately informed. The first part of this process involves the disclosure of information. The physician, researcher, or in some cases another individual, must make available to the patient or potential subject sufficient information to make a decision about treatment or participation in research.

What constitutes sufficient disclosure is ambiguous, but there are three plausible ways this can be interpreted. The *professional practice standard* of disclosure requires physicians to give patients as much information as is generally disclosed by other medical professionals about a particular procedure or research protocol. The *reasonable person standard* sets the disclosure requirement at whatever a reasonable person would want to know in a given situation. A final disclosure standard is the *subjective standard*, which states that a physician should tell a patient whatever that subject would want to know. Each of these views on disclosure has advantages and disadvantages.

There is no consensus on which standard best describes the ethical obligation of disclosure. Generally, however, disclosure must include at least a description of the treatment or procedure, the material risks and benefits, and the available alternatives. In research contexts, additional information must be provided to the individual considering participation. Examples of such additional information include: a statement about the experimental nature of the procedures, information about confidentiality of the subject's records, information about what to do in case of injury from the study, and a statement that participation in the research is voluntary.

Legally, state jurisdictions are approximately evenly split between using the professional practice standard and the reasonable person standard in treatment contexts. Only a few jurisdictions hold physicians to the subjective disclosure standard. The U.S. Common Rule provides an itemized list of the information that must be conveyed to potential subjects within research contexts.

UNDERSTANDING. In order for an individual to be informed in the ethically relevant sense, that individual must respond to the disclosure in an appropriate way. That is, the individual must internalize the information that has been made available though the disclosure process. If a patient or potential subject is unable to understand the provided information, informed consent is not possible. It is the responsibility of a physician or researcher to make an effort to maximize the understanding of the patient or potential subject. For example, a researcher should convey the relevant information in language that the potential subject can comprehend and should answer clearly any questions that the subject asks about the protocol. In practice, formal assessment of an individual's level of understanding is rare. Instead, patients or potential subjects may simply be asked if they understand the information they have been given or if they have any questions.

CAPACITY AND COMPETENCY. Capacity refers to an individual's ability to appropriately manipulate the information that has been understood. There are a number of different ways that decision-making capacity could be defined and by which the presence or absence of capacity could be assessed. The ability to appreciate the consequences of one's life options, to weigh the various considerations and come to a decision, to reason logically about one's situation, and to evaluate the situation in light of one's own values could all be used as indicators of capacity. There is no ethical or legal consensus on which of these definitions should be used.

Capacity is a task-specific concept, meaning that the level of decision-making capacity needed to make a given decision varies depending on the nature of the decision itself. As a result, at any given time one may have the capacity to make some decisions but not others. Generally, the higher the risk posed by a procedure, the more capacity one must have to make a decision to undergo that procedure. For example, a patient may have capacity to consent to having an IV inserted but not to having invasive surgery.

Individuals without the capacity to make a given decision about treatment or research cannot give informed consent to undergo that treatment or research. When a person lacks decision-making capacity, informed consent is solicited from a surrogate decision maker, that is, a family member or other individual appointed to made decisions on behalf of that person.

Competency is the legal analogue to capacity. Adults are presumed to have competency unless it has been demonstrated to a court that they are unable to make autonomous decisions, in which case the court declares the adult to be incompetent. At that time, a legally authorized representative is appointed for that individual. In contrast, children and adolescents under the age of eighteen do not have competency to make their own decisions unless a court decides otherwise.

VOLUNTARINESS. An individual's decision to undergo treatment or to participate in research must be voluntary. That is, the individual must not be coerced or unduly influenced by either external or internal factors. Threats of unwanted consequences such as physical harm or withdrawal of medical care are obvious examples of coercion. More subtle challenges to voluntariness include the provision of substantial incentives and the manipulation of an individual's decision-making process through the biased presentation of information. Because of the importance of voluntariness, informed consent is often denominated "free and informed consent" or just "free informed consent."

A physician or researcher may not coerce or unduly influence a patient or potential subject to make a desired decision. The conditions under which and the manner in which the physician or researcher solicits consent should be designed to minimize the possibility that voluntariness will be compromised.

ASSENT. The final element of informed consent is the decision made about undergoing treatment or participating in research. Inherent in the idea of informed consent is a positive decision—one gives informed consent to undergo a particular treatment or procedure. A negative decision—that is, a decision not to undergo the treatment or procedure—constitutes an informed refusal.

Generally, verbal agreement is sufficient for low-risk treatment decisions. When treatment methods involve higher levels of risk, however, the patient may be required to sign a consent form. The form summarizes the relevant information and states that the individual is voluntarily agreeing to the treatment or procedure. In research contexts, an individual's consent to participate in the research protocol must almost always be documented by the individual's signature on a consent form.

Exceptions to Informed Consent

There are a few exceptions to the requirement for informed consent for medical treatment. In emergency situations, treatment can be administered without the patient's consent because it is presumed the patient would consent if given the opportunity. Other exceptions include cases in which an individual poses a threat to public health. In such cases, treatment may be forced on that individual without consent. For example, a person with tuberculosis may be compelled to undergo treatment. Individuals may also waive their right to informed consent, stating that they do not wish to be informed of a diagnosis or to make decisions about their own treatment. Finally, children and incompetent adults do not give informed consent for treatment, although consent must be obtained from parents or guardians.

Informed consent is almost always required prior to enrollment in research. However, federal regulation allows individuals to be enrolled without their consent in research protocols in some emergency situations if obtaining consent would be impossible. It further allows emergent use of an investigational drug or procedure on a case-by-case basis if it is believed that doing so will have therapeutic value for the patient. A second exception to the requirement for informed consent in research contexts enables parents or guardians to give consent for the participation of children and incompetent adults. It has, however, been recommended that physicians and researchers seek the assent of these individuals when possible.

Informed Consent and Science and Technology

Although the concept of informed consent is most thoroughly developed within the contexts of medical treatment and biomedical research, it has ethical implications for the development and use of the products of science and technology more broadly defined. Research into and implementation of innovations in fields such as civil engineering, nuclear energy, genetic engineering, and nanotechnology have inherent risks. In many cases, the members of the community in which these innovations are being developed and put into use are exposed to these risks. The ethical requirement for informed consent, however, suggests that these individuals should not have to bear this burden without their knowledge and voluntary consent.

In most cases, the process of obtaining consent for medical treatment or for enrollment in biomedical research is dyadic, consisting of a dialogue between a physician or investigator and a subject. In non-medical contexts, however, this model of obtaining consent is often not feasible. Practically, it would be impossible to obtain individual consent from each member of the community that could be exposed to risk. Further, many of those who may be affected by these innovations could not even theoretically be asked for consent, such as members of future generations.

Despite these difficulties, the requirement for informed consent generates ethical obligations for those who develop and implement the products of science and technology. These obligations may be discharged through various community consent mechanisms, such as allowing public participation in the creation of policies that govern innovations, consultation with community leaders, and assessment of public opinion. The use of these and other community consent methods may help to ensure that science and technology move forward in an ethically appropriate way, and therefore that the goods that they produce are not achieved at too great a cost.

INSTITUTE OF ELECTRICAL AND ELECTRONICS ENGINEERS

The Institute of Electrical and Electronics Engineers (IEEE) is the largest technical society in the world with more than 375,000 members in 150 nations; it publishes 30 percent of the global technical literature in electrical and computer engineering. The organization was formed in 1963 through a merger of the American Institute of Electrical Engineers (AIEE, founded in 1884) and the Institute of Radio Engineers (IRE, formed in 1912 when two local organizations founded in Boston and New York were merged).

In its early years the AIEE struggled to espouse professionalism in engineering despite strong pressure to the contrary from the businesses (mostly electric utilities) that employed the great majority of its members (Layton, 1986). Indeed, the famous engineer and socialist Charles Steinmetz served as president of the AIEE in 1901–1902. By the late twenties, however, business interests dominated the AIEE, evidenced by a lower membership standards that admitted business executives in the utility industry, restriction of the activities of local sections to purely technical matters, censorship of publications critical of business practices, stifling of dissent and public discussion of the profession through restrictions in the code of ethics, and abandonment of open elections in favor of a nominating committee. Many observers would argue that the AIEE's predisposition toward business interests was carried over to the IEEE and prevails to the present day (Herkert 2003).

The IRE was founded in part out of dissatisfaction with the growing dominance of business interests in the IEEE's affairs and in part due to the strong scientific basis and rapid growth of the field of radio engineering, which resulted in a higher sense of professionalism (McMahon 1984, Layton 1986). The IRE also aspired to become an international organization. Ironically, however, the IRE shied away from speaking for its members on professional and policy matters (Layton 1986). By the time of the merger the IRE had surpassed the AIEE in membership, buoyed by the explosive growth in electronics following World War II. The merger, an inevitable result of this development, resulted in a blending of the two institutional cultures that incorporated the IRE's decentralized management structure and professional groups, now known as technical societies (IEEE History Center 1984).

In 1973 the IEEE amended its constitution changing it from a strictly "learned" society to one that also represented the professional interests of its members. As a result, the United States Activities Board (USAB) was formed to represent the interests of U.S. members. (IEEE History Center 1984, McMahon 1984). The USAB and its successor organizations have played an important role in ethics activities of the IEEE and in promoting policy favorable to the U.S. engineering and business community. The affect of the USAB's presence on efforts to globalize the IEEE has been more controversial.

Codes of Ethics

The AIEE promulgated one of the earliest codes of engineering ethics in 1912. The code provided that the "first professional obligation" was to protect the interests of the engineer's clients or employers (Layton 1986). In 1950 the AIEE code was revised to incorporate the cannons of the code of ethics of the engineers' council for professional development, including a provision that the engineer "will have due regard for the safety of life and health of the public and employees who may be affected by the work for which he is responsible" (CSEP 2004). The first IEEE code of ethics was adopted in the 1970s (Unger 1994) following revisions in 1979 and 1987 (CSEP 2004). The current IEEE code of ethics (adopted 1990), in parallel with other contemporary engineering codes, pledges its members to protect the "safety, health and welfare of the public." Unlike others, however, the IEEE code also includes specific language regarding ethics support, committing its members "to assist colleagues and co-workers in their professional development and to support them in following this code of ethics."

Ethics Activities

The IEEE has long enjoyed a reputation as one of the more proactive professional engineering societies in the ethics area. This positive image derives primarily from ethics activity in the1970s, including preparation of a friend of the court brief supporting the three whistle-blowing engineers in the Bay Area Rapid Transit (BART) case. Much of this activity was encouraged by the formation of a Committee on Social Implications of Technology by Stephen Unger and other organizational activists, which evolved into the IEEE Society on Social Implications of Technology (SSIT). The SSIT, though only 2,000 members strong, has remained an important voice in the IEEE for ethical responsibility and concern for societal implications of technology. The SSIT publishes a quarterly journal, *IEEE Technology and Society Magazine*, hosts an annual conference, and periodically bestows its Carl Barus Award for Outstanding Service in the Public Interest on engineers who uphold the highest ethical standards of the profession. As noted earlier, the IEEE sub-unit that represents the interests of U.S. members has also been active in ethics issues. At the level of the parent organization, however, ethics activity was generally dormant between the late-1970s and mid-1990s (Unger 1994).

The IEEE reputation for promoting engineering ethics was, in the opinion of many observers, seriously tarnished by events that began to unfold in the late 1990s when a staff and volunteer leader backlash crushed gains in ethics support (Unger 1999, Herkert 2003). Prior to 1995, the only committee of the IEEE Board of Directors (BoD) charged with dealing with ethics was the Member Conduct Committee (MCC), founded in 1978. The MCC's purpose was twofold: to recommend disciplinary action for violation of the Code of Ethics and to recommend support for members who when following the Code encountered difficulties such as employer sanctions.

A BoD-level Ethics Committee, formed in 1995 as a result of efforts by members to elevate the prominence of ethics in the organization, was intended to provide information to members and advise the BoD on ethics-related policies and concerns. As one of its first actions, the Ethics Committee, whose membership included Stephen Unger, in 1996 established an Ethics Hotline designed to provide information and advice on ethical matters to professionals in IEEE fields of interest. Cases brought to the attention of the Ethics Hotline included falsification of quality tests, violations of intellectual property rights, and design and testing flaws that could result in threats to public safety. In some instances, such cases were referred to and acted on by the MCC (Unger 1999).

The Executive Committee of the BoD suspended the Ethics Hotline in 1997 after less than a year of operation. In 1998 the Executive Committee rejected and suppressed its own task force report, which recommended reactivation of the hotline. In the same year, the IEEE implemented bylaw changes that reduced the terms in office of members of the MCC and Ethics Committee, and, in apparent disregard of the IEEE Code of Ethics, prohibited the Ethics Committee from offering advice to any individuals including IEEE members. The cycle was complete in 2001 when the Ethics Committee and the MCC were merged. Like the old MCC, the combined committee has a dual-charge of member discipline and ethics support, but its activities are limited by IEEE Bylaw I-306.6: "Neither the Ethics and Member Conduct Committee nor any of its members shall solicit or otherwise invite complaints, nor shall they provide advice to individuals."

In another example of what one IEEE member describes as *ethical timidity*, in 2002 the IEEE denied membership benefits to its members in Iran and several other nations on the grounds that such action was required by U.S. trade restrictions, a position that was not shared by most other U.S.-based scientific and technical societies. Compounding the blow to the IEEE ethics profile, the IEEE leadership initially sought to conceal this action on a *need to know basis* (Gaffney 2003). Though the IEEE later claimed to be vindicated by a government exemption permitting editing and publication of papers submitted by Iranians, the ruling imposed restrictions on collaboration with Iranian scientists and left unchanged the IEEE's suspension of the membership benefits of residents of the sanctioned countries (Foster 2004)

INSTITUTE OF PROFESSIONAL ENGINEERS NEW ZEALAND

• • •

The first engineering society in New Zealand was the Institute of Local Government Engineers, which was founded in 1912. In 1914 it merged with the New Zealand Society of Civil Engineers, founded in 1913, which in 1982 became the Institute of Professional Engineers New Zealand (IPENZ). IPENZ is open to all engineering professionals.

The terms *engineering profession*, *professional engineer*, and *professional engineering* are used by IPENZ in the most general possible manner, to include all those who use a systematic process of analysis, design/synthesis, and implementation; strive to operate in a responsible way; are governed by a code of ethics set by their peers; and engage in continuing professional development to maintain the currency of their competence. IPENZ publishes the peer-reviewed print journals *e.nz* and *Engineering treNz* as well as the member newsletter, *engineering dimension*. Membership is currently about 9,000.

Because of New Zealand's unique geology—it is prone to floods, earthquakes, and volcanic eruptions—IPENZ has a strong focus on natural hazard and risk management. It also supports a heritage project, whose goal is described on its web site as "To inspire and teach present and future generations by preserving the legacy of the past through the identification, maintenance and promotion of New Zealand's engineering heritage."

The IPENZ code of ethics, perhaps under the influence of Engineers for Social Responsibility, gives high priority to social and environmental responsibility; along with the Australian Institution of Professional Engineers, IPENZ was one of the first engineering societies to do so. While it would be incorrect to describe it as an activist organization, IPENZ has on occasion taken strong public stands on issues such as dam safety.

INSTITUTIONAL BIOSAFETY COMMITTEES

• • •

Institutional Biosafety Committees (IBCs) are review boards appointed by an institution to evaluate and approve potentially biohazardous lines of research. IBCs were established in 1976 by the National Institutes of Health (NIH) Guidelines for Research Involving Recombinant DNA Molecules (Guidelines). Their function is to provide local institutional oversight and approval of nearly all forms of NIH-sponsored research utilizing recombinant DNA (rDNA) in order to ensure that such research is in compliance with the Guidelines. IBCs were developed in response to fears about the risks posed by genetic engineering and guided by principles considered at the Asilomar Conference on recombinant DNA molecules.

Although IBCs still serve as the cornerstone for oversight of this research, their role has also been expanded to include review and supervision of a variety of experiments involving biological materials and other potentially hazardous agents. The potential threats posed by "dual use research" has prompted the National Science Advisory Board for Biosecurity (NSABB) to consider further expanding the role of IBCs to monitor research that may have implications for bioterrorism. There are doubts, however, about the ability of some IBCs to perform this expanded function. Furthermore, controversy exists not only about the performance of certain IBCs in their main role of ensuring safety, but also about how transparent their work should be. Judging the validity of these concerns is hampered by a general paucity of evaluations and assessments of individual IBCs and the system as a whole.

Background, Development, and Institutionalization

The risks presented by emerging techniques in rDNA research during the early 1970s led scientists to implement a brief self-imposed moratorium on this work. Research with rDNA eventually continued under the principles and guidelines established at the 1975 Asilomar Conference. A mechanism for institutionalizing review and approval of proposed research was considered but not formally adopted at Asilomar. However, in 1976 such a mechanism was created by the NIH Guidelines in the form of IBCs. The model of local, decentralized review committees created and guided by a mandate at the federal level already existed in the form of Institutional Review Boards (IRBs), formalized by the 1974 National Research Act, to monitor human subjects research. Like IRBs, IBCs serve as a mechanism for delegating oversight and approval responsibilities to the local institutions performing research supported by federal grants.

The 1976 Guidelines created Institutional Biohazards Committees, but in 1978 there was a formal shift in focus from "biohazards" to "biosafety." The same year also brought other changes, including more emphasis on ensuring appropriate review, the appointment of a Biological Safety Officer (BSO) at each institution, and improved training protocols and implementation procedures. In 1984 IBCs became responsible for oversight and approval of human gene transfer research. Two years later, the IBC system formally incorporated the "points to consider" developed by the Recombinant DNA Advisory Committee (RAC) Working Group on Human Gene Therapy, and in 1990 the emphasis was shifted to gene transfer rather than gene therapy. The NIH Guidelines were further expanded with additional appendices during the 1980s and 1990s as emerging techniques presented novel regulatory requirements. In 2000 the gene transfer protocols were amended to require RAC review prior to IBC approval (Grilley and Gee 2003).

Although the core responsibilities (review and oversight of rDNA research) of IBCs have remained stable throughout these changes, they have also been expanded to include oversight of other potentially hazardous research, including work on such materials as infectious agents and carcinogens. In March 2004, the U.S. government announced plans to create a National Science Advisory Board for Biosecurity (NSABB), which would identify possible "dual use research" (legitimate scientific work that could be misused to threaten public health or national security) and develop guidelines and recommendations for oversight. The task of implementing the board's recommendations will fall mostly on the roughly 400 IBCs (Couzin 2004).

Each IBC must be composed of no fewer than five members, and at least two members must be unaffiliated with the institution and represent the environmental and public health interests of the surrounding community. Members must be selected in a manner that ensures adequate expertise in rDNA technology and competence in assessing potential risks of proposed research. The functions and responsibilities of IBCs include: assessing containment levels required by the Guidelines for the proposed research; implementing contingency plans; maintaining proper facilities; ensuring adequate training of personnel; ensuring compliance with all surveillance, data reporting, and adverse event reporting; and additional responsibilities for human gene transfer experiments in accordance with Appendix M of the Guidelines. The NIH Office of Biotechnology Activities (OBA) manages and evaluates the conduct of the IBCs as part of its broader mandate to implement oversight mechanisms and information resources to promote the science, safety, and ethics of rDNA research (Shipp and Patterson 2003).

Criticisms and Assessments

Transparency, or openness to public review, is the most contentious issue surrounding both the conduct of individual IBCs and the system as a whole. Proprietary rights and privacy issues often conflict with demands for information about research that could threaten public health. IBCs have been targeted by several watchdog organizations, including the Sunshine Project, which investigates activities that could undermine the 1972 Biological and Toxin Weapons Convention and the 1993 Chemical Weapons Convention. The question of transparency is especially contentious when it involves biodefense research. Such activities require secrecy, yet in the absence of public oversight they could cross over into offensive research or generate new risks (Enserink 2004). The increasing awareness that terrorists could misuse some of the research regulated by IBCs only intensifies the conflict as some call for tighter controls on information and others demand increased public involvement.

There are additional concerns that several IBCs are not only reluctant to publicize information but may be lax in their oversight responsibilities. The Sunshine Project (Enserink 2004) and Diana Dutton and John Hochheimer (1982) accused some IBCs of meeting too infrequently or informally to adequately fulfill their duties. This raises further doubts about the ability of certain IBCs to take on the additional responsibilities of monitoring dual use research. The charge could also be made that a more neutral body should be responsible for oversight and evaluation of IBCs, because the OBA is housed within the NIH, which may raise conflict-of-interest issues.

Dutton and Hochheimer (1982) and Philip Bereano (1984) carried out detailed evaluations of IBCs. Both sets of researchers agreed that IBCs represent novel and promising experiments in the joint regulation of technology by lay and technical communities. However, both also argued that several shortcomings in the IBC system have severely limited its potential to forge consensual judgments about the acceptable risks of scientific research. Bereano argued that the Guidelines were developed primarily by the group being regulated, which narrowed their scope and unduly constrained the purpose of the IBC system. In a related critique, he claimed that IBCs are often dominated by rDNA scientists, which leads to a narrow perception of risk and a general hostility toward regulation. Dutton and Hochheimer argued that IBCs rarely realize their potential for genuine public participation, both for the reasons Bereano outlined and because IBCs often lack adequate resources.

Follow-up on these evaluations has been relatively sparse, which may reflect the difficulty in assessing a decentralized system designed to tailor oversight responsibilities to specific project proposals. The paucity of neutral, comprehensive evaluations, however, also means that many criticisms of IBCs are difficult to substantiate and operationalize into reforms that could improve the regulatory system.

INSTITUTIONAL REVIEW BOARDS

Established by Congress in the 1974 National Research Act, institutional review boards (IRBs) are decentralized committees that review and monitor nearly all federally funded research projects involving human subjects in the United States. In most other nations these groups are called research ethics committees (RECs). The purpose of IRBs is to ensure that research conforms to ethical standards and protects the rights and welfare of the people who participate as research subjects. This is accomplished through the IRB Review of Research process, which involves the review of protocols, informed consent documents, and related materials for proposed research. Although flawed and contentious, the IRB regulatory framework is improving in its ability to assure the upholding of ethical standards in a rapidly evolving research context.

Background

The unethical practices of Nazi doctors at concentration camps spurred several attempts to formulate ethical principles for the conduct of research involving human subjects and institutionalize political mechanisms capable of upholding those principles. The most notable international efforts include the 1948 Nuremberg Code and the 1964 Declaration of Helsinki made by the World Medical Association. In 1975 the Helsinki Declaration was revised to include a statement recommending that independent committees review research proposals. The declaration has been revised five more times (1983, 1989, 1996, 2000, and 2002), but the role of ethical review committees has remained central.

In the United States the first federal document requiring committee review was issued in 1953, but it applied only to research conducted at one National Institutes of Health (NIH) facility. In 1966 the U.S. Public Health Service required recipients of its grants to establish committees to review the ethical merits of proposed research involving human subjects. In the early 1970s the U.S. Food and Drug Administration (FDA) and the U.S. Department of Health, Education, and Welfare (DHEW) (forerunner to the Department of Health and Human Services [DHHS]) both promulgated regulations that required committee review of research conducted in institutions.

In 1974, one year after the unethical Tuskegee syphilis study was discontinued, the National Research Act established a statutory requirement for review of FDA- and DHEW-funded research by a committee to which it called an institutional review board (IRB National Research Act 1976). That act also created the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research (hereafter the Commission) to identify the basic ethical principles that should underlie the conduct of research involving human subjects and to develop guidelines to assure that that research is conducted in accordance with those principles. In 1978 the Commission added a requirement to ensure the equitable selection of research subjects.

In the next year the Commission issued its basic ethical principles and guidelines in the Belmont Report, which resulted from a four-day period of discussions held in February 1976 at the Smithsonian Institution's Belmont Conference Center. The three basic ethical principles identified in the report are justice, beneficence, and respect for persons. The Belmont Report did not make specific recommendations for administrative action by the Secretary of DHEW. Instead, the Commission recommended that the report be adopted in its entirety as a statement of the department's policy. The subsequent adoption of the Belmont Report represents a rare instance of the federal government formally accepting a moral theory as the foundation for legislation (Callahan 2003).

Each of the three principles outlined in the Belmont Report has engendered specific regulations for the practice of research involving human subjects. The principle of justice focuses on the question of who should receive the benefits and bear the burdens of research. It has given rise to both federal and NIH regulations that ensure that the selection of research subjects is equitable (that is, no discrimination against such groups as women, children, and minorities) and that research subjects not be coerced or manipulated in any way. The principle of beneficence entails producing the greatest good while minimizing harm. This principle is reflected in federal regulations that require risk-benefit assessments. The principle of respect for persons highlights researchers' responsibility to treat autonomous persons as such and to protect those with diminished autonomy. The first aspect of that principle is reflected in the regulation requiring informed consent from potential participants. The second is embodied in special regulations designed to protect vulnerable populations, including children, fetuses, and prisoners.

Institutionalization and Criticism

In 1981 the FDA and the U.S. Department of Health and Human Services issued regulations in reaction to the Belmont Report. In that year the FDA created noninstitutional review boards (NRBs) to accommodate the increased scope of the review process. In 1991 more than a dozen federal departments and agencies adopted the IRB process as the official Federal Policy for the Protection of Human Subjects, or "Common Rule." The Common Rule includes requirements for (1) assessing compliance; (2) informed consent; (3) IRB membership, function, operations, review of research, and record keeping; and (4) protection for vulnerable research subjects.

The IRB system has improved research practices by making researchers aware of ethical norms and exercising the power to withhold approval for substandard proposals. It is essential for the protection of human subjects and "is an important structural innovation in the social control of science" (Robertson 1979, p. 29). Nonetheless, the IRB system is "under strain" and "in need of reform," and "significant doubt exists regarding [its] capacity to meet its core objectives" (Federman et al. 2003, p. 5).

Central to this debate is whether the regulations unduly inhibit scientific output and progress. Before this question can be answered, however, more data about the impacts of IRBs must be collected. Frustrating this task is the absence of a national registry of all subjects participating in biomedical or social science research. Also, many people claim that the system is too strict in regard to less invasive social science projects and too lenient in regard to more risky research. A failure to balance risk-benefit ratios often hurts the credibility of the IRB system, and this weakens its capacities to achieve its goals (Levine 1986).

A third contentious issue is the decentralized structure of the system and the difficulty of applying general guidelines to specific research projects. Although the decentralized system allows IRBs to remain close to ongoing research, there may be too much local discretion and inadequate oversight of both researchers and individual IRBs. Without adequate assurance of compliance, research institutions may utilize IRBs to protect themselves and researchers rather than to protect subjects.

A fourth area of debate concerns the proper scope of IRB authority. An example from this set of issues is the question of whether IRBs should have the authority to approve or disapprove the scientific design of research protocols.

Assessment

IRBs have been the subject of intense scrutiny, and in 1979 the Hastings Center established a journal, *IRB: A Review of Human Subject Research,* devoted exclusively to issues raised by and within the system. As with any regulatory framework, the IRB system has had a host of administrative and structural challenges, yet it has proved to be resilient and adaptable. One example is the membership structure of IRBs. Early review committees were limited to immediate peer groups within the research community, but subsequent reforms have led to the requirements of gender diversity, the presence of at least one nonscientist, and the inclusion of at least one member not affiliated with the institution. Further reform efforts are improving the ethics education and certification requirements for IRB members.

The charge that the IRB system may impede scientific output is dubious in light of the rapid development of new drugs and other products and the fact that very few research proposals are rejected by IRBs. Daniel Callahan states that current scientific practice is motivated more and more by the imperative to do research and less and less by the quest for meaningful, life-enhancing knowledge and products (Callahan 2003).

RECs in other countries may offer lessons for reform of the U.S. IRB system. One example is the use of regional, national, and even international committees in other parts of the world. For example, in contrast to the U.S. commitment to local IRBs, many European RECs are regional (McNeill 1989). One issue that will always plague RECs and IRBs, however, is the difficulty of establishing objective criteria by which to evaluate their effectiveness. Most likely, assessment will remain a contested topic that is as much philosophical as it is empirical in nature.

INSTRUMENTATION

Instrumentation refers to the use or application of instruments or specialized technologies for observation, measurement, control, or production. In the last sense one even speaks of the instrumentation of a piece of music, meaning its adaptation to being produced or played by a particular set of musical instruments. Technologies in the form of instrumentation have also played a crucial role in the production of human knowledge science prehistory. In all these senses, instrumentation calls for general philosophical reflection, including ethical reflection.

Instrumentation, Ancient and Modern

The usual story about the origins of science cite ancient Greek philosophical speculations such as the prescient hypothesis of Democritus (460–370 B.C.E.) that there must be ultimate small bits of matter, which he termed "atoms," that constitute the most basic things of the world. Plato (428–347 B.C.E.), in opposition, developed an alternative hypothesis of a finite set of ideal geometrical forms into which the universe fits, a finite number of polyhedron shapes or Platonic solids at the base of things. Yet neither Democritus nor Plato produced any concrete, verifiable knowledge about the physical universe through their speculations. It was not until the later Hellenic period of Greek antiquity that heirs to the intellectual tradition initiated by Democritus and Plato began to produce lasting scientific knowledge of physical phenomena by developing measuring instrumentation.

When Robert Crease (2003) asked physicists to identify what ten experiments in the history of science were the most "beautiful," number seven turned out to be the measurement of the circumference of the Earth by Eratosthenes of Cyrene (c. 276–c. 194 B.C.E.). Combining a shrewd set of assumptions with a simple instrument, a gnomon or variation on a sundial, and mathematical measurements, Eratosthenes made a reasonable estimate of planetary size. Assuming a spherical Earth and a Sun at great distance, when the shadow of a gnomon was vertical at Syene he instrumentally measured its angle some 800 kilometers away at Alexandria; then using angular geometry he calculated the curvature necessary to account for such a difference, and extended this to reach an estimate of the circumference that remains respectable to the present day.

The vote that confirmed this as a "beautiful experiment" should come as no surprise, because it simultaneously validates popular belief in the genius of the Greeks, confirms human nostalgia for this particular history, and emphasizes the geometrical thinking that characterizes what later became modern science. But this experiment neither stands alone, nor is it even close to being the most ancient example of knowledge production embodied in technological instrumentation. A multicultural survey of almost any pre-historic set of peoples would show that instrumentation played a role in the knowledge of natural processes that in the early twenty-first century would be called *astronomy* or even *cosmology*. Virtually all larger cultures of the past were sky-watchers and developed often deep knowledge of celestial motions, solstices, seasons, moon cycles, eclipses, sometimes parallax, and other complex astronomical phenomena. These were recorded upon calendars, some of which were superior to calendars within Western traditions until very recent times. Moreover, although sometimes simple, most such observations were made through instrumental mediations. Indeed, *archeoastronomy*, the study of ancient astronomies, has led to the recognition that many of the stone circles of antiquity and prehistory had instrumental uses for establishing solstices, moon and sun cycles, and the like. Examples include Stonehenge, Mesoamerican equivalents, and even ancient North American sites in the Mississippian cultures. Calendar signs of moon cycles can be recognized on antler markings that go back to the last Ice Ages of more than ten millennia ago. Thus technologies have been incorporated into the production of what would now be called "scientific" knowledge from pre-history and within multiple cultures, all using instruments.

Within what some would term the Western master narrative, much is made of a seventeenth century "scientific revolution" as the turning point of early modern science. Yet it is possible to reframe this episode in the accelerated production of scientific knowledge as a second high point in the crucial development of instrumentation as well. Its predecessors were the Renaissance, itself a revival of ancient knowledge, much of it developed and conveyed by Islamic cultures that had perfected instruments and preserved ancient texts, thus creating an instrument-saturated and instrument-fascinated epoch.

Instrumental Perception

Instruments embody *measuring perceptions*. Those previously mentioned entail *visual* sightings, using some stable feature (the instrument) to make repeated observations. Of course the motivation and human contexts for performing such practices differed across cultures. Edmund Husserl (1970) recognized that a simple geometry arose out of the *lifeworld* practices of re-measuring agricultural fields after the annual floods of the Nile in Egypt. In other contexts, the annual renewal of kingships (as in ancient Sumeria) called for accurate dates and times. Islamic cultures needed accurate instruments to identify directions to Mecca, instruments such as the astrolabe and world maps with mathematical grids allowed such measurements, but later were also applied to navigation in the age of exploration. In the early 2000s, with space exploration such as that of the Cassini spacecraft orbiting Saturn, much more precise instrumentation is called for.

Measuring perceptions are not restricted to visual perceptions. Auditory perception has also been mediated through a variety of instruments. Listening tubes, later stethoscopes, amplify the capacity of auditory perception to determine interiors, including voids and shapes. More complex and later acoustic devices, including early sonar, remained auditory but gave way to a preference for visualization in scientific culture. Contemporary radar and sonar produces visual imagery on screens.

Further, various animal-analogues became technologically produced, one example being the development of thermal imaging. Thermal perception is common with reptiles, particularly snakes, which can even sense the shapes of prey through thermal awareness. Thermal awareness in the human case does have a moment in Western science. William Herschel (1792–1871), experimenting with a prism, detected warmth beyond the edge of the red end of the spectrum and correctly inferred the radiation that became known as *infrared*. Thermal imaging in military instruments has become highly sophisticated. But again, the tendency is to translate the thermal image into a visual one, such as obtains with certain types of night-vision instruments (other night vision instrumentation amplifies ambient light).

Tactile instrumentation plays especially important roles in medical practices. The setting of broken bones traditionally employed direct physical, bodily manipulations, and even with early instrumentation, the trained surgeon could "feel" what he was doing through the instrument. In dentistry, for example, the tools used to examine teeth reveal the cracks, soft areas, and cavities that are of dental interest. These perceptual experiences are *mediated* through the instruments, or the instruments are embodied by the practitioner. Contemporary instruments, however, often change previous practice. For example, laparoscopy, or even more extremely, distance surgery, entails practices that more resemble video games than earlier forms of surgery. Here miniscule tubes outfitted with imaging devices and connected to microsurgical tools are operated by the surgeon through skilled eye-hand coordination to perform the operation (sometimes called "Nintendo surgery").

Instrumental Hermeneutics

To this point, instrumentation has been described in relation to the way in which bodily-perceptual capacities are amplified or magnified. A different set of instrumentations, again going back to antiquity, relates more obviously to the human capacities for making and reading *inscriptions*, that is, instrumentation that engages interpretive or *hermeneutic* practices. Inscriptions found on reindeer antlers, dated as much as 30,000 years ago, have been found with twenty-eight cycle patterns, thus likely signifying a lunar cycle. Abstract hatch marks and other inscriptions have been found alongside the highly isomorphic or "realistic" depictions of animals in the cave regions of France and Spain have also been found (18,000 to 15,000 years ago). With early modernity, calculating machinery began to be employed, usually with counters inscribed with numbers or letters and driven by complex gearing. Dials, gauges, readable panels, all are forms of instrumentation engaging "reading" or hermeneutic skills.

The recognition of perceptual patterns, particularly as *images*, and the recognition of inscriptions in number-like (counting) or letter-like (reading) form, are both instrumental. The philosopher of science Peter Galison (1997) calls these the *image and logic* traditions that dominate late modern physics. But the data-to-image-to-data inversions are also a newly dominant form of instrumentation in contemporary science.

Technoscientific Instrumentation

Contemporary science is *technoscience*—that is, a science thoroughly embodied in its technologies and instruments. Only since the middle of the twentieth century has astronomy broken the bounds of both ancient "eyeball" and then early modern optical instrumentation. First, with the breakthrough provided by radio astronomy (associated with the development of radar), then through forms of spectroscopy that range from very short gamma-waves to very long radio-waves, has the limitation of optical wave frequencies been exceeded. In the early twenty-first century, slices of the microwave spectrum, such as x-ray imaging, can show pulsars in action, or map the dark emissions of the radio spectrum. In a parallel fashion, medical imaging, ranging from photography through the x-ray devices from 1895, to MRI and PET scans since the 1970s, perform the same function with respect to imaging the human body.

These processes are made possible through: (a) the data-image conversions possible through computer tomography and computer-aided technology (CAT) processes, (b) modeling and simulation techniques again employing computations, and (c) the algorithmic projection of imagery such as may be instanced in fractal patterning. Thus contemporary imaging may be either processed as data (numbers, counting, calculational) or as imaging (picture-like), and each form is transposable to the other. More important, however, is that the range of phenomena detectable through contemporary forms of sensing may not only be remote, but it exceeds all ordinary bodily perceivability, as has been analyzed at length by Ernesto Mayz Vallenilla (1990).

Yet, indirectly or in the form of new mediations, such instrumentation *translates* its results into countable/readable ones. Contemporary Mars and Saturn missions image the surface of Mars or the rings of Saturn, close up, and return these to the earth-bound observer for perceivable, close-up results. Or in the case of the Chandra X-ray source, images of the explosive nebulae through "false color" depictions can be perceptually grasped in human visual form. Instrumentation provides science with its own sensorium.

Popular Instrumentation

While the above overview of instrumentation has been focused upon various science practices, the same or similar types of instrumentation have more common manifestations. Some have said that the twenty-first century will be the century of one big and one little technology. The big technology is the home entertainment and work center, containing a high-definition screen for television, computing, and communicating, and a multimedia, multi-tasking station that incorporates the Internet, word processing, communications, and entertainment. The small, mobile technology that incorporates digital photography, mini-screen, for everything from cell phoning to email to reading barcodes for purchases is the other extreme of the big/little technofantasy. This is a not unrealistic extrapolation from extant technologies that are also social-cultural-economic instruments.

In one sense, these technologies are the same as those noted in science. Each transforms the texture of human experience. If contemporary astronomy produces near-distance with its images of multi-billion-year-old galaxies, so does electronic communication make near-distance of every electronically accessible spot on the globe. If the technologies are state-of-the-art audio-video ones, then any online place can produce conference interchanges. Or if lapsed time is used, as in videos, cinemas, or Internet technologies, then the result is even more like the galaxy example, and lapsed-time phenomena are made into present-time phenomena. Academic experience is illustrative: Many first time contacts are electronic, by email, or telephone. Arrangements for conferences, lectures, travels, are almost always arranged electronically—including air tickets. First person contact may or may not follow, and when it does, the follow-up reverts to the electronic instrumentation. Academic globalization is already electronically embodied and actual.

Ethics of Instrumentation

This communication-entertainment-information instrumentation also entails complex ethical-political, cultural-economic dimensions. Especially in the area of medical instrumentation, a primary question concerns safety. In the area of communications instrumentation more generally, a primary issue is privacy.

But more generally still one can examine the social justice of who has access to the whole communication-entertainment-information instrumentation complex. Is the globally interconnected world merely another elite? Is the trajectory centralist or decentralist? Many have noticed the extreme irony of the Internet—originally designed to be a fail-safe mode of communication for a military-university elite, it has become a diffuse, world-connecting instrument for everything from spam, electronic scams, and virtual romances to instant political dissemination of news and politics—and a new mode of campaign financing. No one knows if the outcome will be more democratic or more totalitarian. Yet by virtue of both the unpredictability and the indeterminacy (or, better, underdetermined) qualities produced by these new instruments, new opportunities have clearly come into being.

While prognosis is ambiguous, in part because all technologies display multiple possible developments and uses, the human-instrument relationship exhibits its own multiple dimensions. Many contemporary instruments are complex and characterized as "high tech" machines, implying the need for a highly skilled, technically informed set of users—technocrats and technically trained individuals. But although some subset of technically proficient persons is needed for the infrastructure of such technologies, a different set of skills is required for instrumental uses. For example, generational differences are often remarked upon in that young children quickly become computer literate whereas older people often display reluctance or "technophobias" regarding these technologies. Yet the child is not so much a technician as a skilled user. One need not know computer programming to play a video game, any more than one needs to know physics to ride a bicycle. Yet it is also interesting that the emergence of both many software developments and the location of much worldwide hacking and virus development is associated with countries once thought to be underdeveloped or under-technologized.

Instrumentation, whether in knowledge production, communication, commerce, entertainment, and much of the full range of human activity, is a means by which human perceptual and interpretive activity is embodied. As the above examples show, instrumentation may be very simple (a gnomon) or very complex (Internet), but the diffusion, adaptability, and spread of instrumentation technologies is more dependent upon the easy adaptability into human use practices—which then change—than the degree or type of complexity built into the technology. Historically, photography, radio, cinema, and television all were rapidly diffused, whereas modern agricultural and transportation technologies were not, or took much longer to be adapted. One possible reason for this may be the ease with which bodily-perceptual actions are quickly and without much technical training brought into play. To hear a radio and recognize a voice, to see a movie, to recognize a photograph is an almost immediate phenomenon. Contrarily, to transfer a set of agricultural practices or ship building skills is much more complex. Instrumentation, in the very contemporary sense, entails both kinds of complexity. The evening news, or the Cassini image of Saturn's rings, both involve large, complex infrastructures and global or even interplanetary connections—but both yield perceivable results as focal outcomes of instrumentation.

INTEGRITY

SEE *Research Integrity*.

INTELLECTUAL PROPERTY

The concept of *property* is as old as civilization. As people acquired possessions or inhabited land or shelters, they sought to secure these items for personal or collective use. Customs and rules evolved to define ownership and specify the rights and responsibilities that attached to ownership. In conjunction especially with developments in science and technology, property has taken on intellectual forms that embody ethical stances and have policy implications.

From Property to Intellectual Property

The definition of property evolved as society invented or identified new things that can be owned. *Property rights* began with the physical or concrete, such as land, and eventually expanded to include more intangible or abstract phenomena (Horwitz 1992). Interference with such rights shifted from a physical invasion to interference with a proprietary right or a decrease in market value.

Property rights are a series of formal and informal rules governing what owners are allowed to do with their property and the degree to which they can exclude others from its use. Such rights describe relations "not between an owner and a thing, but between the owner and other individuals in reference to things. Property rights reflect societal values of how wealth should be distributed and protected.

Intellectual property is abstract and refers to the products of human intellect such as inventions, literary works, music, and art. Many societies historically have not recognized ownership in intellectual property. Others have associated names with achievements but have not provided serious protection. As societies industrialized, they found a need to protect intellectual property, especially the valuable products of science and technology. Intellectual property rights (IPRs) describe a bundle of rights or privileges that, like other property rights, allow the owner to use, derive income from, and transfer the ownership of the property.

Intellectual Property Rights

IPRs define the rights and privileges attached to ownership of intellectual property. Such rights allow owners to exercise a temporary monopoly over the use of their creations; they have exclusive rights, for a limited time, to decide who may use a product or work and under what conditions. Such rights define ownership and specify the degree to which inventors and creators may profit from their work, the access others may have to the works themselves or to information about them, and how others may use or improve upon existing works.

IPRs involve issues of wealth distribution, incentives for innovation and creativity, access to information, and basic human rights. Ethical issues attach to questions of what should be publicly or privately owned, how ownership is established, how much and how long the owner can control the property, and whether public policy should create exceptions to intellectual property rules to serve social interests.

IPRs encourage innovation by protecting new work from appropriation by others and allows people and institutions to profit from their work. Such rights promote the communication of information; as long as the right is in place, information can be published without fear of loss. IPRs also define public rights by indicating when private protections expire.

Rationales for IPRs fall into two categories, "instrumental rationales, which view intellectual property in terms of its benefits to society as a whole, and natural rights which stresses the inherent authority of innovators to control works they have created" (Schecter and Thomas 2003, p. 7). *Instrumental* rationales focus on the need for protection to promote societal goals, such as economic growth or technological innovation. *Natural rights* arguments, grounded in the philosophy of John Locke, assert that people are entitled to protection for the products of their minds, regardless of whether the protections serve other societal goals. The two rationales may lead to different policy decisions about the appropriate type and level of intellectual property protection.

Intellectual property protection is regarded as a basic human right. According to Article 27 of the Universal Declaration of Human Rights (1948), "Everyone has the right to the protection of the moral and material interests resulting from any scientific, literary or artistic production of which he is the author." The reach of the right differs across nations, with industrial nations generally providing higher levels of protection than developing nations.

Constructing an IPRs system requires the balancing of often conflicting societal values and needs, such as the need to promote innovation; concerns for equitable distributions of wealth, information, and other benefits; and the desire to allow authors or inventors to profit from the fruits of their labor and imagination. Increasing protection in one area often detracts from another.

Types of Intellectual Property Law

The international system recognizes two types of intellectual property: industrial property, including but not limited to inventions, trade secrets, and trademarks; and copyright. Systems of IPRs laws differ across nations but often include the following.

Copyrights protect works of creativity and authorship such as literary, musical, and visual art, as well as audio recordings, choreography, and computer software. Laws specifying such protection must consider issues such as fair balance between private and public use, the need for public access to information, when protection should begin and how it can be triggered, and how to enforce protections.

Patents protect innovative products and processes by allowing the patent holder to control use of the invention for a limited period of time. In exchange for patent protection, inventors generally must agree to disclose information about their inventions to the public. Patents are generally restricted to inventions, including both products and processes, although the restrictions on patents have narrowed in recent years. Products of nature have generally not been patentable but improvements in biotechnology have challenged definitions of what is natural.

Trademarks identify the origin of products or services and are used to promote them. Trademark protection prevents others from using a trademark to promote a product or service of a different origin. Such protection prevents the appropriation of the competitive advantage trademarks are intended to provide.

Trade secret law protects proprietary business information from misappropriation. Some information, such as an industrial process, might be eligible for protection either under patent law or trade secret law but not both. Trade secrets must be protected from disclosure, while the patent process generally requires making information public.

Science, Technology, and Intellectual Property

Science and technology provide many societal benefits, such as the enhancement of economic growth or quality of life. They also can produce negative, unintended consequences. Most societies promote science and technology, but this can be costly. Establishment of IPRs that protect new works and give innovators the right to profit from their creations provides incentives for expensive innovation without the need for direct government subsidies (Posner 2004). At the same time, IPRs may maintain or aggravate wealth inequities.

Rights have little meaning unless they can be enforced and modern technology has made IPRs enforcement increasingly difficult. Photocopiers make it possible for anyone with access to a machine to reproduce works entitled to copyright protection and the Internet allows anyone to make literary or musical works available to the world.

Science and technology challenge intellectual property systems, particularly patent laws. New fields such as information technology and genetic engineering force courts to decide how to apply laws made before such technologies were contemplated. As knowledge itself becomes more valuable, people and institutions seek additional protection for control of the knowledge and its profits. At the same time, society has an increasing need for access to some kinds of knowledge and protection from the use of others.

Abstract ideas cannot be patented but their applications can qualify for patent protection. For example, "Einstein could not patent his celebrated law that $E = MC^2$; nor could Newton have patented the law of gravity. Such discoveries are 'manifestations of Nature, free to all men and reserved exclusively to none.'" (Diamond v. Chakrabarty, p. 309, quoting Funk Brothers Seed Co. v. Kalo Inoculant Co., 333 U.S. 127, 130, 1948). General ideas remain in the public domain but their applications may be privatized through the patenting process.

Biotechnology, perhaps more than any other field, has challenged courts and lawmakers to reconsider intellectual property laws. In 1972 Ananda Chakrabarty, a microbiologist, sought a U.S. patent for a genetically engineered bacterium. The U.S. Patent Office denied the application because bacteria are products of nature, and living things cannot be patented under U.S. law. The case was appealed and eventually reached the U.S. Supreme Court. The Court restated the principle that natural phenomena cannot be patented, but found that Chakrabarty's bacterium was "a product of human ingenuity," and therefore was patentable under U.S. law.

So many biotechnology patents have been issued for such small innovations that some fear the creation of a *tragedy of the anti-commons* in which new innovations involve so many existing patents that innovation is discouraged. At least one study has found the anti-commons is not yet a significant deterrent to innovation, but that the situation should be monitored.

IPRs can be attached to writings or products regarded as dangerous or immoral, and IPRs tend to legitimize such works by implying social approval. Societies must decide whether to provide protection for harmful or otherwise objectionable work. New technologies, particularly those that create or replicate life, often trigger debate over whether the work should be done at all, much less be protected by law. IPRs also establish ownership of particular innovations, which may help to determine liability if a product causes harm. This raises questions of whether innovators should be held responsible for their products, particularly when the products are used in unintended ways.

Public funding for science and technology further complicate intellectual property issues. Who should benefit from works developed under public funding, the creator or the public? What balance of public/private benefits best serves societal goals?

Academics build their reputations by producing intellectual works. They seek recognition for their accomplishments, control over any economic benefits, and protection against plagiarism. IPRs promote release of information to the public by assuring the author of protection for the work, even after it is made public. IPRs protect authors from possible appropriation of ideas by others, including peer reviewers, before the work has actually been published.

Ownership can be a major IPRs issue. Who owns the product of collaborative work? At what point does a contribution by a supervisor, graduate student, or coworker deserve coauthorship? When the creator works for a corporation or a university, does ownership lie with the creator or the institution? What about funding agencies? In many cases, ownership or authorship is established by disciplinary customs or by agreements among the parties (Kennedy 1997).

Plagiarism is professionally unacceptable and sometimes illegal, but timing is critical to determining whether plagiarism has occurred. According to Donald Kennedy, "To take someone else's idea and use it before it has been placed in the public domain is a form of theft . . . [t]o make further use of someone else's idea after it has been published is scholarship" (1997, p. 212). Of course attribution is critical even, or especially, in scholarship, whether or not a work is protected.

International Intellectual Property Rights

The absence of an international sovereign makes a global IPRs system problematic. Every nation has different intellectual property laws, making cooperation difficult, although many international IPRs agreements have been developed. Which nation's standards should apply? Most international agreements take a national approach in which a country agrees to provide foreign innovators with the same protection provided to its domestic citizens. Creators of intellectual property generally must seek protection separately in each jurisdiction, a cumbersome process.

The United Nations World Intellectual Property Organisation (WIPO) provides support for the international intellectual property system. Its mission is "to promote through international cooperation the creation, dissemination, use and protection of works of the human mind for the economic, cultural and social progress of all mankind."

Globalization has increased the need for more international IPRs coordination. Multinational organizations seek consistent laws across borders and inventors want universal protection for their inventions. The World Trade Organization Agreement on Trade-Related Aspects of Intellectual Property Rights (TRIPS Agreement) attempts to provide a more standard IPRs system and sets minimum protection that must be provided by all member states.

Ethical issues become particularly important at the international level (Rischard 2002). Some fear that increasing IPRs protection will increase inequities between the developed and the developing world. Others are concerned that IPRs deny access to products desperately needed by the poor or powerless. Still others believe adequate IPRs standards are critical to promoting technology transfer and foreign investment.

IPRs can deny access to essential products and information to those who need them most, particularly in developing countries. Drug research and development is extremely expensive, and pharmaceutical countries price drugs to recoup expenses and make a profit. No one else is allowed to manufacture drugs protected under patents. Those who need the drugs often have little money. Is it fair to allow people to die because they cannot afford drugs that could prolong their lives?

The TRIPS Agreement allows for compulsory licenses, an exception to IPRs in special cases such as emergencies, that give developing countries access to essential drugs for major health problems such as HIV/AIDS or malaria. Such policies may have a boomerang effect; pharmaceutical companies may be less likely to invest in research to develop drugs for conditions found primarily in poor countries if there is no profit to be made. The answer to the drug access problem may be better addressed by turning to solutions unrelated to intellectual property rights, such as foreign aid. Some pharmaceutical companies have made drugs available at drastically reduced rates to those who cannot afford them.

Inspiration for new products often comes from local or traditional knowledge. Who should benefit when a drug company develops a new drug based on knowledge about the properties of a plant gained from an indigenous tribe in a remote region? Is the company that developed a commercial drug entitled to all the profits or should it share revenues with the people who supplied the information or with the country from which the plants are harvested?

Conclusion

Consensus exists over the need for IPRs but not over the content of such rights. Countries that produce more science and technology and other intellectual property support more protection than other nations. Globalization requires more consistency in IPRs than has traditionally been available. IPRs help to promote innovation and the communication of information, but questions remain about the appropriate balance between public and private rights, the nature of ownership, and the equitable provision of access to products and information. Debates continue over the types of intellectual property that should be protected by law. New technologies intensify such debates, particularly technologies that create new or duplicate old life forms.

INTERDISCIPLINARITY

Any attempt to consider relations among science, technology, and ethics is by definition interdisciplinary. This entry distinguishes among basic approaches to terminology, reflects on the intersection of interdisciplinarity and ethics, and assesses future prospects. Because it provides an existing model, with both strengths and weaknesses, for examining science, technology, and ethics interactions, references will often be made to the existing interdisciplinary field of science, technology, and society (STS) studies.

Forms of Interdisciplinarity

Interdisciplinarity has both broad and more restricted meanings. In the broad sense it includes a number of different forms, one of which is interdisciplinarity in a more narrow sense. There are three forms of interdisciplinarity in the broad sense that are important to distinguish, and that provide a framework for discussions of types of interdisciplinary interactions.

Multidisciplinarity juxtaposes separate disciplinary approaches around a common interest, adding breadth of knowledge and approaches. But the disciplines continue to speak as separate voices in encyclopedic alignment. Underlying assumptions are not examined, and the status quo remains intact.

The major disciplines in STS multidisciplinarity have traditionally been history, philosophy, and sociology of science (Cozzens 2001). Studies of science in literature and scientific literature also received attention, and anthropology became prominent in the 1990s. Although disciplinary identities remain strong, there are specialized interdisciplinary bridges, such as alliances of economists of scientific research and technological development with historians and sociologists of technology interested in technological innovations. Gary Bowden (1995) distinguishes three methods of explanation in STS: topic-, issue-, and combined-focus. Topic-focus is the most common, using methods and techniques of one discipline to study an aspect of science or technology. The result is an amalgamation of contextualist approaches. Both Bowden and Susan Cozzens characterize STS as a multidisciplinary array of activities.

Interdisciplinarity integrates separate data, methods, tools, concepts, theories, and perspectives in order to answer a question, solve a problem, or address a topic that is too broad or complex to be dealt with by one discipline (Klein and Newell 1997). In education, content is revised and the curriculum is restructured around a theme, problem, or issue. In research, the task at hand becomes the primary focus, and in interdisciplinary fields a new body of knowledge emerges.

Several added distinctions appear. *Instrumental, strategic, pragmatic,* or *opportunistic* forms tend to focus on economic and technological problems. During the 1980s, interdisciplinarity gained heightened visibility in science-based areas of intense economic competition such as computers, biotechnology, and manufacturing. In this instance, interdisciplinarity served the political economy of the market and national needs.

Critical and *reflexive* interdisciplinarities differ. They interrogate the existing structure of knowledge and education, raising questions of value and purpose that are silent in instrumentalist forms (Weingart 2001, Klein 2001). Bowden also aligns interdisciplinarity with *combined focus methods,* marked by a common culture of investigation and a coherently integrated package of analytic resources and, often, new concepts. Insofar as STS becomes interdisciplinary, Cozzens adds, it ceases to be anchored in constituent disciplines.

Transdisciplinarity was initially defined as an overarching synthesis that transcends the narrow scope of disciplinary worldviews. General systems theory, structuralism, Marxism, the policy sciences, feminism, and complexity theory are leading examples. Likewise, sustainability and science, technology, and society reorganize and further develop knowledge and education around new synthetic frameworks. The term has also been a descriptor for broad fields (for example area studies, cultural studies), and synoptic disciplines (philosophy, geography). Recently in humanities it has been aligned with new critical paradigms, and it is a label on web sites in areas as varied as education, health care, and engineering sciences. In the 1980s and 1990s, three new connotations appeared: a new structure of unity informed by the worldview of complexity in science (Nicolescu 1996); a new mode of knowledge production that fosters synthetic reconfiguration and recontextualization by drawing on expertise from a wide range of organizations; and collaborative partnerships for sustainability that cross the boundaries of social sectors as well (Klein et al. 2001). Bowden also associates transdisciplinarity in STS with analytic *issue-focused methods* that emphasize a particular theoretical issue. They are not limited to the particulars of a specific substantive topic. The problem of reflexivity, for instance, is not unique to social studies of science and technology. Postmodernism also appears across a wide range of subjects.

Relation to Science, Technology, and Ethics

These basic distinctions are apparent in science, technology, and ethics (STE). In multidisciplinary STE, science, engineering, and ethics all retain their distinctive superdisciplinary features. Science is a superdiscipline that includes physics, chemistry, biology, geology, and other kindred disciplines. Comparably, engineering encompasses mechanical, chemical, electrical, and other fields of engineering. Ethics, in turn, encompasses distinctive forms that range from consequentialism and deontologism to virtue ethics. Applied ethics in its first incarnation took ethics as is and put it to work in and for science and engineering. In interdisciplinary STE, new fields emerged that combined a science and ethics. Applied ethics in its second incarnation appeared as fields of computer ethics, engineering ethics, environmental ethics, bioethics, and so on. In an instance of transdisciplinary STE, some philosophers also attempted to create a general ethics of technology that transcends any one type of science or engineering while subsuming other forms of ethics. Examples include Hans Jonas's argument in *The Imperative of Responsibility* for an overarching ethical obligation to protect the future of human and all life. Other examples include proposals for sustainability as a moral obligation and the precautionary principle as a general guideline for scientific research and technological innovation.

Interdisciplinarity intersects with ethics in science and technology in many ways. During the 1960s and 1970s, a renewal of ethics occurred in philosophy, driven by new problems of justice, fairness, and values in professional practice. In the ensuing decades, new categories of moral thought and action emerged, the moral and ethical dimensions of every field began to be explored and, in general education, related issues were incorporated into disciplinary and interdisciplinary core courses. As David Edge (1995) observes, it is not accidental that new critical approaches evolved hand in hand with new developments in training technical experts. Such developments were part of a broad shift from positivist models and programmed research on applied problems toward critical scrutiny of their implications. The distinction is not absolute though. Research on problems of the environment and health, for instance, often combines programmed problem solving with critique of current practices and institutional structures.

The interdisciplinary character of STS also fostered greater attention to implications and consequences. Before the 1980s, Bowden recounts, social science and humanities research in the field was primarily historical, philosophical, and, to a lesser degree, sociological. Science and technology were treated as autonomous entities separate from social context. Philosophers examined the logic of the scientific method, historians documented the evolution of ideas and technological artifacts, and sociologists looked at the institutional structure and internal patterns of science. In the mid 1960s, especially among historians of technology and some in engineering education, notions of autonomous technology and the neutrality of technology were challenged by new understandings of technology as a complex enterprise in specific contexts that are shaped by, and in turn shape, human values.

This development generated a sizable literature on ethics and values in relation to technology. The new discourse of problem understanding and political choice placed greater emphasis on social impacts and policy as well. In the mid-1970s, developments in philosophy and history of science opened up the content of scientific knowledge to sociological scrutiny, fostering empirical examination of social bases of scientific knowledge and challenging the authority and epistemological privileging of science. In the late 1980s, a turn toward technology occurred. The first two developments involved conceptual reformulations that contextualized science and technology and the manner in which context affects creation of scientific knowledge and the impact of science and technology on society.

Analogously multidisciplinarity, science, engineering, and ethics retain their distinctive features. *Applied* ethics takes ethics as it is and puts it to work in and for science and engineering. In science-technology-ethics (STE) interdisciplinarity, new fields that combine a science and ethics emerge, producing areas such as computer ethics, engineering ethics, environmental ethics, and bioethics. In STE transdisciplinarity, some philosophers and ethicists have created a general ethics of technology that transcends any one type of science or engineering and subsumes other forms of ethics.

Assessment

Interdisciplinarity and STS are both conflicted discourses, marked by unresolved questions and differing positions. Disagreements center on key issues and problems, the role of disciplines, and priorities of integration versus critique. Moreover, the full range of options exists simultaneously, from multidisciplinary juxtapositions to interdisciplinary integrations to transdisciplinary frameworks. Both interdisciplinarity and STS are also maturing movements. Knowledge is widely considered to be increasingly interdisciplinary and, Bowden observes, the scholarly endeavor of STS has come of age. Nonetheless the widely touted interdisciplinary transformation of the university has not occurred. Multidisciplinary approaches are more common, institutional impediments retain their force, and Cozzens concludes, the integrated whole of STS thought is more of an ideal than a pervasive reality. The practice of STS often remains discipline-bound and removed from the world of practice. Edge concurs, asking whether "the heady sense of interdisciplinary adventure" and "seductive combination of academic priority and practice urgency" has disappeared (Edge 1995, p. 3).

There is also a constant tension between the particular and the general. Interdisciplinary STE is often criticized for trying to be too general: for instance in comments that "there is no such thing as 'technology' but only 'technologies'" and "all general principles are vacuous." At the same time, applied ethics fields such as computer ethics and biomedical ethics are criticized for reinventing the wheel: for instance in talk about risk analysis or informed consent and in their failure to synergize achievements from different applications.

In existence only since the early-1970s, STS has attained an expanding presence and established a platform for greater interdisciplinarity. An identifiable group of scholars and teachers has formal affiliations with the field, and an infrastructure for communication is in place. Cozzens highlights, in particular, the generation emerging from interdisciplinary STS programs in the early-twenty-first century. They are less bound to disciplinary identities than their professors and more prepared to move in the direction of *postdisciplinary* research that goes beyond narrowly circumscribed conceptual categories and analytical practices while often critiquing underlying premises of disciplinarity as well. Yet much work remains. The gains that have been made must be secured and the field must continue to develop on its own terms, not as the cumulative sum of its disciplinary parts. Doing so will require diligence to insure sufficient economic and symbolic capital; inclusion in funding categories of research agencies; an adequate number and scale of programs; full-time appointments in STS programs and departments; secure locations in organizational hierarchies; and autonomy in decisions about curriculum, budget, and staffing.

In both STS and STE, there is constant tension between the particular and the general. Both, moreover, raise the same question that all interdisciplinary fields raise. Where do they *fit?* The problem of fit, Lynton Caldwell (1983) advises from the experience of environmental studies, prejudges the epistemological problem at stake. Interdisciplinary categories arose because of a perceived misfit among need, experience, information, and the prevailing structure of knowledge. If the structure must be changed to accommodate the new field, perhaps the structure itself is part of the problem.

INTERNATIONAL AFFAIRS

SEE *International Relations*.

INTERNATIONAL COMMISSION ON RADIOLOGICAL PROTECTION

The International Commission on Radiological Protection (ICRP) is a non-governmental organization that issues recommendations for radiation protection from ionizing radiation. With Wilhelm Roentgen's 1895 discovery of x-rays that, unlike the rays of visible light or of radio transmissions, tend to break down or ionize atomic structures, a new phenomenon was added to human experience. As this phenomenon became increasingly utilized especially in medical work, its dangers were likewise progressively recognized. The recommendations issued by the ICRP are used by many national and international radiation protection agencies to deal with such dangers and have a profound influence on radiation protection all over the world.

History and Activities

The ICRP was established in 1928 by the Second International Congress of Radiology, in order to address health and safety issues concerning radiation used for medical purposes. Until 1950 it was called the International X-ray and Radium Protection Committee. The new name reflected a widened scope to include all aspects of protection against ionizing radiation.

The ICRP functions as an advisory body to national and international agencies in the field of radiation protection. According to its constitution, the ICRP shall provide recommendations and guidance on all aspects of radiation protection and consider the fundamental principles and quantitative bases for radiation protection, while leaving to national bodies the responsibility of formulating specific advice, codes of practice, or regulations best suited for each country. No country or international organization is obliged to follow the recommendations of the ICRP. International organizations that use the ICRP recommendations include the International Atomic Energy Agency (IAEA), the World Health Organization (WHO), the International Labor Organization (ILO), and the Nuclear Energy Agency of the Organization for Economic Cooperation and Development (OECD).

The ICRP is registered as an independent charity in the United Kingdom and is mainly financed by voluntary contributions from international and national bodies with an interest in radiation protection. The organization consists of the Main Commission and five standing committees. The Main Commission has twelve members and a chair. The Main Commission elects itself, and three to five members of the Main Commission are replaced after each four-year period. According to the constitution of the ICRP, members shall be chosen on the basis of their recognized activity within professional fields of relevance to radiation protection. The standing committees are chaired by members of the Main Commission and consist of fifteen to twenty experts (mostly biologists, physicians, and physicists) appointed by the Main Commission. The committees are Committee 1 (radiation effects), Committee 2 (doses from radiation exposure), Committee 3 (protection in medicine), Committee 4 (application of ICRP recommendations), and Committee 5 (protection of non-human organisms). In addition to these committees, the ICRP also appoints task groups comprised of radiation protection experts outside the ICRP. At any given time, about 100 scientists are involved in ICRP work.

The ICRP publishes reports containing guidelines on a variety of topics related to radiation protection. Examples of such reports include: "Radiological Protection in Biomedical Research" ICRP Publication 62, 1993), "Radiological Protection Policy for the Disposal of Radioactive Waste" (ICRP Publication 77, 1998) and "Principles for Intervention for the Protection of the Public in a Radiological Emergency" (ICRP Publication 63, 1993). The *ICRP Recommendations* are special reports containing fundamental principles for radiation protection advocated by the ICRP. The main objective of these recommendations is "to provide an appropriate standard of protection for man without unduly limiting the beneficial practices giving rise to radiation exposure" (ICRP 1991, p. 3). The ICRP recognizes that this objective cannot be achieved solely on the basis of scientific data, but must also include value judgments and ethical considerations.

ICRP Recommendations

The basic principles of the ICRP recommendations for radiation protection have evolved considerably over time. In 1928 the first ICRP report on health effects concerned primarily damage to the skin and the destruction of blood forming tissues, that is, injuries caused by massive cell death following exposure to high levels of ionizing radiation. There is a *threshold dose* for these effects, which means that they occur only when sufficient numbers of cells are destroyed. The first ICRP report aimed to prevent these kinds of effects by providing recommendations on working practices and guidelines for use, but due to problems of defining a relevant dose measure, a dose limit was not included. In a subsequent 1934 report, however, the ICRP did recommend a dose limit, called a *tolerable dose,* which added a margin of safety to the threshold dose.

The system of tolerable doses was retained into the 1950s when a new appreciation of the risks from ionizing radiation altered the foundation for radiation protection. Previously it had been assumed that in the absence of no immediate negative health effects below a threshold level, there were also no long-term effects. But evidence had accumulated that ionizing radiation could also cause cancer and hereditary defects. Such longer-term results are called *stochastic effects* and are caused by modification, rather than the destruction, of cells, and occur with a certain probability, which was taken to be proportional to the dose. It was argued likely that no threshold existed for these kinds of effects. This meant that every dose implied a risk—that there was no completely safe level for ionizing radiation. Ever since, radiation protection has had to deal with the implications.

In 1950 the ICRP recognized the potential for cancer and hereditary effects from ionizing radiation, and recommended new, lower dose limits, called maximum *permissible doses.* But if there is no wholly safe dose, the concept of permissible dose becomes problematic. What is permissible or not? The ICRP based its judgments on a comparison with other hazards in life. The ICRP also recommended that exposure to ionizing radiation should be reduced to the lowest possible level, meaning that doses should be kept as low as practicable and that any unnecessary exposure should be avoided. Eventually this evolved into the principle that doses should be kept *as low as reasonably achievable* (ALARA), which became known as the *ALARA-principle.*

The next major step was taken in 1977 when ICRP introduced a protection system consisting of three BASIC principles. No practice involving exposure to radiation should be adopted unless it produces a positive net benefit (the *justification principle*). All exposures should be kept as low as reasonably achievable, economic and social factors being taken into account (the *optimization* or ALARA-principle). Doses to individuals should not exceed specified dose-limits (the *dose-limitation principle*). The emphasis was no longer on permissible doses, but on the requirement that doses should be kept as low as reasonably achievable (optimization). Mere compliance with dose limits was not sufficient—exposure must also be justified and optimized. The ICRP recommended that the optimization procedure should operate on the *collective dose,* defined as the product of the number of exposed individuals and their average dose.

Subsequent recommendations were adopted in 1990 (ICRP 1991) retaining the overall structure from the recommendations of 1977. The emphasis was still on the optimization principle, but in order to limit inequities that could follow from application of its three principles, the ICRP introduced a restriction on the optimization process. The reason for this was to prevent situations where the optimization principle would advocate a protection alternative (that is, the lowest collective dose) where, although all individuals would be below the dose limits, a few individuals would also be exposed to much higher doses than the rest of the exposed population. This is obviously a problem if there is no threshold for the risk from exposure to ionizing radiation. To avoid this the ICRP recommended additional individual limits, usually much lower than the old dose limits, called *dose constraints.* The concept of dose limits was retained but the definition was changed in order to define a boundary above which individual risk was considered unacceptable. Another difference was that the dose constraints were *source-related,* while the dose limits included exposure from all relevant sources.

The recommendations from the ICRP have been updated at intervals of ten to fifteen years, and the ICRP plans to deliver the next general recommendations in 2005. The proposed recommendations (ICRP 2003) involve further emphasis on the concept of dose constraints. The new system is based on the idea that constraints should be applied for each individual. The starting point for selecting the level of these constraints should, according to the proposal, be the *concern that can reasonably be felt* about the annual dose from natural sources. After applying the dose constraints there will still be a requirement to reduce doses even further. The proposal also suggests less emphasis than previously on the application of the collective dose and that individual doses below a fraction of the average annual dose from natural sources should be excluded from the system of protection.

The proposal for the new recommendations has been publicly discussed by the ICRP since 1999. Critics claim that the 1990 recommendations work well and that no substantial change to the basic system is needed. It has also been argued that the previous application of the collective dose ought to be retained, and that the introduction of a general exclusion level for very small doses has not been satisfactory justified.

INTERNATIONAL COUNCIL FOR SCIENCE

The International Council for Science, still known by the initials of its former name, International Council of Scientific Unions or ICSU, is a nongovernmental organization (NGO) that includes more than one hundred national scientific bodies and close to thirty international scientific unions. The ICSU mission is to:

- Identify and address major issues of importance to science and society.
- Facilitate interaction among scientists across all disciplines and from all countries.
- Promote the participation of all scientists—regardless of race, citizenship, language, political stance, or gender—in the international scientific endeavor.
- Provide independent, authoritative advice to stimulate constructive dialogue between the scientific community and governments, civil society, and the private sector.

The main philosophy of the organization is perhaps best reflected in section 5 of its statutes, where the principle of the universality of science is expressed:

> This principle entails freedom of association and expression, access to data and information, and freedom of communication and movement in connection with international scientific activities, without any discrimination on the basis of such factors as citizenship, religion, creed, political stance, ethnic origin, race, colour, language, age or sex. ICSU shall recognize and respect the independence of the internal science policies of its National Scientific Members. ICSU shall not permit any of its activities to be disturbed by statements or actions of a political nature.

History

ICSU was founded in Brussels in 1931, originally under the name International Council of Scientific Unions. It emerged as an extension of two earlier bodies, the International Association of Academies (1899–1914) and the International Research Council (1919–1931). The main change brought about through the founding of ICSU was the dual membership: Both national scientific bodies (initially forty) and international scientific unions (initially eight) make up the membership, and the unions received a more prominent and independent role.

World War II marked an interruption in ICSU activities. But after the war ICSU was the first NGO with which the newly founded United Nations Educational, Scientific and Cultural Organization (UNESCO) signed an agreement.

In light of wartime experiences and the new political prominence of science and technology, Joseph Needham (1900–1995), then Head of the Natural Sciences Division of the Preparatory Commission of UNESCO, addressed the ICSU Committee on Science and Its Social Relations, outlining the prospects of postwar scientific cooperation. This was discussed during ICSU's London General Assembly of 1946, and the first agreement between UNESCO and a non-governmental organization, i.e. ICSU, was signed shortly thereafter. Topics discussed included a plea for the elimination of military secrecy, a hope for increased international collaboration in applied science especially with regard to atomic power, a request for scientific "frankness, openness and integrity" so as to promote the common good, and advancement of the public understanding of science.

During the ensuing cold war period a new challenge emerged within the ICSU structure, namely the free circulation of scientists across national borders. Prewar ICSU statements already expressed the universality of science. For instance, in 1934, ICSU president George Ellery Hale proclaimed: "We welcome to our meetings the man of science in all countries and we appreciate the opportunity to join with them in the pursuit of our common object" (Greenaway 1996, p. 93). With the creation of the North Atlantic Treaty Organization (NATO) in 1949, however, realities became very different. For instance, East German scientists were refused visas for entry into NATO countries thus effectively blocking their participation in scientific meetings in these countries.

In 1963 ICSU formed the Standing Committee on the Free Circulation of Scientists (SCFCS), which in 1993 was renamed the Standing Committee on Freedom in the Conduct of Science and given an expanded mandate. The work of this committee became increasingly important as political tensions increased. The SCFCS worked primarily by correspondence contact with key persons in countries that either prevented entry or exit of individual scientists. The balance between safeguarding free scientific communication and keeping a politically neutral position was always a delicate one, and necessitated low-key action. By and large, the SCFCS managed to fill its watchdog role. In 1976 the SCFCS published its first edition of the "blue book," which is currently entitled "Universality of Science" and contains the principles pertaining to the rights of scientists and their freedom of movement.

Structure

The main decision-making body within ICSU is the General Assembly, which convenes every three years at various locations around the world upon invitation from a host country. Currently the General Assembly is assisted by an Executive Board, which consists of six executive officers and eight ordinary members, four from the unions and four from national members. The Executive Board is assisted by a permanent Secretariat, headed by an executive director.

Since 1972 the ICSU Secretariat has been based in Paris with French government support. A small structure was built up under the leadership of Julia Marton-Lefèvre (1978–1997) and has become a cornerstone in ICSU activities. Since 2002 ICSU has been headed by Thomas Rosswall as executive director. Compared to other international bodies or to its national members, the ICSU Secretariat of twelve people is strikingly small in size.

Activities

ICSU activities are varied and have changed character over the years. Some of its activities serve as examples of international scientific cooperation, despite political situations that at times seem to render them impossible. One such example was the International Geophysical Year (IGY), 1957–1958, which involved sixty-seven nations. The IGY established the principle that "expeditions and explorations in the remoter parts of the earth are now geophysical in intention" (Greenaway 1996, p. 156). An International Polar Year is planned for 2007–2008.

ICSU also engaged in other areas of common concern for international science. ICSU in 1966 set up its interdisciplinary Committee on Data for Science and Technology (CODATA) aimed at making scientific data of various kinds accessible to scientists beyond their origin. In 1969 the Scientific Committee on Problems of the Environment (SCOPE) was established to plan and facilitate, among other things, a global monitoring network and a training program for future environmental managers. SCOPE contributed to the Untied Nations (UN) Conference on the Human Environment in Stockholm, Sweden, in 1972 and the International Geosphere-Biosphere Programme (IGBP), which was initiated in 1986.

Such activities strengthened the ICSU role in the area of global environment and development, and led to close collaboration with various UN bodies. The International Conference on an Agenda of Science for Environment and Development into the 21st Century (ASCEND 21), held in Vienna in 1991, contributed to "Agenda 21: Science for Sustainable Development," the major document to emerge from the United Nations Conference on Environment and Development in Rio de Janeiro in 1992 (commonly called the Earth Summit). When the follow-up World Summit on Sustainable Development was held in Johannesburg in 2002, ICSU was again among the key NGOs addressing scientific issues.

ICSU now sponsors three global observing systems (GOS)—the Global Ocean Observing System, the Global Climate Observing System, and the Global Terrestrial Observing System—in collaboration with partner organizations such as UNESCO, the World Meteorological Organization, the Food and Agriculture Organization of the United Nations, and the United Nations Environment Programme. The goal of the GOS is improved monitoring of the global Earth system.

ICSU links with the social sciences and engineering remain relatively weak. Of the member unions in ICSU, four can be counted as belonging to the social sciences, among them the International Union of the History and Philosophy of Science (IUHPS). Already during the 1980s and early 1990s it was recognized that the global problems facing humankind required cooperative efforts from scientists, social scientists, and engineers. Efforts were made to bring these various fields together through closer cooperation between ICSU and the International Social Science Council (ISCC). In 1996, then, ICSU, ISCC, and other organizations became cosponsors of the International Human Dimensions Programme on Global Environmental Change (IHDP), originally established in 1990. In the early 2000s the IHDP, IGBP, and related programs were brought together under the banner of the Earth System Science Partnership (ESSP) to promote international and interdisciplinary research within four focal areas: carbon, food, water, and human health. It remains to be seen how the challenge of multi- and interdisciplinarity across the various fields will be met in practice.

Standing Committee on Responsibility and Ethics of Science (SCRES)

At the end of the 1980s and the beginning of the 1990s under the presidency of M. G. K. Menon the ICSU Executive Board took up issues of the ethics of science. Two observations spurred this discussion. First, previous views that simply identified progress in science with social progress were more and more difficult to uphold. In the light of environmental and developmental issues, science was seen as not only part of the solution but to some extent as part of the problem. Second, scientific activities need to be guided by a sense of social responsibility. While ICSU already had established a mechanism to deal with the rights (freedom) of scientists, it lacked a platform to deal effectively with scientific responsibilities.

Following these discussions IUHPS was contacted for further suggestions on how to deal with this challenge. L. Jonathan Cohen (Oxford University), then secretary-general of ICSU and member of IUHPS, and Jens Erik Fenstad (University of Oslo), member of the Executive Board and former president of IUHPS, were among the driving forces in this effort. In collaboration with ICSU a workshop in London on ethical issues in science was arranged by Philip Kitcher (Columbia University) and Nancy Cartwright (London School of Economics and Political Science) in 1994 on behalf of the Philosophy of Science section of IUHPS (with contributions eventually published in *Perspectives on Science*, 1996). IUHPS then focused its activities on ethics of science, leading to a special session on this topic during the 1995 International Congress on Logic, Methodology, and Philosophy of Science in Florence, Italy (see Dalla Chiara et al. 1997). As a general outcome of these activities ICSU set up an informal working group that proposed a Standing Committee on Responsibility and Ethics of Science (SCRES). This proposal was endorsed by the General Assembly in Washington, DC, in 1996.

The remit of SCRES included:

- to act as a focus within ICSU and with outside partners for questions pertaining to scientific responsibility and ethics;
- to clarify issues of moral principle which affect the choice of policies for scientific research . . .;
- to raise awareness of important ethical issues among scientists, policy makers and the general public . . . (ICSU documents GA 1996)

An offer from the Norwegian Academy of Science and Letters led to SCRES being based in Oslo and sharing offices with the National Committees for Research Ethics.

SCRES was a small committee, compared with the more established Standing Committee on Freedom in the Conduct of Science, and it struggled to define its agenda. This took a new turn in the planning of the

World Conference on Science (WCS) that was jointly hosted by ICSU and UNESCO in Budapest, Hungary, in 1999. Cooperation with the UNESCO World Commission on the Ethics of Scientific Knowledge and Technology (COMEST) led to a special WCS session on "Science, Ethics and Responsibility." Indeed, SCRES prepared a WCS background document that was one of only two such documents distributed to all speakers, chairs, and rapporteurs (ICSU-SCRES 2000).

The WCS also placed a new topic on the SCRES agenda. The WCS keynote speech of Joseph Rotblat (b. 1908), the Polish-born physicist and international activist, called for a universal oath or pledge to be taken by scientists when receiving a degree in science. Such a "Hippocratic oath" would make explicit the commitment to social responsibility in science. This proposal spurred intense discussions, and while it proved impossible to include Rotblat's suggestion in the final endorsed documents of the WCS, section 3.2 of the "Science Agenda—Framework for Action" calls for COMEST and SCRES to follow up with a view to encourage young scientists to "respect and adhere to the basic ethical principles and responsibilities of science."

In response, SCRES produced a study of 115 ethical guidelines and codes of ethics that was presented to the ICSU General Assembly at its Rio de Janeiro meeting in 2002. At the same time SCRES presented an evaluation of its own activities and suggested that ICSU reconsider how best to place the ethics of science within its structure. SCRES pointed out that a body of its kind and structure could not meet the expectations expressed in its remit, especially regarding public awareness of science and society issues. Its impact remained peripheral, perhaps with the exception of China where SCRES activities spurred a major influence at the national level.

SCRES furthermore suggested that a better balance be found for ad hoc activities directed at special areas of wide ethical interest and addressed through cooperation with other partners, while retaining the continuity and identity that a standing committee can provide. ICSU was asked to consider whether a revised and renewed SCFCS with an explicit mandate for ethics might not be a better framework. As a result SCRES was dissolved in 2002, and ICSU established a strategic review committee to work out suggestions for the future of ethics within ICSU. While the importance of ethics of science is widely recognized by many of the ICSU members and by the Executive Board, ICSU still needs to find its own profile in this area that would not duplicate activities of other bodies, but at the same time provide a voice for global and international concerns.

INTERNATIONAL RELATIONS

The term "international relations"—subsuming "international affairs" and "foreign affairs"—refers to interactions among nation states, and includes such diverse topics as international law, international trade, and the international monetary system. Although international corporations and non-governmental organizations influence these interactions, and international bodies such as the United Nations help manage them, the primary actors remain nation states. Insofar as nations carry and articulate values, and find their powers conditioned by changes in science and technology (from military effectiveness and productivity to means of communication and bureaucratic organization), international relations also function as an important site for science, technology, and ethics interactions.

Historical Transformations

Following the Peace of Wespthalia (1648) and acceptance of the nation state as the sovereign arbiter of values and power within its borders, questions arose about how to manage interstate relations. The assumption, shared more by theorists than political leaders, from the seventeenth through the nineteenth centuries was that all nations desired peace, which was to be achieved through international law, which laid out the rules of the game for managing the balance of power through international treaties. The failure of this system in World War I, in which technological destructiveness exceeded civilized control, and the subsequent rise of state actors empowered by new techniques of organization, driven by aggressive ideologies in Russia and especially in Germany committed to the marshaling of science and technology for violent conquest, challenged the classic consensus. As Hans J. Morgenthau (1948) observed, peace and security is the ideology of satisfied powers.

The study of international relations grew after World War II into a major focus of social science to encompass these new realities, new states, and new issues, and developed in two directions. In the first case, social scientific studies endeavor to understand why state actors behave as they do, including how technology helps to determine their capabilities. In the second case, advances in science and technology became integral aspects of the relations between and among states including, among others, their role in war and peace, in the management of conflict, in the promotion of economic development, and in the analysis of decision marking.

Other less spectacular but equally far-reaching changes have been the ability to reach any telephone instantaneously and inexpensively worldwide, increased dependence of weapons systems on competitive technological innovation, the relevance of scientific competence to national economies, and the immediacy and global reach of television. Advances in the technologies of transportation, communication, and information thus contributed measurably to such phenomena as the fall of Soviet Communism and the end of the Cold War (1990), public demands for international humanitarian action, the increased unification of Europe, and economic globalization. Still others underline causal connections between local actions and global consequences, such as destruction of stratospheric ozone as a result of the widespread use of chlorofluorocarbons (CFCs), the far-reaching consequences of a disruption in energy supplies or a failure of information systems, and the climatic effects of the accumulation in the atmosphere of waste gases. (International response to the CFC problem in the form of the Montreal Protocol for their elimination has become one of the success stories of multi-state cooperation in response to issues both engendered and identified by science and technology.) The transnational impacts of space exploration and environmental issues, plus the post-Cold War rise of non-state actors adapting technologies for terrorism are further examples of new science and technology-related issues altering international affairs.

Yet the international significance of science and technology goes beyond physical power. The intellectual currents of the Enlightenment, which was largely a product of the experimentation and rationality of the scientific revolution, have stimulated massive forces for change in the West—and have been interpreted as forces involved in a post-Cold War "clash of civilizations" (Huntington 1996).

Moreover, science and technology are not static. By 2003 worldwide investment in research and development (R&D) had risen to $750-800 billion per year, leading to rates of innovation that defy accurate forecasting, let alone estimation of their social effects. There is now in place a formidable and growing system for dedicating human ingenuity to the rapid expansion of knowledge and the production of new technologies to serve perceived or speculative needs. Not only do the results of this system have significant international implications, its very operation favors the creation of global markets. Science and technology may not *cause* changes in international affairs, but their interaction with a mosaic of social, economic, and political factors clearly does so.

The present and future implications for the international system may be summed up in a cliché: Advances in science and technology and their application have led to an unprecedented degree of interaction and mutual dependence among nations in their economies, social structures, and security relationships. The result has moved nations to a new level of interdependence. Nevertheless, the fundamental principles and organization of the international system have *not* been altered substantially. Although multilateral and transnational organizations have increasingly important roles to play across the spectrum of issues from security to economies, this does not imply the end of nation-states. The world is still organized as a system that retains the basic structure of states, each jealous of its independence, seeing itself in competition with others, attempting to maintain maximum freedom of action, and committed to enhancing national welfare and influence. At the same time the state capacity to act as an independent unit increasingly depends on the breadth and depth of its links to other states. Indeed, degrees to which states are intertwined with others may affect internal matters as well. And the frequency with which domestic and foreign policies related to science and technology are confronted with ethical issues concerning the effect of policies on other states and peoples is a product of such intensive linkages.

Ethical and Political Issues

Changes in international relations resulting from interactions with science and technology have raised ethical and political issues that range in scale and consequence from minor inconveniences in travel or communication to decisions that may dictate the immediate violent deaths of thousands of people or choices that have long-term, potentially large, but uncertain effects.

WEAPONS SYSTEMS. Perhaps the most obvious instance arises from the development of weapons systems that directly or inadvertently target civilian populations as well as military forces. The most dramatic are the nuclear weapons used by the United States against Japan to end World War II but not used since. In 1945 there was some debate in government circles and the scientific community about using a weapon with such destructive power and unleashing a means of warfare that would have a profound effect on international relations.

That decision remains controversial, but at the time the imperative to end the war and avoid large losses of American lives in an invasion of Japan was irresistible to the U.S. president. Moreover, a different technological weapon—incendiary bombs—had already been used against both Germany and Japan with equivalent loss of life; the atomic bomb did not appear radically different in terms of the number of lives at risk. There are other arguments about the moral use of this weapon, but these were decisive at the time (Alperovitz 1996).

The decision to proceed with development of the hydrogen (fusion) bomb in 1950 was likewise fraught with moral and political consequences because of the extent of the destruction it could unleash (Bundy 1988).

The policy of nuclear deterrence that is based on the destructive power of nuclear weapons—that is, the paradoxical threat of use in order to avoid use—has been highly controversial. Conventional weapons systems that cause considerable "collateral" damage—the death and destruction of noncombatants—raise moral issues as well, though on a smaller scale.

Other weapons-related programs and policies that have been proposed and questioned on ethical grounds include nuclear test ban treaties and ballistic missile defense. The Limited Nuclear Test Ban Treaty (1963) and subsequent proposals to limit testing in space and underground have necessarily involved politicians working closely with scientists and engineers on programs that had wide moral support. In the case of President Reagan's Strategic Defense Initiative or "Star Wars" program to create a shield against nuclear armed ballistics missiles, a program revived by President George W. Bush as the National Missile Defense, there have been important questions about feasibility and functionality in which science, technology, and ethics are intimately intertwined.

GLOBAL CLIMATE CHANGE. A major environment-related ethical issue of international significance is the threat of global climate change or warming, which (like CFC emissions) became an issue only as a result of theoretical calculations made by scientists, not evidence of actual damage. Based on computer models and solid evidence of the accumulation of carbon dioxide and other atmospheric greenhouse gases, scientists have warned that more solar radiation will lead to a growing heat burden for the planet. Depending on the timing and magnitude of the effects, the impact could be very large, with a major effect on low-lying nations (because of sea-level rise) and on agricultural production, especially in developing countries. The calculations of the scientists are controversial, but the relevant scientific community has accepted the validity of the threat. The Intergovernmental Panel on Climate Change (IPCC), an international panel of scientists from many countries charged by governments to assess the danger, increasingly accepts the existence of the phenomenon and in its last assessment predicted a temperature rise between 1.4 and 5.8 degrees Centigrade by the end of the twenty-first century (Intergovernmental Panel on Climate Change 2001).

International negotiations have been proceeding since the "Earth Summit" in Rio in 1992, itself a major science and technology related international event, with a Framework Convention on Climate Change that was negotiated that same year and entered into force in 1994; in 1997 the Kyoto Protocol was accepted for ratification (Skolnikoff 1999, O'Riordan and Jager 1996). The United States under President Clinton signed the protocol, but President George W. Bush withdrew the signature and has refused to consider ratification. The U.S. Administration argument is that the science is not proven, the developing countries that eventually will be major producers of carbon dioxide have no obligations under the protocol, and the costs to the American economy would be too great. Modest alternative policies, largely voluntary, have been pursued instead by the Administration. Regardless of the merits of the general arguments, the ethical issue is stark: Does the United States, which is by far the major producer of greenhouse gases (25 percent or more of global emissions), have the right to ignore an issue that could have a catastrophic effect on other countries and peoples? The United States will suffer from global warming, but its wealth will make it relatively easy to adapt to the effects of changes in climate. That is not true for other countries, especially the poorer ones.

GENETICALLY MODIFIED ORGANISMS. Genetically modified organisms (GMOs) raise significant ethical questions. These organisms, which so far have been used largely in the agriculture domain, are familiar crop strains (corn, soybeans, wheat, cotton) modified by biotechnological techniques to have valuable new characteristics, such as reduced sensitivity to herbicides and better cold-weather stamina (Thompson 2002). The new strains have been introduced widely in the United States but have been resisted in some other countries, particularly in Europe.

Companies that market GMO products in the United States assert that the resultant food is indistinguishable at the consumer level from unmodified food; Europeans respond that the evidence is inconclusive. Moreover, consumers in Europe insist that food should be labeled so that they have a choice about whether to buy modified food. The United States takes the position that labeling would destroy the market for the American-produced food, that there is no scientific evidence of danger, and that the European position is a ploy to protect European agriculture from less expensive imports. Some African countries, desperately in need of food aid such as Zambia, Zimbabwe, Malawi, Mozambique, and Angola have refused U.S. food on the grounds that their crops would become "contaminated" and thus unable to be exported to Europe (Bohannon 2002). The United States is taking the issue to the World Trade Organization (WTO) on the grounds that the E.U. policy is a form of protectionism. Yet Europeans argue that the United States is attempting to impose its values in an area that will be irreversible once the modified crop strains are in widespread use. Does one nation have the right to make such a decision regardless of the validity of the political and economic arguments?

FOREIGN WORKERS. An issue that is a perennial focus of criticism of multinational corporations is variance in the standards of treatment of workers in different countries. Is it ethically appropriate for corporations to follow identical standards regardless of local wages or living and employment conditions, or should there be differences that take account of variations in income or environment? U.S. corporations often have been the focus of protest, especially when they pay workers in developing countries wages much below American scales or do not provide equivalent working conditions.

The subcommission for protecting and promoting human rights of the United Nations Commission on Human Rights has been drafting a code on norms of responsibility for multinational corporations, the draft of which was approved in August 2003 (*Draft Norms on the Responsibilities of Transnational Corporations and Other Business Enterprises with Regard to Human Rights* 2003). If the draft ultimately is approved by the full commission and accepted by the member states, it will for the first time create a standard for the ethical behavior of multinational corporations. Final approval will not create an enforcement mechanism but should have considerable influence, particularly on larger corporations that are vulnerable to public pressure and protest.

INTELLECTUAL PROPERTY RIGHTS. An issue with similar characteristics is the general subject of intellectual property rights (IPR). Patents, including those in the pharmaceutical industry, copyrights, and trademarks are issued to provide a protected monetary return for an inventor or artist and thus to encourage innovation and performance. Ethical issues arise when intellectual property is pirated or when royalties or fees are too high for developing countries.

Often new technologies are not available in developing countries because of the cost. When copying of intellectual property is easy and low-cost, as in the case of copying videos or music records without paying the copyright fee, the result has been wholesale reproduction and sale at a fraction of the original price. This would seem to be clearly unethical. Many argue, however, that it is the IPR regime that is unethical and that intellectual property should be considered a public good, freely available or available at a low cost, to anyone. That position is not likely to be accepted in countries that produce most of the intellectual property, which argue that without a chance to recoup costs, innovation and artistry would dry up. It is particularly important for the United States, which is increasingly dependent on high-technology and innovation-intensive goods. The Trade Related Intellectual Property Rights Agreement (TRIPS) of the WTO represents an attempt to reach international agreement on this issue, so far with limited success.

Another IPR debate focuses on the patenting of genetically engineered organisms and of products found in the wild for use in pharmaceutical research and development. In the case of genetically engineered organisms, the European Union is much more restrictive on this practice than the United States, thus raising an IPR issue that requires international harmonization. The patenting of biological discoveries in what are sometimes called "gene-rich" poor countries by corporations based in so-called "gene-poor" rich countries has been criticized as a form of "biopiracy" that fails adequately to compensate the country from which these new resources are derived.

TERRORISM. A more recent issue has arisen from the fear of terrorists' use of scientific data. Since September 11, 2001, the U.S. government has sought to limit the publication of the results of research that might benefit terrorists. This has revived issues of the proper boundaries of government imposed scientific secrecy that were prominent during the Cold War but had abated since, and is particularly relevant in the case of fast-moving biological research but also affects other areas with weapons potential, particularly in the nuclear and chemical fields. Scientists are resisting such regulations on the grounds that they would degrade the scientific enterprise and make it difficult to counter possible weapons development or acquisition by terrorists. Should it be possible to publish in a journal or on the Internet any information, such as the methodology for producing biological agents or the design of a nuclear weapon, that could be misused even though the information is otherwise available and is not classified? What is the ethical (and political) judgment? The issue has not been settled (Skolnikoff 2002), although a number of biology journals have agreed to institute a review process to flag potentially dangerous articles and consider how the suspect material might be reduced or eliminated. No recent cases of "prior" censorship outside classified areas have reached the courts.

Other Issues

Weapons systems, global climate change, genetically modified organisms, foreign workers, intellectual property rights, and terrorism constitute six representative international relations issues intimately engaged with science and technology. Many others might be mentioned, from population growth, economic development (the rich/poor divide and the proper parameters of foreign aid), and world health, to biodiversity loss, the allocation of resources in international waters (as provided for in the Law of the Sea Treaty, 1982) and space (including communication satellite orbits), and remote sensing of countries and individuals from space without their permission.

Issues of these kinds arise ubiquitously and are a natural product of advances in science and technology and the use of those advances in national and international policies. In recognition of this fact, the U.S. National Research Council (1999) argued strongly for major innovations in the department of state to more effectively deal with these issues. Improved education and personnel policies for regular foreign service officers, creation of a new post of science adviser to the Secretary, and recruitment of more scientists and engineers to the department's ranks were advocated and most of the recommendations approved by the then Secretary. Additionally, all sciences and technologies are "dual use" in the sense that they can be used for benign or malevolent purposes. Inevitably, they will often pose choices that raise ethical as well as social, political, and economic considerations. Some of those choices will be minor and insignificant, but others will require careful thought and almost surely will be controversial.

INTERNET

Emerging from the integration of computer and communications technologies, the Internet is a text- and graphics-based communications system that supports people and organizations in the performance of multiple activities. As such it has the potential to transform the worlds of work in industry, government, education, and entertainment as well as everyday life. A variety of ethical issues arise with this technology, involving not only individual users, but also corporations and governments.

There are two basic meanings associated with the word Internet. In a narrow sense, the Internet is a global network *inter*-connecting computer *net*works, from which the word derives. Hence it is a complex network connecting large numbers of devices such as computers, file servers, and video cameras, by means of telephone lines, satellites, and wireless networks. In a broad sense, the Internet also includes that which such technological infrastructure makes possible, which some refer to as *cyberspace*.

For present purposes the Internet will be characterized as constituting a *digital habitat* where people increasingly live. Habitat denotes here an environment in which people carry out activities, possibly in interaction with other people, involving specific actions and things. Because the kinds of things people interact with in the Internet are not *material* in the usual sense of the term, but rather electronic and digital, the Internet may be termed a digital habitat (Stefik 1996).

Emergence and Development of the Internet

Initial development of Internet technology was supported in the 1960s by the Advanced Research Projects Agency (ARPA) of the U.S. Department of Defense in the context of the Cold War between the United States and the former Soviet Union. ARPA's task was to establish the technological and military superiority of the United States. But the agency gave considerable freedom of action to researchers and the development of Internet technology was carried out mainly at university research laboratories by academics whose primary agenda was to develop technologies to allow computers to communicate with each other (Castells 2001).

In 1969 the first nodes of the ARPANET, a packet-switching network, became operational. Subsequently, to deal with the proliferation of computer networks that had appeared in the United States and other countries, additional technology was developed during the 1970s and 1980s to interconnect any kind of network, as long as certain preestablished rules of communication were followed. It is in this context that the Internet, as a network of computer networks, was born (Abbate 1999).

Initially the Internet was used primarily at universities, for the purposes of exchanging electronic mail and for transferring files. It was not until the 1990s, with the development of the World Wide Web—a particular kind of Internet application (Berners-Lee and Fischetti 1999)—that a massive use of the Internet became possible. By mutually reinforcing each other, factors such as an increasing number of users, a growing number of services provided through the Internet, and increasing investment in technologies led to an explosive growth of the Internet. What had started as the ARPANET with four nodes in 1969, had become the Internet with millions of users by the end of the twentieth century.

Ethical Issues

Some have suggested that the ethical issues of the Internet are the same ones that arise in preexisting practices. Another position maintains that although these issues have a correspondence with well known, preexisting dilemmas they nonetheless constitute novel and significant variations (Johnson 2000). Their novelty arises from the very special properties of the entities that populate the Internet.

Because the Internet is composed of digital representations of text, data, music, and software, it can be characterized as a digital habitat. Because of the powerful capabilities of computers and networks, these entities can be *reproduced* and *transferred* with minimal effort and delay. One consequence of these properties is a notable characteristic of the Internet that can be called *virtual nearness*. Every public entity embedded in the Internet, within certain limits, is immediately available to the user—is *near* in a virtual way. This characteristic makes the emergence of virtual communities possible.

People perform activities in the Internet by means of *digital actions* carried out by digital programs. The specific steps programs perform can be easily recorded to leave a trace of the actions. In addition, because actions are carried out by programs, there is a question as to who is ultimately behind them, leading to certain forms of anonymity.

Privacy Issues

People carry out an increasing number of activities on the Internet, including exchanging email messages, visiting Internet sites, and buying goods. Transactions with government are increasingly done through the Internet. Medical records are created and made available online. In all of these activities sensitive information about people is gathered and stored. Because of its interconnectivity, the Internet makes it possible to transfer, combine, and cross-reference personal information at a much higher level than was previously achievable. The existence of multiple databases containing information on individuals about health, education, tax, and police matters, as well as on shopping patterns, enables the development of detailed profiles of individuals. Such profiles can be used for making decisions about them, for example, to grant or deny loans, to grant or deny medical insurance, to hire or not to hire, possibly leading to certain forms of discrimination.

Personal information is routinely used for purposes other than those originally intended, in most cases without the knowledge of the people involved. This situation constitutes a significant erosion of privacy.

Although there is a wide consensus that privacy—in particular, medical privacy—has been negatively affected by Internet technology (for example, Etzioni 1999; Johnson 2000; Parenti 2003), there is less agreement on how to confront the situation. Corporations claim they need personal information on their customers in order to be more efficient and profitable. Government agencies claim they need access to personal information for law enforcement purposes. For some theorists, then, the issue is to find a balance between the desires of individuals to keep information about themselves private and the desires of corporations and government to freely access that information. For others this perspective is too narrow because it transforms privacy issues into the balancing of competing claims. In a broader sense, privacy refers to a fundamental aspect of the human condition. Etymologically it is related to the Latin word *privus*, meaning single, alone. While human beings cannot be understood apart from the communities they belong to, they cannot be understood, either, unless it is recognized that they are unique individuals and have the potential to become increasingly autonomous.

By autonomy is meant the capacity to understand the sources, meanings, and consequences of actions and to exercise that understanding in deciding what actions to take. When information is collected and processed by others, autonomy is endangered in the sense that others can openly or surreptitiously attempt to influence actions on the basis of that information. In this respect, an important consequence of the availability of large amounts of personal information to corporations and government is that it increases their relative power with respect to that of individuals, possibly upsetting a delicate societal balance. For this reason, privacy is not only relevant to individuals but it should also be considered a social good, relevant to society as a whole.

Further discrepancies exist on how to deal with the erosion of privacy. Those who assign an intrinsic value to privacy tend to favor an approach in which individuals must provide explicit consent for the exchange of personal information among corporations, coupled with legislation enforcing such procedures. They claim that existing legislation—such as the Fair Credit Reporting Act, the Driver's Privacy Protection Act, and the Electronic Communications Privacy Act—has been developed piecemeal, and propose stronger forms of regulation similar to those existing in some European countries. Others favor a mixture of self-regulation by companies, use of technology to control access to information, and institutional changes leading to practices where information is less exposed to misuse.

An approach increasingly followed by companies is to develop privacy policies that are made available to their customers, indicating how information about them is used and with what other organizations it will be shared, and offering certain privacy options to customers. But without appropriate legislation many are skeptical that corporations can truly police themselves.

Two factors will exacerbate the erosion of privacy in the future. First, given the pace of technological development it is likely that increasing amounts of personal information will be available online. Second, the fight against terrorism triggered by the attacks that destroyed the World Trade Center on September 11, 2001, will put significant pressure on government agencies to acquire and make use of that information, by wiretapping or other means, to detect terrorism-related activities. The Patriot Act enacted by Congress in October 2001 points strongly in this direction (Hentoff 2003). To conclude, a significant, multi-pronged effort will be required to deal with the erosion of privacy underway at the beginning of the twenty first century and to a large extent catalyzed by Internet technology.

Intellectual Property Issues

Intellectual property differs from tangible forms of property, such as cars and other goods, in that it is easily reproducible. Given that in the context of the Internet intellectual property, such as software and music, is stored in electronic files, people can reproduce and transfer it with minimal effort. It is precisely this notable characteristic of the Internet that is at the source of contentious issues regarding intellectual property. The case of Napster—a company that facilitated the global sharing of music files over the Internet and was shut down in 2001 as a consequence of a lawsuit brought against it by the recording industry—is important because it brought to light subtle issues, both at the core of the notion of intellectual property and on why and how the law protects it.

Ideas, literary works, and music are forms of speech. Freedom of speech, in one sense, implies the freedom to formulate and propagate ideas, as well as to have unfettered access to ideas and forms of speech produced by others. In the latter case, the authors of these works regard them as property and would like to be fairly compensated for their use. In addition, the free flow of ideas, for example of those that emerge in the context of science and technology, is regarded as beneficial to society as a whole. How can the tension between freedom of speech and *progress*, on one hand, and ownership of intellectual works, on the other, be resolved?

The Constitution itself lays out a basic framework for dealing with these issues, and gives Congress the power to enact legislation. Copyright law emerged in this context. An important distinction is established between ideas and expression of ideas, such that only the latter can be owned, and for a limited time.

Copyright law grants exclusive rights of copy to owners of intellectual property or to those whom owners grant permission, but through the notion of *fair use* it also establishes limits on this exclusivity. If a person buys a compact disk containing music, it is considered fair use to make extra copies of the disk for use in a car and for backup purposes. This is also true with regard to software. The law imposes additional restrictions on what can be copyrighted, including that the expression of ideas be novel and developed independently by its author.

Given these subtle distinctions, limits and restrictions imposed on intellectual property, the determination of whether copyrights have been infringed, and the enforcement of these rights are very difficult matters. The advent of the Internet has complicated the issues. The Napster case illustrated how the Internet made the copy and dissemination of music possible on a grand scale. While the recording industry considered it a form of electronic thievery, for some the exchange of files may have been an extreme case of fair use.

Supplemental Ethical Issues

Because the Internet makes it easy for people and groups to publish electronically, and given the potentially large audience that can be reached, the issue of what can be expressed on and accessed through the Internet arises. Again conflicting demands come into play. For example, freedom of access to public information conflicts with the desire to limit the availability of material that many regard as unacceptable.

Specifically impeding access to pornography by children in public libraries through the Internet could interfere with access to those same materials by adults. The Communications Decency Act passed by Congress in 1996 addressed that issue. A year later, the Supreme Court declared the act unconstitutional, siding with freedom of access and against censorship.

As already discussed, virtual nearness makes the emergence of virtual communities in the Internet possible, giving rise to virtual community (Turkle 1995). Some communities, in which people are represented by icons and fictitious names, provide opportunities for socializing in novel ways. In particular anonymity allows for the possibility of altering important elements of one's identity including gender, age, and race. What range of behavior is permissible in these situations? What would count as *violence*, as being too *close* to another person, as an attempted *rape* (Johnson 2000)?

Global Issues

A more global view raises two sociopolitical questions. First, given that the Internet facilitates the association of people with shared views, in particular, political views, and that it allows for the communication of those views to large numbers of people, does the Internet promote democracy as some have suggested? Second, considering that geographical barriers have little or no effect on the Internet, could the Internet contribute to undermine nation-states?

To a large extent, the answer to these questions depends on what the Internet becomes in the future. The Internet could remain as it is in the early-twenty-first century, except that almost everybody, everywhere, would have access to it and more activities would be carried out with its support. Or the Internet could become primarily a *global entertainment machine* by the convergence of radio, television, and the film, recording, and computer game industries. Or finally the reach of the Internet could be extended by ubiquity, wirelessness, and wearable computers.

In the context of these scenarios, the question of promotion of democracy answers itself: Although the possibility of performing political actions through the Internet would continue to exist, in the last two scenarios—the most likely—given the amount of noise that a global entertainment machine and the various extensions to the Internet would put into circulation, anything else would become barely audible and visible, including political action. In addition, the erosion of privacy mentioned earlier could contribute to undermining autonomy with, possibly, negative consequences for democracy.

With respect to the second question, about nation-states, the pressure to have common rules and laws, for electronic commerce, intellectual property, and privacy, that would facilitate the migration of activities to the Internet could undermine the sovereignty of less powerful countries. Although nation-states could try to control what regions of the Internet are accessible to its citizens (Hamelink 2000), given the connectivity of the Internet the effort would fail.

Finally the third scenario posed above leads to a fundamental philosophical question that can only be set out in this entry. Is it possible that the pervasive and substantial intermediation of human activities by the Internet—which would amount to a massive migration from material habitats to a global digital habitat—could invite essential transformations of the way human beings *are?* And what kinds of transformations would they be? But importantly, do people still have the ability to actually ask this question, or will the increasing noise make such questioning impossible?

INVENTION

Invention (from the Latin *invenire,* to find or to discover) in a broad sense refers to any novel idea or the process of its creation. In the technological sense it means the identification of a science or technology potential matching a specific human need or the result of this process: a novel technical product.

Because any invention implies a use, it is intrinsically value-laden and thus of ethical interest. This applies to the intended purpose as well as to the unintended side effects of production or use, the possibilities of misuse, and of so-called dual use (when the function of a product may be employed for either good or bad use). The social promotion or regulation of the inventive process also has ethical dimensions.

Basic Distinctions

Originally there was no distinction between invention and discovery. Invention could refer to theoretical cognition as well as to technical designing. However, beginning with the twentieth century, these concepts usually are distinguished. To discover is to recognize an existing but previously unknown phenomenon. To invent is to conceive of a novel and previously not existing phenomenon.

Invention is the starting point for a new technical development. An innovative cognition in science or technology may precede invention but not necessarily. What is decisive is the notion that some natural or technical effect might function as an artifact that could replace or enhance some human activity or operation. Any invention creates a new means for some human end.

According to the German engineer and writer Max Eyth (1905), there are four types of invention. One is a new means for a new end; an example would be television. Second is a new means for a preexisting end; an example is the transistor as replacement for the electronic vacuum tube. Third is an existing means put to a new end; an example is the telephone to transmit written materials, as in the documents in a telefax. Finally fourth is an existing means for an existing end; an example is when music CDs are used to store data. Completely new inventions are rare; frequently, an invention is a mere combination of elements already in existence. The distinction between these different types of invention naturally raises questions about whether some types might present more serious ethical challenges than others, and whether ethics might be differentially related to different types of invention.

Inventors may apply for patents, which will protect the idea against illegal imitation. Usually, however, the invention by itself is not immediately ready for everyday use. Lengthy designing, testing, and improving are required before a properly functioning form is achieved.

This part of development is called the *innovation process*, and results, if technically and economically successful, in an *innovation* (in the narrow sense). The period between invention and innovation may take years or even decades. The question concerning whether in modern technology this period tends to progressively shorten, is highly debated.

Where Inventions Come From

At one time, the ability to invent was ascribed to the ingenious talent of gifted engineers who were regarded more as artists than as skilled experts. The art of inventing was explained by so-called creativity, an ability limited to only a few exceptional persons. Traditional histories of technology glorified the uniqueness of the inventor by drawing up long lists, in which important inventions were assigned to specific dates and famous names. The phenomenon of multiple inventions, however, disturbed this individualistic view. When both a technological potential and human need are in existence, the idea of bringing them together in an invention readily occurs to several persons at the same time. Although the aura of the individual ingenious creator may be shaken by this phenomenon, the process of inventing itself acquires a more solid explication.

According to John Guilford (1950), cognitive psychology explains creativity as a specific mixture of individual mental activities, partly conscious and partly subconscious. In the conscious stage, a person collects all knowledge available regarding certain problems and possible solutions (*preparation*). This knowledge sinks down to the subconscious, where it is stored, processed, and accidentally combined with additional tacit knowledge, without any explicit awareness on the person's part (*incubation*). Suddenly a new combination of knowledge and imagination emerges from the subconscious, and is identified as the perfect solution to a problem (*illumination*). In a final stage this new idea has to be tested and elaborated explicitly by rational thinking (*verification*).

In design theory, a modern branch of engineering research, the art of inventing is methodologically reconstructed. Instead of accumulating technical knowledge in an accidental and unsystematic way, design theory suggests systematic patterns arranging all the elements of possible solutions according to basic functional and structural features. This procedure, design theory claims, results in the totality of possible solutions to a given problem, and the only remaining difficulty is to choose the optimal solution among hundreds or even thousands of feasible combinations. Thus the associating and combining process, originally hidden in the subconscious, is objectified and rationalized, and is even accessible to computer programming.

Whether this rational strategy of inventing is actually feasible is debatable. Some observers hold that on principle the role of intuition and tacit knowledge in inventing is indispensable. For others the rationalistic approach seems promising for social interaction in teamwork, because individual intuitions from the subconscious are hard to communicate. Also invention cannot be reduced to personal performance alone, but obviously has social implications. Often it depends on the sociocultural context, which technical potentials an individual inventor takes into account, and which human needs and purposes are being realized. Furthermore the inventing activity depends on an innovative social climate and on economic incentives to motivate persons and corporations. Some hold that in the early twenty-first century the majority of inventions are made by large corporations, but there remain many individuals who also perfect basic inventions.

Ethical Issues

Recognizing that numerous inventions are ambiguous or even harmful to environment and society, several critics have considered whether an effective assessment and approval of the innovation process might be instituted. Some of them refer to historic examples, when certain inventions, in ancient Greece or medieval eastern Asia, had been suppressed systematically on ethical grounds, either by the very inventor or by political forces. The German economist Werner Sombart (1934) made the radical suggestion that every invention ought to be submitted to a National Council of Culture, which would release only such inventions as prove beneficial without question. Less radical approaches to improve the ecological and social quality of inventions are discussed at present in *engineering ethics*, which focuses on the professional responsibility of individual inventors, and in *technology assessment*, which concentrates on industrial strategies and political regulations.

Individual refusal—like that of the father of cybernetics, Norbert Wiener, who in 1947 rebelled against doing any further work for the military—usually is not very effective, because nearly always there will be found others to continue a questionable project. Therefore, moral sensitivity of the individuals has to be supported by corporate and political institutions such as those of technology assessment, which proves to be the social organization of teleological ethics.

Some commentators question the ever growing rate of inventions and innovations, mostly driven by economic forces, which possibly threaten natural environment, the stability of cultural traditions, and personal self-fulfillment. Such views are, of course, at odds with the dominant innovation tendencies in modern industrial and information society.

IN VITRO FERTILIZATION AND GENETIC SCREENING

The first birth following in vitro fertilization (IVF) took place in the United Kingdom in 1978, and the number of IVF births per year has increased steadily since then. More than 35,000 infants were born with the help of IVF in 2000 in the United States alone, and more than 1 million infants have been born worldwide following IVF. Although IVF has become an integral part of fertility medicine, ethical and policy issues continue to be debated as technologies change and IVF becomes more common. Among the topics debated are those relating to the moral status of embryos, disposition of frozen embryos, use of genetic testing of embryos to detect the presence of moderate rather than serious genetic disorders, and the adequacy of regulation.

Technologies

For an IVF cycle, physicians stimulate a female patient with hormones to induce the release of more than one egg. When tests show the eggs are ready to be released, physicians remove the eggs in an office procedure, fertilize them in vitro (in glass) with spermatozoa from the male partner or a donor, culture the fertilized eggs for two to three days to at least the stage of a four-cell embryo, and transfer the embryos to the woman's uterus for possible pregnancy.

Although IVF was primarily designed for women with blocked fallopian tubes who could benefit from the way IVF bypasses these tubes, advances over the years have extended the versatility of IVF as a method for circumventing infertility. For example women who do not ovulate can use donated eggs, and men with extremely low sperm counts can be aided by the manual injection of a single spermatozoan into an egg in a technique known as intracytoplasmic sperm injection (ICSI).

Another technique used in conjunction with IVF is pre-implantation genetic diagnosis (PGD), which is available for couples at risk for passing serious genetic diseases, such as Tay-Sachs disease and cystic fibrosis, to their offspring. In one form of PGD, the embryo biopsy, technicians remove a single cell from an embryo created through IVF and amplify the DNA to detect the presence of the disease-linked gene in question. Physicians then selectively transfer only those embryos without the anomaly to the woman's uterus. PGD is also used to detect chromosomal abnormalities that cause serious disorders in offspring or that interfere with conception. The first birth following IVF/PGD occurred in 1990. More than 1,000 infants had been born worldwide by 2002, with a pregnancy rate of about 24 percent (Robertson 2003).

Moral Status of Embryos

Perspectives about the moral status of embryos differ significantly among individuals. Some believe that early

In vitro fertilization. Many ethical questions surround the process, in which egg cells are fertilized outside the mother's body in cases where conception is impossible through normal intercourse. (*© Owen Franken/Corbis.*)

stage embryos are human beings with the moral status of persons that must be protected from injury or destruction. Others believe embryos are potential human beings warranting special respect but not the moral status of persons. Policy advisory groups in the United States have generally adopted the latter perspective (Ethics Advisory Board 1979). Due to a lack of consensus about the status of embryos, however, as of 2004 federal funds cannot under law be used to finance research in which human embryos are injured or destroyed. To the extent that investigators study human embryos, they do so with private research funds.

Disposition of Frozen Embryos

When couples undergo IVF or IVF/PGD, extra embryos are often created and frozen for later thaw and transfer. More than 100,000 embryos were frozen in the United States alone in 2002. Couples who no longer want or need their spare embryos can direct that the embryos be discarded, donated for research and eventual destruction, or donated to other couples. Difficulties can arise, however, if a couple divorces and has no prior written agreement about what should be done with the embryos or if one party seeks to nullify the agreement. The first appellate court to rule on this matter held that the person who wants to avoid parenthood (by not transferring the embryos) generally ought to prevail over the person who wants to achieve parenthood (by transferring the embryos) (*Davis* v. *Davis* 1992). Judges rely on case-by-case rule making in frozen embryo cases. In general they accept the principle established in *Davis* v. *Davis*, but differ on whether they will enforce prior agreements (Elster 2002).

Extending PGD

PGD is generally regarded as an ethically acceptable way of preventing human suffering when the disease in question is serious or fatal. Some have voiced reservations, however, about the potential for tests that can be used to detect less serious diseases such as deafness or predispositions to diseases such as Alzheimer's disease or breast cancer. The concern is that this will discourage tolerance for imperfections and devalue the inherent worth of individuals. Another concern is that negative selection (discarding affected embryos) will, when technologies allow it, set the stage for positive selection (seeking embryos with socially desirable traits), which would magnify differences between the rich and the less well-off; have eugenic overtones; and contribute to the mindset that people can be made to order, like commodities.

Those who do not share these concerns argue that IVF/PGD is so costly and intrusive that only a small number of people will use it. They point out that PGD is an alternative to prenatal testing for at-risk couples who know they will not terminate the pregnancy of a fetus with serious disorders and who welcome the opportunity to transfer only unaffected embryos for a potential pregnancy. In addition supporters of PGD question the wisdom of interfering with a technique that could prevent the birth of babies with serious disorders now on the basis of speculative concerns about possible future uses of PGD.

Policy Issues

IVF and other reproductive technologies are governed in a decentralized manner in the United States. Debates continue about whether more oversight is needed and, if so, what forms it should take. One point of view is that the system of oversight, which is based on state laws, medical licensing requirements, tort law, self-regulation by professional associations, administrative rule making, and the power of the marketplace, is thorough and effective (Adamson 2002). One federal law directs the government, in conjunction with professional associations, to collect and publicize data from fertility clinics to educate patients and the public about clinic performance. Those who believe that the oversight system is sufficient point to statistics on healthy children and improved birth rates for IVF as indicators of effective regulation and professional caution. They argue that concerns, such as those questioning the sizeable number of twin, triplet, and higher order births following IVF, can be addressed by professional self-management and improved technologies.

From another point of view, the government should take a more active role in monitoring IVF/PGD practice by developing a centralized oversight system and taking other steps to protect the health of patients and offspring. According to this view, the government should develop a centralized data gathering system or, at least, a national level forum for debating issues relating to infertility treatment. It should also enact laws to address specific concerns; for example, to limit the number of multiple births, and regulate by law the number of embryos that can be transferred per IVF cycle (International Society for Law and Technology [ISLAT] Working Group 1998).

The ability of the federal government to regulate IVF is limited by constitutional protections of reproductive liberty. In addition political controversies over the status of embryos make legislation difficult to enact. The likelihood of enacting in the United States a central oversight board for assisted reproductive technologies, as exists in the United Kingdom, is slim. In the meantime researchers are engaged in data gathering to assess the long-term safety of IVF, state legislatures are considering various forms of regulation, and practitioners are continuing to produce practice guidelines as part of self-regulatory policies.

Conclusion

IVF has led to the birth of more than 1 million children who may not otherwise have been born to couples experiencing various infertility problems. Issues about the status of embryos, disposition of frozen embryos, proper reach of PGD, and optimal forms of oversight have recurred in the years since 1978. New ethical issues arise as the technologies and applications change. For example what payment is appropriate for egg donors? Should practitioners accept single persons as patients? What should be done with embryos abandoned by couples? What issues are raised when egg or sperm donors are related to the recipients? Should PGD be used to determine predisposition to disease? Should children conceived with donor eggs, sperm, or embryos be told how they were conceived?

Although no central forum exists for debating these issues in the United States, the public fascination with IVF ensures that the issues are aired and discussed. While it is tempting to call for governmental controls, the issues raised by rapidly changing technologies are not easily amenable to preemptive legislation, which can be rigid and easily dated. Moreover government policy precludes funding research in which embryos are injured or destroyed, which removes the *power of the purse* as a vehicle for oversight. Consequently, robust discussion, public education, regulations of medical facilities in general, and self-regulation by professional associations all contribute to oversight. Though complex and decentralized, this system allows monitoring while also respecting the reproductive liberty of couples seeking the services of fertility clinics.

IQ DEBATE

In 1905 two Frenchmen, Alfred Binet (1857–1911) and Theophil Simon (1873–1961), invented the IQ (Intelligence Quotient) test to distinguish between mentally retarded and normal school children. They set tasks that normal children could do; for example, five-year-olds were asked to compare two weights, copy a square, repeat a sentence of ten syllables, count four pennies, and unite the halves of a divided rectangle.

By 2005 there were thousands of tests but two have special significance. The first, Raven's Progressive Matrices, measures on-the-spot problem solving where no previously learned method is applicable. It presents a pattern of shapes from which one piece is missing, offers six alternative missing pieces, and then asks the examinee to choose the correct one (Raven 2000). The second, the Wechsler Intelligence Scale for Children (WISC), supplements Raven's by using ten to twelve subtests to measure a variety of cognitive skills. These tests constitute technologies that raise significant ethical issues.

What IQ Tests Measure

Various cognitive skills go into problem solving. One such skill is mental acuity, which involves both solving problems without a previously learned method and the active creation of alternative solutions. The WISC subtest called Similarities measures mental acuity: The subject must decide what certain things, such as dawn and dusk, have in common. Similar subtests include Block Design, Picture Concepts, and of course Matrices. Another set of subtests are quite different. Clearly, a wide range of basic knowledge and a large vocabulary enhance problem-solving ability. These are measured by the Vocabulary and Verbal Comprehension subtests and, until recently, by the Information and Arithmetic subtests that were dropped in the fourth edition of the WISC. Although there is learned content in these subtests, it is the kind of learning that intelligent people will master more easily and more thoroughly. A third kind of relevant skill is speed of information processing—which is measured by the Coding and Symbol Search subtests. Finally, that ability called memory, which allows individuals to access accumulated knowledge, is tested by the Digit Span (the number of digits a person can repeat after they are read out —and the ability to repeat them in reverse order) and the Letter-Number Sequences subtests.

Given that the WISC tests cover the cognitive skills that go into problem solving, it may seem surprising that there is so much debate about whether IQ tests measure intelligence. There are several reasons why the controversy endures.

Attitudes affect cognitive skills because people invest mental energy into problems only if they feel they are significant. Attitude shifts over time have enhanced performance on some subtests more than on others (Flynn 2003). Members of a street gang may see little point in problems that appear to lack practical significance. Lots of noncognitive skills contribute to problem solving such as empathy, tact, setting people at ease, and being a good listener. In addition, IQ tests do not measure a host of attributes regarded as important, such as artistic and musical ability, honesty, and generosity.

Most debate about what IQ tests measure consists in endless repetition of these points and inventing a host of intelligences, such as emotional intelligence, social intelligence, surviving-in-a-wilderness intelligence, and musical intelligence, among others (Jensen 1998). This sterile debate can perhaps be circumvented by a modest claim: IQ tests measure *cognitive* skills relevant to problems encountered in the *mainstream of industrial societies;* and test the *basic knowledge* needed to function in those societies. However, there is a caveat: IQ tests cannot determine when a person scores better than others because of *attitudes* friendlier toward the kind of problems that are to be solved.

Uses of IQ Tests

IQ tests perform three main roles: comparing individuals for cognitive skills; comparing groups; and measuring cognitive skill trends over time, this last being a special case of comparing groups because it entails comparing one generation with another.

IQ scores give each person a percentile rank using Standard Deviations (SDs) as the link. An IQ of 100 is average for any particular age and is at the 50th percentile. An IQ of 130 is two SDs above the mean (an SD = 15) and is at the 98th percentile (only 2.3% of the subject's peers have a higher score); an IQ of 110 is 0.67 SDs above the mean and is at the 75th percentile; an IQ of 70 is two SDs below the mean and equals the 2nd percentile (only 2.3% of the subject's peers have a lower score). Certain IQ scores set the threshold for performing certain social roles. Few people with IQs below 130 will receive a Ph.D. from an academically superior university; few with IQs below 110 will enter the elite professions, that is, medicine, law, accounting, natural science, and engineering; and few with IQs below 100 will hold a professional, managerial, or technical post of any kind. Those with IQs below 70 are often regarded as being unable to cope with normal life and are labeled mentally retarded.

Race Differences

The existence of IQ thresholds for occupations generates group comparisons unfavorable to blacks. The mean IQ of white Americans is 100, while black Americans have a mean IQ of 85 or one SD below whites. The pool of potential professionals, managers, and technicians has a threshold of 100. Therefore, 50 per cent of whites would qualify but only the highest scoring 16 per cent of blacks (a score of 100 is at their 84th percentile). The Berkeley psychologist Arthur Jensen suggests that even if environments were equalized, blacks would still have a mean IQ of only 90 (Jensen 1973, p. 363). If he is correct, even then, only 25 percent of blacks would qualify.

Some believe scholars should not debate whether ethnic groups show genetic differences for intelligence. This moral advice will fail and should fail. Those who read Jensen will quickly find that he has an argument that must be answered, high professional standards, and no trace of racial bias. Thus the only reason not to test his hypothesis is that it would be unpleasant if it were true. In addition, if those who have offered evidence in favor of genetic equality were to opt out of the debate, Jensen's hypothesis would remain undisputed, a sort of unilateral disarmament. The debate should proceed and be conducted purely along evidential lines. The strongest evidence supporting a genetic hypothesis is the under performance, both on IQ tests and academically, of children of the black middle and upper classes—who do fall at least 10 IQ points short of their white counterparts (Herrnstein and Murray 1994, p. 288). The strongest evidence in favor of an environmental hypothesis was obtained as the result of an historical event: the U.S. military occupation of Germany after World War II, which removed thousands of black males from the American environment. The U.S. army left behind many illegitimate children. The mean IQs of those with black fathers and those with white fathers were the same (Flynn 1999).

Whatever the causes of the IQ gap between black and white Americans, it exists. When standardized tests are used as screening devices, the lesser representation of blacks leaves the realm of theory and becomes fact. The debate as to whether affirmative action should be used to redress the balance is complex. Opponents point to cases of underprivileged whites who are rejected in favor of the child of a black professional, lower performance in key areas such as police protection, and the fact that blacks may actually suffer harm, for example, by being admitted to universities where they are doomed to fail (Herrnstein and Murray 1994).

Proponents argue that black Americans suffer from their group membership in many ways, ranging from police behavior toward them, higher consumer prices in the ghetto, discrimination in housing and employment, and an unfavorable marriage market. White men very rarely marry black women. Therefore, black women are restricted to marrying black men and many are unlikely to find permanent partners—because too many black men die young, are imprisoned, or are not regularly employed. Therefore, more than one-half of black children are raised in solo-mother homes, often below the poverty line (Flynn 2000, pp. 148–149). Supporters of affirmative action also contend that most efficiency gains would accrue if standardized tests were only used to disqualify those without essential skills and if job-related criteria were substituted to rank applicants above that level. They cite data showing that when blacks admitted to elite universities (for which they would not normally qualify) are matched with blacks who went to other universities, the graduation rates are similar—and that the former profit by earning higher incomes (Kane 1998).

Genes and Environment

Studies of identical twins separated at birth and raised apart show that, at adulthood, twin and co-twin are far more alike in IQ than randomly selected individuals. This appears to be because of their identical genes—and does that not mean that genes are far more potent than environment? Jensen calculated that if environment were in fact this weak, no plausible environmental difference within a society such as America could account for a one SD IQ gap—which is the gap between the IQs of blacks and whites (Jensen 1973, pp. 166–169).

In 1987 James R. Flynn, a moral philosopher at the University of Otago, challenged this reasoning with evidence showing the existence of massive IQ gains over time. For example, the Dutch gained fully 20 IQ points on Raven's Matrices from one generation to the next, that is, from 1952 to 1982, a result replicated in several nations. Since there can be little genetic upgrading in a single generation, Flynn contended that these huge gains must have been due to environment (Flynn 2003). Thus, a paradox arose that baffled the discipline for many years: How can twin studies show environment to be so weak, while IQ gains over time show environment to be so enormously potent?

In 2001 William T. Dickens, an economist at the Brookings Institution, and Flynn offered *reciprocal causation* as a possible solution. Imagine identical twins who were separated at birth and raised apart in a basketball-mad state such as Indiana. Their identical genes dictate that they are born both a bit taller and quicker than average. Thus, although raised in different cities, both tend to be picked for informal basketball games at school. The extra play upgrades their skill advantage and they both get picked for the school team. They then play a rigorous schedule and get professional coaching, which upgrades their skill advantage further. At adulthood, they end up with basketball skills that are remarkably similar and well above average—and their identical genes get all the credit. But that assumption is a mistake. It overlooks the fact that these identical twins also had atypically similar basketball environments—their genes are getting credit for shared factors like more practice, playing on a team, and professional coaching. The kinship studies mask the potency of environment.

Skill gains over time show the true strength of environment. In 1950 TV brought basketball into American homes and basketball put baseball into the shadows—those close-ups look so good even on the small screen. Suddenly everyone was playing basketball and skills escalated. At first, to be better than average, a player needed merely to pass and shoot well. However, the rising quality of the average performance became a powerful factor in its own right. To excel, a few people learned to shoot with both hands. Then everyone who wanted to compete had to try to do the same, which pushed the mean up further. Soon a few people learned to pass with both hands and then, everyone had to try to do that. Every rise in the average performance encouraged a further rise.

So now this has resolved the gene-environment paradox: The key is reciprocal causation as a potent multiplier of skill differences. Within a generation, genes drive the feedback process and get credit for the environmental input—which gives the illusion of environmental weakness. Between generations, a persistent environmental factor (the rising popularity of basketball) drives the feedback process—and shows how environment can produce huge skill differences between groups separated by only a few years of time.

New Spectacles

The concept of reciprocal causation provides spectacles that improve our perception of what may cause group IQ differences. Do blacks start with what may be a modest but significant genetic disadvantage, one that gets multiplied into a 15-point IQ deficit? Or are there persistent environmental factors that divide black and white, analogous to belonging to the pre-TV and post-TV generations? Some have attempted to identify the kind of factors that might inhibit black academic achievement and IQ test performance: that they feel threatened by intellectual competition with whites; that black males are ambivalent about intellectual success and may even strive to fall below the class mean (so blacks would have negative multipliers!); and, as has been seen, that the problems of black males affect black children, so that a majority of them are raised by solo-mothers struggling to avoid poverty.

The brute fact that average IQ scores increase over time adds a new dimension to another debate: whether IQ tests should be used to classify people as mentally retarded. IQ gains mean that subjects will get higher IQs on an out-of-date test. If someone was average when compared to the test performance of their peers today (and therefore gets an IQ of 100), they would automatically be better than average compared to their peers of 20 years ago (and therefore get an IQ well above 100). After all, the fact that the average performance was worse in the past is what constitutes IQ gains over time. There is no doubt that people have been denied special education or have been executed on death row because taking obsolete tests inflated their IQs above 70, the usual cut-off point for mental retardation (Kanaya et al. 2003). These facts strengthen the argument of those who believe in purely behavioral criteria for mental retardation: School children should be classified as such if they cannot understand the rules of games they play frequently; prisoners should be executed only if their life histories show they can cope with the usual activities of everyday life, for example, by qualifying for a driver's license.

Are IQ Gains Real?

The United States and other nations have been making massive IQ gains for at least as far back as the 1930s. Are these really intelligence gains? The answer is that they are piecemeal cognitive skill gains that affect the real world—but they are not gains in terms of the kind of general intelligence IQ tests are designed to measure.

When an IQ test measures individuals competing with one another, certain people tend to do better than average on all or most of the WISC subtests—which is to say part of what is being measured is a better functioning brain that gives someone an advantage for most cognitive skills. Society does not upgrade average brain quality from one generation to another because it does not run radical experiments in selective breeding. What it does do is manipulate environmental factors that have a differential effect on various cognitive skills. If Americans fill more leisure time with cognitively demanding games, and fill more professional positions in which they must make decisions rather than simply following rules, scores on the Similarities subtest should rise—and they have enormously. If efforts to improve reading in the United States have not made people love books, and if visual entertainment of a largely escapist sort tempts people away from books, one would not expect better ability to read serious literature, or bigger non-specialized vocabularies, or the command of more general information—and the relevant WISC subtests show that this is indeed the case (Flynn 2003).

In sum, IQ tests are good tools for comparing the cognitive skills of individuals and alerting researchers to group differences. However, finding causes and solutions for those differences involves the totality of social science. The general intelligence factor that IQ tests are designed to measure may indicate which mind competes best with other minds at a certain time and place. But it is a crude measure of what society is doing to a wide variety of cognitive skills over time. We must free our minds of it and look at trends on the various WISC subtests. They reveal the intellectual history of these times.

ISLAMIC PERSPECTIVES

Islam is at once a religion, a community, and a civilization. In all three senses, Islam is a source of unique perspectives on relations between science, technology, and ethics. As a religion, Islam upholds knowledge as the key to both individual and societal salvation. With the idea of unity of reality and knowledge as a guiding principle it refuses to entertain any distinction between the religious and the secular in the realm of knowledge. Science and technology are as relevant as the so-called religious sciences to the human pursuit of the divine. As a community, Islam stresses on the divine law as the most important source of ethics to guide human actions in all sectors of personal and public life and as the most visible expression of Muslim cultural identity. This law is generally viewed as not only all-embracing in the scope of its applications but also as dynamic enough to be adaptable to the changing needs of space and time. Science and technology are to be regulated by ethics embodied in this law. As a civilization, Islam seeks to promote the interests of all humanity by standing up for the perspectives of universalism, the common good and inter-faith understanding. As so many of Islam's thinkers have asserted over the centuries science and technology are the most powerful and the most enduring universal elements in human civilization and should be pursued for the sake of the common good and inter-faith peace, Islam places strict limits on technology and subordinates scientific rationality to revelation. As a community, Islam is more concerned to adapt science and technology for practical benefit.

Historical Background

Islam was born in Mecca, Arabia, in 610 C.E. when Muhammad, an illiterate but highly respected member of Arabia's most powerful tribe, the Quraysh, claimed he had received revelations from God. During one of his regular spiritual retreats in a cave on the outskirts of Mecca, the archangel Gabriel appeared before him instructing him to recite a few verses in Arabic and proclaiming him God's new messenger to humankind. That initial revelation was essentially about the true spirit of human learning: Seeking knowledge is to be done in the name of God who is humanity's best teacher, and the best human instrument of knowledge is the intellect as symbolized by the pen. This tenet supported the new religion's claim to be essentially *a way of knowledge*.

The Prophet, as every generation of Muhammad's followers call him, received further revelations intermittently over a period of twenty-three years until just before his death in 632 C.E. These revelations were systematically compiled into a book known as the *Qur'ān* (literally meaning *The Recitation*). The precise arrangement of the *Qur'ān* itself is traditionally thought to be divinely inspired. This book, believed sacred both in text and meaning, is the most authentic and the most important source of Islamic teachings. The names Islam for the religion and Muslims for its followers are set out in the *Qur'ān*. Islam means both *submission to God's will* and *peace*, while Muslim means *one who submits to the divine will*. More than anything else the *Qur'ān* is a source of guidance in the domain of knowledge. Muslims believe that the *Qur'ān* contains the principles of all sciences. Islam claims to revive the pure monotheism of Abraham while presenting itself as the synthesis of all previously revealed religions, which has helped foster a positive attitude among Muslims toward the intellectual and cultural legacies of other civilizations.

As a full-fledged religious community (*ummah*) with distinctive characteristics as envisioned in the *Qur'ān*, Islam was founded in Medina, formerly known as Yathrib, in 622 C.E. (although the nucleus of the community had formed earlier in Mecca). The Prophet and his followers migrated to Medina to escape persecution following his uncompromising stand on idol worship. This flight, known as the *hijrah*, marked a major turning point in the history of Islam. The original group grew to become a worldwide community that is estimated at 1.2 billion followers in the early-twenty-first century. As an extension of his community, the Prophet established a city-state that he named *Madinat al-Nabiy* (City of the Prophet) or simply *al-Madinah* (The City). This pluralistic city-state, multiethnic and multireligious, reflected

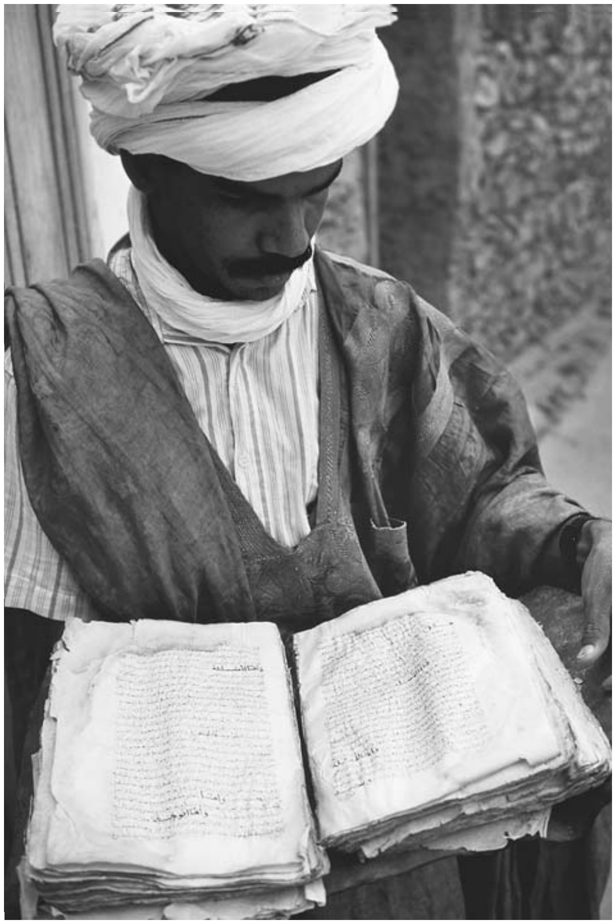
the moral and ethical basis of the sociopolitical teachings of Islam. In postprophetic Muslim history, Medina is an enduring model of Islamic polity.

As a civilization (*tamaddun*), Islam manifested itself when the community organized all aspects of daily life in accordance with the spiritual and ethical values set out in the *Qur'ān* and as interpreted by the Prophet. The cultural identity of Muslims became easily visible in the way they cultivated *a knowledge culture* that did not separate the religious and the secular, envisioned and practiced moderation in religious life, merged temporal life with the spiritual, championed social justice, permeated ethical concern in all individual and societal activities, engaged pluralism, and approached relations with other faiths. But the happenings in Medina merely lay the foundation of Islam. Fuller development of the civilization occurred after the religion spread throughout the world, encountering other civilizations, and the *ummah* grew into a more ethnically and culturally diverse circle of believers.

Islam and the world did not have to wait long to see the realization of a civilization that was innovative, unique, and unrivaled in brilliance for its times. The spread of Islam to distant places was astoundingly swift. Within a century from the death of the Prophet, Islam swept through North Africa reaching Spain in the west and central Asia in the east, and even became a minority religion in China. With a generally positive attitude toward the cultural and scientific legacies of past and contemporary civilizations, Islam tried to create a new civilization by merging the best of these traditions with its own resources. The hallmark of Islam, the civilization, is *the grand synthesis*. Islam, the religion, inspires the Muslim mind to create a human civilization that is basically *synthetic* in nature.



Man holding an ancient copy of the Koran. Muslims believe that the Koran is the literal word of God and culmination of God's revelation to mankind, revealed to the Prophet Muhammad over a period of 22 years by the archangel Gabriel. *(© Nik Wheeler/Corbis.)*

Islam, Science, and Technology

This historical background provides a context to understand science, technology, and ethics in Muslim culture and civilization. Muslims believe the *Qur'ān* affirms the supreme role of knowledge in ordering human life and thought and delivering success. Knowledge is regarded as the key to human salvation and to human happiness in this world and in the afterlife. But knowledge that saves must be sacred in nature. Sacredness is not defined in terms of primacy of revelation over reason. Among Muslim philosophers and scientists the distinction between revelation and reason is rather blurred. This is because reason is regarded as a minor revelation given to every human individual and as such is itself sacred in nature even if many humans are not aware of it. By sacred knowledge the *Qur'ān* means knowledge that is related in some way to God, pursued in the name of God, and used and applied in the name of God. As Muslims see it, human knowledge, including science, possesses a sacred character because God is the ultimate source of all knowledge regardless of whether humans acquire it empirically or otherwise. The *Qur'ān* speaks of God as the All-Knower and the giver of knowledge to humans through various avenues ranging from physical senses to intellectual reflection, dream interpretation to divine revelation. The Muslim idea of sacred knowledge is contained in the very first revelation Muhammad received.

The *Qur'ān* also maintains that the ultimate purpose of human knowledge is to know God. This objective is attainable because human knowledge of creation will lead to knowledge of the divine reality, which is considered to be the highest form of knowledge possible. The *Qur'ān* is emphatic in acknowledging that God is knowable. Muslims approach the study of different branches of knowledge, including science and technology, with this spiritual objective in mind. Scientists view their study of the natural world as a form of religious worship, but the lesser objectives of knowledge are duly recognized. Knowledge helps humans to fulfill their rational and mental needs, such as clarity of mind, certitude of thought, and rational explanations of both natural and social phenomena, as well as those material needs that can be met by technology. In the traditional Muslim pursuit of knowledge, the deepest theoretical understanding of things goes hand in hand with an earnest appreciation of their practical utility.

It was the Prophet who inspired Muslims to pursue knowledge of things for both their theoretical and practical considerations. He encouraged his followers to reflect and contemplate natural phenomena pursuant to the *Qur'ān* with a view toward deepening understanding of divine power and wisdom in creation. But the Prophet also compared knowledge that had no practical benefits to a tree without fruit. He often prayed to God seeking protection from *useless knowledge*. On the basis of this tradition, Muslim scholars progressively sought to articulate ideas, concepts, and theories on the broader issue of the ethics of knowledge as activities of knowledge production and applications in the new civilization expanded and became more complex. Major issues included clarifying the meanings of beneficial and harmful knowledge in the perspective of Islamic law and determining the general criteria for each type of knowledge. Muslim preoccupation with the knowledge culture took many different forms. One was classification of knowledge, which proved to be a good way of keeping track of the state of knowledge at any given time. Classification of knowledge divided the sciences into thematic groups of well-defined disciplines, and preserved their hierarchy.

The Arab philosopher al-Kindi (c. 801–873) authored the first Muslim classification of the sciences in the ninth century. Since then many scholars have devoted considerable effort to expositions of this theme. The last significant work on the subject is the classification written by the Indian theologian Shah Waliallah of Delhi (1703–1762) in the eighteenth century. The importance and popularity of classification of the sciences was evident not only from the number of books written on the subject but also from the diverse nature of the scholarly community that produced them. Theologians, philosophers, scientists, historians, and jurists, among both Sunnis and Shiites, were represented in this unique enterprise. Classifications had been particularly useful to the organization of educational curricula. Interestingly there appeared to be a correlation between the rate of production of classifications of knowledge and the intensity of knowledge expansion. The interest in classifications was at its height during the era when Muslims were the most productive in terms of adding new scientific disciplines to the existing body of human knowledge. After the sixteenth century when intellectual and scientific innovations began to decline in most parts of the Muslim world, work on classifications dropped sharply. The fact that hardly any work has appeared on the subject since the eighteenth century testifies to the reduced importance of the role of knowledge among Muslims in the early-twenty-first century world.

It is clear from past classifications that Muslims were concerned with the need for a balanced approach to both theoretical and practical knowledge. In addition, Muslims accord relative importance to each science in the context of human knowledge as a whole. Generally scholars use three criteria to determine the epistemic position of each science in what is traditionally called the hierarchy of knowledge. The criteria are defined in terms of the relative excellence of the objects of study, methods of study, and benefits of study. Some sciences may be viewed as more laudable than others on the basis of one or more of these criteria. The greatest science in light of the three criteria is the science of God or theology in the true sense of the word.

Islamic Culture, Science, and Technology

As clearly reflected in classifications over the centuries, Muslims do not consider science and technology to be the most important branch of knowledge, as do many people in Europe and North America who view science as the sole basis for reliable knowledge and technology as the best means to solve human problems. From the Muslim perspective, science could never take the place of metaphysics and theology in either temporal or moral importance because the latter have God and the divine realities as their *object of study* whereas science and technology focus on natural objects created by God. Additionally technology could never replace divine law (*shari'ah*) as the best provider of efficacious solutions to human individual and societal problems. Despite these beliefs, at the apex of their cultural influence, Muslims demonstrated a degree of appreciation of science and technology unseen in earlier times. Such appreciation was contextual, as dictated by the *shari'ah* itself.

Muslims distinguish between two types of obligatory knowledge. The first type is *fard 'ayn,* meaning obligatory for everyone to have as, for example, in the case of knowledge of canonical prayer. The second type is *fard kifayah,* meaning obligatory for society to possess, though the task of acquiring it may be left to certain individuals or groups. Implicit in the meaning of this category of knowledge is that without it a society would lack something that is important to its well being. *Shari'ah* confers the status of *fard kifayah* knowledge to science and technology on the basis of their immense benefits to human society. A society without a level of science and technology proportionate to its problems is considered unhealthy. Political philosophers like al-Farabi (870–950) went so far as to claim that science and technology are necessary ingredients in the pursuit of human happiness. But to Muslims, science and technology serve society best when pursued and employed in the light of ethical-legal principles of *shari'ah.*

Muslims believe both *shari'ah* and science and technology are necessary to societal salvation, and that the two should be joined within the ethical and legal framework of *shari'ah. Shari'ah,* which is primarily based on the teachings of the *Qur'ān* and the prophetic *hadiths,* is considered by Muslims to be the most important source of ethical values and principles to guide human actions and conduct. In the case of the Shiites, the *hadiths* extend to embrace the teachings of their supreme spiritual leaders known as *Imams. Shari'ah* refuses to separate between ethical and legal thought. What is legal has to be ethical, and vice versa. The religious significance of scientific and technological activities resides in the fact that the *shari'ah* divides all human actions into five categories. These categories are the obligatory (*wajib*), the meritorious or the recommended, the indifferent (*mubah*), the forbidden (*haram*), and the reprehensible (*makruh*). The main significance of these ethical categorizations for science and technology in Muslim culture is that society and the state are in broad agreement on what ought to be the priorities in scientific and technological pursuits. Obviously scientific and technological products and activities in the obligatory and meritorious categories are given the greatest priority. At the same time *shari'ah* is ever present to remind society and the state of the need to refrain from indulging in scientific and technological activities belonging to the forbidden category because *haram* would be harmful to society. *Shari'ah's* general objectives, namely to protect religion, reason, life, progeny and property, and its specific exhortations pertaining to both worship and social duties determine the types and scopes of scientific and technological activities to be encouraged or shunned. Muslim science and technology over the centuries had more or less developed along the ethical track that *shari'ah* provided. Muslims emphasized sciences like mathematics, astronomy, geography, medicine, botany, and agriculture because of their practical relevance to *shari'ah.* For the same reason, Muslims developed civil engineering and medical, agricultural, and navigational technology to new heights in the medieval period. But on the whole, harmony between science, technology and ethics was rarely shattered.

Contemporary Issues

In many early-twenty-first century Muslim societies worldwide, the traditional bond between divine law and technology has been severed. For various reasons, *shari'ah* is no longer seen as relevant to the shaping of technological pursuits. Muslims face the ethical challenge of dealing with science and technology issues that are largely not of their own making, and that pose numerous challenges to traditional Islamic ethics.

Perhaps the most serious challenge derives from military technology and biotechnology including medical technology that enables humans to, literally, determine life and death. Modern military technology in the form of weapons of mass destruction, such as nuclear and biological weapons, clearly transgresses the limits of traditional Islamic war ethics. Some Muslim states are defending the right to acquire such weapons on what they claim to be *Islamic grounds,* although it seems clear that their motive is primarily political. Many scholars in Sunni Pakistan defend that country's *Islamic bomb* on the basis of geopolitical considerations. In Shiite Iran clerics are divided on the issue of possessing nuclear weapons with President Seyed Mohamed Khatami (elected 1997) taking the stand that such weapons are contrary to Islamic ethical teachings. Muslims throughout the world are divided on the issue not along theological or jurisprudential grounds but by political, ideological perspectives. However one thing is clear: Pronuclear weapons advocates have been able to sustain their views largely by appealing to political considerations rather than to the more fundamental Islamic ethics on the conduct of war. Proponents of the supremacy of Islamic political power are likely to endorse such weapons.

Biomedical technology has impacted the social fabric of Europe and North America in an unprecedented way and has sent shock waves into the Muslim world. The range of biomedical technology currently employed in Muslim countries is still limited. But that limited use is apparently dictated far more by economics than by perceptions of ethical incompatibility with Islam. But the few richer ones as well as Muslim minorities in the west have helped Muslims to keep abreast with ethical issues arising from modern biomedical practice. In countries such as Nalaysia, Indonesia, Turkey, and Kuwait issues in biomedical ethics such as debated in the west are likewise discussed in the medical profession and the academia. The Islamic Organization for Medical Sciences based in Kuwait is exceptionally active in organizing international meetings of Muslim medical doctors to discuss implications of contemporary biomedical technology for Islamic societal values. Quite often experts in Islamic law are invited to these meetings for religious consultation. This meeting of Muslim scientific and religious minds has been successful in coming up with well-defined criteria for Muslim acceptance of biomedical technology. There is a particular concern for the impact of biomedical technology on traditional family values and institutions. The general Muslim view is that while that technology is not the cause of the breakdown in traditional family and marriage institutions, it nonetheless has created new possibilities that allow the viability of alternative lifestyles. Life-support machines that call into question the traditional definition of death, technology that uncovers information about babies still in the womb, sperm banks, and artificial insemination are major examples of modern-day scientific and technological innovations that have attracted the attention of Muslim ethicists. Debates on those issues had hardly settled when the more serious ethical issue of cloning emerged.

On some issues such as the technology associated with prenatal information and artificial insemination the Muslim debate has been fairly brief as religious experts and political authorities quickly find satisfactory answers to initial Muslim grievances on the possible misuse of the technology. On other issues such as the life-supporting machines the debate rages on. The majority view is that as traditionally held the community of believers should help to facilitate "easy and peaceful" death of the dying and not to prolong agony and suffering such as through the use of the life-supporting machine. The traditional belief is that death, a passage to afterlife, is itself a suffering. To be in a state of neither life nor death is viewed as being in a state of suffering. The traditional way of facilitating peaceful death is recitation of verses from the *Qur'ān*. The minority view is that use of the machine is permissible because religion also teaches the saving of every human life through every possible means. While debates on such issues rage on the more serious ethical issue of cloning emerged. Muslims are unanimous in rejecting human cloning. But they are deeply divided on the use of stem cells for research. The overwhelming majority oppose using human embryonic stem cells for research. But many Muslim groups consider use of adult stem cells as religiously permissible.

The following patterns emerge in the still-fluid Muslim response to bioethical issues. First Muslims are increasingly turning to Islam's inner resources as found in the *Qur'ān*, prophetic traditions, and traditional ethics in looking for answers to dilemmas posed by new technologies. Second Muslims are evaluating the potential value of new technologies while remaining committed to defending *shari'ah*-sanctioned social institutions. They are likely to adopt new technologies within the constraints of *shari'ah* as they have already done in many cases. For example, Muslim jurists have permitted artificial insemination as long as the couple is legally married according to Islamic law and the semen is that of the husband. Third Muslims are questioning whether humanity needs to have better and more encompassing ethical ideas than just those that appeal to *research interests* or *search for medical cures* in order to justify controversial, new scientific research and biomedical technology. As Muslims become more immersed in technological matters they more often find the need to consult the ethics of *shari'ah*.

A deep interest in ethical issues in science and technology presupposes a certain level of scientific and technological progress. As things are, most Muslim countries have hardly attained that level of progress. Many factors ranging from the religious and the political have contributed to the present Muslim lack of progress in science and technology. One of these is the neglect in Muslim education of that dimension of Islamic teachings favorable to scientific and technological progress. The current lack of interest in the ethics of science and technology in Muslim societies is thus understandable. But this lack of interest does not at all reflect the intellectual richness that characterizes the traditional treasury of Islamic ethical wisdom. Students of the *shari'ah* and the ethical dimension of Islamic science and technology when it was at its best are quite aware that Islamic ethical thought remains largely relevant to many of the contemporary ethical issues. There is nothing more glaring than the example of environmental ethics to illustrate the wide discrepancy between Islam's actual teachings and the current index of Muslim environmental awareness. The *Qur'ān* is replete with verses of environmental significance. Traditional Islamic architecture and urban planning has been one of the best Muslim attempts to embody the ideals of Islamic environmentalism as taught by the *Qur'ān*. Yet in the early twenty-first century Muslim countries are plagued with environmental pollution and urban degradation.

A promising Muslim country is Malaysia. It is one of the most advanced Muslim countries in science and technology. While seeking to reap the benefits of modern western science and technology Malaysia has also shown much interest in Islamic values as a contributing factor to scientific and technological progress in the twenty-first century. There is a visible attempt in the country to create a new synthesis of tradition and modernity not only in science and technology but also in other fields of civilization. The Malaysian government has created several institutions with that goal in mind. The most well known is perhaps the Malaysian Institute of Islamic Understanding, which has organized many programs on ethical issues in science and technology. Malaysia is quite advanced in genetic engineering. For a country noted for its Islamic fervor it is rather interesting that Islam does not appear to be a hindrance to the progress of genetic engineering. The new Badawi administration (succeeding that of Mahathir in 2003) has unveiled an agricultural policy that places great emphasis on genetic engineering and biotechnology. Interestingly, Badawi views this agricultural policy as an integral part of his Islam policy now known as civilizational Islam.

The case of Malaysia is important. It is not Arab but predominantly Malay like its neighbor Indonesia, which is the largest Muslim nation on earth. And yet in the early 2000s Malaysia appears to be more vocal than all the Arab states in championing modern Islamic issues. And many Muslims do make a careful distinction between *Islamic* and *Arabic*' while acknowledging the Arabic coloring of Islam by virtue of the Muslim belief that God has revealed the *Qur'ān* in Arabic. Islamic issues as distinct from Arabic are those that concern all Muslims transcending ethnic barriers. The Islamic organization in Kuwait may be led by Arabs but the ethical issues they discuss are Islamic issues of importance to all Muslims. Similarly the Malaysian institute of Islamic understanding is led by Malays who are non-Arabs but its programs on ethics in science and technology have the participation of Muslims from various parts of the world including Arabs.

Muslim attitudes toward modern science and technology are far more positive in the early twenty-first century than in the colonial period when they generally equated modernization with Westernization. From Morocco in the western wing of the Muslim world to Indonesia in its eastern most part colonial attempts at modernization such as in education, agriculture, and business often found stiff resistance from the Muslim populace. Such attitudes became the legacy of post-independence leaders in the Muslim world. But in the last several decades Islam has also emerged as an important source of positive influence on the Muslim thinking on science and technology. Many Muslims now see the possibility of merging the best of modern scientific and technological culture with the best of Islamic intellectual and cultural tradition.

One of the best historical studies of an important scientific institution in Islam, namely the observatory, which initiated a clear inter-dependence between scientific research and technological innovations in the field of astronomy.

ITALIAN PERSPECTIVES

The Italian cultural tradition has historically belittled the cultural, ethical, and social roles of science and technology. This is surprising given that an Italian, Galileo Galilei (1564–1642), was one of the founders of modern science, and that his *Dialogues Concerning Two New Sciences* (1638) praised the cultural role of technology and the philosophical importance of science. In the last half of the twentieth century, Italian appreciation of Galileo's theories increased, especially in relation to ethical discussions of science and technology, along with recognition of the philosophical importance due to technics and scientific thought.

Historical Background

Italian tradition was biased by the circumstances of Galileo's 1633 trial by the Holy Office of the Catholic Church. Despite his defense of science and technology, the trial ended with the Pisan scientist recanting his beliefs and being sentenced to house arrest for life. This condemnation long hindered the free development of scientific research and, together with the Counter-Reformation climate and Italy's difficult economic and political evolution, effectively sidelined the development of science and technology. Even though a few thinkers continued to maintain the importance of scientific knowledge and technological innovation, as a whole Italian intellectual culture became centered around literary, artistic, historical, and political activities.

This attitude was reinforced, in the first half of the twentieth century, by the hegemony of the neo-Hegelian idealism of Benedetto Croce (1866–1952) and Giovanni Gentile (1875–1944), who saw science as possessing no philosophical significance. Croce contended that science produces only *pseudo-concepts* of practical utility. Such concepts were subordinate to truth, which was, in his opinion, the exclusive province of the *sciences of the Spirit* (namely art, literature, philosophy, and history), of which philosophy was the crown jewel. *True* knowledge rises above science, which is irremediably tied to a practical horizon. Giovanni Gentile similarly devalued science, which he saw as oscillating between art and religion, unable to unify the two in a higher synthesis such as that achieved by philosophy. For Gentile, science combined the defects of art, objectivity and universality, with those of religion, subjectivity and rationality, and was thus the fruit of multiple errors and devoid of any autonomous historical development.

This negation of science by Croce and Gentile proved widely influential, both because it was set in a traditionally antiscientific culture and because these two neo-idealists played leading roles in the opposing political movements of liberalism and fascism. Their thinking exerted an almost dictatorial authority and aggravated the general cultural devaluation of science and technology.

Post World War II

Following World War II, the social and economic crisis in Italy contributed to the decline of the theories of Croce and Gentile. A new generation of intellectuals rejected neo-idealism, attacking its ambiguous cultural categories and sterile antinaturalistic, antiscientific polemics. In this climate, a dialog emerged among proponents of various ideologies including neopositivist philosophy, developed in Vienna by Moritz Schlich and Rudolf Carnap, the early ideas of Ludwig Wittgenstein, and the mathematical logic of Bertrand Russell. This led to the formation of a neo-enlightenment movement (Dal Pra and Minazzi 1992), with the participation most notably of Ludovico Geymonat (1908–1991) and Giulio Preti (1911–1972). Geymonat and Preti—through numerous studies, books, translations, and reviews—

critically introduced neopositive issues into Italian thinking, arguing both the cultural value of science and the importance of technology.

Geymonat, beginning with his *Studies for a New Rationalism* (1945), delineated a neo-enlightenment philosophy centered in the philosophy of science, logic, and the history of science and technology, arguing for replacement of *static* with *dynamic* studies of scientific theories. Geymonat became, in 1956, the first Italian to hold a chair in philosophy of science (at the University of Milan) and, in 1974, to win the *Médaille Koyré* for history of science, awarded by the Académie Internationale d'Histoire des Sciences in Paris. He also was mentor to a group of young scholars working in these fields. Geymonat's own work culminated in the publication of the highly regarded, seven-volume *History of Philosophical and Scientific Thought* (1970–1976) and *Science and Realism* (1977). In these works, he developed a materialistic-dialectic perspective and placed the fundamental role of the *scientific-technical legacy* at the heart of critical comprehension of knowledge and of the historical development of society. Preti, in a series of books including *Idealism and Realism* (1943), *The History of Scientific Thought* (1957), and especially *Praxis and Empirism* (1957), related neopositivist themes to both the pragmatism of John Dewey and the philosophy of the young Karl Marx.

Parallel with work conducted by the neo-enlightenment thinkers was that of Valerio Tonini (1901–1992), a Catholic engineer and philosophy of science scholar. After working in the field of engineering for many years, Tonini turned to information theory, epistemology, the sociology of work, and bioethics. A member of the *Académie Internationale de Philosophie des Sciences* (International Academy of Philosophy of Science), in 1950 Tonini founded the *Società Italiana di Logica e di Filosofia della Scienza* (Italian Society of Logic and Philosophy of Science) and, in 1955, started a review of human sciences and philosophy of science called *La Nuova Critica* (The New Critic), which he edited until his death. Tonini also raised important issues regarding the philosophy of technology, to which he devoted a book titled *Structures of Technology* (1968). In the ambit of what was described as his *long march to scientific realism,* Tonini defined technology as the *science of praxis.* He argued that technology implemented processes that modify the environment and, as a *new science,* was capable of achieving semantic precision, synthetic rigor, and verification of its theories. It created a direct link to communication theory, information theory, cybernetics, control theory, process theory, and systems theory.

Contemporary Contributions

In the last quarter of the twentieth century, Italian scholars became particularly interested in science, technology, and ethics. Discussion of biomedical ethics, not only from a Catholic perspective, broadened, with reflections on nuclear weapons and environmental ethics. In 2001, the Council of Genetic Rights was founded in Rome by Mario Capanna.

In the early-twenty-first century, two of Italy's most influential thinkers in the area of science, technology, and ethics are Evandro Agazzi and Luciano Floridi. Agazzi especially has made important contributions to the critical study of these issues. Born in Bergamo in 1934, Agazzi studied philosophy at the Catholic University in Milan, and continued his education, in physics and philosophy, at Marburg, Oxford, and Münster. Agazzi was part of the logical-mathematical team founded by Geymonat in the 1960s. He thereafter became a professor at universities in both Genoa and Fribourg (Switzerland), and published a number of studies on mathematical logic, including *Introduction to Axiomatic Problems* (1961), *Symbolic Logic* (1964), and *Themes and Problems of the Philosophy of Physics* (1969), in which he outlined an original objectivist and realistic epistemological perspective.

Agazzi's positive philosophical revaluation of technology is rooted in the antitheoreticism with which he reacted to the epistemology of the neopositivists and Karl Popper (cf., his philosophical dialogue with Geymonat in *Philosophy, Science, and Truth* [1989]). He developed his own interpretation of the hermeneutic dimension of science, embodied in *Wisdom the Technique* (1986) and most influentially in *Right, Wrong and Science: The Ethical Dimensions of the Techno-Scientific Enterprise* (1992).

The merits of Agazzi's analysis rest with his arguments regarding the ethical dimensions of the scientific-technological undertaking. Agazzi proposed to distinguish between technics (know-how that works without an awareness of its purpose), technology (which he used to denote, by contrast, effective action that has an awareness of its purpose), and science (knowledge capable of explaining empirical facts by adducing reasons that explain *why* reality is configured in a given way). Technology represents the result of the development of science, and Agazzi stresses the subtlety of the interconnections between science, technics, and technology, analyzing the scientific ideology, technological system, and complex encounter between ethics, norms, and values within human action. By defending a dynamic model of knowledge, Agazzi opts for a systemic approach in which the regulation of research is configured as a projection of responsibility. From this perspective, his science and technic studies are closely entwined with those devoted to bioethics, fostering a debate between Catholic and secular thinking that has contributed to the development of a freer and more responsible society.

Luciano Floridi, a professor of philosophy (at the University of Bari in 2004), has done influential work on the relationship between philosophy and computing from an ethical perspective. For Floridi Information Ethics represents the philosophical foundational counterpart of Computer Ethics which is thought as a non-standard, object-oriented and ontocentric theory.

J

JAPANESE PERSPECTIVES

In the early years of the twenty-first century ethical concerns related to scientific and technological developments are receiving a great deal of attention in Japan. A focus on globalization has resulted in a renewed concern with the impact of traditional values on technology, as well as in the adaptation of some western perspectives on ethical issues. Currently evolving discussions, in areas ranging from bioethics to nuclear power, make an excellent case study of how a society's ethical considerations both arise out of a given historical context and interact with a wider global context.

Japan is an ancient nation of 127 million people (2003) living mostly on four mountainous islands in the Northern Pacific off the coast of Asia. Records of inhabitance date back to the early centuries of the Common Era. After a long history of isolation followed by tentative openings, during the period of the Tokugawa Shogunate (1603–1868), Japan almost totally closed itself off from the outside world and consequently also from the influences of Western scientific and technological developments. It even successfully abolished the production and use of firearms, thus becoming one of the few examples where a more advanced technology, after having been widely utilized, was suppressed for an extended period of time. Toward the end of the Shogunate, however, it became clear that Japan would have to adopt Western technology in order to survive as an independent state, as was made evident in 1853 by the arrival of Commodore Matthew C. Perry in his black ships with their superior firepower, demanding an opening of trade. The subsequent Meiji Restoration of the emperor in 1868 accelerated a period of change in Japan, during which Western science and technology were rapidly integrated into an agrarian social system in flux. The slogan for the process of adoption was *wakon yōsai* or *Japanese soul with Western technology*, indicating an unwillingness to identify modernization with a transformation of the national cultural characteristics.

Historical Evolution of Ethical Issues

An initial movement to bring in experts from throughout the world and send students abroad, while adapting foreign learning to the Japanese cultural context and improving on it, set the pattern for much of the twentieth century. Japan became known as a society that emphasized incremental improvements on revolutionary innovations developed elsewhere. This reflected a societal objective of catching up to European and North American powers in economic and military strength, where the national government assumed the primary leadership role in building up the infrastructure necessary for scientific and technological growth. In this process, Japan became the first country to establish a college of engineering within a university system. As early as the 1870s, the Imperial University (later the University of Tokyo) established a Faculty of Engineering with its own service departments in the sciences. Ever since, the university system has produced many more engineering graduates than ones in the sciences. Under this system relatively less attention was given to basic or pure scientific research; the dominant focus was on applied science and technology for industrial development. As a result, the demarcation between science and technology has not been as evident in Japan as in the Western tradition. Neither has been the close cooperation between corporations and universities typical in the United States.

To understand how the historical evolution of science and engineering is connected to ethics in Japan, it is necessary to gain some insight into Japanese social values, which are influenced both by the general Asian traditions of Buddhism, Daoism, and Confucianism, and by the native Shintō religious perspective. As a unified value system, these social values have resulted in an emphasis on the group over the individual; a focus on family and clan, with priority being given to loyalty and hierarchy; sacredness associated with the elements of nature, and an integrated perspective on body and spirit. In addition, there are still religious connotations associated with the emperor and the land of Japan itself as having divine origins. All of these values, in turn, have influenced Japanese conceptions of ethics, which in general are dominated by relativistic and situational group norms.

During the late-nineteenth and early-twentieth centuries, a large percentage of engineers and scientists came from the samurai class. Thus, as Nitobe Inazo pointed out in his influential *Bushido: The Soul of Japan* (1900), the heritage of science and engineering ethics in Meiji Japan was associated with Japanese ideals of *chivalry*. However, perhaps as a result of Japan's ethnic and linguistic homogeneity, a written code of ethics for engineers and scientists was not introduced until 1938, when the Japan Society of Civil Engineers adopted the first one. This code, based upon its U.S. counterpart, was a pioneering work largely authored by Aoyama Akira (1878–1963), a leading engineer of the time, who had worked on the construction of the Panama Canal and had a well-developed international perspective, reflected in his humanitarian philosophy and his Christian beliefs. As Imperial Japan was hastening toward World War II, however, his work must be considered to have been well ahead of its time.

Ethical Concerns in the Postwar Recovery Period

In the postwar recovery period, during which first priority was given to materialistic goals, Japan experienced a tremendous turmoil in thought as Western idealism and democracy rapidly replaced prewar ultranationalistic values and the associated ethical framework. These were denied in large part because they were identified in the minds of the people with the political stand of Imperial Japan. In particular, the memories of Hiroshima and Nagasaki had a critical impact on how Japanese scientists, especially physicists, viewed their role in society. The Science Council of Japan (SCJ) declared at its first assembly after its establishment in 1949 that the aim of scientific research should be to contribute to the welfare of humankind and to world peace. When the government officially made budgetary arrangements for utilizing nuclear power in 1954, the SCJ demanded that research on and the use of nuclear energy be conducted on the principles of "openness, democracy, and independence." The first Japanese Nobel Laureate, the theoretical physicist Yukawa Hideki (1907–1981), was one of the signatories of the Russell-Einstein Manifesto (1955). After recommending to the government in 1962 and 1976 that it establish the Basic Act on Scientific Research, the SCJ proposed a Charter for Scientific Researchers, reemphasizing basic values such as human welfare, world peace, freedom of scientific research, safety, and internationalism. SCJ efforts to emphasize the social responsibility of scientists were important historically; however, because most members of the organization are senior scholars and researchers, its statements appear to have had limited influence on young scientists and engineers with career ambitions.

Changes in engineering ethics had a similarly limited impact. Modeled after the American system of consulting and professional engineers, and the British system of chartered engineers, the Japanese version of engineering licensing was legally institutionalized in 1957, and the Institution of Professional Engineers, Japan (IPEJ), formed in 1951. IPEJ adopted a code of ethics in 1961. However because of the limited number of licensed engineers (approximately 40,000 since 1958) and the general lack of interest in engineering ethics, this code was not widely promoted. In addition, the concept of *engineering as a profession* is unequivocally absent in Japan, most likely because the development of engineering was dominated by the state and industry, rather than by public forces. The Japanese employment system has also encouraged engineers to develop identities with their company rather than as part of a professional association.

Aside from such attempts to formalize ethical concerns, the postwar period could well be characterized as an *ethical vacuum,* in which traditional values dominated, but without an underlying ethical framework. The situation in bioethics perhaps best illustrates the difference between traditional and Western perspectives. The medical establishment is quite paternalistic in its approach. Informed consent has been recognized, but is not well institutionalized, with physicians sometimes using patients in experimental procedures without their knowledge. Truth-telling and patient autonomy are only slowly being recognized as significant values. Traditionally concealing the truth from patients, and more rarely from their families, has been seen as protecting the health of even dying patients. The assumption has been that physicians are authority figures, so that explanations to patients are not necessary. Only recently, for example, have physicians been held to account for practicing involuntary euthanasia.

On the societal level the impact of Japanese values has also been influential in the medical field. Despite legalization, religious and social norms have prevented any significant use of organ transplants. Conceptions of human nature have resulted in a hesitancy to adopt Western standards of brain death, further inhibiting both transplants and a widespread *death with dignity* movement. At the same time, abortion is commonly practiced in Japan without social stigma, both because the woman and fetus are considered to be one entity and because contraceptive pills are not generally available.

However any assessment of the state of scientific and engineering ethics in Japan must recognize that the society is entering a period of structural change, which has already begun to influence discussion about a variety of ethical issues. During the entire postwar period developments in technology were considered issues of national security and survival. National interests took priority over popular consumer desires. In order to spur economic development, the government took a central role in technological planning activities and in guiding research. Major corporations adopted systems of lifetime employment and seniority-based pay to foster workforce loyalty. Japan quickly became an economic juggernaut based on the total commitment of its workers and on the innovative use of management and production strategies such as quality circles and just-in-time supply procurement.

A New Emphasis on Ethics for the Twenty-First Century

Then came the decade-long recession of the 1990s, resulting in fundamental changes in corporate life and public attitudes. Japanese increasingly accepted the need for more global approaches, a move away from governmental direction, and more attention being given to the public. The impacts of these changes are evident in a variety of new discussions of ethical issues. In the area of bioethics, for example, there is a burgeoning patient rights movement and an increased emphasis on physician accountability.

Many of the cutting edge technological innovations in Japan have come from corporations rather than out of the university system. Consequently any changes in the corporate environment tend to influence discussions of research ethics. For example, notions of intellectual property are undergoing testing. Traditionally researchers received little monetary reward. However as Japan is moving toward more mobility in its professional class, with the weakening of lifetime employment and seniority-based pay, researchers are increasingly seeking a greater ownership stake in their work. University researchers are likewise being granted greater independence with a shift away from government direction of the university system as a whole. University science departments, operating on the chair system, in the past have been awarded a set amount of research funding rather than operating on a competitive grant basis. With change to a more merit based system, it can be expected that research priorities will be different and that increased coordination between university and corporate researchers will be established, in turn resulting in new discussions about ethical issues.

Another area that is undergoing change is concern about the natural environment. Although respect for nature is a dominant factor in the Japanese value system, during the period of economic expansion environmental preservation was considered secondary to economic growth. Since the late-twentieth century, especially after the signing of the Kyoto protocol in Japan, a renewed concern with the environment has been in evidence. Japanese are moving away from an ethics that emphasizes disposal to a recycling culture. There is also increased recognition of the global nature of environmental issues such as the heavy use of wood products in Japan and the lack of suitable disposal opportunities for refuse.

The 1990s was also a decade of awakening for engineering ethics. Various incidents and accidents having to do with engineering practice occurred, including a major sodium leak at the Monju fast-breeder reactor in 1995, the sarin gas attack in the Tokyo subway system that same year (by members of a religious cult who were educated as engineers and scientists), and the disastrous nuclear criticality accident in Tokaimura in 1999. These prompted increased interest in engineering ethics and major engineering societies established codes of ethics one after the other, starting with the Information Processing Society of Japan in 1996. The Japan Society of Civil Engineers revised its code honoring the spirit of Aoyama's contribution in 1999. By 2003 most of the major engineering societies had adopted codes, which in general include fundamental values such as giving first priority to the safety of the public, in common with their North American counterparts.

The process of globalization has had great impact on engineering ethics. In 1999 the Japan Accreditation Board for Engineering Education (JABEE) was established to harmonize engineering education with international standards, to enable participation in mutual recognition of engineering qualifications. This required ethics education as one of its components and set in motion a flurry of activity, ranging from short courses on the subject, to conferences, to modification of engineering curricula to include required courses on engineering ethics. All of this activity is financially well supported by the government, so that large numbers of people are involved in what is essentially a new area of inquiry in Japan. In this work there is a twofold emphasis on application to specific ethical problems and on theoretical philosophical analysis. Given the scientific-technological heritage of Japan, the emphasis in the discussions tends to be broader than it has been in the United States, leaning more toward a science, technology, and society (STS) perspective than one that emphasizes strictly professional responsibilities. This is in part because Japan has an existing tradition of STS studies and lacks a tradition of professional identification. The JABEE accreditation criteria therefore require the study of engineering ethics conceptualized as "understanding of the effects and impact of technology on society and nature, and of engineers' social responsibilities," as opposed to the U.S. standards that emphasize "professional and ethical responsibility" and put these in a separate category from the need to "understand the impact of engineering solutions in a global and societal context."

Given the attention to engineering ethics present in Japan, it can be expected that the discussion will increasingly impact the overall consideration of ethical concerns in Japanese society and its scientific community. The population as a whole appears to be seeking new standards of accountability in many areas of life, including business, government, and universities, and in relation to the environment. These discussions will be influenced by both local traditions and a more global outlook.

JASPERS, KARL

Psychiatrist and philosopher Karl Jaspers (1883–1969), who was born in Oldenburg, Germany on February 23, became one of the most important representatives of existential philosophy. He died in Basel, Switzerland on February 26.

Jaspers developed an existential analysis of technology in two distinct phases. His early conception of technology, which he put forth in *Man in the Modern Age* (1931), revolved around the transformation of human society into a mass, mechanized culture. His initial assessment of this transformation was negative. He wrote of the *demonism of technology,* describing technology as an independent power that had been summoned into existence by human beings but that now has turned against them. According to Jaspers, technology transforms human society into a mass culture, alienating human beings from themselves and from the world around them.

Jaspers considered mass-rule a byproduct of the close interaction between technological development and population growth, which results in a vast number of human beings whose existence becomes utterly dependent on technology. This dependency requires a quite specific social and cultural formation. Besides a mechanization of labor, society needs a smoothly operating bureaucratic organization in order to keep functioning. Society becomes a machine itself, described by Jaspers as *The Apparatus.*

This apparatus of workers, machines, and bureaucracy increasingly determines how human beings carry out their daily lives. It has two different but related effects. First its system of mass production fosters a homogenization of the material environment in which human beings live. No attachment is possible to mass produced objects, which only exist as exemplars of a general form and are primarily present in terms of their functionality. Second the apparatus approaches human beings not as unique individuals, but as fulfillers of functions who are in principle interchangeable. Both effects of the technological transformation of society impede human beings from being present as authentic existences, and from living their lives authentically and in existential proximity to the world around them. From an existential point of view, therefore, technology deprives human beings of their highest possibilities.

After World War II, Jaspers's analysis of technology changed course. Rather than viewing technology as a threat to authentic human existence, in *The Origin and Goal of History* (1949) and *The Atom Bomb and the Future of Man* (1958), Jaspers saw technology as what was *at stake* in it. He concluded that technology is ultimately neutral or no more than a means for human goals, because it is incapable of generating its own goals. This neutrality makes human beings responsible for what they make of technology: Technology requires human guidance.

Jaspers no longer considered demonism to be an intrinsic property of technology, but a result of the fact that humans have handled it as an end in itself, rather than a means for human ends. To overcome this demonism, therefore, humanity needs to ask itself the question of what it wants to do with technology. The task for human beings is to reassert sovereignty over technology.

This sovereignty, according to Jaspers, requires a reversal in thinking in which technological thought, or *intellect* (*Verstand*), is transformed into an existential way of thinking that he calls *reason* (*Vernunft*), and in which individuals are present authentically as themselves. Only this way of thinking will allow humans to experience the situation in which they find themselves as *their* situation, for which they are *responsible*. Reason can turn the contemporary situation into a task, and allow humanity to seek new goals for applying technology.

Jaspers's later perspective allowed him to discern not only a threatening side of technology but also ways in which it opened up new existential possibilities. These include new proximity to reality, by understanding the laws of nature lying behind the functioning of technology; recognition of the beauty of technological constructs; and making use of the possibilities opened up by media and transportation technologies, which allow humans to experience the Earth as one whole for which they can feel responsible.

Karl Jaspers, 1883–1969. The German philosopher wrote important works on psychopathology, systematic philosophy, and historical interpretation. *(David E. Scherman/Getty Images.)*

Jaspers's analysis is important as an existential philosophy of technology. Yet in light of later understandings, his separation of technology and society—with autonomous technology dominating society or a sovereign society guiding technology—has become problematic. An existential analysis of technology should take as a starting point the interrelationship of human existence and technology, and investigate how technologies mediate the ways in which human beings realize their existence, by impeding specific aspects of human existence and creating space for new ones.

JEFFERSON, THOMAS

The early American political philosopher and politician Thomas Jefferson (1743–1826), was born in Albemarle Country, Virginia on April 13. By the time of his death at his home of Monticello just outside Charlottesville, Virginia on July 4, Jefferson considered his three greatest achievements to be writing the Declaration of Independence, writing the Statute of Virginia for Religious Freedom, and founding the University of Virginia. It is nevertheless also the case that Jefferson's views on science, politics, and ethics present a uniquely American perspective on technological progress as flowing from individual liberty, economic freedom, and personal Christian morality.

This "American System" of viewing advances in scientific knowledge as part of political freedom and moral development, remains a distinctive approach to the social issues of economic development, education, crime, religious freedom, and personal happiness. Its confidence in technological and scientific progress tempered by religious and ethical considerations is the basis for American concerns with problems of medical/genetic ethics, environmentalism versus economic development, and private rights versus social responsibility. Its enthusiasm for the free individual and for relatively unrestrained international expansion of these American values has, at times, caused it to be accused of imperialism, hegemony, and disregard for traditional nontechnological and more hierarchical societies (including Islamic, African, and Asian societies) and for socialist economics. Much of contemporary world conflict, such as terrorism, is to some extent an extension of the debate over this "Jeffersonian" worldview of progress, knowledge, religious liberty, democracy, and individual freedom.

Jefferson as Scientist and Inventor

Jefferson's scientific and technological interests were wide ranging. He investigated every branch of science, from botany to biology, meteorology, archaeology, astronomy, chemistry, geology, mathematics, paleontology, and ethnology. He designed the curriculum at the new University of Virginia (1819) to revolve around a core of natural philosophy (science), including physics, engineering, and mineralogy, when most American colleges still focused exclusively on the liberal arts and divinity. He wished to develop as a discipline "the science of the mind" (contemporary psychology), calling it "moral zoology." Throughout his life, Jefferson conducted scientific studies and collected data. He studied new methods for determining the heights of mountains (using mathematical calculations with barometer measurements), tested atmospheric moisture with a hygrometer, and used double-refraction optical instruments to measure small angles, eclipses, lunar movement, and Earth's longitude. Jefferson was a close observer of nature, recording the appearance of many plants, animals, and birds on his Monticello estate and wherever his travels took him. He kept weather data all his life and shared it with other meteorological observers around the country.

Not confining his scientific interests to observation alone, Jefferson invented several useful products. His most famous invention was a new design for a moldboard plow, the simple and efficient design of which drew attention throughout the Association of Agricultural Societies in America and within England's Board of Agriculture. He also invented a swivel chair, a writing desk that could be placed on one's lap, a walking cane that converted to a chair, and a copying machine that duplicated letters as they were being written. He enthusiastically supported other inventions, including the hot-air balloon, dry docks for ships, the submarine, fireproofing for houses, telescopes, the camera obscura, carriage odometers, and personal pedometers. He was an advocate of the decimal system of American currency.

While U.S. minister to France (1785–1789), Jefferson consulted with European scientists on new inventions and the natural environment of the Old World. When he moved to Philadelphia as vice president in 1797, Jefferson brought a box of prehistoric bones for the American Philosophical Society museum. As U.S. President (1801–1809), Jefferson conducted botanical expeditions around the Washington, DC, area and distributed European seeds to the local vegetable markets. In the White House, he displayed scientific instruments, globes, charts, a dry-dock model, a mockingbird, and a grizzly bear (in the garden) brought back by the Lewis and Clark expedition (1803–1806), which he had commissioned. He led discussions on the serious cowpox disease and presented an evening slide show on "The Natural History of French Parrots."

Jefferson's Science Policy

Jefferson's main interest in science was as technology, or for its *usefulness*. The practical benefits to humanity, economic development, and individual happiness were always foremost in his mind. This explains his special devotion to agriculture, because food production was, for him, the basis of all other social wealth. For the same reason, he believed in the free sharing of scientific knowledge: that it would enhance the prosperity of all people in the world. He gave every new discovery to his neighbors without charge, showing that such shared knowledge "is the great parent of science and of virtue; . . . a nation will be great in both, always in proportion as it is free" (Letter to Joseph Willard, March 14, 1789). Therefore, the advance of science and technology, for Jefferson, necessitated economic freedom (capitalism, free markets) and intellectual freedom (freedom of speech, press, and academic inquiry), including religious freedom. Thus, political democracy is integral to technological advances.

Jefferson's intellectual attitudes and scientific interests sometimes earned him ridicule, especially from his political opponents (who caricatured them as "philosophical fogs"). But his own international reputation for scientific inquiry raised the prestige of American science throughout the world. Jefferson was elected to the Institut de France, the Dutch Royal Institute of Sciences, the Board of Agriculture in England, the Agronomic Society of Bavaria, and the Linnaean Society of Paris. His comparative study of European and North American animals refuted the French naturalist Buffon's claim of New World degeneracy (proving, for example, that North American otters weigh more than their European counterparts).

The cosmological foundations of Jefferson's scientific ethics may be described as "deistic science." That is, he believed (after Aristotle, Thomas Aquinas, Isaac Newton, and John Locke) that a divinity created the universe, rather than that the world emerged out of itself randomly. "[I]t is impossible for the human mind," Jefferson wrote, "not to perceive and feel a conviction of design, consummate skill, and infinite power in every atom . . . up to an ultimate cause, a Fabricator of all things from matter and motion, their Preserver and Regulator . . . an eternal pre-existence of a Creator" (Letter to John Adams, April 11, 1823). Such Creationist ethics for Jefferson implied that all of nature, including humankind, exists within God's laws. This commends, for him, a humble, reverent appreciation of the universe and shows the limits of human knowledge. Such divine, moral limitations serve as checks on scientific presumption and hubris, or human pride. Ethical concerns regarding genetic engineering, embryonic research, euthanasia, and nuclear power in the early twenty-first century reflect such Jeffersonian ethical sensibilities.

Jefferson's ethical philosophy reflected his scientific empiricism by placing values in a human "moral sense" (akin to other physical senses such as sight and hearing). Though of divine origin, this moral sense provides for Jefferson a biological basis for ethics, or knowledge of good and evil, justice and injustice. As with Aristotle's teleological ethics, however, this human capacity is innate but undeveloped. Society must educate and refine this ethical faculty, especially through religion, politics, and law. "I consider ethics, as well as religion, as supplements to law in the government of man," Jefferson wrote (Letter to Judge Augustus B. Woodward, March 24, 1824). The highest ethics for him was "the ethics of Jesus," or what he called "the most sublime and benevolent code of morals which has ever been offered to man" (Letter to John Adams, October 12, 1813). This consisted of a simple Christian ethics, such as that presented in Jesus' Sermon on the Mount. But the best means of learning these ethics, for Jefferson, was freedom of religion—the liberty of every individual to investigate, proclaim, and believe religious truth, and the freedom to change religious faiths on the basis of personal conscience. Jefferson believed that such religious freedom, like freedom of intellectual inquiry, economic activity, and scientific advancement, would produce the most prosperous, happy people.

JEWISH PERSPECTIVES

Judaism is the most ancient of three Abrahamic religions (the other two being Christianity and Islam) that are distinct from other world religions in at least three respects: they are all strongly monotheistic; they claim divine or supernatural intervention (revelation) into the world through their historical founders in ways that are in tension with natural reason; and they place special authority on one or more written texts. Judaism (like Christianity) also has a close historical relation with modern science and technology; historians of science have argued that in its origins science was dependent on a view of the world as well ordered and subject to human investigation and control precisely in the ways presented by the Jewish revelation, and certainly Jewish scientists especially are disproportionately represented in the technical community. At the same time, science and technology have presented specific challenges to Jewish tradition and identity, the responses to which offer special contributions to more general discussions of science, technology, and ethics.

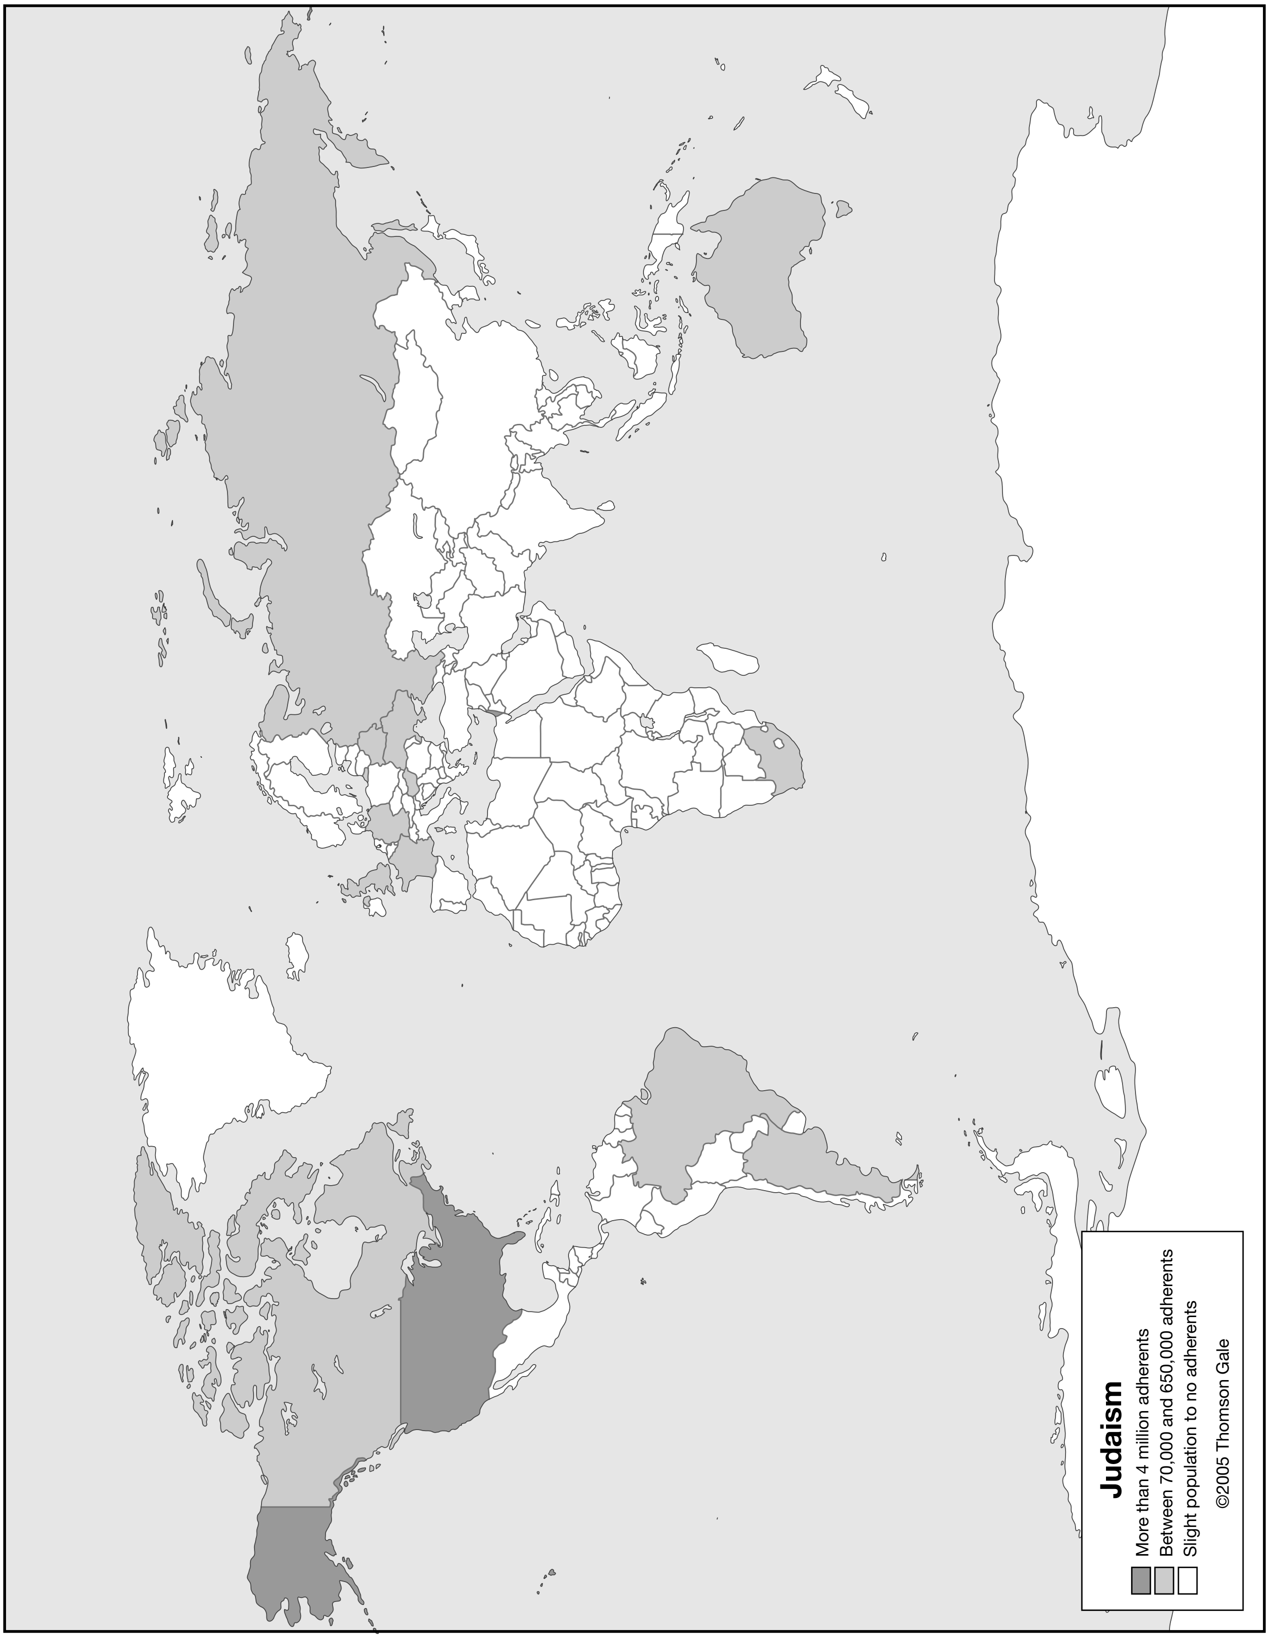
Approaches to Judaism

Individuals explain their adoption of a Jewish designation by their adherence in various degrees to one or more facets of the "Jewish way of life." Among the most important aspects are the beliefs that there is only one God; that the first five books of the Hebrew Scriptures (known as the Torah, containing 613 commandments and canonized between 700 and 200 B.C.E.) were handed down from God to Moses around 1500 B.C.E.; and that Jews should follow both the oral and written laws that have been handed down through the generations. These laws, which number in the thousands and whose varied selection or adoption accounts for the varieties of Judaism, are found in a number of tracts:

- The Mishnah (the oral law handed down from Moses and put into writing in six volumes about 1800 years ago).
- The Gemara, comprising commentaries on the Mishnah and other aspects of Jewish life and stories, found as part of the Talmud.
- The Talmud (of which there are at least two versions: Babylonian, with about 2.5 million words, and Jerusalem, about one-eighth the size), which is a commentary on the Mishnah and Gemara; it was compiled and redacted (canonized) between 300 and 500 C.E.
- The Midrash (also considered a part of the Talmud), a commentary on the first five books of the Old Testament.
- The Kabala, a book that emphasizes the mystical relationships between humans, God, heaven and its inhabitants, and hell with its entourage.
- The remaining thirty-four books of the English Old Testament, referred to as the Prophets and the Writings.
- The Apocrypha, which contains the books that were left out of the Bible when the latter was canonized to include additional sections on the prophets and writings (a process that began with Ezra in 530 B.C.E. and continued until the fall of the second temple in 70 C.E.).
- The Shulchan Auruch, a summary of the laws drawn up in the sixteenth century.
- The Haggadah, a story of the Exodus of the Jews from Egypt in about 1450 B.C.E., whose formulation began in pre-temple times (1000 B.C.E.); put into its conventional form in the thirteenth century but still provides the basis of numerous modern variants.

In addition to belief in the holiness of the above writings and the requirement to follow all or a selection of the laws, Jews may also define themselves in relation to:

- their descent from other Jews (in particular a Jewish mother, although in biblical times it is clear that patrilineal descent also pertained);
- their conversion;



Judaism
More than 4 million adherents
Between 70,000 and 650,000 adherents
Slight population to no adherents
©2005 Thomson Gale

- Jewish traditions such as those that pertain at rites of passage such as birth (plus penile circumcision in the event of a male child), confirmation as in a bar mitzvah for boys at thirteen and recently bat mitzvah for girls at twelve or thirteen, marriage, and death;
- the annual calendar of religious events such as the New Year (Rosh Hashanah), Day of Atonement (Yom Kippur), Passover (Pesach), Festival of Lots (Purim), Festival of the Lights (Chanukah), and others;
- culture defined in terms of types of food, cooking methods, respect for learning and education, charity, style of clothing, and modesty;
- the acceptance of the rulings of a court of Rabbis referred to as a Beth Din;
- the need to have at least ten men (a minyan—and recently, may count women) in order to have a fully competent prayer meeting;
- the State of Israel, which is the country in the world where a persecuted Jew may seek succor without further fear of the pogroms or selective legislation that has been a characteristic of the history of most other countries;
- or a membership in an internationally dispersed community that has a common history or treatment in the hands of a variety of host communities.

In structural terms, a Jew who seeks to follow the laws may refer to the literature cited above or consult a rabbi. There is an extensive correspondence extant that consists of individuals or communities asking for guidance from the most eminent rabbis of the day. The *responsa* that result constitute the norm for the behavior of the respondent. This worked well for ghettoized communities living in relatively static circumstances, but history since the mid-eighteenth century has been anything but static.

On the basis of which tenets an individual Jew adopts, he or she will associate (or not) with one or more of the recognized religious groups. These range from the ultra-orthodox (themselves divided into sects such as the Lubavich, Satmars, Aish, Chasidim, and Chaderim) who reject the opportunities of the modern world and generally do not permit their children to view television (although they may make use of the Internet for Midrashic discussions, with Web sites such as http://www.vbm-torah.org), to the Liberal Progressives with whom virtually anything goes. In between there are the Orthodox, Masorti, Conservative, Reform, and Liberal groupings.

Science, Technology, and Judaism

The European Enlightenment of the seventeenth and eighteenth centuries sowed the seeds of the modern world in which science and technology have changed both the way people think and the way they live. Beginning with the works of Francis Bacon (1561–1626), René Descartes (1596–1650), Isaac Newton (1642–1727), and others, the Enlightenment challenged the Jewish community as it did other religious groups. Those who were in occupations that brought them into contact with prominent business people, politicians, or royalty rapidly learned the language of the host country and became both educated and secular to differing degrees. In the late 1700s and early 1800s, Jews in Germany, Poland, Russia, Holland, France, and Austria set up schools where the medium of education was the national language and where Yiddish (or Jewish German) was in some cases outlawed for education and business transactions. At this time science was beginning to make a showing in these curricula, especially at the secondary level. As time advanced, science began to provide secular explanations of the biblical miracles, of the creation of the universe, of the creation of life, and of the creation and nature of humans and their relationships to the rest of the living world. Not only did science provide challenges to the intellect and belief system, but technology and engineering offered new ways of working, of traveling, of writing, and of doing business. How did Judaism and the Jews respond to these changes?

In the contemporary world, the Jewish people live either in Israel or outside Israel in the so-called Diaspora. In the early twenty-first century in Israel about one third of the Israelis are secular, another third are religious and follow the dictates of the laws with varying degrees of observance, while a middle third would acknowledge a belief in God and do not follow many of the laws in their day-to-day lives, but observe them during rites of passage or special occasions such as the reading of the Haggadah at Passover. Nevertheless, the secular government of Israel does not generally legislate on matters of a religious nature. While the government allows Jews a right of return to Israel, it has not so far made a legal definition of who is a Jew. The government does, however, require a religious marriage for official dealings; nevertheless, foreign civil marriages are recognized. Local authorities, however, may choose to operate transport systems on the Sabbath or may ban them as being contrary to religious laws that forbid travel on the Sabbath. Similarly, erotically suggestive advertisements may be banned by some localities while accepted in others. Work on the Sabbath is generally banned nationally, although particular industries may obtain special dispensations from the government. Those industries that are essential to the economy such as defense, food, and health care find it easy to obtain licenses to operate, as do industries that rely on continuous processes, an interruption to which will disrupt production with considerable economic loss.

The introduction of new technology has presented religiously disposed Israelis and Diaspora Jews with many concerns. This is because the laws as defined by that body of literature that is accepted as the Halakhah expressly forbid many of the applications that are made possible by contemporary machines and devices. There are four main areas where such concerns are expressed. The first relates to the observance of the laws pertaining to work on the Sabbath. A second concerns determinations as to whether certain food preparations are in compliance with the religious laws of kashruth—that is whether they are, or are not, *kosher*. This latter term derives from the biblical laws of what foods are allowable (Lev. 11:2–47); for example, it is allowable to eat meat from cloven hoofed animals that chew the cud but not shellfish, a calf may not be cooked in its mother's milk, and creatures that crawl on their bellies are forbidden. A third set of issues relate to health care and medicine. Finally, a fourth area of concern focuses on changes occurring in agriculture.

The fourth commandment requires Jews to keep the Sabbath holy and to do no work on that day. But what is work? This is often held to be activities of a constructive nature such as preparing food, making a tool or object, giving professional advice, teaching (but learning is acceptable), and doing anything that creates fire, such as making a spark whenever an electrical contact is made. Similar laws apply on holy days.

These prohibitions are managed in a number of ways. First, one may appeal to an overriding statement by God in the Torah (*Deut.* 30:19): *Therefore choose life* . . .''; if work is effected in an effort to save life, it would be acceptable. Secondly, it is possible to employ a non-Jew to do the constructive work on the Sabbath, such as to make the fire, heat food, or run a factory. A third option is to use an automatic device such as an electrical timer switch. A battery of these switches may be programmed and used to effect the daily routine jobs that require electrical equipment (heating, lighting, cooking, communicating, elevators, and alarms). It is moot as to whether a modern computer can be used as part of this automation process or whether its use is proscribed because it is an instrument of writing.

To engage in more detail with those issues where a technological fix can obviate a religious prohibition, the Institute for Science and Halakhah was founded in Jerusalem. This body seeks to use sensor systems, robotics, computers, and information devices to loop around the traditional laws and accomplish ends that would otherwise have been forbidden. Its work is proving so successful that this independently-funded body has been adopted as an element of the national government.

Whether or not food is kosher is defined by the rabbis of the local jurisdiction or on appeal to a more respected rabbi with international stature. Clearly, because food is now purchased as pre-prepared items or is made as a composition in tins, it is difficult to know whether or not such material is kosher. While many food producers act under the supervision of the rabbinate, it is possible to produce kosher foods outside this restriction. A food ingredients list is helpful, but it does not specify the way the ingredients are produced in sufficient detail to satisfy a rabbi that non-kosher material was not been prepared with the same equipment and the washing process was effected with sufficient (and often excessive) thoroughness that it could be used for kosher manufacture.

In addition to pig insulin, pig heart valves are generally deemed acceptable for transplantation into observant Jews. As and when pigs are reared that are immunologically compatible with human immune systems, the transplantation of pig hearts, livers, lungs, kidneys, and other organs might also be deemed acceptable by the orthodox Jew.

However, there are medical issues in the area of abortion and *in vitro* fertilization that exercise the minds of those seeking ethical acceptance from a Judaic standpoint. Facing infertility, an orthodox Jewish couple could receive a dispensation from a rabbi for *in vitro* fertilization, even if this means creating extra embryos that are eventually killed. Abortion, however is generally forbidden unless the health of the mother is threatened. There are other issues that raise concern, such as blood transfusion: many religious people believe that a person's life is in the blood, and to accept another person's life (albeit in part) is not allowable (*Lev.* 17:13–15).

The relevant agricultural restriction is that it is forbidden to plant two different kinds of seed in the same field. From this standpoint, genetically manipulated seeds do not present a problem nor do trees that are grafted because the stock and the plant are of the same type. However, the production of hybrid plants that derive from clearly different stocks does cause difficulty and some religious kibbutzim (Israeli agricultural settlements) do not permit themselves the advantages that hybrid vigor provides.

Where science challenges religion most is in those areas that have to do with origins and miracles. Judaism seems to be able to ride the resulting intellectual issues with aplomb. It takes evolution in its stride by asserting that Darwin's ideas are but hypotheses; they have not been, nor can they be, proven. The account of creation in the Torah, however, is a truth as it was given to Moses by God and this constitutes the "gold standard" of knowledge. A mere hypothesis cannot seriously challenge such a truth. The miracles may be treated similarly. There may well be scientific explanations for some of the miracles. For example, the turning of the river Nile into blood by Moses may be explained by the emergence of a bloom of a euglenoid alga that has lost its chlorophyll and appears red by virtue of its red carotenoids. It yet remains possible that God performed the event to provide Pharaoh with evidence of his powers to effect miracles.

When it comes to metaphysical considerations such as the nature and origin of matter, Judaism relies on a belief in an all-powerful God who created all things. Theories of the big bang still leave dangling the origin of the matter that made the "bang" possible, or the process whereby all the matter in the universe was made in an unimaginably short time. The possibility of God creating other universes is not considered, although there is no reason to uphold the claim that humans (and maybe others) inhabit the only universe. Since the beginning of the twentieth century, humans have come close to understanding how an abiotic (lifeless) world some four billion years ago gave rise to a molecule that evidenced the properties of life. The story of the evolution of this notional entity to humans, is also well thought out. Nevertheless, those who profess a strict adherence to the literature and the codes of Judaism will not brook such thinkings because they adhere to the letters and words of Genesis.

JONAS, HANS

The intellectual heritage of Hans Jonas (1903–1993) spans and reflects the twentieth century. Born in Mönchengladbach, Germany, on October 4, he died in New Rochelle, New York, on February 5, having become one of the most important contributors to philosophical reflection on science, technology, and ethics. For more than half a century, Jonas worked consistently to develop a persuasive alternative to modern nihilism in its diverse existentialist, positivist, scientific, and technological manifestations.

Life and Works

In Germany Jonas studied with the major figures of philosophy such as Edmund Husserl (1859–1938), Martin Heidegger (1889–1976), and the Protestant theologian Rudolf Bultmann (1884–1976). His doctoral dissertation adapted Heidegger's Dasein analysis from *Time and Being* (1927) to demythologize Gnostic texts from the early centuries of the Common Era, revealing the extreme dualism and world estrangement of this ancient religious literature. Increasingly aware of the social estrangement of Jews in Europe (his mother would be murdered in Auschwitz), Jonas joined the Zionist movement and, as the Nazi's came to power, left Germany for Palestine. During World War II he joined the Jewish Brigade of the British forces in Italy as an artillery soldier; in 1948 he fought in the Israeli War of Independence.

During this period Jonas also began to reflect on the philosophical problems of modern science, especially biology, distancing himself from Heidegger and Gnosticism by noting the parallels between the inimical cosmos of Gnostic belief and the conception of an indifferent nature found in science. In 1949 he left Israel for Canada, and after a few years moved to New York, where he taught at the New School for Social Research until his retirement. From the 1960s on, Jonas made a number of visits to Germany and as a result published frequently in the German language. He became influential in the land of his birth, especially in the Green movement. He received European recognition for his work, beginning with the *Friedenspreis,* the peace prize awarded by the German Book Trade, in 1987.

Jonas first major book was *The Phenomenon of Life* (1966), his initial foray into a phenomenological interpretation of biology that might disclose the metaphysical significance of organic phenomena. *Philosophical Essays: From Ancient Creed to Technological Man* (1974) contains his first essays on the ethics of technology. His single most important book, *The Imperative of Responsibility: In Search of an Ethics for the Technological Age* (1979), brings together these two lines in an attempt to ground his ethics of technology in a philosophy of nature. Over the last two decades of his life, Jonas sought to extend the practical applications of his thinking while deepening its cosmological and theological foundations in such works as *Technik, Medizin und Ethik* (Technology, medicine, and ethic) (1985) and *Mortality and Morality* (1996). *Errinnerungen* (Recollections) (2003) is a collection of autobiographical interviews.

Hans Jonas, 1903–1993. The German-born philosopher is best known for his influential work, *The Imperative of Responsibility*. His work centers on social and ethical problems created by technology. (*© Bettmann/Corbis.*)

Responsibility for Integrity and Sustainability

In his central work, *The Imperative of Responsibility,* Jonas spells out the need for an early formulation of the precautionary principle that he calls the *heuristics of fear,* which gives "prevalence to the bad over the good prognosis" in case of unforeseeable and irreversible technological risks to the future of humankind (Jonas 1984, p. 31). For Jonas, such a procedure is justified by the ontological idea of humanity as that being which is able to bear responsibility. Because of this capacity, Jonas argues that humans have an unlimited responsibility to preserve life on Earth, in which they, as those who bear responsibility, may be primary, but which encompasses all of nature. This responsibility is total, continuous, and future oriented. Parental responsibility for children is archetypical, although in this case there is a terminus: Children grow up and become adult bearers of responsibility themselves. But with regard to nature, responsibility does not cease. The imperative of that responsibility associated with technology is to pass on responsibility, or more generally, to safeguard conditions for the continual existence of responsibility on Earth. Indeed, for Jonas, "The presence of [human beings] in the world is demanded to ensure the very premise of responsibility—the existence of mere candidates for a moral order" (Jonas 1984, p. 10).

Until the modern period, responsibility for the integrity of life on Earth was not a human imperative, because nature took adequate care of itself. But the human relation to nature has decisively changed. Human responsibility is disclosed in its new intensity by the vulnerability of nature to human destruction and to the potential mutilation of the human genetic heritage by long-range effects of modern science and technology. The world now needs human care to a degree previously unexperienced in the history of humankind. This theory holds insofar as one accepts Jonas's argument that a striving, teleological nature, revealed in the attempts at self-preservation among even the most primitive forms of organic life, constitutes an objective affirmation of good that is infinitely superior to a cold and indifferent universe.

Criticisms

Four main criticisms have been leveled against Jonas's ethics of technological responsibility. A first is that his responsibility is too general or formal. Who is responsible for what? Jonas maintains that humanity ought to exist. But Richard Bernstein (1995) replies that even if one accepts the general goodness of organic nature as a whole, no obligation to exist follows for humanity, nor does obligatory human existence imply any specific moral guidance for medical or environmental practices.

But the imperative of responsibility is not meant to be part of a deductive system. Instead the heuristics of fear and criticism of utopianism offer more practical counsel. According to Jonas, utopianism is a form of idolatry that the heuristics of fear counters by pointing out how in the technological pursuit of utopian goals the integrity of natural species or even of human existence may itself be at stake. Categorical responsibility functions as the overriding argument for preservation.

A second criticism asks whether Jonas's ethics is compatible with democracy and personal autonomy. Jonas has little faith that democratic politics works beyond short-term interests. Eventually a noble tyrant might have to avert the apocalypse. There is a parallel in medical ethics in which Jonas treats the requirement of informed consent as a problem instead of a solution. In both cases, Jonas seems to hold the view that fallible autonomous subjects need to be protected from themselves.

This reflects the asymmetry of the concept of responsibility. For Jonas, morality is not based on a social contract made up by self-reliant individuals, but originates with the call for protection from vulnerable beings. Human beings have to work to ensure the welfare of future generations because those generations cannot do it for themselves. In medical experiments, the sick should be the last to be recruited as subjects because they are the most vulnerable and dependent. Nevertheless the implied paternalism, though restricted to negative injunctions (*Do not* or *Refrain from doing*) represents an unpopular and therefore important perspective.

Third is whether the restoration of a metaphysical ethics is necessary to answer questions posed by modern technology. Karl Otto Apel (1994) strongly rejects Jonas's metaphysical principle of responsibility as incompatible with justice. The survival of humanity might entail the starvation of many people in developing countries, which Apel refers to as a social Darwinist solution.

But as in the case of democracy and autonomy, Jonas is well aware of the dilemma. Moreover he does not dismiss the demands of justice but relates their obligating force to the still higher duty of sustainability. Whereas Apel argues that there is no meaning in survival without justice, Jonas replies that there is no meaning in justice without survival. According to Jonas, sustainability is finally a metaphysical issue. Prevailing attempts in the ethics of technology based on nonmetaphysical, symmetrical rationality seem unable to enter substantive discussion on topics involving individual liberties. Therefore it becomes impossible to put a hold on the insatiable demands of the modern individual for justice, safety, health, and welfare. Jonas meets this vacuum with his *first rule:* that no future condition should be accepted that would affect the integrity of humanity.

Finally the boldest aspect of Jonas's ethical theory, involving the move from *is* to *ought*, is his claim that living nature objectively appeals to human responsibility to heed its integrity. Lawrence Vogel, however, criticizes such *cosmic deontology* as unnecessary in his 1996 introduction to Jonas's *Mortality and Morality*. Jonas clearly aims to replace Kantian deontology with an equally categorical imperative in which nature serves as a good in itself. If this were not the case, human obligation might be illusory. But perhaps it is not cosmology that teaches people to be responsible for living nature and the future. Maybe the reverse is the case: A basically self-evident responsibility teaches respect for a cosmos that brought forth life in its manifold of species and in its depth of subjective intensity. Yet while others argue for an ethics rooted solely in the social world, Jonas deliberately invokes an argument that overarches both the social and the natural domains. When considerations of the limits of progress lead to discussions of the limits of the human condition, people have to proceed from ethics to metaphysics in a new attempt to answer eternal questions regarding poverty, illness, and evil, in both natural and human forms.

JOURNALISM ETHICS

Journalism is the profession of writing, editing, and publishing high-frequency periodicals that aim to report and comment on events of public interest, commonly called *news*, with its frontline practitioners those who gather the data—reporters, photographers, videographers—and those who approve the data and prepare the collection of text and visuals for presentation—editors and producers. The unique role-related responsibility of journalists, which includes all of these practitioners, in democracy is to communicate to citizens information needed for self-governance. Self-governance includes the most mundane of decisions, such as what weather to prepare for when driving to work, and the most complex of choices, such as voting on referendums or candidates for public office.

As a profession journalism is dependent on certain ethical standards to maintain the credibility needed to perform its role-related responsibilities. The professional acts of discovering, reporting, and disseminating the news is dependent on various technologies. Thus insofar as both changes in science and technology alter the practice of journalism and journalists report on scientific and technological news, journalism ethics is of relevance to science, technology, and ethics, and vice versa.

Origins and Ethics

Journalism has emerged parallel with the development of technologies for the rapid, mass dissemination of written texts and broadcast messages. Although anticipations can be found in serial official announcements such as the *Acta diurnal* (Daily proceedings) of the Roman Empire or the *Tching-pao* (Palace news) of the Chinese T'ang dynasty, the first modern news sheets appeared in Germany in the 1450s, where Johann Guttenberg invented the printing press. The first true newspaper was probably the *Gazette de France*, which began publication in Paris in 1631. Since then both Germany and France have maintained strong journalistic traditions, which after World War II exhibited special expertise in reporting on science and technology in relation to, for instance, nuclear weapons and environmental issues. Indeed one can argue that the strength of the environmental movement in Europe rests in part on such reporting.

The early 1700s is sometimes described as the golden age of English journalism, with what are now classified as more literary journalist-publishers such as Joseph Addison (1672–1719) and Richard Steele (1672–1729), among others, developing the occasional general interest essay in the *Spectator* and the *Tatler*. Such essays are no doubt ancestors of the personal columns and op-ed perspective pieces of the present. In another development, when the London *Times,* founded initially in 1785 as the *Daily Universal Register*, published dispatches from correspondents at the front during the Napoleonic Wars (1793–1815), it was the first time the public was able to read about the results of military battles from other than government sources.

In the United States the rise of the journalism profession is strongly associated with the writing and publishing of early patriots such as James Franklin's *New England Courant* and his younger brother Benjamin Franklin's *Pennsylvania Gazette*. In part because of the contributions of the press to successful revolutionary politics, the first amendment of the U.S. Constitution (1791) guaranteed freedom of the press to a historically unprecedented degree. The development of this freedom during the mid-1800s drew on new technologies to create a pluralistic, mass circulation *penny press,* which in the late-1800s began to be consolidated into a set of newspaper chains that themselves drew on new means of communication such as the telegraph. These major newspapers subsequently separated themselves into the high-standards press (*New York Times*, *Washington Post*, among others) and more popular publications that practiced what was criticized as *yellow journalism*.

Reaction to the distortion and sensationalism of yellow journalism, with its power to influence events through muckraking exposes and jingoistic politics, led to efforts to professionalize the field. In 1892 Joseph Pulitzer proposed the creation of a school of journalism at Columbia University (which did not happen, however, until twenty years later). At virtually the same time, in 1909, reporters themselves established their first professional association (the Sigma Delta Chi fraternity, which in 1988 changed its name to the Society of Professional Journalists). It was in these two contexts that ethics began a process of explicit development, with the first code of ethics for professional journalism written by members of Sigma Delta Chi in 1926. Two organizations focused on science writing emerged at about the same time. The American Medical Writers Association traces its origins to 1924, with the development of its own code of ethics in 1976. The National Association of Science Writers was formed in 1934 to promote the dissemination of accurate information regarding science.

Following from the interdependence of technical and professional growth, wire services contributed to the development of common journalistic standards. Wire services, which sent a single story or photograph to multiple outlets via telegraph, then telephone lines, then satellite, both reflected and influenced subscriber news organization standards. The service had to meet the professional demands of its subscribers, but it also served as a model for local news organizations.

Journalism ethics at the macro level describes and criticizes the practices of news organizations and the role journalism plays in society. Drawing on the disciplines of history, sociology, philosophy, and political theory, scholars work to distinguish those practices that are ethically obligatory, desirable, and proscribed. At the micro level journalism ethics both describes and argues for normative behaviors of individual practitioners and the profession.

In a democracy, journalists play a central role in providing citizens with the information they need to practice self-governance. In a highly scientific and technological democracy this responsibility extends to accurate reporting on science, technology, and engineering. This role-related responsibility in journalism to present informative accounts of issues and events, including of science and technology, serves as the basis for a cornucopia of ethical issues.

At the macro level such issues include critical assessment of (a) domination of media attention and story spin by the most powerful; (b) the presence of less powerful individuals and groups often not considered immediately newsworthy; and (c) the determination of events, issues, and people as newsworthy based on audience interest, government promotion, or corporate influence. These macro issues are apparent in which scientific actions get reported and which get ignored. The science that finds its way into the public press is that most easily distilled, most eagerly promoted by articulate spokespersons, and which attracts funding or policy discussions.

At the micro level issues include (a) conflicts between media exposure and individual desires to limit such exposure; and (b) conflicts between professional journalist responsibilities and recognized or unrecognized bias by reporters.

Scientific and Technological Change

While the Internet has made it possible for all people with computer access to broadcast their messages, recognized news outlets remain in the hands of a few corporate owners. "In Britain now, 85% of the national daily press is in the hands of four groups . . . In the United States . . . six companies control most of the media" (Bertrand 2003, p. 5). Technology has offered the tools for true participatory democracy, but technology has also limited the countries and corporations that can reach the world through satellites in geostationary orbit.

Since the early-1800s, technology has influenced how journalism is practiced, produced, and presented. Technological advances that have affected journalism include methods of recording events as well as methods of data transmission from the field to the news organization and from the news organization to its audiences. The challenge for the profession is to use evolving technology to meet the institution's unique role-related responsibilities. Technology also makes some unethical acts, such as fabricating photos or recorded quotes, easier to perform and more difficult to detect.

The standard of *objective reporting*, for example, finds its origins in the development of the wire service in the early-twentieth century. For the first time, it was possible for reporters, and then photographers, to be present at a distant scene and disseminate coverage of the event to large numbers of news organizations at the same time. What sold best to audiences in a variety of markets was journalism that appealed to the broadest possible interests. Journalists covering the story could not make assumptions about the political, religious, or cultural beliefs of readers and viewers as they might have when reporting for a specific hometown audience. Thus the reporting that worked best for the most general audience became the standard. Generations of students in journalism schools learned to report the five W's and an H—who, what, when, where, why and how—with the importance of each obvious in its order of appearance in the news product. The technology of precomputer pagination dictated an inverted pyramid style of reporting that put the most important facts at the top of the story so that the layout staff could lop off from the bottom of an account material that did not fit into limited space.

While these technologically influenced norms served as standards for the field of journalism, they did not necessarily assist in meeting role-related responsibilities. For example, one general interpretation of objective balancing of facts is the myth that each story has two sides that must be accurately presented. Complicated stories involving policy decisions have many sides. When a story is reported as a two-sided issue, the reporting itself creates a polarized debate rather than a nuanced public discussion. The attempts to establish a national healthcare system in the United States in 1994, for example, was reported as a political debate between the Clinton White House and the Republican-controlled Congress. The story of the need for uninsured citizens to access needed healthcare was overpowered by the win-lose style of its presentation. It took another decade before the public issue of developing a new healthcare policy could be discussed without the goal being lost in the reporting. Technological advances during the 1990s added to technology-accommodating norms, such as photo-transmitting cell phones. Digital cameras and satellite transmission made the delivery of information from the field to the news organization instantaneous. In homes the introduction of cable and satellite television and the World Wide Web (WWW) allowed for multichannel broadcast, 24-hour news channels, and instantaneous transmission of material from the news organization to the audience. Indeed, in an era of live coverage, the news organization itself is bypassed by journalists and nonjournalists who are on the scene, broadcasting and making their own decisions about what to reveal and what is and is not news.

The resulting norms, as questionable as the striving for two-sided objective news coverage, include the following:

1. an assumption that on-the-scene coverage is the best;
2. accessible information is synonymous with news;
3. news is a never-ending evolution of first impressions or viewable dramatic events—while interpretation and context building may get viewers and broadcasters through quiet periods, it is access to new and dramatic pictures that creates *breaking news;*
4. mediated reality is reality.

The first news team on the scene is more likely to report speculation than fact. Turning a camera to a scene and flooding viewers' homes with dramatic images creates mediated events, not news.

News stories developed for print dissemination or electronic news packages are more than recordings of slices of reality. If information is to be useful to citizens for self-governance, they need to understand the context and meaning behind events. Citizens are dependent on journalism to know what is happening in the world, but it is easy to confuse mediated reality with reality.

Experiencing the events of September 11, 2001 in New York City, or at the Pentagon, was far different from watching the scenes played out on television. Yet most viewers felt they *experienced* the terrorist attacks through the media. *Watching* the second plane hit the South Tower, *watching* the towers tumble, *watching* those on the scene scramble for safety was possible for everyone with access to a television screen, what one author calls *mass interpersonal communication*. (Newton 2001, p. 153). But making sense of a mediated event is limited by what the videographer, story producer, and news organization has chosen to show the audience.

American journalism has cultural domination of broadcast media in that it serves as primary source material for historians and others who create records of contemporary events (Winch 1997, p. 4). The importance of these accounts create the ethical necessity for journalists to use technology to enhance their ability to meet role responsibilities rather than allowing technology to create standards that interfere with meeting those responsibilities. The technological worldwide domination of American journalism also creates the ethical necessity for journalists to perceive of themselves as representing global, not national, interests. Reality, if left unrecorded, is not available for public consideration or discussion.

According to communication scholar Paul Ansah, a problem with the domination of technology and news is "the paucity of the horizontal flow of news among developing countries in the South, thus compelling people in those countries to see one another from the perspective of foreign correspondents whose value systems, ideological options and even prejudices are reflected in the reports" (Ansah 1986, p. 66).

The Internet gives every person with access to that technology the opportunity for free expression and access to a world of ideas. In twenty-first century university life in the United States, where professors expect students and colleagues to exist in a wired world, it is easy to forget that such access actually exists only for the privileged few. According to a 2003 UN report, 91 percent of Internet users represent 19 percent of the world's population.

Yet in a world in which anyone with access can find an audience—what might be called information anarchy—credible journalism is more necessary than ever to sustain democracy. Citizens "need a guarantee of authenticity. . . . There is an ever greater need for competent, honest journalists to filter, check, and comment upon the information available" (Bertrand 2003, p. 4).

Specific Ethical Concerns of Reporting on Science, Technology, and Engineering

Science coverage rose steadily from the mid-twentieth century into the early-twenty-first century. The explosive growth in technology and in medical knowledge fueled a steady stream of science news. The need for average citizens to achieve a higher degree of science literacy so that they could understand and operate new technological equipment and so that they could understand and access advanced medical technology created a greater and sustained need for mediation between experts and general public.

Increasing awareness and concern for environmental impact on the part of scientists, policy makers, and the public created the same need for the development of environmental journalism as a specialization. Journalism education responded with the development of science writing courses and curriculum.

A 1978 directory (Friedman, Goodell and Verbit) found fifty-nine colleges and universities teaching 104 science communication courses including those in general science, technical writing, environmental journalism, and agricultural journalism. A mid-1990s update of Sharon Dunwoody's directory found an increase in the number of programs, courses, and specializations. For example, specialized communication courses were offered in risk, engineering, cyberspace, marine science, and earth sciences, in addition to general science, and technical, environmental, and medical writing.

Journalists and scientists continue to recognize the need for collaboration between the professions and to understand the different professional conventions that make such collaboration difficult. Professional societies, web resources, and workshops for scientists and journalists are necessary to create a communication bridge between science and the public it affects.

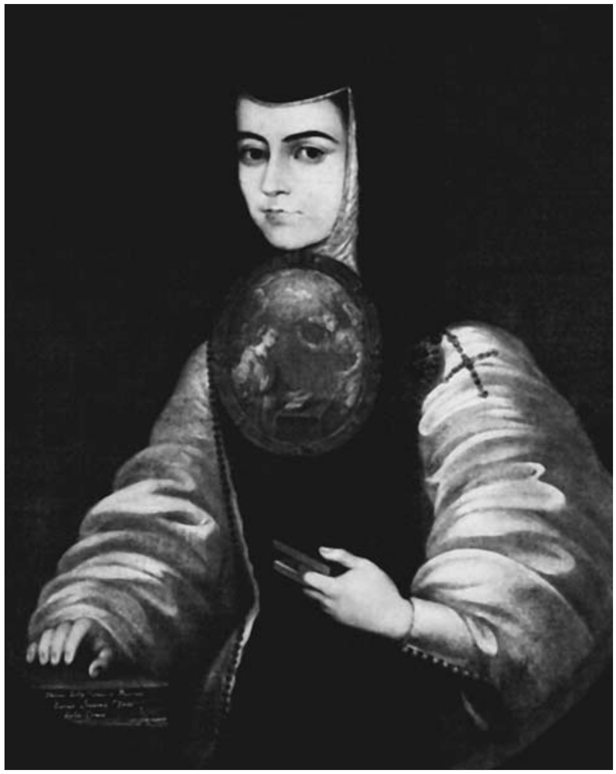
JUANA INÉS DE LA CRUZ

Born in Nepantla, near Mexico City, Sor Juana Inés de la Cruz (1648 or 1651–1695) is best known as one of the greatest Baroque poets and as the iconic forerunner of Hispanic feminism. However, the significance of her work and life in studies of the relationships among gender, science, and society in New Spain (Mexico) and colonial Spanish America has been gaining greater recognition.

In 1662 Sor Juana, then known by her birth name, Juana de Asbaje y Ramírez, was admitted into the service of the viceroy's wife, the marquise of Mancera, who became her protector, a role later filled by the wife of the succeeding viceroy, the countess of Paredes. Believing that a religious life was most compatible with her intellectual pursuits, Sor Juana entered a Carmelite convent in 1667 but left after three months, eventually joining the more lenient order of San Jerónimo in 1669. In the convent Sor Juana pursued her scientific studies—of which little is known—and wrote the bulk of her literary works despite the opposition of her confessor and the archbishop of Mexico.

The first volume of her collected works was published in Madrid in 1689, with the publication of the second volume occurring in 1692. In 1694, under ecclesiastical pressure, Sor Juana renounced all literary activity, sold her library and scientific instruments, and signed in blood a profession of faith in which she described herself as "the worst of all." She died on April 17, 1695, during an epidemic. An unfinished poem and some money were found in her cell. The third volume of her collected works was published in 1700.

Her poetry, especially "Dream" (1692), which is less a description of a dream than an allegory of the acquisition of knowledge, has been read as a feminist interpretation of Cartesian thought and, alternatively, as the most complex instance of the confluence of hermetic science—as exemplified by the works of the German Jesuit Athanasius Kircher (1601–1680)—and literature in the Baroque period. However, it is in her autobiographical works, such as the "Letter of Monterrey" (1681), addressed to her confessor, and the public "Response to Sor Filotea de la Cruz" (1691), a true *apologia pro vita sua,* that her most explicit critique of the limitations placed on the intellectual and scientific endeavors of women by the colonial patriarchal religious and political hierarchies can be found. In defense of her right to engage in intellectual activity, Sor Juana identifies in the "Response" a genealogy of women intellectuals—including such diverse examples as Hypatia of Alexandria (370–415), Saint Gertrude the Great (1256–1311), and Queen Christina of Sweden—and argues that humanistic and scientific pursuits are compatible with theology and necessary for its comprehension. Sor Juana also defended the importance of what in her time were spaces and activities for scientific knowledge, claiming that "Aristotle would have written more if he had cooked" (Sor Juana 1951–1957, p. 460).



Sor Juana Inés de la Cruz, 1651–1695. Sor Juana Inés de la Cruz was a Mexican nun renowned for her phenomenal knowledge of the arts and sciences of her day, her devotion to scientific inquiry, and her lyric poetry. *(Philadelphia Museum of Art/Corbis-Bettmann. Reproduced by permission.).*

Although Sor Juana's tragic fate demonstrates that her words were ignored by the misogynist and antirational establishment of seventeenth-century colonial Mexico, her criticisms of the ethical limitations of patriarchal science and knowledge have begun to be acknowledged as prefiguring feminist approaches to the study and history of science.

JUNG, CARL GUSTAV

Psychologist Carl Gustav Jung (1875–1961), who was born in the village of Kessweil, Switzerland on July 26, and died on June 6 in Zurich was, along with Sigmund Freud (1856–1939), a creator of depth psychology. His controversial research in this area has ethical implications for both makers and users of modern technology. Jung received an undergraduate degree in psychiatry at the University of Basel and completed his doctoral studies at Burghölzli mental hospital in 1902. In 1907 he achieved international recognition with his seminal study of dementia praecox (schizophrenia), leading to a five-year collaboration with Freud, the originator of psychoanalysis. By 1912, however, Jung found his ideas diverging from those of Freud, and from that point until the end of his life, Jung's intellectual journey was both creative and independent.

Like his former mentor, Jung was determined to penetrate and comprehend the human psyche at the deepest possible level. Unlike Freud, who emphasized the central importance of childhood experience in the understanding of neuroses, Jung focused on adult psychology, treating patients whose neuroses did not seem rooted in infantile experiences and fantasies. Among Jung's now-familiar concepts are the personality traits of introversion and extroversion; psychological types (which lead to the standardized Myers-Briggs typology test); stage of life distinctions, including description of the mid-life crisis; primitive mental frameworks called archetypes embedded in a collective unconscious; and the notion of the *Shadow,* a part of the psyche all but inaccessible to the conscious mind but often revealed in dreams.

Carl Jung, 1875–1961. A Swiss psychologist and psychiatrist, Jung was a founder of modern depth psychology. *(© Bettmann/Corbis.)*

Jung's body of work, together with that of Freud and Alfred Adler (1870–1937), formed the basis of modern psychoanalytic techniques. These methods of treating mental disorders are today used alongside behavioral and cognitive therapy and (increasingly) psychoactive drugs. Criticism of Jung has tended to focus on the teleological (i.e., that psychic events have a purpose towards future development) and mystical elements of his thought, a significant source of the latter being his explorations of his own complex psyche. His belief in *synchronicity,* a non-causal linkage of mental and physical phenomena, has also been criticized as speculative and without scientific foundation.

Can the concepts of the collective unconscious and the Shadow help people to better understand their connection to the natural world and to their own technological creations? Prominent Jungian psychologists James Hillman (b. 1926), Stephen Aizenstat, Marie-Louise von Franz (1915–1998), and Robert Sardello have postulated that psychological health in the modern world may demand less focus on the narrow confines of the human mind and more on the connection of the human mind, both conscious and unconscious, with the rest of the natural and technological world. Historian Theodore Roszak (b. 1933) has suggested that an *ecological unconscious* links the human psyche with the natural world just as Jung's collective unconscious links human beings with each other, while biologist Edward O. Wilson (b. 1929) has argued that evolution has built into human beings an innate connection with and affinity for the natural world that should be explored by psychologists.

Jung himself was much concerned with the impacts of modern life on the psyche. Four years before his death, he published *The Undiscovered Self*, in which he argues that European civilization's obsession with the externalities of life had left largely untouched the mysteries of the human mind.

The psyche, which is primarily responsible for all the historical changes wrought by the human hand on the face of this planet, remains an insoluble puzzle and an incomprehensible wonder, an object of abiding perplexity—a feature it shares with all of Nature's secrets. In regard to the latter, says Jung, human beings still have hope of making more discoveries and finding answers to the most difficult questions. But in regard to the psyche and psychology there seems to be a curious hesitancy to explore.

Jung's fear was that humankind's collective Shadow, empowered by modern technology, could be released destructively in all its irrational fury. "The more power man had over nature, the more his knowledge and skill went to his head, and the deeper became his contempt for the merely natural and accidental, for all irrational data—including the objective psyche, which is everything that consciousness is not" (Jung 1957, p. 47).

Failure to advance self-understanding thus becomes, in Jung's view, a dangerous moral problem:

> It is not that present-day man is capable of greater evil than the man of antiquity or the primitive. He merely has incomparably more effective means with which to realize his propensity to evil. As his consciousness has broadened and differentiated, so his moral nature has lagged behind. That is the great problem before us today. *Reason alone no longer suffices*. (Jung 1957, p. 54, Jung's emphasis)

In *Memories, Dreams, Reflections* (1961), Jung's personal memoir completed just weeks before his death, he stresses that the solution to the problem of evil lies in self-knowledge, to be arrived at through psychological inquiry:

> Today we need psychology for reasons that involve our very existence . . . [W]e stand face to face with the terrible question of evil and do not know what is before us, let alone what to pit against it. And even if we did know, we still could not understand "how it could happen here." (Jung 1961, p. 331)

His argument for the necessity of such psychological knowledge remains a basic challenge for the future development of scientific technology. For Jung, solutions to the problems of evil do not lie in simply extending power over nature, but in better understanding humankind and its place in the universe.

JÜNGER, ERNST

Ernst Jünger (1895–1998) was a German soldier and a controversial author who was best known for his militarism and prophetic descriptions of a new world being created by the interplay of nationalism, industrialization, and advances in technology. Born in Heidelberg on March 29, Jünger served on the western front in World War I. During the interwar years he studied entomology, contributed to several right-wing journals, and criticized both the Weimar Republic and the National Socialists. Although politically opposed to many aspects of Adolf Hitler's regime, Jünger served as an officer in the German army in World War II. After the war he continued to write novels, including prescient depictions of dystopias, and pioneered the prose style now called magic realism. His work was independent and dispassionate, indifferently observing and commenting on historical and social developments. A longtime friend of and influence on the philosopher Martin Heidegger (1889–1976), Jünger died in Wilflingen, Germany, on February 17.

World War and Mobilization

World War I left a lasting impression on Jünger. Three characteristics of that conflict shaped his view of the world: the destructive power of the new armaments, their lethality, and the consequential subordination of individual courage to the power of machines. In the end whoever made the best use of the war industry would be victorious. The new weapons changed the character of killing and dying because violence was inflicted at a distance and on a massive scale. The person who falls is not seen, his last breath is not heard, and his blood does not splatter the aggressor. At a distance death is wrapped in indifference and anonymity. The slaughter becomes more sudden, massive, and above all reciprocal.

Jünger's first book, *In Stahlgewittern* (1920), is a memoir of his four years on the western front. In this work he showed his ideological embrace of technology even as he struggled with the tension between human will and the power of mechanized warfare. His interpretation of the larger meaning of the war is presented in *Die Totale Mobilmachung* (1931). The title refers to the fact that the mobilization of all forces, including industrial and productive capacity, becomes decisive in the definition of conflicts. Jünger read these phenomena as signs of a historical transition. A new reality was emerging, dominated by the "figure of the worker."

In his single most influential work, *Der Arbeiter: Herrschaft und Gestalt* (1932), Jünger developed his vision of a radically antibourgeois future based on total mobilization. This work often is interpreted as a totalitarian or authoritarian rebuttal of the bourgeois conception of freedom, the market economy, and the liberal nation-state. In it Jünger envisioned the "worker" as the destiny of the coming age, to be characterized by technocratic control in place of the anarchy of liberal individualism. The bourgeois individual will be replaced by the worker "type" in an "organically constructed" political order. Freedom will become identical to obedience. Individuals will be folded into the unity of the whole. Both this metaphysical substructure, or gestalt, of the worker and Jünger's political philosophy of detachment deeply influenced Heidegger.

Der Arbeiter also is predicated on Jünger's concept of "heroic realism," which seeks out the danger that bourgeois reason domesticates by making all risk calculable. In opposition to bourgeois concerns for comfort and convenience, modern technology has an inner destructive character as "the way in which the gestalt of the worker mobilizes the world" (Junger 1932, p. 156). The conversion of all activity into some kind of work is a manifestation of the predominance of this work character. Indeed, the term *worker* does not so much designate a class or social affiliation as it defines a *Lebenstand,* or "state of life," to which Jünger attributed the formative power emerging in history. Jünger thus disassociates his conception from the proletariat of Marxism. It is indicative of Jünger's political complexity that *Der Arbeiter* was regarded by the right as communistic and by the left as fascist.

Total mobilization and the predominance of the worker express a new reality in which the efficacy of an action has priority over its legitimacy. In this sense Jünger's philosophy is aligned with Friedrich Nietzsche's (1844–1900) "active nihilism" and Heidegger's "empire of technics." In fact, Jünger's greatest influence on Heidegger stems from this metaphysical analysis of technology as an essential way of being in the world.

Outside National Socialism

Jünger's *Auf den Marmorklippen* (1939) is a covert criticism of National Socialist tyranny. A poetic and obscure book that seems to aestheticize violence, it presents types more than concrete characters and in that way achieves a general critique of totalitarianism. Indeed, by the time of the 1938 *Krystall Nacht* (the Nazi attack on Jewish businesses in Germany) it was evident to Jünger that the National Socialist regime was essentially the same crude form of proletariat totalitarianism as the Bolshevik regime in Russia.

Gläserne Bienen (1957) raised the moral dilemma of the use of technology in society and foreshadowed modern developments in robotics and nanotechnology, presenting a world where "even the molecules were controlled." The novel questioned how people might retain a sense of place and identity in light of the accelerating pace at which the old is replaced by the new. It also expressed a growing contempt for both an impersonalized, bureaucratized society and the scientific, materialistic worldview that discredits meaning and purpose and cosiders humans to be lowly cosmic accidents.

Jünger did not produce a systematic philosophy, but his complex, inconsistent, and fierce independence often captured an emerging technoscientific world in an indifferent but therefore critical gaze. Jünger disdained any nostalgic form of antitechnology but refused to hail a world of sustained technological progress culminating in rationality and moral decency. His heroic realism is a qualified yes that comes out of an encounter with the emerging: It is as useless to attempt to avoid the power of modern technology as it is naive to ignore its enormous potential for destruction.

JUSTICE

Justice has to do with the distribution of benefits and burdens, rewards and punishments. Among the most important benefits and burdens of contemporary society are science and technology, their products and their costs. Although science and technology are involved with the administration of legal justice in many ways—from their uses in forensics to identify and prosecute criminals to the testimony of scientific and engineering experts in civil cases—the primary focus in this entry will be on the nature of justice in its own right, pointing out some implications for science and technology.

Versions of Justice

As an instrument for the distribution of benefits and burdens, the general concept is clear, but the various interpretations of the concept, and its applications are more contentious. Is justice a transcendent reality, as Plato held? A formal property having to do with proportional distribution, as Aristotle contended? Simply what contracting parties invent in mutually self-interested agreements, as Thomas Hobbes argued? An artificial construct as David Hume maintained? Or does justice have to do with ownership, a rendering to each according to one's due, as Polemarchus reports in Plato's *Republic* (331e) was the definition of the poet Simonides—a view also advanced by the Roman legal philosophers Cicero and Ulpian, as well as Thomas Aquinas? Is it possible that scientific and technological progress promote justice, especially the just power of human beings over the unjust forces of nature, as Francis Bacon argued? Or is a kind of natural justice thereby diminished, as Socrates in the *Republic* (372e) and Jean-Jacques Rousseau, in quite different ways, both proposed?

The traditional symbol of justice is a woman wearing a blindfold, holding a pair of equally balanced scales in one hand, and a sword in the other. The metaphor points to the symmetry between the quality of human judgment on one side and the rewards or punishments on the other. Justice is blind to all irrelevant considerations such as birth or social status or race or gender, and is concerned only with giving one what is deserved.

The earliest definition of justice in the West is the Simonides quote from Plato's *Republic:* "Justice is to render each person his due," giving to each person what each deserves, based on the person's character traits, including ability, virtues, and vices. If one is excellent, a suitable reward is appropriate. If one is vicious, punishment is warranted. A mediocre individual earns a mediocre benefit. Indeed Plato's *Republic* describes a meritocracy, made up of people in three classes, categorized according to their abilities.

The classic conception applies both to distributive and retributive versions of justice. Distributive justice concerns the distribution of benefits and burdens. Retributive justice deals with punishments and rewards. Immanuel Kant argued that not only should people who are good be rewarded with happiness in proportion to their goodness, but people who willfully do bad things should be unhappy in proportion to their bad intentions. Following this thought, he argued that crimes such as murder justified imposition of the death penalty. Kant used this thinking as a premise for the existence of God and life after death, arguing that justice required a god and a future existence for persons to receive their just rewards and punishments.

This classic view has been held by many philosophers throughout history. It is found in the Hindu and Buddhist idea of karma, which holds that each person will be reincarnated according to individual moral character, and in the Bible, which states, "whatsoever a man soweth that shall he also reap" (*Gal.* 6:7). Somewhat unexpectedly, even Karl Marx in his labor theory of value (a worker should be rewarded for the full value of his work) seems to share the classical theory of just desert. The utilitarian philosopher John Stuart Mill also advocated a version of this doctrine, deeming it the central meaning of justice, which in turn signifies simply the most stringent requirements of utilitarian morality. Is justice simply the secular analogue to the religious doctrine of rewards and punishment according to merit? Contemporary political philosophers, such as John Rawls and Derek Parfit rejected or qualified the salience of this classic conception of justice as desert by arguing more egalitarian or need-based conceptions.

Contemporary Conceptions

In current discussions Rawls's *A Theory of Justice* (1971) and Robert Nozick's *Anarchy, State, and Utopia* (1974) remain common reference points. Rawls argues a view of *justice as fairness* defined by that impartial, hypothetical contract that people would adopt from behind a veil of ignorance regarding with what benefits or burdens they might begin their lives in a social order. Extending a perspective developed in John Hospers's *Libertarianism* (1971), Nozick defends justice as grounded in rights to liberty and ownership. Other contemporary analyses of justice include arguments by Parfit (1984), that justice requires some consideration of need; and by Michael Walzer (1983) and Nicholas Rescher (2002) that justice is not a single concept, but a plurality of concepts relative to different social contexts.

According to Hume, questions of justice typically arise when, in situations of scarcity, human beings seek to adjudicate between competing claims for limited goods. Such goods might be material benefits, social prestige, or power—any of which could be closely associated with science or technology. Suppose 100 competitors apply for a highly desirable position such as candidate at a leading graduate program in science or director of a major engineering project. What are the correct moral and legal criteria by which to decide who should be granted the position? Should selection be based on technical knowledge, need, utility, previous effort, likely contribution to be made? Should market forces be a factor? Race, ethnicity, or gender? If in the past blacks or women or the disabled were systematically discriminated against, should affirmative action come into play?

Or consider the use of kidney dialysis machines in a county hospital that can afford only five machines, but has a waiting list of twenty or thirty people. How should doctors decide which five people should be treated? By lottery? By a process of first come first served? By greatest need? By merit? By desert? By utility, for example, if one of the candidates is the mayor of a town that is part of the county and who has served the community well for many years? Or should a complex set of factors (including age, contribution, responsibilities, merit, and need) be used?

The most significant controversial issue in the debate over distributive justice is that of economic justice. How should wealth be divided up in society? Should the free enterprise system determine how much money and wealth people end up with or should an effort be made to redistribute wealth through some sort of income tax policy? Should there be a vigorous welfare program, ensuring that no one falls below a certain economic threshold?

Types of Justice: Formal and Material

Theories of justice may be divided into *formal* and *material* types. A formal theory of justice provides the formula or definition of justice without directly filling in the content or criteria of application. Material theories of justice specify the relevant content to be inserted into the formulas. They dictate what the relevant criterion is. The classical principle of formal justice, based on Book V of Aristotle's *Nicomachean Ethics* is that "equals should be treated equally and unequals unequally." The formula is one of proportionality:

$$A \text{ has } X \text{ of } P = A \text{ should have } X \text{ of } Q$$

$$B \text{ has } Y \text{ of } P = B \text{ should have } Y \text{ of } Q$$

That is, if person A has X units of a relevant property P, and B has Y units (where Y is more or less than X), then A should pay proportionally more or less of the relevant burden Q than B. For example, if A has worked eight hours at a job and B only four hours, and time worked is the relevant criterion for reward, A should be paid twice as much as B.

The formal principle is used in law in the guise of *stare decisis*, the rule of precedent—like cases should be decided in like manner. The principle applies not only to the case of distributive justice, but also of retributive justice or punishment and commutative justice, in which obligation is based on a promise or contract that requires fulfillment.

The formal principle of justice seems reducible to the principle of universalizability: Treat like cases similarly unless there is a relevant difference, which itself is simply the principle of consistency. Be consistent in decisions. If there is no relevant difference between agents, treat them similarly. Insofar as there is no relevant moral difference between the sexes, this applies to the morality of sexual relations. If it is all right for Jack to engage in premarital sex, then it is also all right for Jill to engage in premarital sex; but if it is immoral for Jill to engage in premarital sex, it is also immoral for Jack. The formal principle of justice does not indicate whether some act is right or wrong, but simply calls for consistency. If people were content to live only with the formal principle, they might treat others very badly and still be considered just. As player Henry Jordan once said of Vince Lombardi, the legendary coach of football's Green Bay Packers, "He treated us all the same—like dogs."

Some philosophers, such as Stanley Benn, believe that the formal principle of equal treatment for equals implies a kind of *presumption* of equal treatment of people. But there are problems with this viewpoint. As Joel Feinberg (1970) points out, sometimes the presumption is for unequal treatment of people. Suppose that a father suddenly decides to share his fortune and divides it in two, giving half to his oldest son and half to his neighbor's oldest son, but nothing to his other children. This kind of impartiality is arguably misguided and, in reality, unjust. Society must determine in which respect people are equal and so deserve the same kind of treatment; this seems to be a material problem, not a purely formal one. In other words, Benn confuses an *exceptive principle* (Treat all people alike except when there are relevant differences among them) that is formal with a *presumptive principle* (Treat all people alike *until it can be shown* that there are relevant differences among them).

The formal principle does not tell which qualities determine which kinds of distribution of goods or treatment. Thus material principles are needed to supplement the formal definition. Aristotle's own material principle involved merit: People are to be given what they deserve. A coach could justifiably treat his players like dogs only if they were doglike; otherwise, he should treat them more humanely.

Types of Justice: Patterned and Nonpatterned

Material theories of justice may be divided into *patterned* and *nonpatterned* types of justice. A patterned principle chooses some trait(s) that indicates how the proper distribution is to be accomplished. It has the form:

To each according to ————.

Robert Nozick (1974) rejects patterned types of principles, such as those of Aquinas, Rawls, and Rescher, because this type of attempt to regulate distribution constitutes a violation of liberty. The point can be illustrated by considering how a great inventor can justly upset the patterned balance. Suppose the existence of a patterned situation of justice based on equality. Imagine also that there is a great demand for some inventor's product and that people are willing to pay the inventor well for it. If millions of people pay for the product, the inventor takes home a great deal more than the patterned formula allows, but seems to have a right to it. Nozick's point is that, in order to maintain a pattern, one must either interfere to prevent people from allocating resources as they wish, or intervene to take from people resources that others have transferred to them.

Nozick argues for a libertarian view of nonpatterned justice, which he calls the *theory of entitlement*. A distribution is just if all people have those things to which they are entitled. In determining what people are entitled to, the original position of holdings or possessions is an important factor, as is what constitutes a just transfer of holdings. Borrowing from John Locke's theory of property rights, Nozick argues that people have a right to any possession so long as ownership does not worsen the position of anyone else.

Continuing Debates

As in the past, justice in the early twenty-first century remains a widely contested concept. The main current rival positions are the classic theory of just desert, egalitarian theory of distribution according to need, and rights theories. The challenge for political philosophy is to sort out the competing claims of such theories and make sense of people's deepest but conflicting intuitions—especially with regard to the uses and influences of science and technology.

With regard to retributive or criminal justice, the scientific study of human behavior has, for instance, raised important questions about levels of human accountability. To what extent should psychology and neuroscience inform the legal justice system? Forensics and studies of evidence that, for instance, question the reliability of eyewitness accounts, along with increased reliance on scientific experts, likewise have implications for court procedures. Some philosophers such as Brian Barry (1989) argue the importance of the sciences of game theory and decision theory to analyses of justice.

With regard to distributive justice, science and technology, by their discoveries and inventions especially in the areas of new drugs and lifesaving medical devices, create new challenges for justice. How shall society use these drugs and therapies? Should drugs for AIDS be distributed gratis to African countries that cannot afford to pay the market price? Is it just for pharmaceutical companies, which produced the drugs, to charge the same price to all buyers, or should allowances be made for depth of need and relative ability to pay?

With regard to science and technology in general, what constitutes a just distribution of the benefits of scientific discoveries and engineering inventions? Do owners of patents have an obligation to make some sacrifice in foregoing potential profits from their work to enhance distribution? Or does justice allow them to sell their work to the highest bidder, independent of the social result? Does the state promote justice through the regulation of science and technology, or is regulation properly constrained by respect for liberty and property? In advanced technological societies where, according to Langdon Winner (1986), technological design can be a hidden form of politics, and for Ulrich Beck (1986), the avoidance of risk is now a scarce commodity, do different theories of justice imply different responsibilities for scientists, engineers, citizens, politicians, or corporations? Indeed in a social system in which corporations are granted the status of legal persons, and serve as major vehicles for scientific and technological research, development, and innovation, what concept of justice best enlightens responsibilities in the public realm?

Finally because of technological transformations of the public realm, questions of justice have been extended both spatially and temporally. Increased telecommunications promotes questions of international justice. Increased ability to impact future generations raises questions of intergenerational justice.

JUST WAR

The term *just war* refers to the major moral tradition of Western culture that deals with the justification and limitation of the use of force by public authority. Just war tradition has particular relevance for moral reflection about many scientific and technological developments related to military affairs.

Historical Background

Just war tradition can be traced back to Saint Augustine (354–430) in the fourth and fifth centuries and through him to the Old Testament and the ideas and practices of classical Greece and Rome. Augustine, however, did not write systematically or at length about the idea of just war; his treatment of these issues is found in passages about the use of force in works on various topics. A coherent, systematic body of thought and practice on just war did not emerge until the Middle Ages. The thought of Augustine and other earlier Christian writers was drawn together by the canonist Johannes Gratian, whose *Decretum* dates to the middle of the twelfth century. Two generations of canonists who built on Gratian's work, the Decretists and the Decretalists, took the development of the just war idea into the thirteenth century. In the second half of that century theologians, including most notably Thomas Aquinas (1224–1274), placed the canonical materials in an overarching theological framework that showed both a strong dependence on Augustine's thinking and a new effort to give ideas about just war a footing in natural law.

During the thirteenth century but more during the fourteenth and fifteenth centuries, secular factors began to reshape this canonical and theological concept into a broad cultural consensus. These factors were the growing study of Roman law, especially the idea of *jus gentium* (law of peoples or nations); the maturation of the chivalric code as a guide to the conduct in arms of the international brotherhood of knights; and increased reflection on the experience of governing found in works dealing with the characteristics of a good ruler.

By the end of the Hundred Years War in the mid-fifteenth century the resulting synthesis (seen particularly in writers such as the theologian and scholar Honoré Bonet [1340–1410] and the poet and historian Christine de Pisan [1363–1430]) had defined a cultural consensus in western Europe on the justified use of armed force and the restraints to be observed in using that force. This consensus included the major factors that continue to define the idea of a just war. From canon law and theology came the requirements that for a resort to armed force to be just it must be undertaken on the authority of a sovereign and for the public good; be for a just cause, defined as defending the common good, retaking that which had been taken wrongly, and punishing evil; and right intention, defined negatively as the avoidance of self-aggrandizement, bullying, implacable hatred, and so on, and positively as aiming to restore the peace that had been violated.

The chivalric code joined canon law to provide two kinds of restraint on the employment of force: noncombatant immunity, defined by lists of persons not normally involved in war and thus not to be subjected to direct harm in war, and limits on means, defined by efforts to ban certain weapons (specifically arrows and siege machines) as *mala in se*. The *jus gentium* and the growing consolidation of political authority reinforced these developments in useful ways: the former by placing them in a broader theoretical framework to define relationships among autonomous political communities and the latter by sovereigns' adoption of these rules both in the use of force to maintain public order and in warfare against external threats.

In this manner the just war tradition was passed to the modern era. Theological and secular theorists of the law of nations, including the theologian Francisco de Vitoria (1492–1596) in the sixteenth century and the jurist Hugo Grotius (1583–1645) in the seventeenth, placed the inherited just war tradition in the context of a general theory of international law based on natural law and the *jus gentium*. After Grotius and as a result of the international order created by the Peace of Westphalia (1648), emphasis on the former part of the tradition, by then called the *jus ad bellum*, began to be reduced as sovereigns' rights to use force were redefined as *compétence de guerre* at the same time that a new emphasis was placed on the restraints to be observed in the use of force, the *jus in bello*.

This has been the pattern of the development of the just war tradition during the modern period. Beginning in the 1860s with the work of Francis Lieber and the U.S. Army's General Orders No. 100 of 1863 and, at almost the same time, the international adoption of the First Geneva Convention, positive international law has played a major role in defining the just war *jus in bello*. Through much of the nineteenth century and continuing into the nuclear age, moral thought on war has focused on efforts to rule out recourse to armed force by states, in effect denying that a *jus ad bellum*, a justification of the resort to armed force, exists any longer, or severely restricting the terms of such justification. During this period, because of its concentration on eliminating war, moral thought effectively lost sight of the just war *jus in bello*. At the same time, however, the increasing codification of international law reframed the tradition's *jus in bello* as positive-law rules for the conduct of nations in war.

The law of armed conflict in international law remains one of the important arenas for the efforts to restrain war first defined in the just war tradition. In moral thought, largely as the result of work by the theologian Paul Ramsey (1913–1988) and the political philosopher Michael Walzer (b. 1935) and public debate occasioned by the U.S. Catholic bishops' 1983 pastoral *The Challenge of Peace*, just war thinking has reemerged in American and some European debates over the use of armed force, informing not only the religious and philosophical spheres but also public policy discussions and professional military education. Just war is studied in all the service academies and the war colleges and by military lawyers, and it is a common topic in academic and policy-oriented conferences and workshops on military issues.

Science and Technology

Both historically and in recent debates just war tradition has responded to developments in the science and technology of the use of force. In the Middle Ages this involved efforts to eliminate the use of weapons that were deemed too harmful or destructive. Specifically, there was an effort to ban crossbows and bows and arrows, which could penetrate armor and kill, whereas the normal weapons of knights—swords, maces, and lances—were likely to injure but not kill armored opponents. Siege weapons capable of causing heavy and indiscriminate damage when used against fortified places were also the target of a ban.

These themes were carried forward into efforts to restrict or eliminate certain weapons or uses of weapons in positive international law. The first Hague Conference (1899) sought to ban exploding bullets for being too lethal and tending to inflict especially cruel wounds. That conference sought to ban asphyxiating gases, though this did not become positive law until the 1925 Geneva Protocol on gas warfare. Various efforts, beginning from the first Hague Conference, have been made to prohibit bombardment of unfortified population centers from the land, sea, and air. Since World War II international conventions have been adopted prohibiting the use of chemical and biological weapons as "weapons of mass destruction," and the nuclear proliferation treaty has sought to restrict possession of nuclear weapons as a way to limit the likelihood of their use. A 1980 United Nations Convention prohibits or restricts the use of certain conventional weapons "deemed to be excessively injurious or to have indiscriminate effects." The 1997 Ottawa Convention, responding to technologies that have made antipersonnel mines cheap, difficult to detect, and ubiquitous, formally prohibits their production, stockpiling, transfer, and use.

These are all examples from positive international law, a major modern carrier of the just war tradition. In the moral debate some have argued that the entire technology of contemporary warfare—not only weapons of mass destruction, including nuclear weapons, but also conventional weapons because of their ability to produce widespread death and destruction—is disproportionately and often indiscriminately harmful. This position, often called "modern-war pacifism" (including nuclear pacifism as one of its forms) holds that the technology of modern warfare is so destructive that the moral requirements of the *jus in bello*, avoidance of direct harm to noncombatants and of disproportionate destruction, cannot be met, and so there can be no just resort to force.

Opponents of this position, including Ramsey, Walzer, and James Turner Johnson (b. 1938), distinguish between the availability of highly destructive weaponry and the decision about how to fight: The latter is a moral decision, and it implies moral control over whatever means are available. In the debates over nuclear weapons during the early 1980s this difference of judgment about the technology of warfare led to two sharply different policy conclusions. Nuclear pacifists argued against nuclear weapons as inherently immoral and against the development of targeting technologies intended to make them more accurate and thus more discriminating. Others argued that development of such capabilities was a moral imperative both because it could reduce direct harm to noncombatants and because it opened the door to the development of lower-yield warheads, including conventional explosives, that could perform the same strategic and tactical functions as high-yield nuclear and thermonuclear warheads.

Questions of Technological Superiority

The policy decision at that time was to continue developing more accurate targeting technologies and delivery systems. Since then this line of development has matured progressively to produce a "revolution in military affairs" characterized by laser- and satellite-guided bombs and missiles, stealth technology that allows airplanes to get close enough to their targets to enable direct guidance of weaponry onto a target, drone airplanes and satellite imaging to identify and target enemy armed forces without collateral damage to noncombatants, and increasingly sophisticated means of gathering enemy intelligence to lower the levels of force needed for combat.

These developments first became general knowledge with publicity over the "smart bombs" of the 1991 Persian Gulf War. The use of such technology also marked the bombing of Serbia in the conflict over Kosovo (1999), and it was both ubiquitous and decisive in the conflicts in Afghanistan (2001) and Iraq (2003), where in the latter the technological superiority of the U.S. and British forces made possible a campaign that used far lower numbers of troops than previously would have been necessary, destroyed the Iraqi army while coalition forces suffered only a small number of casualties, and allowed bombs and missiles to destroy major Iraqi government targets with unprecedentedly low levels of collateral damage.

All this is morally significant from the standpoint of the just war tradition, for even in an age of weapons of massive destructive power such technology allows armed force to be used in a way that honors the just war requirements of noncombatant immunity and as low a level of destruction as possible. At the same time, from the perspective of the technologically inferior, the use of superior technology may appear to represent a refusal to accept an equal playing field in which courage and loyalty to opposing causes have a fair chance to compete with each other. What is to be made of this objection?

The latter argument cannot be used to justify means of fighting that disregard moral and legal restraints. In the moral terms of the just war tradition as well as the legal terms of the law of armed conflict, technologically superior and inferior adversaries are equally bound by the same rules. Technological inferiority is no excuse, for example, for terrorist actions against civilians or the Fedayeen Saddam's use of noncombatants as human shields in the 2003 Iraq war, both of which were clear violations of the moral concept of noncombatant immunity and the legal restrictions laid down in international law. In a conflict involving technologically asymmetrical adversaries each force is restricted, both morally and legally, to means that do not violate noncombatant immunity and do not involve prohibited weapons, such as weapons of mass destruction.

Technological asymmetry is not a new problem ushered in by precision-guided munitions. In earlier ages technological superiority was conferred by the use of Greek fire, firearms, rifled handguns and artillery, repeating rifles, the use of railroads for military transport, semaphore signaling systems and later the telegraph and radio, and the development of armored fighting vehicles. A technologically inferior armed force faces an enormous practical problem: how to match or overcome an enemy that is technologically superior. However, this is a practical problem, not a moral one. The idea of a "level playing field" means that both adversaries must play by the same rules; it does not mean that within the framework of those rules neither side may use means that it alone possesses.

The possession of superior technology, it may be argued, imposes a special moral responsibility to use that technology in ways that honor the *jus in bello* restraints. The moral rule of double effect has long been used to determine when collateral harm to noncombatants is morally allowed; by this rule such harm is allowed only when it is the indirect, formally unintended result of an attack on a legitimate military target that cannot be attacked except with such collateral harm. Thus, when an enemy places artillery next to a school or deploys troops with rifles to fire from the windows of a hospital, the artillery and the troops can be attacked despite the harm to the school and hospital and the noncombatant persons who may be inside.

However, Michael Walzer (1977) has argued that the rule of double effect also should be understood to impose a proportionality criterion; therefore, a projected attack against an otherwise legitimate target should not go forward if the collateral harm to noncombatants is judged to be disproportionate to the ends to be gained from the attack. In such cases, an alternative weapon or another means of neutralizing the target should be used or the target should be bypassed. This reasoning seems to have been employed in the targeting decisions made by U.S. forces in the 2003 Iraq conflict, in which the choice of weapons systems, the angle of attack, the time of day, fuse timing, and other factors were employed to avoid or reduce collateral damage. The possession of superior technology thus imposes an added moral burden: to use that technology to avoid harm that would be allowed in its absence.

This means that from a moral standpoint based on the just war tradition the question of the technology of warfare does not stand alone. It is also necessary to consider whether overall planning and policy, strategy, rules of engagement, means of command and control, tactics, and military training allow the use of the available technology in ways consonant with the aims of discrimination and proportionality. Not only does the U.S. military in the early twenty-first century have a virtual monopoly on the technology of the "revolution in military affairs," it is the only national military that has made operational all these elements in the channel of decision that leads toward conducting military actions within the framework required by the *jus in bello*. Arguably, the ability to conduct war more closely in accordance with just war requirements implies the moral obligation to do so. For example, carpet bombing of a mixed combatant-noncombatant area to destroy a legitimate target cannot be the moral option if precision guidance technology allows that target to be destroyed without harming noncombatants.

The question is what this implies for societies that lack such technology: Do they have the obligation to develop it, or may they not fight wars anymore? On just war reasoning, they have the moral obligation to use whatever means they have in the most moral way possible; they do not, for example, have the moral right to target civilians directly or use weapons of mass destruction, which are both indiscriminate and disproportionate. Beyond this they are obliged to try to develop more discriminate and proportionate means of fighting within the capabilities available to them and taking into account their other responsibilities. If they cannot fight according to the minimum standards of noncombatant immunity and avoidance of weapons *mala in se*, by just war reasoning they should not fight. However, the question whether to engage in armed conflict with a technologically superior adversary is not one of morality but one of political prudence.

The moral obligation to develop more discriminating and proportionate means of fighting extends also to technologically advanced militaries. During the Vietnam War Paul Ramsey (1968) argued for the use of incapacitating gases as morally preferable to the use of weapons such as napalm and even bullets because those gases could incapacitate soldiers without killing them or producing lasting harm. The United States Defense Advanced Research Products Administration has been encouraging research and development in nonlethal weapons technologies. Just war reasoning tends to support the development and use of such weapons in principle, though any particular weapon, even if nonlethal, still would have to be judged by the standards of the *jus in bello*.

In summary, just war tradition places the use of armed force in a moral framework in which some technologies are good and others are bad. The criterion is whether a specific technology makes it possible to use military force, when justified and used on public authority for the common good, in ways that honor the principles of noncombatant immunity and minimal overall destructiveness.

K

KANT, IMMANUEL

Immanuel Kant (1724–1804) was born in Köningsberg, East Prussia (now Kaliningrad, Russia), on April 22 and died there on February 12, having lived such an uneventful life that one early commentator questioned whether he had one. Yet his critical philosophy constituted a watershed in Western intellectual history. For science, technology, and ethics the significance of the Kantian watershed lies in the analysis of human experience as constructive and the argument that reason has insight only into that which it produces according to its own plan. With this argument Kant developed a new critical interpretation of scientific knowledge and of ethical reason that presents both as exhibiting constructive, not to say technological, dimensions.

Prior to Kant, modern philosophy was characterized by a contest between rationalism and empiricism. Rationalists such as René Descartes (1596–1650) and Gottfried Wilhelm Leibniz (1646–1716) considered reason to be the origin of all true knowledge, sensation merely a degraded form of thought or source of illusion. By contrast, empiricists such as Francis Bacon (1561–1626) and John Locke (1632–1704) argued that all knowledge derived from the senses, with thought being no more than an extension of sense perception. Kant's precritical writings included works in natural philosophy, aesthetics, and ethics reflective of the rationalist tradition. But reading the British empiricist David Hume (1711–1776) awakened Kant from what he described as his "dogmatic slumbers." This awakening led, in turn, to a synthesis of these two approaches in his major work, *The Critique of Pure Reason,* which argued that the form of human experience is constructed a

Immanuel Kant, 1724–1804. The major works of this German philosopher offer an analysis of speculative and moral reason and the faculty of human judgment. He exerted an immense influence on the intellectual movements of the 19th and 20th centuries. *(© Corbis-Bettmann. Reproduced by permission.)*

priori by reason while its material content arises a posteriori from sensation. This is the core of Kant's transcendental or critical idealism, which he subsequently extended into ethics and aesthetics in order to respond to what he considered the three main questions of philosophy: What can I know? What ought I to do? What can I hope for? He later added a fourth question that synthesized the first three: What is the human being?

The Critique of Pure Reason (1781)

Kant's major work undertakes what he terms a "Copernican revolution" in philosophy. Whereas traditionally philosophy had begun with particular objects of experience, Kant's transcendental method begins with experience in general and tries to uncover the "transcendental preconditions" that make such experience possible. For Kant, objects are seen as fitting into human representational structures rather than representational structures simply arising from objects. As Hume had shown, the necessity that these representational structures possess, the fact that all objects must appear in space and time, simply cannot be derived from sensory experience. According to Kant, then, space and time are the *a priori* forms of sensibility, the ideal or transcendental forms that make it possible for human beings to experience any object.

Only as a manifold of content within space and time is sense intuition or experience possible. But objects that first appear to the senses within the necessary structures of space and time are further known using concepts such as substance and causality. For Kant, the expectation that events necessarily have causes is not so much derived from experience as brought to experience, although of course the particular causes are determined by experience. Experience would not be what it is, would not be intelligible or knowable, without these *a prior* pure concepts of the understanding. The justification of these categories rests with their constitutive role in human experience and the fact that they work to make experience possible.

What is it that is known when sensation and understanding cooperate in this way to make experience scientifically intelligible? The answer is phenomena. Perhaps the single most important distinction in Kant's thought is that between phenomena and noumena, things as they appear to people and things in themselves, respectively. The former are open to positive knowledge, whereas the latter can be thought but never known in a positive or scientific sense.

The human mind nevertheless has a tendency to try to extend itself beyond phenomena to things-in-themselves. This includes claiming to have positive knowledge of supersensible realities such as God, the soul, and freedom, the topics of traditional metaphysics. These ideals of pure reason can never be scientifically verified. Thus Kant argued that traditional metaphysics, which focuses on objects that transcend experience rather than the transcendental preconditions of experience, is not an authentic form of knowledge. Yet, although the ideals of pure reason cannot be experienced they can be thought, and in their thinking serve what Kant calls a regulative function.

Critique of Practical Reason (1788)

The second critique turns from science to ethics and deals with practical or moral reasoning. This book was preceded by an introductory *Foundations of the Metaphysics of Morals* (1785), which developed a deontological theory of ethics, that is, one based on the primacy of duty. For Kant, the only unconditional good is a good will, one that wills to do what is a duty merely because it is a duty, or to choose duty for its own sake. The philosophical challenge for ethics is to explicate what this means, and to identify the transcendental preconditions of its possibility.

Kant thus approaches ethics not in terms of the consequences of actions or whether decisions make a person happy, but in terms of moral obligation. The idea of duty leads Kant to the idea of freedom as its basis. Although with regard to many actions the will may be influenced by factors outside itself, that is, be heteronomous, at least in some instances the will is able to decide for itself, that is, act autonomously. In exercising its own decision-making capacity, the will may also reason according to hypothetical imperatives (If one wants *X* then do *Y*) or categorical imperatives (Do *Y*, no matter what). Practical reason at the highest level displays a spontaneity that makes its own law for itself, simply because this is the right way to act, independent of any particular consequences.

Hypothetical reasoning may be described as the basis of technological thinking. Indeed, Kant calls one form of a hypothetical imperative a technical imperative, which focuses on discovering the means to achieve some end. Categorical reasoning, by contrast, focuses on the identification of worthy ends. According to Kant the most worthy end, and thus categorical imperative, is to act according to a maxim that is universal, that is, applies to all, or to treat all persons as ends in themselves. Human beings have an inherent worth or dignity, unlike objects that have exchange value. To recognize this and act accordingly is to begin to construct something more than a traditional society or state, which presumes people acting out of self-interest and treats others as means to their own ends, and to begin to construct instead a new kind of social order that Kant calls a "kingdom of ends." This moral ideal has been applied widely to a range of ethical issues related to science and technology, from the treatment of human subjects in medical research, to privacy in the use of computers and debates about the permissibility of human reproductive cloning.

The second critique postulates freedom, the existence of God, and immortality of the soul as necessary presuppositions of moral experience. Freedom is necessary to make sense of the human experience of moral responsibility, God to guarantee the ultimate triumph of moral order, and immortality to allow for the final realization of the good will. In this regard, practical reason provides access to a supersensible reality closed to science, though in a manner that can only be an issue of rational faith.

The Third Critique and Kant's Influence

Kant's *Critique of Judgment* (1790) attempted to show how theoretical and practical reason—science and ethics—are unified in the sense of beauty. For Kant, the judgments of beauty and purpose provide a sensible symbol of the supersensible realm. They suggest that the natural and ethical realms make up a unified whole. The purposeful structures humans observe especially in organic bodies and their beauty provide clues to the further understanding of nature. The idea that nature is purposeful lies behind the human belief that a system of laws of nature is possible. It can also lead to the extension of humanity's empirical investigations of nature. Judgments of beauty are based on a subjective feeling of delight in an object, but this feeling has a universal validity deriving from the harmony of the faculties of imagination and understanding. The feeling of the sublime depends upon the moral feeling Kant supposed common to all of humanity.

Taken together, Kant's three critiques thus answer what he takes to be the basic questions of philosophy. The fourth question was to find its answer in a study of anthropology. What can be known are intelligent constructions of science that constitute the basic form of knowledge. What ought to be done is to treat human beings as ends in themselves in order to establish a kingdom of ends. For the individual human being there is hope for personal immortality in order to be able to make infinite moral progress. For the human race there is the hope that human progress will be instantiated in the moralization of the human race, so that the advance of human capacities, including humankind's scientific understanding of the world, may contribute to the construction of a harmonious moral social order.

Kant's influence is inestimable. Although in the next generation Georg Wilhelm Friedrich Hegel (1770–1831) challenged Kant's distinction between phenomena and noumena, Hegel's alternative system never became as influential as Kant's. Future efforts to explicate the unique power and limitations of science and the independent validity of ethics have repeatedly returned to formulations of what have become known as various forms of neo-Kantianism. Ernst Cassirer (1874–1945), for instance, widened Kant's appreciation of human construction in science to include the entire range of cultural symbolic production, including the realms of language, myth, and religion. Bernard Gert's *Morality: Its Nature and Justification* (2004) develops a Kantian-like set of moral rules, often explicitly considering issues related especially to biomedical technologies.

More generally, Friedrich Dessauer (1881–1963) developed a broadly Kantian interpretation of technology, going so far as to propose a fourth Kantian critique of the transcendental preconditions of technological invention (Mitcham 1994). More recently, Ernesto Mayz Vallenilla (1989) has provided an analysis of the transformations of technical rationality brought about by new instrumentations that reflects a Kantian and phenomenological heritage. Finally, detached from its transcendental moorings, Kant's approach may also be seen as supporting contemporary social constructivist interpretations of science and technology (Bijker, Hughes, and Pinch 1987).

In his first critique, Kant sought to limit positive scientific knowledge to phenomenal reality so that noumena may be posited without interference by rational faith and that ethics may be able to rest on its own foundations. In this way, ethics could be freed from the dogmatic assumptions and skepticism associated with traditional metaphysics.

> [E]ven the *assumption*—as made on behalf of the necessary practical employment of my reason—of *God*, *freedom*, and *immortality* is not permissible unless at the same time speculative reason be deprived of its pretensions to transcendent insight . . . thus rendering all *practical extension* of pure reason impossible. I have therefore found it necessary to deny *knowledge*, in order to make room for *faith*. The dogmatism of metaphysics, that is, the preconception that it is possible to make headway in metaphysics without a previous criticism of pure reason, is the source of all that unbelief, always very dogmatic, which wars against morality. (Kant 1965 [1781], pp. Bxxix–Bxxx)

Kant's philosophy sought the harmonious development of human faculties but ended in separating scientific intellection and ethical reflection. Both exhibit the free and spontaneous constructive activity of the human mind. Yet Kant did not foresee how scientific (and technical) development could outpace the application of ethical reflection. As a result, ethical thought often appears to lag behind technoscientific achievements. To what extent should ethical concerns establish limits on scientific inquiry? This question manifests itself repeatedly in contemporary discussions of advancing science, new technologies, and ethics.

KIERKEGAARD, SØREN

Søren Aabye Kierkegaard (1813–1855) was born in Copenhagen, Denmark, on May 5. A prolific author, he produced an impressive series of books devoted to philosophical and religious themes, including a parallel series published under various pseudonyms. He is perhaps best known for his critical engagement with the guiding values of Protestant Christendom in the mid-nineteenth century. Fearing that Christianity had become dangerously enmeshed in the bourgeois malaise sweeping Europe at the time, he urged his readers to aspire to lives of greater passion, intensity, inwardness, and faith. In a sustained provocation that won him few contemporary admirers, he vowed to reintroduce the practice of Christianity into Christendom.

Kierkegaard's most influential pseudonymous work, *Fear and Trembling* (1843), challenges the primacy assigned to the universality of ethical life. With specific reference to the biblical story of Abraham on Mount Moriah, Kierkegaard raises the possibility that some religious obligations may actually trump the recognized ethical obligations of contemporary Christian practice. As indicated, supposedly, by the trial of Abraham, the pursuit of faith may eventually oblige individuals to seek the truth of their existence *beyond* the ethical universal, in the religious sphere. Through his pseudonym, Johannes *de silentio,* Kierkegaard alleges that the "greatness" of Abraham remains an anomaly within contemporary Christian belief and practice. Abraham can be considered "great" only by virtue of his faith, and the most compelling expression of his faith was his decision to obey his God's command to sacrifice his only son Isaac. If Johannes is correct in his analysis, then the "greatness" of Abraham is inextricably linked to his willingness to perform what Johannes calls a "teleological suspension of the ethical," that is, an abrogation of

Søren Kierkegaard, 1813–1855. The Danish philosopher and religious thinker was the progenitor of 20th-century existential philosophy.

his moral obligations in the service of a higher, religious obligation.

Some readers insist at this point that Kierkegaard simply misidentifies or exaggerates the "greatness" of Abraham. Still others allow that Christians continue to honor Abraham only as a symbol of their Judaic prehistory. Yet, the point Kierkegaard raises bears further consideration: Do people not, at least occasionally, admire individuals who exempt themselves from acknowledged moral conventions? If so, how can people persist in their avowed allegiance to ethical universality as the highest expression of human flourishing? Do people not in fact reserve an even higher status for those "knights of faith" who, like Kierkegaard's Abraham, sacrifice morality for a supposedly higher purpose?

As these questions indicate, Kierkegaard's critical engagement with conventional morality was motivated in large part by the overriding value he attaches to the life of authentic individuality. Although conventional morality serves most people, most of the time, as a perfectly adequate expression of their humanity, it proves to be inadequate, and even inhospitable, to those who seek an authentic, singular existence. The individuals whom Kierkegaard most admired find the truth of their existence not outside themselves (for example, in public expressions of the ethical universal), but *within* themselves, in the passion and spirit that constitute their essential inwardness. The greatest expression of inwardness, he further believed, is faith, wherein the individual is raised above the ethical universal and placed in an absolute relationship to God. Kierkegaard thus concluded that conventional morality may actually pose a formidable obstacle to the pursuit of a life of faith.

Kierkegaard rarely commented directly on the rise of modern technology, but his writings are peppered with insights into the subtle ways in which emerging technologies contribute to the overall leveling of social life. The busyness that defines life in the modern epoch is both supported and exacerbated by the introduction of technological wonders, which enable modern people to distract themselves ever more effectively from their spiritual emptiness. While not the cause of the spiritual poverty that Kierkegaard detects around him, technology encourages people to postpone indefinitely the difficult regimen of self-examination and introspection that he prescribed.

Toward the end of his life, Kierkegaard engaged in an increasingly vituperative attack on the Danish state church, which, he believed, had fallen captive to the dispassionate values of bourgeois modernity. Owing in part to the fallout from this attack, he died in disrepute on November 11. Since the time of his death, however, his philosophical reputation has grown steadily. In the early twenty-first century he is widely read for his pioneering contributions to depth psychology; his prescient criticisms of the spread of bourgeois values; his fresh interpretations of Christian faith and practice; his astute observations on contemporary political life; his challenge to ethical universality; and, perhaps most prominently, his spirited defense of authentic individuality.

KUHN, THOMAS

Historian and philosopher of science, Thomas Kuhn (1922–1996), who was born in Cincinnati, Ohio, on July 18, was perhaps the most influential theorist of science in the second half of the twentieth century. Kuhn received all his degrees (in physics) and his first job at Harvard University, though he failed to be awarded tenure there in 1956, shortly after the departure of his mentor, Harvard President James Bryant Conant. Kuhn was finally tenured at Princeton University in 1964, on the basis of what remains his best known book, *The Structure of Scientific Revolutions* (1962). In 1979 Kuhn moved to the Massachusetts Institute of Technology (MIT), where he eventually retired as Laurence Rockefeller Professor of Philosophy and Linguistics. Essays from Kuhn's Harvard and Princeton years appear in *The Essential Tension* (1977). Essays from his MIT years are collected in *The Road Since Structure* (2000). At the time of his death, in Cambridge, Massachusetts, on June 17, Kuhn had been long working on an update of the perspective first developed in *Structure*.

Kuhn's influence rests mainly on *Structure,* his second book, which departs from the then prominent logical empiricist efforts to understand science through its rational reconstruction in favor of a more historically based appreciation of its internal dynamics. Kuhn presents a theory of scientific change as a cycle of relatively clearly defined phases, centered on the creation, development, and destruction of a *paradigm,* a word that has entered the general vocabulary in the early twenty-first century. For Kuhn, the distinctiveness of science lies in the ability of its practitioners to take hold of the means of knowledge production by agreeing on a theoretical framework, methods, and suitable problems to pursue. Kuhn's protean use of paradigm to cover every aspect of this process has led to much confusion. Nevertheless the overall thrust of his account is clear. *Normal science,* the rather routine pursuit of paradigmatic puzzles, is the heart of the scientific enterprise, and the source of whatever progress science displays. Kuhn's picture was very much at odds with the more heroic Galilean image of scientists as bold destroyers of tradition. On the contrary, for Kuhn, scientists themselves worked within strict traditions of practice that were typically passed down through apprenticeship with master practitioners.

Kuhn's image of science is profoundly conservative, a point overlooked by most of his supporters. To be sure, *revolution* figures in the title of Kuhn's first two books—the first being *The Copernican Revolution* (1957)—and is the basis on which many readers have imagined him to be a *radical* thinker. Nevertheless Kuhn draws on a conception of revolution received from the conservative political tradition, whereby a revolution eventuates in a restoration of natural order. Thus, for Kuhn, revolutions in science happen only as a last resort, when the paradigm can no longer solve the problems it has set for itself. In that case a *crisis* ensues, the result of which is a new paradigm that then provides the basis for a new kind of normal science. Philosophically inspired criticism of fundamental assumptions in science is licensed only once a paradigm is in crisis. Under normal circumstances, scientists take a more *heads-down* approach to their work.

The widespread misunderstanding of Kuhn's theory has been an ironic source of its influence. Although Kuhn himself was careful to restrict the evidence base of his theory to roughly three centuries of the history of the physical sciences (1620–1920), he was quickly read as referring to a pattern of change that could be found in all sciences—even the humanities—across all periods. This misreading is partly due to the fact that Kuhn does not distinguish science by reference to its technological applications or material impact on the world. On the contrary, for Kuhn, a field becomes scientific by becoming autonomous from such external concerns. Thus physics is a science not because it produces real-world effects but because physicists are in full control of the physics research agenda. Many of Kuhn's hopeful readers outside of physics drew the conclusion that their own fields could similarly acquire the status of science by generating their own paradigms. Thus in the early 2000s virtually every discipline outside physics has at least one theorist or methodologist whose reputation is based on the claim of having founded a paradigm of some sort.

In first two decades after it was written, *The Structure of Scientific Revolutions* was subject to much philosophical criticism, especially from Karl Popper and his followers. They questioned the normative backdrop to Kuhn's history of science: Was Kuhn effectively valorizing the most conformist elements of scientific practice? The answer appeared to be yes, but that did not prevent the book from entering the philosophical canon after 1980. Eventually most philosophers took for granted Kuhn's overall account of scientific change, especially his methodological assumption that science needs to be understood from the *inside*, so to speak. A mark of Kuhn's influence on contemporary discussions in the history, philosophy, and sociology of science is the preoccupation with demonstrating one's mastery of the inner workings of a science. In his later years, Kuhn grew closer to the standard philosophical understanding of these matters, while openly dissociating himself from *relativist* and *constructivist* sociologists who claimed to have been inspired by his work.

In taking the measure of Kuhn's legacy, it is puzzling how a physicist with an amateur understanding of the history, philosophy, and sociology of science could have had such a profound impact on these fields, which already enjoyed a relatively high degree of sophistication. In effect, Kuhn's *Structure* offered a historian's sense of philosophy, a philosopher's sense of sociology, and a sociologist's sense of history. That this particular book should have such an enduring impact cannot be explained simply by its content, because many of its supposedly distinctive theses could also be found in the work of contemporaries such as Norwood Russell Hanson, Paul Feyerabend, and Stephen Toulmin. However, unlike them, Kuhn singularly benefited from the patronage of Conant, to whom *Structure* is dedicated. *Structure* was written while Kuhn taught in a general education program that Conant had created to instill faith in science as an autonomous enterprise in a time—the Cold War—when it would be increasingly subject to public scrutiny. This helps explain Kuhn's peculiar inclusions and omissions. As conceptual horizons become detached from Kuhn's Cold War moorings, his work will probably lose its hold on the meta-scientific imagination.

L

LASSWELL, HAROLD D.

Born in Donnellson, Illinois, Harold D. Lasswell (1902–1978) was an innovator in a number of scientific disciplines and the major figure in developing the policy sciences. The son of a teacher and a Presbyterian minister, he was educated at the University of Chicago, earning a doctorate in political science and then joining the faculty in 1926. In 1938 Lasswell moved to Washington, DC, to serve as a researcher and policy adviser. After the war, as a professor at Yale, Lasswell collaborated with the lawyer legal scholar Myres S. McDougal (1906–1998) and others on law, science, and policy. His broad interests and travels brought him into direct contact with many of the major intellectual and political figures of his time.

Lasswell wrote that "it is growth of insight, not simply of the capacity of the observer to predict the future operation of an automatic compulsion, or of a non-personal factor, that represents the major contribution of the scientific study of interpersonal relations to policy" (1951, p. 524). Insight brings those factors into conscious awareness, leaving the individual free to take them into account in making choices. Freedom through insight often modifies interpersonal relationships; hence, all propositions about those relationships are subject to new insight. Lasswell took the lead in developing the intellectual tools of the policy sciences to integrate and apply natural and social science insight to the fuller realization of human dignity for all, including freedom.

In his presidential address to the American Political Science Association, Lasswell chose "to inquire into the possible reconciliation of man's mastery over Nature [through science-based technologies] with freedom, the overriding goal of policy in our body politic" (1956, p. 961). At the outset he considered atomic weapons in order to entertain the proposition that "our intellectual tools have been sufficiently sharp to enable political scientists to make a largely correct appraisal of the consequences of unconventional weapons for world politics." After using those tools to sketch the kind of analysis that could have been done before the use of atomic weapons in 1945, he concluded that the profession had not institutionalized procedures to anticipate technical developments that had been reported publicly before the war and clarify in advance the main policy alternatives open to decision makers: "As political scientists we should have anticipated fully both the bomb and the significant problems of policy that came with it" (Lasswell 1956, p. 965).

Lasswell qualified this statement of professional responsibility, however: "I do not want to create the impression that all would have been well if we had been better political scientists, and that we must bear upon our puny shoulders the burden of culpability for the state of the world today. We are not so grandiose as to magnify our role or our responsibility beyond all proportion. Yet I cannot refrain from acknowledging . . . that we left the minds of our decision makers flagrantly unprepared to meet the crisis precipitated by the bomb" (1956, p. 965). Moreover, the profession was not responsible for information on the bomb withheld by officials. "We must however assume responsibility for any limitation of theory or procedure that prevented us from making full use of every opportunity open to us" (Lasswell 1956, p. 964).

Turning to the future, Lasswell asserted, "It is our responsibility to flagellate our minds toward creativity, toward bringing into the stream of emerging events conceptions of future strategy that, if adopted, will increase the probability that ideal aspirations will be more approximately realized" (1956, p. 966). Lasswell accepted that responsibility when he applied the intellectual tools of the policy sciences to potential applications of science in production of material goods and evolution of intelligent organisms (including humans) and machines as well as weapons. Particularly creative and prescient were certain remarks on the implications of genetics, embryology, and intelligent machines for evolution (Lasswell 1956, pp. 975–977):

- Because new species already had been created or re-created experimentally, "A garrison police regime fully cognizant of science and technology can, in all probability, eventually aspire to biologize the class and caste system by selective breeding and training."
- Because machines already had solved complex problems, "at what point do we accept the incorporation of relatively self-perpetuating and mutually influencing 'super-machines' or 'ex-robots' as being entitled to the policies expressed in the Universal Declaration [of Human Rights]?"
- Perhaps most disturbing was "the possibility that super-gifted men, or even new species possessing superior talent, will emerge as a result of research and development . . . introducing a biological elite capable of treating us [as] imperial powers have so often treated the weak."

Lasswell concluded by outlining a program of contextual and problem-oriented research using the tools of the policy sciences to address the aggregate effects of any specific innovation: "Our first professional contribution . . . is to project a comprehensive image of the future for the purpose of indicating how our overriding goal values are likely to be affected if current policies continue" (1956, pp. 977–978). The concluding task is "inventive and evaluative. It consists in originating policy alternatives by means of which goal values can be maximized. In estimating the likely occurrence of an event (or event category), it is essential to take into account the historical trends and the scientifically ascertained predispositions in the world arena or any pertinent part thereof."

Lasswell later noted discrepancies between the earlier promises of science-based technology and current reality: "If the promise was that knowledge would make men free, the contemporary reality seems to be that more men are manipulated without their consent for more purposes by more techniques by fewer men than at any time in history" (1970, p. 119). After a diagnosis of such discrepancies, he observed that their potential effects on science are not trivial, "for science has grown strong enough to acquire visibility, and therefore to become eligible as a scapegoat for whatever disenchantment there may be with the earlier promises of a science-based technology." The proposal again called for the perfecting of institutions to apply the intellectual tools of the policy sciences (Lasswell 1971, Lasswell and McDougal 1992) on a continuous basis toward policies to advance human dignity for all.

Relatively few scientists have answered the call despite the continuing relevance of Lasswell's proposal. This may be partly the result of a specialized vocabulary that critics claim is a barrier to the policy sciences. Nevertheless, if more scientists do not come forward, humankind's growing mastery of nature will jeopardize human dignity and the privileged position of science in society.

LEIBNIZ, G. W.

Diplomat and court councilor to the house of Brunswick in Hanover, Gottfried Wilhelm Leibniz (1646–1716) was born in Leipzig on July 1. By the age of twenty-one he had earned a doctorate of law and written a *Dissertation on the Art of Combination,* which allowed him to lecture in philosophy. Though he never formally held an academic position (he had jobs as a jurist, librarian, mining engineer, and historian), his duties in Hanover enabled him to travel and meet many well-known thinkers of his time, such as mathematician Christian Huygens (1629–1695), who tutored Leibniz in mathematics during the latter's visit to Paris from 1672 through 1676. While he published several scholarly articles and only one book during his lifetime, the *Theodicy,* his large body of posthumously published work reveals Leibniz's contributions to mathematics, logic, science, law, philosophy, and ethics.

A rationalist, Leibniz exhibited a characteristically modern ambition with an ambitious scientific attempt to create a universal science of all human knowledge, which consisted of a universal, simple (i.e., numerical) language and a formalized calculus for reasoning. Though he eventually acknowledged the impossibility of completing the task because of the perspectivity of human knowing, he pursued this project until the end of his life. Leibniz's crowning achievement was his discovery of the infinitesimal calculus. Although Isaac Newton (1643–1727) discovered the infinitesimal calculus several years earlier, their achievements were independent and Leibniz's system of notation (published before Newton's) continues to be used in the early twenty-first century.

G. W. Leibniz, 1646–1716. Leibniz was a German mathematician and philosopher. Known as a statesman to the general public of his own times and as a mathematician to his scholarly contemporaries, he was subsequently thought of primarily as a philosopher. *(The Library of Congress.)*

To understand Leibniz, one must acknowledge the fundamental premise behind his thought: God created the best of all possible universes by achieving the maximum amount of diversity consonant with unity. This cannot be proven but must be accepted as true for rational inquiry to be possible. From this premise Leibniz identified five basic *a priori* metaphysical principles to guide inquiry: the principle of sufficient reason (for every event or thing there is a reason for its being what it is rather than otherwise) the principle of non-contradiction (that an essence cannot contain opposite properties in the same way at the same time) the principle of perfection (that God always creates by choosing the maximum amount of perfection) the principle of the identity of indiscernibles (that no two things can be identical in all respects save spatial location) finally, the principle of continuity (that there are no "gaps" in the perfection of the created order). In revised version, these premises may still be argued to underlie even empirical scientific research.

Leibniz's scientific method, "the conjectural method a priori," assumes certain hypotheses to demonstrate that natural occurrences follow from them. It is a priori because it relies on his five basic metaphysical principles. Leibniz used it to improve the mechanics of philosopher René Descartes (1596–1650) by distinguishing between speed and velocity, and to criticize Newton's description of force. Moreover, this method was not meant merely for demonstration, but also for technological invention (which motivated Leibniz: for example, he invented a calculator). Most of his technologies nevertheless failed, but many of his proposals foreshadowed later technological developments. For example, he attempted to use windmills to remove water from mines and proposed a system of ball bearings to improve the efficiency of carriage rides.

Leibniz rejected Descartes's metaphysical dualism of mind and matter, and its major scientific presupposition, namely that the physical universe is a *res extensa,* whose causality is exclusively mechanistic. One reason for rejecting matter as the basic element of the universe is its infinite divisibility. This leads to an infinite regress when trying to explain matter, thereby constituting a violation of the principle of sufficient reason. Instead, Leibniz argued for the monad as the most basic element of reality.

Monads are immaterial, "windowless" (that is, there is no causal interaction between monads), microcosms of the universe, the basic activity of which is perception. God harmonizes each monad (which contain all of their predicates analytically) according to his supremely perfect divine plan. Moreover, each person, as a unified collection of monads, has a unique perspective on the universe and, consequently, gets at some degree of truth. Hence, Leibniz insisted that rational inquiry must take place within an intersubjective community.

Leibniz's emphasis on intersubjectivity is reflected in his ethics, which focuses on three concepts: wisdom, virtue, and justice. Wisdom leads to happiness because all moral action must be guided by thought. Happiness is a durable state of pleasure (i.e., understood as perfection). Virtue is the habit of acting according to wisdom, and justice is the charity of the wise person, who pursues the good of others. These are assumed to be the motivations of all technology.

Leibniz's impact cannot be adequately measured. In addition to influencing such thinkers as Immanuel Kant, Edmund Husserl, and the quantum physicist David Bohm, Leibniz's aspirations continue to be a resource for those seeking to reconcile modern science, technology, and ethical responsibilities.

LEOPOLD, ALDO

Aldo Leopold (1887–1948), who was born in Burlington, Iowa, on January 11, was a pioneer of the American environmental movement. His essay "The Land Ethic," published in *A Sand County Almanac* (1966 [1949]), has become a foundational text of American environmental ethics. Leopold challenges his readers to reevaluate their relationship to the land they inhabit and act in accordance with a "land ethic" that "enlarges the boundaries of the community to include soils, waters, plants, and animals, or collectively: the land" (Leopold 1966, p. 239). In his work the land and the biotic community become more than symbolic or abstract entities; they become beings with an intrinsic right to exist. Extending ethics and rights to the land, according to Leopold, necessarily "changes the role of *Homo sapiens* from conqueror of the land-community to plain member and citizen of it" (Leopold 1966, p. 240). Leopold died in Baraboo, Wisconsin, on April 21.

Leopold's love of the land began when as a young naturalist he hunted and fished in his native Iowa. He took his interest in the natural world to Yale's School of Forestry in 1904. During his four years at the school founded by Gifford Pinchot (1865–1946), the first director of the U.S. Forest Service, Leopold absorbed the utilitarian philosophy of the early conservationists (Nash 1989). He served in the Forest Service from 1909 to 1928, working in Apache National Forest in Arizona and then managing the Carson National Forest in New Mexico. By 1928 his earlier studies in ecology and practice of game and forest management had taught him to see the world as a web of interrelated systems. He also came to understand the lasting consequences of individual action on the landscape. In "The Land Ethic" Leopold uses the term *biotic pyramid* to describe the dynamic relationships that exist among organisms and their environments. "Land," he argues, "is not merely soil; it is a fountain of energy flowing through a circuit of soils, plants, and animals" (Leopold 1966, p. 253). In 1933 Leopold accepted an appointment in wildlife management at the University of Wisconsin.

The year 1935 was an important one for Leopold: His concern for vanishing American primitive areas led him to cofound the preservationist group the Wilderness Society. Leopold also purchased an abandoned, 120-acre farm in Sauk County, Wisconsin. It was in that setting that Leopold tried to articulate what it means to have an ethical relationship to the land. *A Sand County Almanac*, the record Leopold created of his years on the farm and his maturing environmental philosophy, was published in 1949, a year after he died fighting a fire on a neighbor's farm.

In his short piece "Axe in Hand" from *Almanac* Leopold provides an illuminating vignette on bias, showing how he imagines his relationship to the plants and animals that coinhabit his space and how he executes, sometimes literally, his decisions involving land management. The context for Leopold's dilemma is the felling of a tree; the decision he must make is between the white pine and the red birch, two species that crowd each other in those woods. Leopold examines the biases that influence a conservationist, which he defines as the axe wielder "who is humbly aware that with each stroke he is writing his signature on the face of the land." He is specifically intent on examining the "logic, if any" behind his own biases (Leopold 1966, p. 73). Leopold understands that his biases are a filter through which he passes the details of the landscape, making his world and the objects in it comprehensible.

The examination of individual biases—in this case Leopold's inquiry into his preference for the pine over the birch—forms the first stage in the development of an ethical relationship to the land. What Leopold describes is land as a system with an integrity of its own. The boll weevil, for instance, will or will not attack the pine if certain relations with the birch exist or do not exist. Some plants will thrive and others will not, depending on whether the birch or the pine is there to give them shelter. When the axe wielder enters the scene, he has the potential to disrupt that system. His examination of bias enables Leopold to see all the possible consequences of his actions and act in a thoughtful manner.

In this essay Leopold paints a portrait of a community in which he is as much a part of the environment as are the trees, insects, and birds; he, like them, has a role to play. In "Axe in Hand" Leopold demonstrates what he calls in "The Land Ethic" the "ecological conscience"; that conscience, he writes, "reflects a conviction of individual responsibility for the health of the land" (Leopold 1966, p. 258). Leopold summarized the principle behind the land ethic as follows: "A thing is right when it tends to preserve the integrity, stability, and beauty of the biotic community. It is wrong when it tends otherwise" (Leopold 1966, p. 262). Leopold's land ethic forces a reevaluation of the "value" of land broadly conceived and requires that limits be placed on the individual in favor of the health of the biotic community.

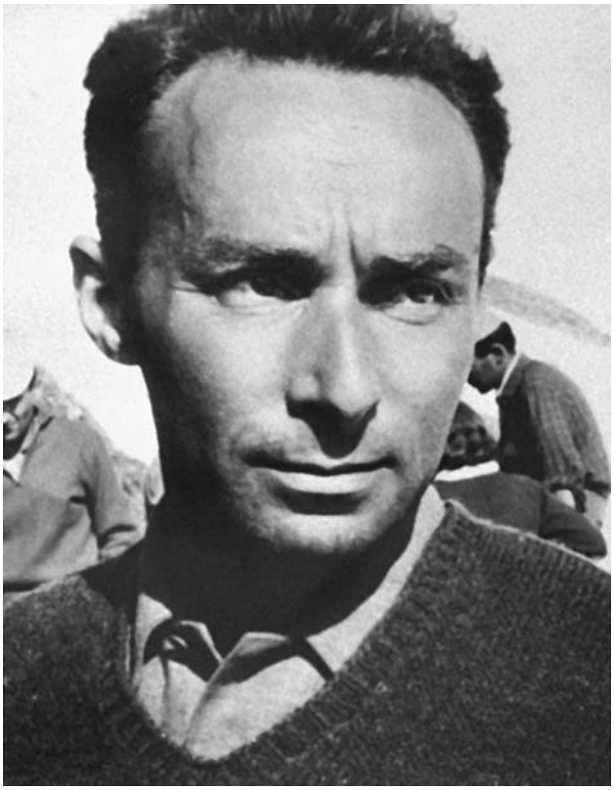
LEVI, PRIMO

Primo Levi (1919–1987) was born to an assimilated Jewish family in Turin, Italy. In 1944, after training as a chemist, Levi joined a group of antifascist partisans, was captured, and was deported to the concentration camp at Auschwitz. He survived and returned to Turin in



Primo Levi, 1919–1987. An Italian author and chemist, Levi was considered one of the foremost writers of concentration camp literature. *(The Library of Congress.)*

1945, at which point he embarked on joint careers as an industrial chemist and an author, publishing the account of his experiences titled *Se questo e un uomo* (If this is a man) in 1947. The book, published in the United States as *Survival in Auschwitz,* is considered to be among the finest accounts of the death camps.

Levi retired from his work as a chemist in 1978 and fell to his death in his Turin apartment building on April 11, 1987. Debate continues about whether Levi, who experienced repeated bouts of depression, killed himself or fell by accident.

Throughout his work Levi stressed the connections between science, literature, and ethics. His use of chemistry as an inspiration for storytelling in *The Periodic Table* (1984) made scientists more attuned to literature and readers of literature more appreciative of science.

One theme unifying Levi's diverse essays and short stories is his belief in the importance and value of work. Levi believed that human beings are naturally constituted to need to work, to strive toward a goal and solve problems encountered in doing so. He emphasized the importance of practice and effort and saw science as a particularly important forum for the struggle to survive and grow.

Levi argued that technology does not necessarily alienate humanity from nature but can enhance the rapport between them. At the same time he emphasized the capacity of humanity for self-transformation, which necessarily means defying and altering nature. He believed that through its inventions humankind has turned its back on nature, damaging both people and the natural world but also improving the lot, and raising the stature, of individuals. Levi argued that one must learn from nature but that one also learns from struggling against it.

Levi eschewed both triumphalism and despair regarding humanity's prospects and the contributions to them made by science. He emphasized that progress will always be noisy, dangerous, and limited. However, because people are adaptable and capable of courage, reason, and strength, progress is possible. Levi celebrated the "cheerful strength" and "sober joy" connected with thought and invention, which allow human beings to endure and learn. He spoke of himself as a man sustained by curiosity about the world and emphasized the value of the inquiry that human curiosity fuels. However, he also acknowledged that the struggle to unlock the secrets of nature through measurement and categorization can be monstrous as well as heroic.

Levi, who was particularly worried by the proliferation of nuclear weapons, called on his fellow scientists and technicians to "return to conscience," to become aware of their immense and potentially sinister power. He insisted that science is not neutral; it either helps or harms human beings. Scientists should not stop doing research for fear of the possible negative consequences of their work, but they should concern themselves with the results of their work and avoid research that leads to immoral results. Scientists should resist the temptation of material rewards and intellectual stimulation, engage in work that will benefit and not harm their fellow human beings, and speak out against the misuse of science by others.

Levi's short stories often satirize the arrogance, ambition, and desire for control or enrichment that can lead scientists to ignore or abandon moral scruples in pursuing and applying knowledge. He warned against submissiveness to power and urged that "a precise moral consciousness" be instilled in scientists as part of their training; he also recommended that scientists take a sort of Hippocratic oath to do no harm (Levi 2001, pp. 71, 89–90).

Levi's reflections on the ethical dimension of science emphasize potential benefits as well as limitations, hope as well as danger, and the joys of discovery as well as moral responsibility. He believed that human beings are alone in a universe not made for their well-being and warned that although science gradually reveals the secrets of the cosmos, those secrets do not provide answers to "big questions" regarding the aims of human life; those answers can come only from within human beings. People's reason for being, he concluded, rests on their nature as, in the words Levi quoted from Pascal, "thinking reeds" who seek knowledge and excellence, and this quest is the source of human dignity.

LEVINAS, EMMANUEL

Emmanuel Levinas (1906–1996), who was born in Lithuania of Jewish parents, studied the Hebrew Bible along with the works of the Russian authors Aleksandr Pushkin (1799–1837), Fyodor Dostoyevsky (1821–1881), and Lev Tolstoy (1828–1910). In 1928 and 1929 he attended the philosopher Edmund Husserl's (1859–1938) lectures in Freiburg, Germany, and started writing a dissertation on Husserl's theory of intuition. He also attended lectures given by the philosopher Martin Heidegger (1889–1976). Levinas was largely responsible for introducing Husserl and Heidegger to French philosophers, most notably Jean-Paul Sartre (1905–1980).

Emmanuel Levinas, 1906–1995. Levinas was a major philosopher of the 20th century who attempted to proceed philosophically beyond phenomenology and ontology and to engage in a more immediate and irreducible consideration of the nature and meaning of other persons. (© *Bassouls Sophie/Corbis Sygma.*)

Levinas's first major work, *Totality and Infinity,* was published in 1961. It was only in the 1980s that a wider audience acknowledged Levinas's work, and his thought eventually became central to postmodern ethics. A number of authors, including philosophers and theorists such as Jacques Derrida (b. 1930), Zygmunt Bauman (b. 1925), John D. Caputo (b. 1940), Robert Bernasconi (b. 1950), and Simon Critchley (b. 1960) adopted his ideas, so that any discussion of ethics outside the analytical tradition would be incomplete without reference to Levinas. This is also true with regard to ethics in science and technology.

Ethics: Not Theory but Happening

For Levinas ethics is not a theory, a rule, an idea, or knowledge of how people ought to act or live. In this sense it can be said that his work falls outside the traditional field of ethical theory. For Levinas ethics is a profound and disruptive event in which the Other disrupts and shatters the self-certain I. Levinas uses the term *Other* (with a capital letter) to refer to the absolute singularity of each human being. Ethics is a disruptive event in which a person's claims to rights and deserts is questioned radically in the face of the infinitely singular person before that individual here and now—the "widow and the orphan." If such persons call on an individual for help or support, that act recalls the individual's guilt, pointing out that that individual has from his or her very beginning taken the place in the sun of the person who has asked for assistance. Levinas would argue that an individual's particular existence has its origin in and through a terrible and violent act seizing the place of the Other who is calling on that individual. This primitive primacy of the individual's guilt, the birth of the ethical question, is Levinas's most profound insight, elaborated in all his works.

Why is the individual already guilty? In taking up his or her personal existential project (to be that particular person), the individual has taken the "place in the sun" of the Other. Further, in making sense of the world and those who cross his or her path, the individual continues to *reduce* the Other to the themes and categories (mother, criminal, politician, manager, man, black, etc) of his or her comprehension. Others become "domesticated" as themes or categories "for-me" through and by the individual's ongoing comprehension of them. This domestication prolongs and extends the violence that began at the birth of a person's individual existential project. Thus, that person has been guilty from the start. For Levinas ethics becomes possible when a person acknowledges that the Other—the particular singular person facing the individual—is infinitely more than any idea (theme, category, attribute) that the individual can use in his or her ongoing comprehension. How, then, can a relationship with the Other be anything but comprehension, how can one encounter the other as Other? Working this out is Levinas's task.

Levinas claims that ethics happens in the "saying" or speaking of language. When the particular Other faces a person and speaks or makes a nonlinguistic gesture, there is more in the words than the message: There is a residue, a trace, of the Other that disturbs the hearer. Levinas uses the familiar event of a doorbell ringing and disturbing one's work and thoughts, but when one opens the door, there is nobody there. Was there nobody there? Did the hearer imagine it? The hearer cannot recall anything but the disturbance. Just when the hearer settles back into his or her thoughts, the doorbell rings again, but there is never somebody there. In the recalling of ethics people are affected without the source of the affection becoming something they can think about as such. It is this relationship of incessantly there but never present that Levinas calls proximity: the disturbing face before the individual that is (re)calling that individual's responsibility. The only recourse in this moment of ethics is to respond, to take up the responsibility for one's original and ongoing violence. For Levinas one is a particular person because one has these particular responsibilities. This is the only possibility for ethics. As he expresses it: "In her face the Other appears to me not as an obstacle, nor as a menace I evaluate, but as what measures me. For me to feel myself unjust I must measure myself against infinity" (Levinas 1996b, p. 58).

Is the individual not also a face? Who will look out for that person? These questions lead to the issue of justice. The radical asymmetrical ethics of Levinas must be reinserted into the symmetrical relationship of justice in which all people are equal before the law. Thus, Levinas claims that it is necessary to add "the third" (all other people) to the relationship of the self and the Other. This is the moment of justice. It involves the need to compare what is never comparable, the dilemma a judge faces in the courtroom every day: to treat all people as equal even though they are absolutely different ("singulars" in Levinas's terminology). Nevertheless, for Levinas the urgency of justice stems from the radical asymmetry of the original ethical relationship. Without such a radical asymmetry—the ethical relationship—the claim of the Other always can be subject to codes, rules, and regulations. Then justice becomes mere calculation and (re)distribution. Thus, justice has its standard, its force, in the proximity of the face of the Other: "The equality of all is born by my inequality, the surplus of my duties over my rights. The forgetting of self moves justice" (Levinas 1991 (1974), p. 159).

Implications for Science, Technology, and Ethics

Levinas's ethics is important in thinking about ethics more generally. One could say that it is a call to rescue ethics from theory. Nevertheless, Levinas's work is particularly important to science and technology. In the epistemological categories of science and the mechanisms and algorithms of technology the absolute singular (the individual particular person) does not fit well. One could see how the singular person becomes a subject, subjected to the logic of the method. In the mechanisms and algorithms of technology the individual person can become an exception (perhaps an error) to be discarded in favor of the categories those technologies rely on for their smooth operation.

Given this seemingly obvious conclusion one could draw from Levinas' ethics above, it is surprising to find that Levinas (1990) takes a very positive view of science and technology. In discussing the space program he argues that science and technology strips nature of its divine pretentions, thereby allowing humans to harness it in the service of humanity. Nevertheless, such a view that posits science and technology as neutral 'tools' that can and ought to be applied in the service of humanity denies the value ladenness of science and technology as well as the political structures within which these human endeavours function. Thus, as Peperzak (1997) argues: "the inherent violence of technology cannot be overcome by technological practice. The micro-ethical practice of persons who are well disposed to others, nature, and art, notwithstanding the distorting networks in which these people function, can point the way towards a better disposed constellations of justice, technological utility, and natural beauty" (p. 143).

Thus, ethically minded designers of technology must ask which categories they assume when they are designing. What about those who do not fit? Moreover, as people apply science and technology in the ordering of society, many singular faces may suffer as they fall through the cracks of method and machine. Does that mean that science and technology are inherently violent? Levinas (1990) would argue that this is necessary violence in the service of freedom and justice. Nevertheless, in its service of justice the ultimate measure should be the proximity of the face of the Other; without this standard it would pursue its path as pure violence.

One could say that Levinas's ethics leaves humankind with plenty and with nothing. The call of the Other is powerful, but how can it be worked out in every instance? Ethical theories such as utilitarianism and consequentialism provide resources to decide what one ought to do in a particular case. However, according to Levinas, all people are guilty and must respond, yet when they respond, they may perpetuate violence. Derrida (1992) claims that Levinasian ethics is impossible because it provides no clear answer or procedure for deciding what to do. This, paradoxically, is an answer. It is the impossibility of ethics that provides the urgency of ethics and interrogates every decision. If making ethical decisions were possible through the use of a rule or procedure, people might forget the plight of the particular individual, the Other. Impossibility is what keeps people open to the possibility of encountering the other as Other in every situation. For Derrida and Levinas it is impossibility that makes ethics possible.

Is Levinas's ethical system anthropocentric? Can other animals and other things have a face? Are they also absolute singulars? Does Levinas deny a responsibility toward nonhuman others? A number of authors have argued against Levinas's ethics on these grounds. Feminist authors have stated that his work is based on the predominant view of the male ego of autonomy and competition as opposed to the female ego of affiliation, empathy, and nurturing (Chanter 1988). Deep ecologists have argued against his exclusion of nature from the realm of morality (Gottlieb 1994). Levinas scholars such as John Llewelyn (1991) and Adriaan Peperzak (1997) have responded to these criticisms. In contrast to these critical comments, Benso (2000), with the help of Heidegger, uses Levinas to make a powerful argument for an "ethics of things." Such an approach points toward the application of Levinas's thought to science, technology, and ethics.

LEWIS, C. S.

Novelist, critic, poet, essayist, and Christian apologist Clive Staples Lewis (1898–1963) was born in Belfast on November 29, served in France, and was wounded during World War I. He completed his undergraduate studies at University College, Oxford, in 1922, and from 1925 until 1954 was a Fellow of Magdalen College, Oxford, and tutor in English. From 1954 until just before his death he was Professor of Medieval and Renaissance Literature at Cambridge.

Lewis once wrote that although he was a rationalist who had *scientific impulses*, he could have never been a scientist. He considered the role and direction of science for nearly three decades and mentioned and alluded to it in many of his works. He was aware of its limitations and methodology, and was respectful of its status as a type of knowledge that could be used for the benefit of humanity. Lewis praised genuine scientific accomplishment and said that scientific reason, if accurate, was valid, although it was not the only kind of reasoning. Truth, value, meaning, and other ideals were necessary presuppositions to the scientific method but were not themselves scientific phenomena.

Lewis was sometimes accused of being unscientific and discrediting, or even attacking, scientific thinking. In reality he criticized what he called *scientism*, a reductionist outlook on the world that popularized the sciences. Scientism (*science deified*) occurred when a naturalistic worldview was linked to the empirical method of experimentation. Scientism as radical empiricism rejected the truth of a nonquantifiable reality such as God.

C. S. Lewis, 1898–1963. An author and scholar, Lewis is known for his work on medieval literature and for his Christian apologetics and fiction, especially *The Chronicles of Narnia*. *(AP/Wide World Photos.)*

Lewis saw the Genesis creation accounts as non-literal folk tales or myths. In *The Problem of Pain* (1940), he presented a modified view of creation and the Fall because scientific evidence that "carnivorousness was older than humanity" had led him to believe that evil had manifested itself long before Adam (Lewis 1940, p. 121). He had a theistic view of evolution but resisted attempts to draw broad philosophical implications from various scientific theories of it. He was never directly opposed to science, but believed many scientific theories were tentative and dependent on changing presuppositions and *climates of opinion*. Early evidence from his letters indicate that he denied that biological evolution was incompatible with Christianity; in later letters he became increasingly pessimistic about evolutionism as a progressive philosophy. Earlier he felt that the theory of evolution was often held because of dogmatic, not scientific reasons, but he never gave up his long-held view that biological evolution was compatible with Christian accounts of creation. He opposed evolutionism as a philosophical theory, not evolution as a biological theory.

In many of his writings Lewis tried to redefine the role of science and its proper role in society. He believed that scientism was in error in that it reduced life to abstractions and denied the possibility that physical events and human experiences had God behind them. He observed that since scientism was only concerned with how things behave, it was not qualified or capable of *looking behind things*, particularly the power behind the universe.

In his much-praised defense of natural law, *The Abolition of Man* (1943), Lewis discussed the possibility of a world that no longer believed in objective truth and value. He saw this as possibly leading to a power struggle in which societal elites tried to control and recondition society. "Man's conquest of Nature, if the dreams of some scientific planners are realized, means the rule of a few hundreds of men over billions and billions of men . . . Each new power won *by* man is a power *over* man as well" (Lewis 1955, p. 70).

Many of Lewis's ideas in *The Abolition of Man* were expressed dramatically in his space novel *That Hideous Strength* (1945). In the story, the degeneration of humanity nearly occurs as a result of a gross scientific materialism controlled by bureaucrats that is devoid of all idealistic, ethical, and religious values. Lewis satirized materialistic scientists in *That Hideous Strength* by showing them as ignoring metaphysical reason and refusing to submit their claims to any kind of moral or religious authority.

He wrote his trilogy of space novels (the others being *Out of the Silent Planet* [1938], and *Perelandra* [1943]) as a result of reading Olaf Stapledon's (1886–1950) *Last and First Men* (1930) and the Cambridge biochemist J. B. S. Haldane's (1892–1964) essay "Man's Destiny" (1927), both of which took interplanetary travel seriously but contained an immoral outlook that denied God. He was openly critical of Stapledon's fictional universes, in which science represented the greatest good and Christian ideals played no essential role. After reading Stapledon's *Star Maker* (1937), Lewis said that the race Stapledon described was concerned primarily for the increase of its own power by technology, a technology that was indifferent to ethics, and a *cancer in the universe*.

LIBERALISM

Liberalism as a theory about politics and society upholds freedoms of belief, inquiry, expression, action, association and elections. In liberalism, freedom coalesces with value-commitments to equality, individualism, toleration, pluralism, and rationality. All of these commitments have interacted with science and technology in multiple ways.

Classical Liberalism

Liberals differ over determining the nature of freedom. Isaiah Berlin's distinction between negative and positive freedoms (freedom *from* as against freedom *to*) is useful in explaining the difference between classical and modern forms of liberalism.

In classical liberalism, freedom is interpreted in terms of a *private* sphere of non-interference that is supported by the rule of law. Free agents are protected from arbitrary interference, being left to enjoy their possessions, to retain personal beliefs, and to act in preferred ways on the condition that they respect the freedom of others to do the same. Support for private property and free markets goes hand in hand, in classical liberalism, with a prescription that power (economic as well as political) be divided so as to alleviate the risk of its being abused.

John Locke (1632–1704), whose *Second Treatise of Civil Government* (1690) started the tradition of liberal thought, encapsulated classical liberalism in stating that "Liberty is to be free from restraint and violence from others which cannot be, where there is no Law" (1960, p. 324). Locke's form of liberalism supported parliamentary government and the rule of law in England against absolute monarchy.

Among French thinkers, Charles de Secondat, Baron de Montesquieu, in *The Spirit of the Laws* (1748), praised the English constitution for its separation of the powers of government and reflected adversely on the absolutism of the French monarchy. Tolerance, aversion to fanaticism, and advocacy of freedom of discussion and of the press characterize the writings of the eighteenth-century *philosophes,* including Marquis de Concordet and Francois-Marie Voltaire. After the turmoil of the French Revolution and of Napoleon Bonaparte's rule, Benjamin Constant (1767–1830) and Francois Guizot (1787–1874) conceived of a liberalism that was conservative and admiring of English political institutions, while Alexis de Tocqueville (1805–1859) warned that democracy gives no guarantee of freedom and might end in tyranny.

Pre-eminent among German liberals, Immanuel Kant (1724–1804) conceived of liberty as the will determining itself according to its rational law, converting pure reason into practical reason. Kant's state is a legal organization, *limited* in its role of ordering legal rights, reconciling the free will of each individual with that of all others. The sphere of morality, for Kant, consists in individual conscience as the judge of the righteousness of acts. In 1927 Guido de Ruggiero contended that Kant's liberalism served to constrain the exercise of power in Germany through the nineteenth century because, "even in periods of the strictest absolutism," governments were checked "by a profound consciousness of" being restricted to the sphere of rights (de Ruggiero 1927, p. 220). In his *Essay on the Limits of the Action of the State* (1851), Wilhelm von Humboldt argued that the worthy faculties and qualities of individuals only develop in an environment that a minimalist state protects as free and pluralist. In Germany, as in France, liberals were nowhere near as committed to the market economy as were their English counterparts.

Among the sources of nascent U.S. liberalism was Locke with his ideas of natural rights, government by consent, and the entitlement of subjects to revolt against a government that betrays their trust. French *philosophes* could envision human perfectibility, but the liberals who contributed to the formation of the U.S. republic were skeptical. Their understanding of human nature derived from the Scottish Enlightenment: Adam Ferguson, David Hume and, particularly, Adam Smith who, in *The Wealth of Nations* (1776), argued for capitalist economics (the price mechanism as a beneficent *invisible hand*), the rule of law in a constitutional order, and equal freedom. Smith believed that a strong presumption exists against governmental activity, but his advocacy of laissez faire was not doctrinaire. A rule of thumb with Smith was that government should arrange social conditions in ways that would assist the market to provide public services; Jeremy Bentham and his circle embraced this theory. Adopting the principle of utility as his axiom, policies being calculated to advance the greatest happiness of the greatest number in society, Bentham inferred that joint stock companies should bid for government contracts to operate public institutions (prisons and poor houses).

Modern Liberalism

The emphasis in *modern* liberalism is placed on freedom as empowerment (freedom *to*). There has been no closer approximation to the ideal type of classical liberal society than nineteenth-century England in the era of William Gladstone and Richard Cobden. Nevertheless, after the reform of Parliament in 1832, governments in England—partly from the impetus received from Benthamite utilitarianism—became more active: reforming the administration of the poor law and of public health; regulating working hours, the police, and inspection of factories; and overhauling the civil service and local government.

Liberal thought in England also underwent a major revision with Lionel Hobhouse in 1911 describing the *liberal socialism* of John Stuart Mill (1806–1873) as the link *between the old and the new liberalism.* The *new liberalism* of the Hegelians Thomas Hill Green (1836–1882) and Bernard Bosanquet (1848–1923), appreciated the value of freedom as a positive power and recommended a more constructive mode of government. Agreeing with Mill that the core of liberalism consists in the "liberation of ... [the] spiritual energy" of agents (Hobhouse 1911, p. 137), Hobhouse proposed that the state should act so as to secure the economic conditions that would enable individuals to develop their faculties and to fully participate in the life of the community.

Two world wars and the intervening Great Depression led governments to assume a greater role in European and North American societies. John Maynard Keynes's *General Theory of Employment* (1936) explained how governments should use their fiscal powers of taxing and spending to regulate economic activity and control money supply as a means of mitigating the business cycle and unemployment.

In 1935, in the United States, John Dewey (1859–1952) expressed hostility to the free market order and its disparities in wealth. The Humboldt-Mill ideal of individual development as grounded in freedom that had impressed Green and Hobhouse was assimilated by Dewey and by many other liberal philosophers through the twentieth century. Dewey saw the ends of liberalism—"liberty and the opportunity of individuals" to fully realize "their potentialities"—as requiring governmental planning of "industry and finance" (1963, p. 51, 55).

The ideal of individual development is discernible in the most important work of liberalism to appear in the second half of the twentieth century, John Rawls's *A Theory of Justice* (1971). Arguing for redistribution and the welfare state, Rawls relied on principles of liberal justice. One of Rawls's tenets attributes freedoms of conscience, conduct, and religion to citizens; his other basic belief dictates that a redistribution of resources may only take place on the condition that the least well-off members of society will benefit from it. As a corollary, inequalities determined by an agent's social circumstances, and by that person's talents and abilities, are deemed to be illegitimate.

Prominent among the responses to Rawls's Kantian liberalism is *communitarianism*. Michael Sandel in *Liberalism and the Limits of Justice* (1982) demurred to Rawls's use of an abstracted individual to reason about justice, envisaging the self as being socially formed, and the individual as exercising reason only within the community.

The term *modern* liberalism does not mean that classical liberalism is an anachronism. The writings of neoliberals—Ludwig von Mises, Friedrich Hayek, Ayn Rand, and Milton Friedman—that influenced the governments of Margaret Thatcher and Ronald Reagan, confirm the durability of the classical liberal position. Neoliberals argued that the meliorist activity of democratic governments must be kept to a minimum if liberal societies are to avoid what Hayek sign-posted as *the road to serfdom*.

The distinction between classical and modern liberalisms is not a sharp one, the positions shading off into each other. Walter Lippmann (1889–1974), for example, was convinced that many services in modern society can only be provided by large governmental enterprises and he defended a redistribution of wealth as socially stabilizing. Lippmann held with the ideals of Smith, however, which turned him against Franklin Roosevelt's New Deal and other forms of *collectivism*. The political thought of Karl Popper (1902–1994) can be located with Lippmann's near the middle of the continuum between classical and modern liberalisms.

Science and Technology as Supporting the Achievement of Liberal Ideals

Liberalism and science have commonly been seen as buttressing each other. While recognizing that scientific research needed governmental funding, liberals argued that because scientists are experts in research they should be free to select their topics of, and methods for, research. In the 1940s, Michael Polanyi defended the autonomy of science against Soviet-style planned research, and Popper supported free inquiry by showing that knowledge advances in an unpredictable manner. Like Polanyi and Popper, Robert Merton depicted science as an exemplary liberal community, highlighting norms of universalism, communalism, disinterestedness, and organized skepticism.

Since the detonation of the atomic bomb, with the proliferation of weapons of mass slaughter and with the deterioration of the environment, even liberals have become ambivalent toward science and technology, although most remain sure that science and technology are conducive to liberal values. Without science and technology, liberals argue, freedoms of modern society—of the press and of the airwaves, for example—would be attenuated. Freedoms of election and association benefit from electronic communications and rapid transport. The technology of publishing serves the marketplace of ideas, and media technology helps in checking the power of government. Travel and the mass media expose more people to foreign cultures, encouraging tolerance of ethnic and cultural diversity. Dissemination of information by way of the Internet assists people in making free choices on matters of health, religion, education, and politics. In contributing to the material conditions of life that underlie the enjoyment of all liberties, science and technology have helped people, particularly in Europe and North America, to live longer, suffer less pain, and enjoy better health and greater comfort.

Science and Technology as Impeding the Attainment of Liberal Ideals

Much of the liberal image of science is out of date. In the early twenty-first century most scientists are a part of *big science*. Typically research is conducted by large teams, is capital-intensive, and is shrouded in secrecy because most scientists aim at producing innovations for industrial and governmental sponsors. While liberals are correct in claiming that science ails when governments and corporations instruct scientists on how to conduct their research, the fact remains that governmental controls on scientific research have become more stringent.

Science and technology may support the liberal values of freedom and tolerance, but in a number of ways they also *standardize* culture and social practices, as James Scott has argued. Paul Feyerabend (1924–1994) examined the idolization of science and technology—scientism and the cult of the expert—that so often takes responsibility away from laypeople and leads to the denigration of non-scientific beliefs and practices. In the first half of the nineteenth century, liberals (Tocqueville, Humboldt, and Mill) worried that newspapers and railways were creating a social *mass* that was hostile to individuality, diversity, and freedom. Concern about technology and the masses was also voiced by Max Weber (1864–1920) and José Ortega y Gasset (1883–1955). In the twentieth century, assembly line mass production and deskilling of the workforce in accordance with the precepts of Frederick Winslow Taylor's *scientific management* gave further impetus to standardization.

Social elites of scientists and technologists have privileged access to government policy makers and to funding agencies. They promote and benefit from scientism and standardization, having a major say over the curriculum and attracting the lion's share of resources for research in their fields.

In the hands of governments and corporations, modern science and technology have intruded deeply into the *private realm*. Although totalitarianism provided the most graphic evidence of mental regimentation by the electronic mass media, the mass media in democracies have been accused of *manufacturing consent*, indoctrinating consumers, and promoting irrationality. Computers and other information handling systems, security cameras, wire taps, and interception of on-line communications represent technologies that subject a citizenry to electronic *surveillance*.

LIBERTARIANISM

Libertarianism is the belief that one has the right to dominion over one's own person, including the fruits of one's labor. Adults are entitled to make their own decisions and agreements. Coercion, particularly by the government, is wrong.

In contemporary American politics libertarians side with the far left in favoring personal freedom and side with the far right in favoring economic freedom. Thus, libertarians argue for the decriminalization of recreational drug use on the grounds that adults should have the right to make choices about their bodies. Libertarians oppose a national health care system as coercive and inevitably interfering with the rights of individuals to make their own choices about health care.

Libertarians view other ideologies as overly paternalistic. Politicians routinely begin a sentence with "We must," as in " We must reduce our dependence on foreign oil" or "We must spend more on education." A libertarian asks, "Who is this 'we'?" Libertarians argue that individuals can decide for themselves how much to spend on their own education. Moreover, people who want to see others obtain more education are free to donate funds for that cause. To libertarians "We must spend more on education" translates into "The government is going to coerce individuals into paying for their own or others' education."

For many people economic freedom is justified on utilitarian grounds. Those individuals endorse free markets because markets deliver economic growth and a high average standard of living. For libertarians economic freedom is justified on first principles. Even when government regulation is intended to make people better off, libertarians oppose such regulation as coercive. Thus, libertarians would not endorse most regulation carried out in the name of protecting consumers, preferring instead that consumers be expected to protect themselves.

Libertarianism faces a number of challenges. First, libertarians must establish the boundaries between freedom and coercion. In theory, one person's freedom can negate another's. The libertarian solution to this problem is to focus on property rights. If a person's property is clearly defined, no one may take that property without that person's consent. The libertarian's ideal role for government is to enforce property rights and nothing else.

Second, libertarianism is criticized for taking social institutions and cultural norms for granted. That is, libertarians speak as if society could function with only markets as institutions. However, markets operate in a context of cultural values and government protections, and chaos would result if those protections were taken away.

On the left critics of libertarianism argue that without social welfare programs the poor might turn to crime or armed insurrection. Without public education people might not acquire the basic tools needed to function in and maintain their society. On the right critics of libertarianism argue that individual morality is too fragile to prevail in the noncoercive environment favored by libertarians. Without the restraints imposed by religion, social opprobrium, and legal sanction people's behavior would degenerate, ultimately reaching the point where they no longer were capable of respecting themselves or one another.

Third, libertarianism is criticized as an ideology that ignores inequality and scorns the disadvantaged. This line of criticism is embedded in lines such as "The rich man and the poor man have equal freedom to sleep in the gutter" and "Freedom of the press exists only if you own one" (the second quote is attributed to the journalist A. J. Liebling).

These critics argue that property rights are not sufficient to make everyone free. They suggest that those born without sufficient endowments of land, capital, and aptitude are at the mercy of the powerful even in the absence of coercion. In response libertarians argue that government programs enacted for the benefit of the disadvantaged often are counterproductive, circumscribing freedom without aiding the intended beneficiaries.

History of Libertarianism

Libertarianism has its roots in Enlightenment philosophy, particularly the writings of the philosopher John Locke (1632–1704). Locke argued that dominion over one's own body and one's own property is a natural right. Locke viewed government as legitimate only if it has the consent of the governed. In Chapter 8 of the *Second Treatise on Government* Locke wrote, "The only way whereby any one divests himself of his natural liberty, and puts on the bonds of civil society, is by agreeing with other men to join and unite into a community for their comfortable, safe, and peaceable living one amongst another, in a secure enjoyment of their properties, and a greater security against any, that are not of it." Locke was a major influence on the founders of the United States, who embodied the contractual theory of government in the U.S. Constitution. The U.S. Bill of Rights also reinforced libertarian ideas of natural rights.

Another major libertarian work is *On Liberty* by the philosopher John Stuart Mill (1806–1873). Mill argued that social condemnation could be as oppressive as government coercion.

In the twentieth century one of the most important libertarian thinkers was Friedrich Hayek (1899–1992), who argued against the dominant view that a modern economy requires central planning and a welfare state. Hayek believed that the price system, fed by local information in markets, is more efficient than any central planner. For him the coercion required to implement the welfare state would undermine freedom and thus was *The Road to Serfdom* (1944).

The Internet and Libertarianism

In 1996, John Perry Barlow, a writer and activist in the Electronic Freedom Foundation (EFF), composed "A Declaration of the Independence of Cyberspace," which argued that government should adopt a hands-off approach with respect to the Internet. Barlow's declaration exemplifies the symbiotic relationship between the Internet and libertarian thinking. Barlow's words contain echoes from Locke ("We are forming our own Social Contract."), Mill ("We are creating a world where anyone, anywhere may express his or her beliefs, no matter how singular, without fear of being coerced into silence or conformity."), and Hayek ("our culture, our ethics, or the unwritten codes that already provide our society more order than could be obtained by any of your impositions") (quoted in Barlow 1996, Internet site).

The Internet is, like the U.S. Constitution, designed as an agreement among consenting individuals. It is a set of communication protocols that allow data to be transmitted from one computer to another. Any communication that uses Internet Protocols (IP) can be sent over the Internet. The protocols impose only minimal constraints on the information that can be transmitted. Video, telephony, text, and data all can be sent via IP.

The Internet is also decentralized. No single computer acts as a hub or main distribution point. Instead, like Hayek's spontaneous order, the Internet relies on local information, contained in routing tables, to pass data from any computer on the network to another. Also, the Internet is configured to facilitate anonymity. This tends to shift the balance of power away from government officials and toward individuals. As a result it has proved all but impossible to regulate pornography and junk mail on the Internet.

The Internet was designed to have multiple routes between endpoints, which makes it more difficult both to attack militarily and to regulate. John Gilmore, a libertarian Internet activist, famously said, "The Internet interprets censorship and damage, and routes around it."

Personal computers and the Internet have changed the relationship between individuals and large organizations. One does not need to own a printing press to publish ideas that can reach the masses. One does not need to lease stores to sell goods to people all over the world. One does not need a mainframe computer costing millions of dollars to write a piece of software.

Because individuals are now better able to bypass large organizations, the rationale for government intervention as a check against corporate power has lost its appeal to many people who make a living using computers and the Internet. In *Cyberselfish*, a critical survey of libertarianism in the technology community, the journalist Paulina Borsook wrote that "with geeks, the attitude, mind-set, and philosophy is libertarianism" and "libertarians are the most vocal political thinkers and talkers in high tech" (Borsook 2000, pp. 3 and 7).

Intellectual Property

The low cost of distributing and copying content on the Internet has opened a schism within the libertarian community concerning the issue of intellectual property. Some libertarians argue that intellectual property rights are legitimate, based on Locke's principle that one has a natural right to property created by one's labor. According to this view, if one composes a song or another creative work, one has a property right that should be protected.

Other libertarians, including Barlow, believe that ideas should not to be regarded as property. One person can use an idea without infringing on another person's ability to use that idea. Barlow argues in the tradition of Thomas Jefferson, who wrote, "He who receives an idea from me, receives instruction himself without lessening mine; as he who lights his taper at mine, receives light without darkening me" (Quoted in Barlow 1996, Internet site).

A potential libertarian approach to the issue of copyright is Digital Rights Management (DRM). The idea behind DRM is that the composer of a creative work would embed in its digital representation a digital "lock" that could be opened only by a consumer who agreed to purchase and use the work within the limitations intended by the author.

However, there are those who doubt that DRM can be effective. Those critics say that the ability of individuals to circumvent DRM will make it impossible to rely on the private sector alone to protect intellectual property. Instead, DRM will require government involvement in the design and enforcement of restrictions on the specifications of equipment. For example, the Digital Millenium Copyright Act (DMCA) criminalized the production of technology that could be used to circumvent copyright restrictions. Many libertarians were troubled by the DMCA.

Biotechnology

The libertarian position on biotechnology, nanotechnology, and other potentially revolutionary scientific developments is one of laissez-faire. The libertarian view is that individuals are capable of addressing the ethical issues raised by new technologies without government interference.

Libertarians tend to dismiss concerns such as those raised by the President's Commission on Bioethics. In *Beyond Therapy* (President's Council of Bioethics 2004) the commission argues that biotechnology poses ethical problems by potentially enhancing human capabilities, eliminating death, and giving parents control over the characteristics of their children. Libertarians believe that individuals are capable of dealing with these issues as they arise. Moreover, libertarians argue that the sort of regulatory regime that would be needed to enforce controls over such technologies would be draconian.

Privacy

Libertarians are mindful of the effect of technology on privacy. Some technologies, such as miniature cameras, radio identification tags, and powerful storage and processing for large databases, seem to threaten privacy. Other technologies, such as the decentralized Internet and cryptography, seem to enhance privacy.

David D. Friedman has painted one scenario for the way these technologies could play out. In Chapter 1 of his draft *Future Imperfect* he writes, "Put all of these technologies together and we may end up with a world where your realspace identity is entirely public, with everything about you known and readily accessible, while your cyberspace activities, and information about them, are entirely private—with you in control of the link between your cyberspace persona and your realspace identity."

The last point—that the individual will control the link between electronic identity and physical identity—is crucial. If the opposite scenario were to emerge, in which the government always would have the ability to trace electronic communications to an individual person, the potential for totalitarian control would appear to be high.

In *The Transparent Society* (1998) David Brin has suggested that the inevitable improvement in surveillance technology is going to cause privacy to be replaced by transparency. Cameras are certain to become smaller, digital radio tracking devices will become more powerful, and all forms of surveillance will become cheaper. In light of this outlook Brin argues that freedom and autonomy can best be preserved by ensuring that individuals have as much access to information about government and large corporations as those organizations have access to information about individuals.

The Future of Libertarianism

In the late industrial age libertarianism went into eclipse. For most of the twentieth century it appeared that the future belonged to powerful manufacturing enterprises and the large government that was thought necessary to regulate and plan the industrial economy. In the Internet age many people are seeing the potential for unplanned order emerging from the decisions of individuals. This has revived libertarianism as an important philosophy.

Libertarianism may have reawakened, but it is far from triumphant. Libertarian approaches to government policy on recreational drugs, education, and health care remain far from the mainstream, where paternalism remains entrenched. Moreover, technology poses problems for which libertarianism, typically absolutist and unabashed, lacks clear answers. Intellectual property poses a conflict between the natural right to own the product of one's labor and the right to engage in free expression and activities that do not infringe directly on another person. New technologies also provide surveillance potential in ways that require libertarians to reconsider the fundamental basis for privacy.

LIFE

In consideration of the ethical uses of science and technology the phenomenon of life, especially human life, has repeatedly played significant roles in both progressive and conservative arguments. In modern philosophy notions of life have also made repeated appearances, from Thomas Hobbes's claim that the fundamental aim of politics is to replace the insecurity of life in the state of nature with a more secure life by means, in part, of technology, to Friedrich Nietzsche's appeal to a life ideal that transcends concerns of personal security. Contemporary debates about the limits of biomedical interventions in terms of whether or not human life begins at conception and feminist criticisms of cultural tendencies to disembody life thus reflect and advance long-standing concerns. Indeed, at the beginning of philosophy in Europe, one of Socrates's fundamental theses was that "The unexamined life [*bios*] is not worth living for humans" (*Apology* 38a); and as a manifestation of his divinity, the Christian scriptures record Jesus's claim to being "the way, the truth, and the life [*zoe*]" (John 14:6).

Life Sciences

Science has from its earliest forms distinguished two fundamental realms in nature: the nonliving and the living. Aristotle (384–322 B.C.E.) was among the first systematic investigators of nature and for centuries provided an authoritative orientation that took its bearings from the living. For Aristotle, living entities reveal the workings of nature better than the nonliving; life provides the key to explain the nonliving—in contrast to modern natural science, which seeks an explanation of life in terms of nonlife. Certainly life more clearly displays the dynamism and purposefulness that Aristotle sees as central to reality as a whole. Purposefulness, final causation, and teleology conceptualize that by which entities seek natural states or places proper to their kind. The acorn matures in order to become an oak tree because that is its inner nature; the oak tree maintains its state through metabolism because this inner nature has been achieved. Living things have an internal principle of motion and rest, which can be grasped by reason, whereas the nonliving are moved by external forces, the rationality of which is more difficult to comprehend.

For modern natural science, however, it is the external forces moving nonliving entities that are most readily calculable, thus giving rise to physics in a new sense. René Descartes (1596–1650), for instance, proposed that animals are simply complex machines, and that all life functions (except human thinking) could be explained in terms of mechanical interactions. From the beginning, however, the adequacy of this view has been contested, and the reduction of life to physics and chemistry challenged. The vitalism of Hans Driesch (1867–1941) and Henri Bergson (1859–1941), who argued that life involved some nonphysical element or is governed by special principles, was but one of the more pronounced examples.

Traditional explanations for the variety of life—namely, that either species are eternal or divinely created—and how organisms change over time had long been scrutinized before Charles Darwin (1809–1882) published *On the Origin of Species*. It was Darwin's theory of evolution by natural selection, however, that produced the first comprehensive account of the changing diversity of life that appeared to go beyond simple mechanism without rejecting it. Fused with the model of biological inheritance developed by Gregor Mendel (1822–1884), the synthesis of evolution by natural selection operating on the gene became the cornerstone of modern biology.

In the early 1940s the Austrian physicist Erwin Schrödinger (1887–1961) proposed that genes functioned by means of a "molecular code-script" present in chromosomes. This pointed toward the idea of molecular biology. A decade later, in 1953, James D. Watson (b. 1928) and Francis Crick (1916–2004) discovered the double-helix molecular structure of DNA. Analyses of DNA eventually elucidated the connection between genetic information and the traits of living organisms, which describes the transcription and translation of genetic information into proteins.

Redefining Life

Difficulties nevertheless remain for developing a post-Aristotelian definition of life as a biological phenomenon. One common approach has been to consider an entity living if it exhibits the following characteristics at least once during its existence: growth, metabolism, reproduction, and response to stimuli. Yet in some sense fire meets all these criteria. Moreover, some entities are not clearly either living or nonliving. Chief among these are viruses, which contain protein and nucleic acid molecules that make up living cells but require the assistance of those cells to replicate. In response, life can be further described as cellular and homeostatic—even though this would continue to classify viruses as anomalous.

Systems theorists such as Ilya Prigogine, Fritjof Capra, and Francisco Varela, however, have preferred to define life as a complex, autopoeitic (self-creating), dissipative feedback system. This conception gave rise to the Gaia hypothesis of James Lovelock and Lynn Margulis, which conceives of the entire biosphere as living insofar as it maintains conditions favorable to its continued existence.

What about the possibility of human-made, artificial life? This term can refer to a number of different research programs. Genetic engineering (and even animal breeding) creates forms of life that might not otherwise occur in nature. For Christopher G. Langton computer programs that model life processes by means of complex algorithms constitute artificial life or "a-life." Some theorists go even further to argue that beyond modeling, life is a process that can be abstracted away from any particular medium and need not necessarily depend on carbon-based chemical solutions.

Precisely when human life begins, whether at conception or some point further along in embryonic development, is also a highly contested issue. The premodern view that human life begins at the "quickening"—that is, when a woman experiences the first movements of a new child in her womb—has been altered by the very biological science that often proposes to treat embryos as no different than many other rudimentary organisms.

Life Philosophies

All such modern definitions have difficulty accounting for life as having any intrinsic ethical significance. The purposelessness of natural selection and the lowered status of humans in a hierarchy of being challenge traditional moral and theological beliefs. When life is conceived as an assemblage of adaptations to random and constantly changing circumstances, there remain no forms or essential types to imitate, and no harmonious order or basic good to maintain. Yet despite the most sophisticated explanations, purposefulness does appear to be an aspect of the living.

One response has been the development of a life philosophy (German *Lebensphilosophie*) that arose as a reaction against Enlightenment rationalism. Life is prioritized over mere understanding, and life philosophy has had many variants, including artistic movements in which life is used as a concept to assess and critique modern society. Certainly over the course of the nineteenth and twentieth centuries life as "vitality" or vividness, a sense of both spiritual striving and joyous experiencing, played an important role in literature, art, and music as a touchstone of criticism of the scientific and technological. Among the most important representations of this view are attempts made by Arthur Schopenhauer (1788–1860) and Friedrich Nietzsche (1844–1900) to grasp life as an all-encompassing metaphysical category or first philosophy.

Nietzsche's life philosophy differed from the thought of Schopenhauer in its naturalism. In his genealogical work, he traced the development of the life-denying ascetic ideal that he saw as dominant in Western (and most Eastern) philosophy and religion. Value comes to being always in support of life, but ascetic philosophies give vital ideals a life-devaluing interpretation. Anything that is part of the natural, changing, life-world is interpreted as wrong and sinful, and ideals of truth and virtue are rooted in otherworldly, changeless realms. The ascetic ideal removes all source of value from nature, whereas modern natural science removed any faith in a realm outside of nature. One interpretation of the "death of God" is the extinction of this transcendent, nonhuman, and ahistorical realm to ground human values. There is nothing but life on which to base values, including truth. Whether Nietzsche successfully distinguished this revaluation of values from nihilism remains a subject of dispute.

During the mid-twentieth century life philosophy made a new appearance in the forms of phenomenology and existentialism. Phenomenology especially criticized science as separating itself from the human lifeworld or as disembodying experience. Related arguments have been carried forward in feminist criticisms such as those of Barbara Duden and Donna Haraway. In her studies of women's medicine and experiences such as pregnancy, Duden (1993) defends the primacy of lived experience over its conceptual analysis. In her notion of "companion species," Haraway (2003) criticizes the primacy of conceptual oppositions in favor of mutuality of living relationships, which harks back to the work of Pytor Kropotkin (1842–1921) and his notion of "mutual aid" among organisms.

Whether molecular biology can account for what is apparently goal-directed behavior in organisms likewise continues to spark controversy (see, e.g., Allen, Bekoff, and Lauder 1998). Finally, given the difficulties of understanding the ethical significance of biological life in the modern sense, philosophers such as Hans Jonas (1966) and Leon R. Kass (1985) have even attempted to revive an Aristotelian approach that would understand the most elementary forms of life in terms of higher forms of life rather than vice versa.

The Human Condition, Bioethics, and Biotechnology

According to Hannah Arendt (1958) the life of human activity, or *vita activa,* may be distinguished into labor, work, and action. Labor pertains to the biological processes of the human body, work to the world of artifice, and action to politics. Political action is so central to the human condition that the Romans used the same term (*inter homines esse*) to signify both "to live" and "to be among men." But as Arendt also notes, "life" takes distinct forms in each level of the *vita activa.* In the first instance life is related to the futile, biological labors of the body in which there is a kind of "deathless everlastingness of the human as of all other animal species" (p. 97). In the second instance life takes on the worldliness of work with distinct beginnings and ends and can be told as a story.

The first notion of life corresponds to the Greek *zoe,* from which English derives *zoology;* the second corresponds to the Greek *bios,* from which comes *biography* and a sense of the historical. For Arendt the modern world may be characterized by an effulgence of *zoe* as labor moved from the most-despised to the most-esteemed position with a productivity that outstripped all traditional work and overwhelmed action. But action and speech, beyond the necessary but lower forms of the *animal laborans* (labor) and *homo faber* (work), is the highest form of human life. The measure of all things, she claims, "can be neither the driving necessity of biological life and labor nor the utilitarian instrumentalism of fabrication and usage" (p. 174).

The term *bioethics* was initially coined by the biologist Van Rensselaer Potter (1911–2001) to refer to an ethics grounded on the science of life, rather than on religion or philosophy. It has since come to signify the field that studies the intersection of biology and biography, or the science of life studied scientifically and life lived experientially (Kass 2002). The focus on biography and the good life, rather than mere biological life, has taken on more importance as new biomedical technologies expand the capacities of human biology, or what Arendt would call the labor of human bodies. This is best illustrated by advances in life-extending techniques used in palliative care. In many instances, one's biological life is extended well beyond the duration of one's biographical life among the world of things and within the plural realm of action and speech. This raises ethical questions about what it means to die a dignified death and who should make such decisions in various circumstances.

Advances in biotechnology offer new powers to alter and to some degree control the phenomena of life. This has brought both reward and risk. In agricultural uses, biotechnology has raised concerns about risks, especially involving uncertain ecological interactions and health effects. In biomedical uses, similar health risk issues occur along with questions of informed consent and privacy. Additionally, the controversial techniques of abortion, cloning, and stem cell research sustain heated debates about when human life begins. New reproductive techniques have stimulated questions about how much control the present generation ought to have over future generations.

This last issue highlights the fact that both in agricultural and medical biotechnology, traditional ethical issues are complemented by deeper concerns about the proper limits to the human activity of "remaking Eden" and "relieving man's estate." How ought humankind responsibly exercise its power over life and where should limits be drawn? For example, even though biomedical technologies offer obvious rewards in terms of satisfying deep human desires, they can also serve (intentionally or not) to diminish human life. As the President's Council on Bioethics remarked in *Beyond Therapy* (2003), "To a society armed with biotechnology, the activities of human life may come to be seen in purely technical terms, and more amenable to improvement than they really are" (p. xvii). Promoting the genuine flourishing of human life is foremost a matter of understanding the good life rather than commanding the tools to manipulate life processes.

LIMITED NUCLEAR TEST BAN TREATY

The Limited Nuclear Test Ban Treaty (LTBT) was signed by the United States, Great Britain, and the Soviet Union in Moscow on August 5, 1963. Ending more than eight years of negotiations, the LTBT prohibits nuclear weapons tests or other explosions in the atmosphere, outer space, or underwater. While the treaty does not ban underground nuclear explosions, it does prohibit tests if they would cause "radioactive debris to be present outside the territorial limits of the State under whose jurisdiction or control" the explosions were conducted. In addition, by signing on to the treaty the countries agreed to the goal of "the discontinuance of all test explosions of nuclear weapons for all time."

Emergent History

After the end of World War II, Great Britain and the Soviet Union joined the United States in the nuclear club and the United States and the Soviet Union tested their first hydrogen bombs in 1952 and 1953 respectively. Public concern about nuclear testing began to grow, especially after the March 1954 test of a thermonuclear device by the United States at Bikini atoll. This test was expected to have a yield equivalent to approximately eight million tons of trinitrotoluene (TNT), but in actuality was about fifteen megatons, or almost double the predictions. The fallout from the explosion greatly exceeded geographical expectations, contaminating a Japanese fishing vessel, the Lucky Dragon, as well as Bikini atoll.

This incident, as well as others, increased the awareness of the effects of fallout and the issue of continued nuclear tests garnered greater public scrutiny. Organizations such as Women Strike for Peace and Physicians for Social Responsibility were formed to increase public pressure on western governments for signing a treaty, as well as informing the public of the dangers of nuclear testing. For instance, Women Strike for Peace originated from an international protest of women against atmospheric testing. Physicians for Social Responsibility documented the presence of strontium-90—a highly radioactive waste product of atmospheric nuclear testing—in children's teeth across the country. As it became apparent that no region of the world was untouched by radioactive fallout, there was increasing apprehension about the possibility of global environmental contamination and the resulting genetic effects. It was in this atmosphere that efforts to negotiate an end to nuclear tests began in May 1955 in the Subcommittee of Five of the United Nations Disarmament Commission.

International interest in the course of the negotiations was intense and sustained. The issue was brought up in statements and proposals at international meetings and the United Nations General Assembly addressed the issue in a dozen resolutions, repeatedly pressing for an agreement to be reached. While the United States, Great Britain, and the Soviet Union engaged in a tripartite effort—The Conference on the Discontinuance of Nuclear Weapons Tests—almost continuously from October 31, 1958 to January 29, 1962, no treaty could be drafted due to differences on a number of issues.

Basic Treaty Issues

The issue of a control and enforcement mechanism to verify compliance to a comprehensive test ban was the primary point of disagreement between the parties. Western European and U.S. powers, especially, were concerned that it would be more dangerous to accept pledges without the means to verify that they were being complied with than to not have a treaty at all. The Soviets, for their part, felt that because, "in the present state of scientific knowledge" (Premier Bulganin writing to President Eisenhower on October 17, 1956, from U.S. Department of State Bureau of Arms Control) no explosion could be produced without being detected, then there could be an immediate agreement to prohibit tests without an international control mechanism at all.

To resolve the issue of how compliance could best be verified, the Geneva Conference of Experts met in July and August 1958 and was attended by representatives from the United States, Great Britain, Canada, France, the Soviet Union, Poland, Czechoslovakia, and Romania. The group of experts developed and agreed on the technical aspects of a verification system to monitor a ban on atmospheric, underwater, and underground tests. This control system included an elaborate network of more than 150 land control posts, ten ship-borne posts, and special aircraft flights. In addition it allowed for on-site inspections to determine whether seismic events were caused by earthquakes or by explosions. While the United States and Great Britain said they would be willing to negotiate an agreement based on the establishment of an international control system, the Soviet Union responded by linking the test ban to other arms control issues and resumed testing. The other nuclear powers refrained from testing until 1961, after France tested its first nuclear weapon in 1960, and in 1962, the four nuclear powers conducted a record 178 nuclear tests.

Disagreement on a control system was focused on four main areas:

(a) The Veto. The Soviet Union wanted all operations to be subject to a veto while the United States maintained that the inspection process should be automatic in order to be effective.

(b) On-Site Inspections. The Soviet Union capped on-site inspections at three per year while the United States and Great Britain insisted that the number should be determined by detection capability and necessity. Eventually the United States said it would accept a minimum of seven inspections, which was rejected by the Soviet Union.

(c) Control Posts. Neither side could agree on the number and location of posts or of the automatic seismic observation stations that would supplement nationally owned control posts. The argument of the Soviet Union that these national posts and observation stations would make inspections unnecessary was rejected by the United States and Great Britain.

(d) The Organization and Control Commission. The Soviet Union proposed a *troika* of administrators for the Control Commission, including one neutral, one Western European or North American, and one Communist member. The Western European and North American countries argued that this would make the Control Commission powerless and unable to take action. The Soviet Union eventually acquiesced to opposition concerns and abandoned this position.

Treaty Creation and Ratification

After the Cuban Missile Crisis in October 1962, both sides were anxious to alleviate public fears about nuclear weapons and therefore restarted the three-power conference on a test ban treaty in July 1963. While the Soviet Union would not agree to a treaty that prohibited underground testing, the three powers were able to agree on a partial ban on atmospheric, outer space, and underwater testing, which were all easily verifiable without intrusive inspections. In just ten days, the three parties had developed and signed the LTBT. The U.S. Senate ratified the agreement on September 24, and President John F. Kennedy signed the LTBT into law on October 7, 1963. The LTBT formally entered into force on October 10, and it is of unlimited duration.

Although the LTBT was touted by all parties as a success, and indeed it was so as it greatly reduced dangerous atmospheric fallout and deadly radiation, including strontium-90, secondary results were mixed. Because neither France nor China signed the LTBT, they continued to test intermittently until the early 1980s. India, Pakistan, and Israel, all signatories of the treaty, were able to join the nuclear club despite the limited ban. And in the United States and the Soviet Union, nuclear weapons development and testing continued unabated, although all tests were moved underground. Additionally there was less international public pressure to develop a comprehensive test ban treaty as the most visible sign of the arms race, atmospheric testing, was eliminated. However despite these failings, the LTBT was an important and symbolic first step and served as a precedent for future arms control treaties.

LIMITS

The question of human limits, both cognitive and moral, is a persistent theme in the history of religion and philosophy. Both Siddhartha Gautama (Buddha, c. 563–c. 483 B.C.E.) and Socrates (469–399 B.C.E.) argued, in quite different ways, for the human acceptance of limits. Indeed, in general premodern traditions in human culture widely acknowledged both theoretical and practical limits on human knowledge and action.

Thus ever since the founding of modernity, with its appeals to transcend many traditional limits in the development of science and technology—and even certain aspects of the human condition—the question of whether and to what extent there might be new limits to the modern project has been a recurring theme. Late eighteenth and early nineteenth century poets such as Johann Wolfgang von Goethe (1749–1832) and William Blake (1757–1827) called for recognition of cognitive limits in modern science; nineteenth and early twentieth century novelists such as Charles Dickens (1812–1870) and John Steinbeck (1902–1968) argued for placing social and political limits on industrial technological practices; and philosophers of limits such as Karl Marx (1818–1883), Friedrich Nietzsche (1844–1900), and Oswald Spengler (1880–1936) proposed the existence of historical and cultural limits to modern development as a whole.

Limits to Growth

Such general discussions were given a new, specialized form with the 1972 publication of *The Limits to Growth* by the team of Donella Meadows, Dennis Meadows, and Jørgen Randers, which brought the environmental predicament of industrial progress to the attention of a world audience. On the basis of a computerized world model, the celebrated but controversial study claimed that continuing high rates of growth would lead to (a) a depletion of vital global resources, (b) increasing pollution, and (c) population outrunning the world's potential food supplies. The study suggested that, unless swift action was taken, absolute limits to growth would appear in the course of the twenty-first century, causing population size and industrial capacity to drop rapidly. This message was instantly seen as a blow against the creed of economic growth dominating at the time, both in the Western and the Communist world. Subsequently, the rift between growth advocates and growth skeptics has continued to divide the contemporary world of science and of politics; in fact, this division reaches deeper than conventional distinctions such as conservative/progressive or right/left.

Do Limits Exist?

The debate on limits carries on where classical economics had left off. Thomas Malthus (1766–1834), for example, still had the implicit vision of the Earth as a closed space, with limits to the size of population and level of human achievement it could sustain. He argued that lack of food supply would ultimately constrain population growth, throwing into doubt the idea of the inevitability of progress. However, he underestimated both the variability of growth and the capacity of technology to overcome natural limits. In contrast, neo-classical economics, operating on the background assumption of the infinite power of science and technology, had subsequently ignored the dependence of economic systems on natural systems completely. This shortcoming had left economic science blind to the impending environmental crisis in the twentieth century.

The attempt of Meadows, Meadows, and Randers to expose this failure set off a replay of the controversy between the "closed space" and "infinite ingenuity" schools of thought. While the former insists on the finiteness of both resource inputs and waste sinks, the latter emphasizes the practically infinite substitutability of natural resources by technology and organizational innovation (Simon 1981). What matters to the biosphere is the scale of resource flows, not just their efficient allocation (Daly 1996). Markets may reduce the volume of resource use through substitution of natural inputs, but continuing growth will eventually cancel out these efficiency gains, increasing volumes again. It is the overall scale of resource flows with respect to both input sources and waste sinks that determines the relationship between the economy and the biosphere.

Scientific findings suggest that for the first time in history, human-induced material flows are presently outgrowing nature-induced flows. In other words, the technosphere eclipses the biosphere. Some well-known facts are symptoms for this imbalance: Humankind has already exhausted 40 percent of known oil reserves, transformed nearly 50 percent of the land surface, appropriates more than half of all accessible freshwater, increases greenhouse gases in the atmosphere over and above natural variability, and causes extinction rates to increase sharply in marine and terrestrial ecosystems (Steffen et al. 2004, p. 6). In general terms, human impacts on the Earth are approaching or exceeding in magnitude the impact of some of the great forces of nature. In addition, they operate on much faster time scales than rates of natural variability. Estimates following the ecological footprint methodology imply that human activities presently exceed the Earth's capacity by 15 to 20 percent—without taking the needs of other living beings into account (Wackernagel et al. 2002). Ecological overshoot has become the distinguishing mark of human history.

What To Do about Limits?

The way "limits" are understood has consequences for politics and ethics. One metaphor for conceptualizing limits is that of a cliff face: The concept implies a fixed line beyond which collapse looms. It insinuates that crucial changes happen in an abrupt as well as catastrophic fashion, making everyone suffer equally. However, changes may also occur in a gradual as well as insidious fashion, and may burden some more than others. A metaphor based on a tapestry—each act of destruction is like pulling a thread from the tapestry—would emphasize linear and not just non-linear processes, multiple smaller losses and not just overall collapse. In particular, it would highlight the presence of political choices along the gradient of degradation (Davidson 2000). The tapestry metaphor, more than the cliff metaphor, encourages one to judge wreckage not only as prelude to the collapse, allows one to trace the differential impact of losses on social groups, and stimulates the politically and ethically essential question: What thresholds are considered tolerable/intolerable for whom and on what grounds?

Thresholds of ecosystem changes represent "limits" only for humans; any definition of limits is therefore a political act. Moreover, limits are rarely scientifically knowable; their definition is therefore an ethical act as well. As a consequence, any definition implies choices in terms of human welfare, equity, and the common good. A first approach centers on risks, putting the spotlight on possible physical, technical, and economic losses resulting from the technology or economic policy in question. Emphasis is placed on the precautionary principle of preventing the worst from happening. Guardrails, for instance, are suggested in order to avoid abrupt and irreversible changes from which human societies would find it difficult or impossible to recover (German Advisory Council on Global Change 1997).

A second approach focuses on institutions, because the rise of external limits is brought about by structures of growth and accumulation that are internally insatiable and limitless. This approach highlights the constellation of social and economic factors driving perilous developments (Harvey 1996). Proposals range from the reform of price structures to the containment of the profit motive, from the reallocation of research funds to the phase-out of certain technologies.

Finally, a third approach calls for a reconsideration of values, bringing into sharp relief the civilizational losses incurred by the predominance of the logic of growth. Natural limits are often preceded by the appearance of social and cultural limits; before growth causes physical perturbations, collective and individual well being has suffered (Illich 1973, Hirsch 1976). Recognizing limits, therefore, implies the emergence of fresh opportunities by restoring a balance. In this approach, limits acquire a positive connotation, making a more accomplished life possible. They turn out to be productive for a civilization that regards economic power and growth only marginally important.

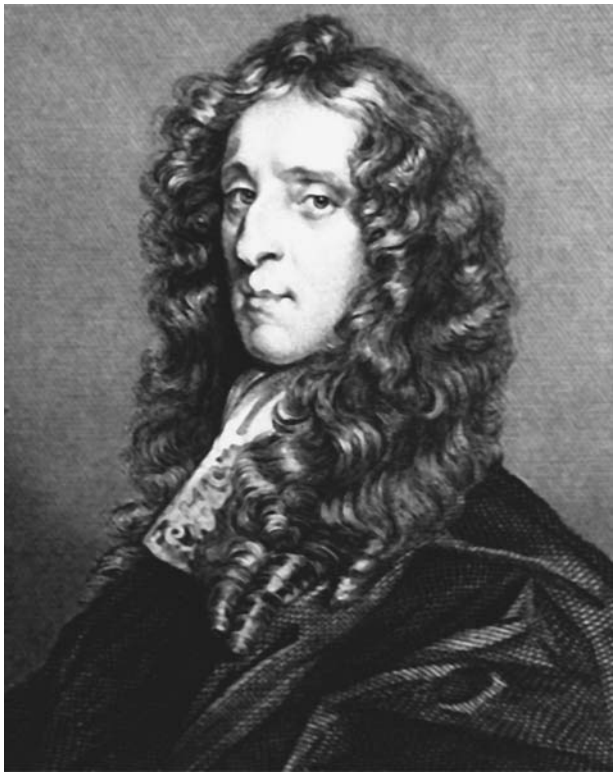
LOCKE, JOHN

John Locke (1632–1704), was an English philosopher, Oxford academic, and occasional bureaucrat. He was born at Wrington, Somerset, on August 29 and died at Oates, Essex on October 28. Locke's fame as a philosopher rests chiefly on two works: *An Essay Concerning Human Understanding* (1689) and *Two Treatises of Government* (1689). The former became a chief textbook of the European enlightenment and subsequent philosophy. The latter deeply influenced both the Declaration of Independence (1776) and the Constitution of the United States (1787), a document that made promoting the "progress of science and useful arts" one of its distinguishing features (Article I, section 8). These facts establish his reputation as one of the most influential modern philosophers and signal his importance in issues related to science, technology, and ethics.

Locke's strategy in his two most influential works is characteristic of early modern thought. First he sets out to clear away errors and conceits left over from classical and medieval science. Next he reduces the subject to its most basic natural constituents, as yet unmodified by culture. Only then does he set about reconstructing new systems of epistemology and political philosophy.



John Locke, 1632–1704. An English philosopher and political theorist, Locke began the empiricist tradition and thus initiated the greatest age of British philosophy. He attempted to center philosophy on an analysis of the extent and capabilities of the human mind. *(Rutgers University Library.)*

The *Essay*

Part One of the *Essay* is devoted to a refutation of the doctrine of innate ideas, according to which all human beings are born with certain principles already stamped upon their minds. It might seem doubtful that the importance of this doctrine justifies the attention that Locke devotes to it; however, its demolition whets the appetite for a more satisfactory account of the mind.

Locke holds to the view that all human ideas are reducible to experiences, a doctrine known as *empiricism*. An *idea* here means anything in the contents of the mind that is definite enough to have a name. Impressions, such as *hot* and *red*, received from the external world are the primary source of ideas. But unlike more uncompromising empiricists, such as David Hume, Locke admits of a second source of ideas: reflection upon the operations of human minds. One may observe what the mind does with the material provided by sensation and so acquire ideas of *thinking*, *willing*, and the like. So, though there are no innate ideas, there are innate sources of information.

Some ideas, such as *hard* or *perception* are indivisible. These are received passively by the mind. But the mind can also act on elementary ideas in three ways: by combining several into one complex idea; by comparing one with another; and by abstracting some idea from the setting in which it actually occurs. By such operations the mind can furnish itself with a potentially unlimited stock of complex ideas. These in turn fall into three categories: *relations* between ideas, *substances* that may exist on their own; and *modes* that exist only in something else. Thus the sun is a substance; it is bright in relation to terrestrial fire; and its brilliance is one of its modes.

Though all complex ideas are products of the mind, they can be anchored in the real world. A substance is known only by its qualities, which are the impressions it makes on the senses. Its primary qualities belong to it independently of observation, so a stone has weight and shape whether anyone perceives it or not. Secondary qualities depend on an observer. The stone is brown only in the right light, and in the eyes of some beholder. One cannot conceive but that these qualities subsist in some underlying thing, but has no idea of what that thing is. Locke subscribes, however, to the corpuscular or atomic theory of matter and supposes that the substratum consists of invisibly small particles.

Locke's philosophy of mind narrows the distance between speculation and technology. Chemistry, once it has purged itself of any alchemical conceits and has arrived at knowledge of the elements, not only understands the world better but provides human beings with means to manipulate it. Similarly Locke offers both a better account of human knowing and a set of useful instruments both for scientific and philosophical investigation.

This raises the question of the rank of philosophy with respect to science and technology. In one respect Locke's view of this matter seems closer to the medieval than to the classical conception. For the Greeks, philosophy was more elevated and more complete than any science, if indeed it did not incorporate all the sciences. In medieval scholarship, philosophy is famously regarded as the *handmaiden of theology*, usually in so far as it supports and clarifies faith. For Locke, philosophy seems to become the handmaiden of the sciences.

In the Epistle to the *Essay* Locke distinguishes between the *Master-Builders* and the *Under-Labourers* of the sciences. Among the former are Robert Boyle, Thomas Sydenham, Christiaan Huygens, and Isaac Newton, whose works stand as monuments to posterity. Locke counts himself among the latter, whose job it is merely to clear the ground and remove the rubbish that obstructs the advance of science. If this is Locke's view, he has reduced philosophy to a preparatory exercise, much of which is necessary only because of the abuses of language committed by psuedophilosophers. Locke's *Essay* is certainly similar to contemporary academic philosophy, which understands itself as clarifying questions up to the point that science can get a grip on them.

The scientists named by Locke are conspicuous for both theoretical and technological achievements. Boyle constructed an air pump; Newton and Huygens built advanced telescopes; Sydenham pioneered new medical treatments. But it is clear that for Locke their greatness lay more in their theoretical work than in any useful devices they may have contrived. He shows no inclination to subordinate the sciences to technology. A few lines after mentioning Newton, he identifies philosophy as "nothing but a true knowledge of the nature of things" (Locke 1975, p. 10). Whatever Locke's view of his business in the "Essay," he had a view of philosophy broad enough to encompass the sciences. It is closer to the classical view than is often supposed.

The *Two Treatises*

In his *First Treatise*, Locke demolishes Robert Filmer's argument in favor of the divine right of kings. This sets the stage for the *Second Treatise*: If political authority does not originate in God's appointment of Adam, then its origin must be sought in human nature.

Typically Locke identifies and isolates the elementary building block of political societies: This is the human being in the *state of nature*. The latter indicates a condition of perfect freedom and equality, with no one having any authority over another. But it is not, as Thomas Hobbes (1588–1679) supposed, a state of license. For there is a natural law available to all human beings, directing them to respect one another's life, liberty, and property.

Oddly enough, it is not viciousness that requires the formation of governments, but the human capacity for righteous indignation. In the state of nature, each person is entitled to punish any transgression of rights. But as each person judges primarily in his or her own favor, one person's enforcement of natural law is another's transgression of the same. Thus the universal distribution of the executive power can lead to endless cycles of revenge. The way to avoid this is for all to surrender their portions of the executive power to some common judge, to whom appeal may be made in case of conflict.

Human beings thus leave the state of nature in order to more securely enjoy those rights that they possessed while still in it. Universal consent is the foundation of political authority, which may be invested in such forms (for example, kings and parliaments) as the subjects think fit. However that grant of authority is always conditional rather than absolute. When the government forfeits the consent of its subjects, or by aggression or neglect fails to protect their liberties, it effectively abdicates. The people are then entitled to abolish it and form a new one.

Property Rights

Locke's theory of property, set forth in Chapter 5 of the *Second Treatise,* is among the greatest achievements of seventeenth-century political and economic thought. Here Locke cuts to the original position immediately: In the beginning all things belonged equally to all human beings, and each had leave to take from the earth whatever he or she needed. What then is the origin of any private rights to property?

Each person has ownership of his or her own body and labor. In order for some external good such as food to be enjoyed it must sooner or later be appropriated. After an apple is consumed it joins with the perfect privacy of the flesh. Locke argues that the moment of appropriation comes when someone's labor is mixed with the bounty of nature. When acorns are first gathered from the wild, they become private property. The right of appropriation is universal, the only limit is that one may gather only what one can use.

Locke weds this account with a theory of economic progress, which includes in turn a labor theory of value and a theory of money. The greater part of the value of any product originates in the labor required to produce it. Invested in a loaf of bread, for example, is a plowed and cultivated field, harvested and milled wheat, a bricked and furnished bakery. All this labor represents a vast increase in the wealth available to humankind over what unimproved nature provides.

But how is it possible to encourage people to labor beyond what their needs require or the durability of their produce allows? The answer lies in money, the exchange of the products of one's labor for some durable medium of nominal rather than real value. When someone settles and improves a piece of land, it is taken out of the common stock; however, in return for money, the settler gives back more value than he or she took away. Locke understood that this process, repeated across a wide range of industries, was an engine of unprecedented economic growth. For that reason, one of the most important ends of government was the protection of private property.

Locke's theory of property may be set comfortably in the context of a fundamental modern project: the conquest of nature. The natural world is not charitable to human beings. It provides little of what they need in advance of their labor. But the potential wealth that exists in nature is vast beyond calculation. Thus the aboriginal inhabitants of America who, Locke says, "are rich in land but poor in the comforts of life" exemplify the situation of human beings in the state of nature (Locke 1988, p. 296). By encouraging labor, a system of money and property rights will result in the most thorough cultivation of nature, for the comfort of all humankind.

It is clear that Locke's approach to all three topics elevates the products of human invention far above the natural materials from which they are fashioned. Complex ideas are more interesting and useful than simple ones. There is both more security and more freedom under government than out from under it. If a government acts to protect property rights, human beings will then make whatever they need to relieve the poverty into which the species was born. Nature will be reduced to a storehouse of useful materials.

LOGICAL EMPIRICISM

Logical empiricism (LE) is a term that was coined by the Austrian sociologist and economist Otto Neurath (1880–1945) to name the philosophical work of the Vienna Circle and related work being pursued by the physicist and philosopher Hans Reichenbach (1891–1953) and his associates. Related terms include *logical positivism*, *neopositivism*, and *scientific empiricism*. The basic intention of LE was to formulate a scientific philosophy for understanding the relationship between science and society. In historico-philosophical terms the aim was to combine the empiricist legacy of philosopher-scientists such as Hermann von Helmholtz (1821–1894), Ernst Mach (1838–1916), Henri Poincaré (1854–1912), and Pierre Duhem (1861–1916), with the new logic developed by Gottlob Frege (1848–1925), David Hilbert (1862–1943), and Bertrand Russell (1872–1970). The intended synthesis was not simply a theoretical project. Logical empiricists considered themselves part of a progressist movement for a more rational and enlightened society. As stated in the so-called Manifesto of the Vienna Circle, LE aimed to foster a "scientific world-conception" ("wissenschaftliche Weltauffassung") that would help create a better world for all people.

The Scientific World-Conception

The characteristic method of LE was logical analysis, which used mathematical logic to clarify the logical structure and meaning of assertions. In this way LE aimed for a logical analysis of scientific and philosophical language that would distinguish clearly between meaningful and meaningless sentences; fight against metaphysics, which was considered as a hotbed of meaningless "pseudo-sentences"; and provide a "unified science" (*Einheitswissenschaft*) that would be formulated in a logically analysed language cleansed of metaphysical elements.

LE claimed that logical analysis demonstrated that there are only two kinds of meaningful propositions, the analytic a priori propositions of logic and mathematics and the synthetica posteriori propositions of empirical sciences. All other assertions were to be considered cognitively meaningless. This holds in particular for all metaphysical propositions. The most famous argument to this effect is found in "Overcoming Metaphysics by Logical Analysis of Language" 1932 by Rudolf Carnap (1891–1970). Moreover, "overcoming metaphysics" was not simply an internal philosophical issue because logical empiricists considered metaphysics to be a medium for propagating politically and morally pernicious ideologies that had to be fought not only in the academic sphere but also in the political arena.

Politically, most logical empiricists were democratic socialists or unorthodox Marxists and thus were partisans of an "engaged scientific philosophy." A few, such as Moritz Schlick (1882–1936) and Friedrich Waismann (1896–1959), were less political but shared a progressive, liberal outlook.

For all logical empiricists scientific philosophy was a collective enterprise that had to contribute to the construction of a modern, enlightened society. That task was to be carried out in close collaboration with the sciences and other progressive cultural forces, such as the artists and architects belonging to the *Neue Sachlichkeit* movement or the Bauhaus. When LE was at its peak in the late 1920s and early 1930s, the more radical logical empiricists of the Vienna Circle, such as Neurath and Carnap, regarded themselves as "social engineers" engaged in the task of forging the philosophical and scientific tools for building a new socialist society. This is expressed emphatically in the concluding lines of the *Manifesto of the Vienna Circle*: "We witness the spirit of the scientific world-conception penetrating in growing measure the forms of personal and public life, in education, upbringing, architecture, and the shaping of economic and social life according to rational principles. The scientific world-conception serves life, and life receives it" (Sarkar 1996, Vol. I, pp. 329– 330).

LE included a multifaceted and variegated group of philosophers and scientists. Its internal diversity often is underestimated. LE was less a school with a common doctrine than a movement whose members shared vaguely progressist convictions. Even closely related thinkers such as Carnap and Neurath disagreed on many basic philosophical issues. Here the focus is on few leading figures of the Vienna Circle: Schlick, its founder; Carnap and Neurath; and Carl Gustav Hempel (1905–1997), the most influential representative of LE in the United States.

In the early 1930s the LE movement in Europe gradually dissipated as a result of disastrous, political developments and indivdual events. The mathematician Hans Hahn (1879–1934), considered by some to be the "real" founder of the Vienna Circle, died in 1934, and Schlick was murdered by a demented student in 1936. In 1934 Carnap left Vienna and moved to the German university in Prague. After the rise of National Socialism in Germany (1933) and clerical fascism in Austria (1934) most logical empiricists emigrated. The majority went to the United States, including Carnap, Reichenbach, and Hempel. The history of LE thus divided into two periods: a European period ending in the mid-1930s and an Anglo-American period from the 1930s until its dissipation in the 1960s.

Major Figures and Their Ideas

The founder and official leader of the Vienna Circle was Schlick, who studied physics under Max Planck (1858–1947). Later Schlick turned to philosophy, and in 1922 he was appointed to the chair of natural philosophy at the University of Vienna as the sucessor to Ludwig Boltzmann (1844–1906) and Ernst Mach (1838–1916). Beginning in 1923, he and his assistants Herbert Feigl (1902–1988) and Friedrich Waismann organized a discussion group (first called the "Schlick circle") that soon became known as the "Vienna Circle."

Schlick had begun as a "critical realist", and later was influenced by Ludwig Wittgenstein (1889–1951). In *The Turning-Point in Philosophy* (1930) Schlick emphatically endorsed Wittgenstein's thesis that the philosophy of science is not to be considered a system of knowledge but instead a system of acts: "[P]hilosophy . . . is that activity whereby the meaning of statements is established or discovered. Philosophy elucidates propositions, science verifies them" (Sakar 1996, vol. II, p. 5). This entailed the idea that only propositions that are meaningful can be verified. Philosophy, as philosophy of science, thus is left with the task of explaining what is meant by verification. Following Wittgenstein, Schlick proposed that the meaning of a proposition is established by its method of verification, that is, method for determining whether it is true or false. Formulated negatively, a proposition for which no verification procedure can be imagined is a meaningless pseudo-sentence.

The principle of verifiability initially appears to be quite plausible. However, it turns, out to be impossible to construct a definition that would classify all the statements of empirical science as meaningful while disqualifying all metaphysical assertions as meaningless. Even if it was easy to formulate criteria that rendered meaningful observational statements such as "it is cold outside now," it turned out to be extremely difficult to distinguish in a principled manner meaningful scientific statements such as "all electrons have the same charge" or "f = ma" from meaningless metaphysical pseudo-statements such as "the absolute is perfect".

Probably the best-known representative of LE is Carnap; there is even a misleading tendency to identify LE with Carnap's philosophy. Carnap began his philosophical career as a neo-Kantian with *The Logical Structure of the World (Der Logische Aufbau der Welt)* (1928), which proposed constitutional theory as a scientific successor to traditional epistemology and philosophy of science. Constitutional theory was to be a general theory of rational reconstruction of scientific knowledge in the logico-mathematical framework of Alfred North Whitehead (1861–1947) and Bertrand Russell's (1872–1970) *Principia Mathematica*. In informal terms the constitution of a concept provides coordinates that determine its logical place in a conceptual system.

Subsequently, Carnap replaced constitutional systems with more empiricist constitutional languages and pursued the philosophy of science as the study of the structure of the languages of science. According to Carnap, the task of philosophy is to construct linguistic and ontological frameworks that can be used in the ongoing progress of scientific knowledge. In *Testability and Meaning* (1937) he argued that philosophy should not formulate its principles as assertions such as "All knowledge is empirical" or "All synthetic sentences that we can know are based on experiences" or the like—but rather in the form of a proposal or requirement. By such a formulation, he maintained, "greater clarity will be gained both for carrying on discussion between empiricists and anti-empiricists as well as for the reflections of empiricists" (Sakar 1996, Vol. II, p. 258). Throughout his philosophical career Carnap saw the task of logical empiricist philosophy of science as formulating a general theory of linguistic frameworks to provide conceptual tools for the enhancement of science and philosophy, as already had been done implicitly in the 1929 manifesto.

The sociologist, economist, and philosopher Neurath was the most radically "engaged philosopher" in the Vienna Circle. He was the driving force behind the rapid change from an academic discussion group to an international philosophical movement that eventually was to dominate the philosophy of science in the mid-twentieth century. A pitiless fighter against traditional metaphysics, Neurath made his most important positive contribution to the scientific world-conception in the form of the project of "unified science."

In contrast to the essentially negative program of eliminating metaphysics, the project for a unified science is the great constructive paradigm of LE. According to Neurath, scientific knowledge does not have the form of an all-embracing deductive system but constitutes an encyclopedia. According to encyclopedism, as he termed his account, scientific knowledge has the following five characteristics: It is fallible, pluralistic, holistic, and locally but not globally systematizable, and it is not an image of the real world. Neurath conceived the encyclopedistic project as a large-scale politico-scientific and philosophical program aimed at the highest possible level of the integration of the sciences without succumbing to the temptation of an exaggerated rationalism that would force the sciences into the straihtjacket of a metaphysical system.

The foundation for Neurath's encyclopedism was a robust physicalism according to which all concepts can be defined ultimately and entirely in terms of physicalist concepts and/or the concepts of logic and mathematics. Physicalist concepts are not simply the concepts of physics but instead are the concepts of everyday language dealing with middle-sized spatio-temporally located things and processes. Physicalist language, cleansed of metaphysical phrases and enriched by scientific concepts, was conceived as a mixed language containing precise and vague terms side by side. Depending essentially on the concrete practices of everyday life, Neurath's encyclopedism turned scientific knowledge into historically and socially situated knowledge. This had strong implications for its form. Instead of the "pseudorationalist" conception of a timeless objective "system" of knowledge that would create a picture of the world "as it really is," Neurath put forth a more flexible, nonhierarchical encyclopedia as the appropriate model for human knowledge.

Although Neurath's account of LE is the version most congenial to science, technology, and social studies, this has not been recognized widely. One reason for this misunderstanding is Neurath's death in 1945, which made it impossible to promote his version of LE in the Anglo-American world. Since the 1980s, however, Neurath's vision has received a considerable reconsideration in both the United States and Europe.

Carl Gustav Hempel was Reichenbach's student in Berlin but also spent time in Vienna. After emigrating to the United States via Belgium he became Carnap's assistant in 1937. He began his philosophical career with a dissertation on the logical analysis of the concept of probability. In the 1950s and 1960s he became the most influential logical empiricist in the English-speaking philosophical community. His papers set a standard for the logical analysis of concepts. For instance, his contributions to the theory of scientific confirmation and explanation, especially the covering-law model, determined the agenda of analytic philosophy of science for decades. His "Fundamentals of Concepts Formation in Empirical Science" (1952) served as an introduction to philosophy of science for generations of students.

Hempel was particularly engaged in pointing out difficulties and paradoxical features in many core concepts of the philosophy of science, arguing for the necessity of a thoroughgoing logical analysis. The "raven paradox" is a famous example: If it is a law of nature that all ravens are black, the observation of a black raven may count as a (partial) confirmation of this law. Moreover, it is reasonable to assume that laws of nature should be independent of their logical formulation. Thus, the law that all ravens are black has the logical form "All R are B," which is logically equivalent to "All non-B are non-R." With this conceded, a green frog, as something that is not black and not a raven, counts as a (partial) confirmation of the original law. However, this is absurd. Hence, something in the conception of natural law and confirmation seems to be wrong. The raven paradox shows that philosophers do not understand even the most basic concepts in the philosophy of science fully.

Hempel's philosophical work was characterized by a careful and circumspect application of modern logic that made the achievements of logical analysis attractive even for those who were not professional logicians and philosophers. For instance, *The Function of General Laws in History* (1942) exerted influence far beyond the confines of philosophy. It is one of the few LE analyses that has had an impact in the humanities. In *Problems and Changes in the Empiricist Criterion of Meaning* (1950) Hempel further criticized the various logical empiricist attempts to formulate a waterproof criterion for distinguishing meaningful and meaningless assertions. In later years Hempel was influenced by Thomas Kuhn (1922–1996), belying the claim that LE and historical accounts of science are necessarily opposed.

Assessment

A special problem in LE is the transformation of the movement when the intellectual exodus from Europe to the United States took place in the 1930s. The transplantation of LE did not leave its philosophical content unaffected. Although a comprehensive history of LE has not been written, important differences between the two versions can be noted easily. European LE was politically much more radical than its U.S. successor. Although the Vienna Circle showed a vigorous interest in political and social issues such as education, technology, architecture, and art, in the United States the political dimension of LE became less visible. For instance, Carnap was a dedidated supporter of the civil rights movement until the end of his life.

One factor in this change from a radically "engaged scientific philosophy" to an academically confined "philosophy of science" is surely the fact that logica empiricists had to adapt to a different political and societal context in which the application of their traditional political categories was difficult. Another reason may have been that to survive in exile it was expedient to use a language that was more cautious than that which was acceptable in the "Red Vienna" of the late 1920s. After all, LE started in the United States among a rather obscure philosophical group of emigrants without much of a reputation. Only gradually did it become the mainstream in Anglo-American philosophy of science and epistemology in the 1940s and 1950s.

The dominance of LE did not last long, however. First, many of the internal problems of the movement, such as the issue of distinguishing neatly between meaningful and meaningless statements, stubbornly resisted a satisfying solution. Second, analytic philosophers such as Willard van Orman Quine (1908–2000) and Hilary Putnam (b. 1926) attacked the very basis of the logical empiricist philosophy of science, that is, the distinction between the synthetic/analytic and the observational/theoretical levels of empirical knowledge. Third, authors such as Norwood Russell Hanson (1924–1967) and Thomas Kuhn (1922–1996) shifted the emphasis from the strictly logical toward the historical and sociological aspects of scientific theorizing, thus challenging the autonomy of a logical philosophy of science in the style of Carnap.

In a sense these and related developments were welcomed as liberations from the straitjacket of the so-called "received view." For instance, one immediate consequence of the logical empiricist thesis that meaningful statements are either analytic or empirical was that all value judgments are cognitively meaningless. Value statements are not analytic because they say nothing about the world and are not empirical because they cannot be verified. Hence, they are meaningless. The dichotomy between analytic and empirical statements led logical empiricists to a strictly noncognitivist (emotivist) ethics according to which there can be no knowledge of values in a proper sense. This stance is not to be considered as necessarily leading to a loss of interest in moral and political problems. All members of the Vienna Circle took a strong interest in the political and social events they were living through. These problems, however, were considered as practical problems, to be strictly separated from the theoretical problems science and philosophy were dealing with.

This emotivist account of ethics, which leaves only a small niche for "theoretical meta-ethics," that is, the logical analysis of moral statements, is insufficient. In a world in which science and technology present increasing numbers of ethical questions and difficulties, it does not provide reasoned arguments formorally relevant actions.

At the same time the complete dismissal of LE by the self-proclaimed "revolutionary" postpositivist philosophy of science might have been a bit hasty, especially if one takes into account its lesser-known European variants. Indeed, the differences between LE and postpositivist philosophy of science might have been unfairly exaggerated. With regard to Neurath's and Hempel's versions of LE, it does not seem far-fetched to suggest that to some extent the allegedly unbridgeable gap between LE and its successors has been an interest-guided social construction. As usual, the critics of LE were unaware of how much they had absorbed of the belief system they so eagerly berated.

In summary, one may propose that LE was a rich philosophical movement that set the stage for a large part of the philosophy of science and epistemology during the twentieth century. However, despite this general claim, a balanced assessment of the movement has not been formulated. In particular, the relationships between LE and its successor disciplines, such as the various currents of "postpositivist" philosophy of science, cultural studies of science, and science, technology, and society studies (STS), are not yet fully appreciated.

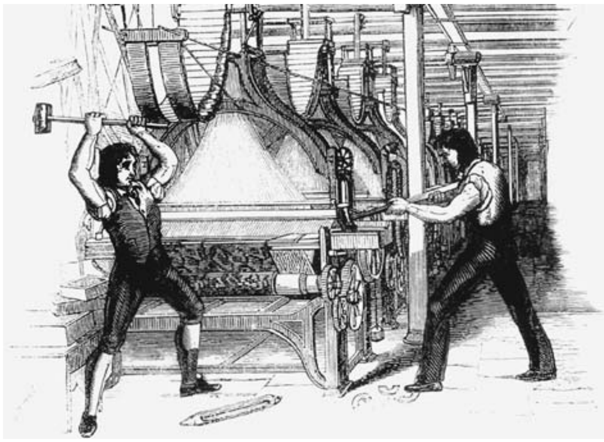
LUDDITES AND LUDDISM

Luddite and *Luddism* are terms of both derision and praise. Depending on context, they have been used to indicate either mindless opposition to or critical assessment of technology and science.

Origins

The first Luddites were English textile workers who in 1811 and 1812, during the Industrial Revolution, resisted and rebelled against the use of wide-frame knitting machines, shearing machines, and other machines of mass production. The term is based on a mythical Ned Ludd who supposedly led the workers in their resistance. The Luddites, however, were not one unified political group. They reflected their regions and local trade organizations, hence the more appropriate use of the terms Manchester, Yorkshire, and Midland Luddites.

Much of the knitting of stockings and other apparel was done in cottages and small shops by knitters (stockingers) who sometimes owned their own frames but usually rented them from the hosiers (the knitting-frame was invented by William Lee in 1589 and introduced in the Midlands in the mid-1600s). The knitting-frame, operated by an individual at home, could make 600 stitches per minute as opposed to about 100 stitches by hand-knitters. Frame-knitting in cottages sustained a way of life for more than a century.



Depiction of the Luddite Rebellion. The rebellion began in 1811 when organized bands of men in England s Midlands began breaking into hosiery factories and smashing looms used to weave stockings. Claiming allegiance to "General Ludd," the Luddites were skilled craftsmen driven to despair by changes in weaving technology that cost them wages and worsened the effects of the already ongoing economic crisis. *(© Mary Evans/Thomas Philip Morgan.)*

The rebellion began in March 1811 in the Midland shire of Nottingham (home of the legendary Robin Hood) and then spread north to Manchester and Yorkshire. At the height of the rebellion, knitters, croppers, and other textile workers smashed textile machinery almost on a daily basis. The Midland Luddites were particularly well organized and led a sustained campaign of focused machine breaking without resorting to the more general violence evident in their northern counterparts. The open rebellion ended in 1812 with arrests and subsequent hangings.

The original Luddite rebellion grew out of intolerable economic and political conditions that threatened the livelihoods of the textile workers and eventually destroyed their cottage industry and their way of life. Economic factors included a depressed market resulting in part from Napoleon's economic blockade of British trade and Britain's counter-blockade of European ports. Wages decreased substantially at a time when a number of poor harvests in 1809 nearly doubled the price of bread.

Political conditions also fueled the rebellion. Fearful the French Revolution would spread to the working class, the Parliament passed the Combination Acts of 1799 and 1800 to outlaw trade unions and muzzle workers, making it a criminal offense for workers to join together to petition employers for fair wages and better working conditions. Furthermore the government's policy of non-intervention in industrial relations abandoned the working class to the captains of capitalist industry. In addition the Midland Luddites believed the acts of Parliament contravened the charter from King Charles II that founded the Framework Knitters' Company. In rebelling, the Midland frame-knitters upheld the principles of their charter to regulate their trade.

Historically Luddism may thus be described as an assertion of the right of organized trade to protect its way of life from the unfair introduction of technology, from technology that reduces the quality of the product, and from political measures that would change the trade without the consent of the trade workers.

Developments

Although the Romantic poet George Gordon Lord Byron (1788–1824) defended Luddites against their critics, by the mid-1800s the term had largely disappeared from use. Then in 1959 the novelist C. P. Snow in his famous lecture defending "The Two Cultures and the Scientific Revolution" revived it to stigmatize *literary intellectuals* such as T. S. Eliot and William Butler Yeats as *natural Luddites*. Following Snow, the term became a common way to disparage critics of the cultural influence of modern science as simply uninformed antitechnologists.

In the late-twentieth century, however, critics attempted to turn the tables on those who would dismiss them as technophobes by adopting the term *neo-Luddite* and *neo-Luddism* as a badge of honor for those who refuse to uncritically accept virtually everything that techno-economic momentum throws up. As Langdon Winner (1986) argued, technology critics are no more antitechnology than art and literature critics are anti-art and anti-literature. The most influential defense of this critical stance was perhaps Chellis Glendinning's "Notes Toward a Neo-Luddite Manifesto" (1990), which argued that technology and technological systems may be beneficial to global capitalism but are not necessarily beneficial to human beings, the environment, and the common good. Although neo-Luddism is not a well-defined creed, it commonly includes critiques of consumer culture, television, and high-energy use automobiles while promoting enhanced participation in technological design, social and economic equity, and respect for nature. Some representatives draw inspiration from religious traditions, especially Quakers, Mennonites, Amish, and Shakers. Others argue an inherent will to power in modern technology that threatens human dignity rather than enhancing it.

LUHMANN, NIKLAS

German sociologist Niklas Luhmann (1927–1998) was born in Lüneburg on December 6. In more than seventy books and 450 papers, he developed what is perhaps the most comprehensive theory of modern society, in which ethics plays an important, but secondary, role. Educated in legal science, Luhmann was inspired by the phenomenology of Edmund Husserl, the systems theory of Talcott Parsons, the theory of autopoiesis of Humberto Maturana, the second order cybernetics of Heinz von Foerster, and the form calculus of G. Spencer-Brown. He synthesized these elements into a systems theory of impressive scope and radicalism, representing what he saw as a paradigm shift in the social sciences. He died on November 6 in Bielefeld, Germany.

A Universal Systems Theory

Luhmann distinguished between physical, biological, mental, and social systems, but his main focus was on social systems, which he subdivided into interactions, organizations, and society as a whole. His main theoretical tool was the *distinction*. In order to observe social systems, the observer must use a *guiding distinction*. Luhmann chose the distinction between system and environment, but admitted that others were possible.

A radical tenet of Luhmann's systems theory is the thesis that social systems consist only of communication—not of persons, of artifacts, or even of actions. Communication is defined as the unity of three selections: information, utterance, and understanding, to which is added the acceptance or rejection of the receiver to continue the communication. Because communications are transient events, the system must generate linguistic structures and themes to create and combine new communications. Social systems are autopoietic systems, creating their own elements within their network of elements. Even though human beings, as information-processing units, are necessary for communication, they are not part of the communication, but of its environment. The physical world is likewise not part of the communication, but is only its object, and it is not the function of communication to mirror the physical world. By using the theory of autopoiesis, Luhmann made systems theory dynamic, with time and change at its center. Everything in a social system is contingent, meaning that alternatives are always possible.

According to Luhmann, social systems cannot be understood in terms of *rationality*, *norms*, or *human beings*. Change must be seen as evolution, a choice among existing alternatives. There is no one point of view from which society can be correctly observed and described. With the cultural death of God, and the attendant loss of the only ostensibly *right* worldview, a poly-centered world remains. In his late-twentieth-century analysis, Luhmann claims that the most fruitful way of imagining society is as a world community with no center, no purpose, and no overarching rationality.

Luhmann analyzes society as a unity of functional subsystems, each having is own symbolic generalized medium and its own guiding distinction. Society can be observed from many points of view, economic (where the medium is money), political (power), scientific (truth), intimate (love), and more. The number of functional subsystems is an empirical question. In addition to his two principal works, *Soziale Systeme* (1984) and *Die Gesellschaft der Gesellschaft* (1997), Luhmann wrote a series of monographs dealing with the various social subsystems.

Functional subsystems make communication more effective. By using symbolic generalized media, it is possible to communicate on a world scale because the simple binary form allows for simplification, motivation, and measurement of success or failure. An observer can quickly decide whether or not he will take over the point of view inherent in the medium. Symbolic generalized media can differ—in operation mode and time relations, among others—but all share a common structure. Though the most effective communications in modern society are oriented towards functional subsystems, Luhmann acknowledged that what is good for a functional subsystem is not necessarily good for society as a whole because proponents of each subsystem have biased and narrow views.

Technology can also be seen as a functional subsystem, operating in the medium of effectiveness. Its code is functioning or broken, its programs are blueprints, its institutions are organizations and universities, and its contribution to society is maintenance of regular processes. Technology has its own internal dynamics and thus it might clash with or be helpful to other functional subsystems.

Functional subsystems are not action systems. They *do* nothing, but can be conceived as semantic discourses. The action systems of twenty-first-century society are organizations; specialized organizations define themselves as agents of a particular functional subsystem, such as technology, religion, or law.

Morals and Ethics in Functional Subsystems

In real life, subsystems must cooperate. Because their respective criteria for success and failure are not the same, conflicts arise with no objective solution, thus creating a need for normative or ethical solutions. As a consequence, many functional subsystems develop special professional ethics criteria to deal with the integration of highly specialized products and methods in society.

It should be noted that no functional subsystem uses the moral distinction between right and wrong. One reason for this is empirical: A moral distinction is not precise enough to facilitate communication. It has too many dimensions. A moral evaluation might focus on motives or on consequences, and be dependent on religious or subcultural assumptions. Moralizing creates conflict, not consensus. Instead Luhmann views morality as a tool for distributing *esteem*, which depends not on professional skills but on the qualities of a person as a whole.

Morals have important social functions and Luhmann wrote extensively on moral issues though he flatly rejected any attempt to understand society in moral or purposive terms. Luhmann conceded that moral distinctions are used with the same spontaneity as empirical distinctions in daily life. Using the distinction between moral and ethics, he argued that ethics is a theoretical reflection of the social phenomenon of morals, and concluded that the most important task of ethics is to warn against morals. He had no illusions as to the effectiveness of ethics to control technological development. Because there is no ethical consensus in modern society, no ethical control is possible or desirable.

Each functional subsystem has its own criteria for success or failure, but it also has a tendency to exaggerate its own importance and blind itself to other criteria. Economy focuses on money, politics on power, and science on truth. When criteria clash, no super rationality can create a rational solution. Luhmann had a lifelong debate with the German philosopher Jürgen Habermas regarding this issue. Habermas stresses the possibility of rational consensus, while Luhmann argues that conflict is not only inevitable, but also fruitful. Consensus is only a transient phase in the ongoing communication of social systems.

Luhmann accepted that functional subsystems have evolved as centers for solving specific tasks, however, he argued the need for *criteria for criteria* or second order criteria. But such criteria, which might be called ethical criteria, are not socially binding. There is no universally accepted viewpoint from which the social and moral implications of technology or pollution, for example, can be observed and judged right or wrong.

Luhmann described each functional subsystem as having its own complexity and society as a whole as a hypercomplex entity composed of many functional subsystems. However Luhmann posited no solutions to the problems he presented. With no rationality, there is only evolution to rely on: Something will happen, perhaps better, perhaps worse, perhaps catastrophic. When nations, organizations and persons try to control technology, they are controlled by the technology they want to control and are unable to control all the other actors trying to control. Technology, like life, will find its way.

LYOTARD, JEAN-FRANÇOIS

French philosopher Jean-François Lyotard (1924–1998), who was born in Vincennes, France, on August 10, was an originator of what became known as postmodernism. After teaching philosophy in secondary schools in France and Algeria, Lyotard was awarded a position at the University of Paris VII, where he also served as a council member of the Collège international de philosophie. Toward the end of his life he also held visiting professorships in the United States. Lyotard died of leukemia in Paris on April 21.

Lyotard's work is marked by a persistent interest in the relations between science, technology, ethics, and politics, as can be seen in the work for which he is most well known, *The Postmodern Condition: A Report on Knowledge* (1984), which focuses on the state of knowledge in highly developed countries. According to Lyotard, the sciences and late twentieth-century societies were in the midst of a legitimation crisis because of the inability to provide a justification in the form of an overarching explanation of the relations between science, technology, and society.

Lyotard explains the crisis using Ludwig Wittgenstein's (1889–1951) notion of language games. A language game is a field of discourse defined by a set of internal rules that establish the types of allowable statements. Different discourse practices, such as science and ethics, have become distinct language games, adhering to different sets of rules. Because disparate language games prohibit statements that fail to conform to their rules, it is impossible to give a single, overarching account that would guarantee the legitimacy of all possible discourse practices. For this reason, Lyotard states that the postmodern situation is marked by an "incredulity toward meta-narratives" (Lyotard 1984, p. xxiv).

If Lyotard is correct and it is no longer permissible to give an overarching account for the diversity of discourse practices, then the postmodern condition demands a new response to the problem of legitimation. Lyotard claims that the appropriate response to the problem in a society marked by the postmodern condition is "paralogy." In the practice of paralogy, the goal of producing an overarching legitimation narrative is replaced by an attempt to increase the possible language moves in a particular language game. Hence, paralogy champions the diversity of discourse practices by prohibiting the hegemony of a single discourse over all others. Paralogy thus resists the tendency to treat ethics and politics as forms of scientific knowledge or technology.

The Postmodern Condition has implications for ethics that are further developed in *The Differend: Phrases in Dispute* (1988). A *différend* is Lyotard's label for an irresolvable conflict between two phrases or parties. The *différend* as a conflict between phrases was implied in Lyotard's earlier work as the inability to unify diverse language games. In this work, however, rather than being concerned with the legitimation of knowledge, Lyotard develops the notion of the *différend* to include a certain type of injustice that occurs to differing language games (or genres), specifically the cognitive and ethical.

The ethical genre, according to Lyotard, is concerned with prescriptive statements of the form "you ought," whereas the cognitive genre consists of descriptive statements. Ethics, with its prescriptive statements, is a discourse of obligation. As such, ethics takes the form of phrases marked by an asymmetry between the addressor and the person addressed. The person who says "You shall not lie" commands interlocutors and places obligations upon them, but the statement "Lying is wrong" leaves out the relation between persons that is characteristic of ethical discourse. Consequently for Lyotard, the nature of ethics is covered over in attempts to transform the prescriptive into the descriptive.

In response to this threat, the task of philosophy, according to Lyotard, is to champion and protect the diversity of discourse and practice. While not providing a unifying account of the relations between genres, philosophy is marked by an obligation to bear witness to the *différend*. Although primarily focused on discourse, this responsibility extends to the sociopolitical world, in which there is the continuous threat of one social entity (individual persons or cultures) being overpowered by another.

Lyotard's thinking continues to be a powerful, cautionary note for the relations between science, technology, and ethics. Rather than subsume distinct discourses under a unifying account, his work argues for maintaining that which marks each as different.

LYSENKO CASE

The debate on the relative influence of heredity and environment took a distinctive form in the Soviet Union in the turbulent years between the 1920s and the 1960s. There was among many committed communists a sense that the socialist revolution should transform everything, including the foundations of knowledge. There was intense debate about what constituted a Marxist approach to every discipline, including biology.

Lysenko's Practice and Theory

Into this context came Trofim Denisovich Lysenko (1898–1976), a young agronomist from the Ukraine, who emerged into the limelight in 1927 in connection with an experiment in the winter planting of peas to precede the cotton crop in the Transcaucasus. The results he achieved in a remote station in Azerbaijan were sensationalized in the national Communist Party newspaper *Pravda*. The article projected an image of him as a sullen, barefoot scientist close to his peasant roots. Lysenko subsequently became famous for *vernalization*, an agricultural technique that allowed winter crops to be obtained from summer planting by soaking and chilling the germinated seed for a determinate period of time. Lysenko then began to advance a theory to explain his technique. The underlying theme was the plasticity of the life cycle. Lysenko came to believe that the crucial factor in determining the length of the vegetation period in a plant was not its genetic constitution, but its interaction with its environment. By the mid-1930s he rejected the existence of genes and held that heredity was based on the interaction between the organism and its environment, through the internalization of external conditions. He recognized no distinction between genotype and phenotype.

Lysenko's theory was an intuitive rationalization of agronomic practice and a reflection of the ideological environment surrounding it rather than a response to a problem formulated in the scientific community and pursued according to rigorous scientific methods. Lysenko seemed to achieve results at a time when there was a great demand for immediate solutions and a growing impatience with the protracted and complicated methods employed by established scientists. This brought a sympathetic predisposition to whatever theoretical views Lysenko chose to express, no matter how vague or unsubstantiated.

Even Lysenko's practical achievements were extremely difficult to assess. His methods were lacking in rigor. His habit was to report only successes. His results were based on extremely small samples, inaccurate records, and the almost total absence of control groups. An early mistake in calculation, which caused comment among other specialists, made him extremely negative regarding the use of mathematics in science.

But Lysenko was the man of the hour, one who had come from humble origins under the revolution and who directed all his energies into the great tasks of socialist construction. He was pictured as the model scientist for the new era, and was credited with conscientiously bringing a massive increase in grain yield to the Soviet state, while geneticists idly speculated on eye color in fruit flies.

Genetics on the Defensive

Catching the ideological demagoguery that was beginning to flourish among a certain section of the young intelligentsia, some denounced the science of genetics as reactionary, bourgeois, idealist, and formalist, and contrary to the Marxist philosophy of dialectical materialism. Its stress on the relative stability of the gene was supposedly a denial of dialectical development as well as an assault on materialism. Its emphasis on internality was thought to be a rejection of the interconnectedness of every aspect of nature. Its notion of the randomness and indirectness of mutation was held to undercut both the determinism of natural processes and human abilities to shape nature in a purposeful way.

The new biology, with its emphasis on the inheritance of acquired characteristics and the consequent alterability of organisms through directed environmental change, was well suited to the extreme voluntarism that accompanied the accelerated efforts to industrialize and collectivize. The idea that the same sort of willfulness could be applied to nature itself was appealing to the mentality of those who believed that Soviet man could transform the world. Lysenko's voluntarist approach to experimental results and to the transformation of agriculture was the counterpart of Joseph Stalin's voluntarist approach to social processes, undoubtedly a factor in Stalin's enthusiastic support of Lysenko during this period.

Trofim Lysenko, kneeling in a field, measuring the growth of wheat. During the Soviet famines of the 1930s, Lysenko proposed techniques for the enhancement of crop yields, rejecting orthodox Mendelian genetics on the basis of unconfirmed experiments, and gained a large popular following. But in 1964 his doctrines were officially discredited, and intensive efforts were made toward reestablishing orthodox genetics in the Soviet Union. *(© Hulton-Deutsch Collection/Corbis.)*

Other political leaders and scientific administrators were not so easily swayed. Geneticists defended their work and had very influential support. There was strong resistance within the Academy of Sciences. The debate reached a climactic point at a special session of the Lenin Academy of the Agricultural Sciences in 1936, devoted to a discussion of the two trends in Soviet biology. The official goal was to achieve a reconciliation of the two schools, some kind of accommodation for genetics within the framework of Lysenko's agrobiology. The outcome was the opposite. The open confrontation of the two trends resulted in drawing the lines more sharply than ever and in highlighting the irreconcilability of the two contrasting approaches.

The sharpest speech in the defense of genetics came from the American geneticist Hermann J. Muller, a foreign member of the Academy of Sciences, who had come to work in the Soviet Union out of a belief in the possibilities of science under socialism. Muller was also inclined to philosophical reflection on science and had definite views as to the place of genetics within the framework of a dialectical materialist philosophy of science. He turned the charge of idealism against the Lysenkoites and accused them of hiding behind the screen of a falsely interpreted dialectical materialism.

The growing ascendancy of Lysenko coincided with the purges that reached into virtually every Soviet institution from 1936 to 1939. The campaign against geneticists became more and more vicious and slanderous. Scientific and philosophical arguments gave way to political ones. The pursuit of genetics was branded as racism and fascism. Geneticists were named and accused of sabotage, espionage, and terrorism. Many were arrested. Of these some were shot, while others died in prison. Still others were witch-hunted, lost their jobs, and were forced into other areas of work. Institutes were closed down. Journals ceased to publish. Books were removed from library shelves. Texts were revised. Names became unmentionable. The 7th International Congress of Genetics, which was scheduled to be held in Moscow in August 1937, was cancelled. When the congress did take place in Edinburgh in 1939, no Soviet scientists were present, not even the internationally respected geneticist N. I. Vavilov, who had been elected its president.

By 1938 Lysenko had been elected to the Academy of Science and replaced Vavilov as president of the Lenin Academy of Agricultural Sciences. In 1940 Vavilov was arrested and Lysenko replaced him as director of the Institute of Genetics of the Academy of Sciences. In 1941 Vavilov stood trial and was found guilty of sabotage in agriculture. After several months of incarceration, Vavilov's death sentence was commuted, but he died in prison in 1943 of malnutrition. Although some of the more outspoken and defiant survived, many gave way under the pressure, engaged in abasing self-criticism, and acknowledged the superior wisdom of Lysenko. The degree of demoralization was overwhelming.

Assessment

Lysenkoism reached its peak in 1948 with official Communist Party endorsement. But almost immediately after Stalin's death in 1953 it went into decline. Vavilov, for instance, was posthumously rehabilitated in 1955. However Lysenkoism continued to be a force in Maoist China, where a promotional congress was held in 1956. The case was thus a protracted episode in the history of science under Communism, and has been the subject of many commentaries.

These analyze the scientific, political and philosophical issues in quite divergent ways. Soyfer and others represent it as a story of personal opportunism and political terror, as a cautionary tale against the dangers of ideological distortion of science. This position tends to see philosophy and politics as alien impositions upon science. Joravsky, Graham and Lecourt put more emphasis on the complexity of the philosophical issues, although with varying degrees of hostility or sympathy with Marxism. Medvedev's account is of historical significance as a critique coming from someone within the world of Soviet science. Some searching and sophisticated explorations of the issues have come from within Marxism, most notably by Lewontin, Levins, and Young. This position is marked by an insistence that science is inextricatably tied to philosophy and politics, even to ideology, opening up a more nuanced investigation of the varying modes of interaction and a more complex critique of Lysenkoism.

M

MACHIAVELLI, NICCOLÒ

Niccolò Machiavelli (1469–1527), born in Florence on May 3, was a Florentine statesman and Renaissance Italy's greatest political philosopher; he died in Florence on June 21. He is often regarded as the first to take a scientific approach to politics.

Major Contributions to Political Thought

Machiavelli is known chiefly as the author of two books, *The Prince* and *The Discourses on Livy* (both c. 1517). The former concerns the acquisition of principalities, a form of government in which the state belongs to an individual or a family. The latter is a meditation on republics, in which the state is public rather than private property. The notoriety of these books is largely due to the absolute ruthlessness advocated by Machiavelli. In *The Prince,* he recommends acting against faith, charity, humanity, and religion. In *The Discourses,* he criticizes Giovampagolo Baglioni because that tyrant had the opportunity, but not the courage, to murder the Pope.

Niccolò Machiavelli, 1469–1527. Machiavelli was an Italian political philosopher during the Renaissance. His most famous book, *Il Principe,* was a work intended to be an instruction book for rulers. Published after his death, the book advocated the theory that whatever was expedient was necessary—an early example of utilitarianism and realpolitik. *(Corbis. Archivo Iconografico, S.A./Corbis.)*

Despite their practical orientation, *The Prince* and *The Discourses* are works of political science. Machiavelli asks theoretical questions: how states are born and what sustains them. But his work marks a fundamental break with premodern political thought. Classical and medieval thinkers were concerned above all with the difference between good and bad forms of government; Machiavelli ignores that distinction in favor of hard realism. In the first chapter of *The Prince,* he classifies states solely according to how they are acquired. In chapter fifteen, he dismisses those who dream of imagined principalities; perhaps referring to heaven, or Plato's *Republic.* Machiavelli thus narrows the horizon of political science; the question is not what kind of government is best, but how do people get the kind they want.

To answer this question, Machiavelli first explains the origin of states. He observes that hereditary principalities are established based on habit: People accept the regime because they are accustomed to it. But every established government was once new. How does a new state survive long enough to *become* hereditary? Machiavelli ignores the traditional answers: God's blessing or natural development. Perhaps just dumb luck? But fortune is fickle by definition, and does not sustain any one thing for long. Because all states originated from some source, Machiavelli proposes that certain people have, within themselves, the power to conquer fortune, to create armies, and to establish and maintain states.

He calls this power *virtue,* a word suggesting the premodern idea of moral excellence. But in fact, Machiavelli's definition of virtue supports the ruthlessness he advocates. Morality and justice as commonly understood exist only as the products of established states. Machiavellian virtue must exist before the state is founded, and is therefore beyond ordinary right and wrong. It does, however, require that certain temptations be resisted: The prince must never rely on fortune or the grace of others, or put off until tomorrow a murder he needs to commit today.

Whereas ancient philosophers were conservative, more concerned with preserving decent governments than with creating new ones, Machiavelli encourages innovators. He especially admires those who create principalities and republics from scratch, or rejuvenate existing ones. In all cases, he insists that the innovator must rely on his own virtue, and have *arms of his own.* By this, Machiavelli means soldiers, loyal to the prince alone. He severely criticized Italian states for their reliance on mercenary and *auxiliary* arms. Paid soldiers, or those borrowed from another prince, have no connection to the innovator's virtue, and so cannot be a secure foundation for the state.

Pertinence to Modern Political Thinking

Machiavelli is regarded by some as the founder of value-free political science. He describes politics as it is, not as it might be, and shows how this knowledge can be exploited to bring greater order into human affairs. But Machiavelli's science is anything but value-free: He prefers glory to security, and admires innovators more than conservatives. Though he writes both for republics and tyrants, many have argued that he favors one over the other. In fact, he clearly has a preference for republics, but believes that the founding father of every republic needs to possess unrestrained power.

Machiavelli's writing has never gone out of fashion. Perhaps this is because he had the courage to face certain hard truths about modern thought. In order to conquer chance and nature, the early moderns were willing to reject the authority both of divine and natural right, thus imposing no moral restraints on the technological power unleashed by their new sciences. Machiavelli's political science vividly illustrates the consequences of their boldness.

Machiavelli paid relatively little attention to the rise of modern science and technology, concentrating much more on the topic of political reform. It was left to Francis Bacon and others to apply Machiavellian principles to the conquest of nature as a whole. But Machiavelli's thought did at least hint at the Baconian project. He speculates that it was natural famine that drove large populations of barbarians out of their homelands in the east to inundate the Roman empire. He likens the movement of such peoples to floods, and speaks of strong political institutions as dams and dikes that can restrain such floods. Machiavelli is thus developing a science of politics that is technological in the modern sense.

MANAGEMENT

• • •

OVERVIEW

The term *management* can name both an activity and persons in charge of the activity. As activity, the term derives from the Italian *maneggiare*, meaning to handle or control a horse, which is itself rooted in the Latin *manus*, or hand. In the late 1500s the word was applied to the governing body of a theater and from there to other business activities, including those involved with industrial manufacture. Shifts in the ownership of large-scale manufacturing companies led to what has been termed a managerial revolution, in which direct control and decision-making became invested in neither owning capitalists nor wage-earning workers but in salaried managers (Burnham 1941, Chandler 1977). This shift has influenced both science and technology, with "big science" and "technoscience" increasingly managed by neither science nor engineering workers—a development that poses questions of ethical responsibility for both technical professionals and managers. Attempts to systematize informal management techniques into either a science or a technology of management further highlight ethical issues.

Historical Background

Humans have always collaborated to reach shared goals. Distributed tasks for common ends require coordination, planning, control, and organization—all of which are as subject to ethical assessment along with the ends to which they are subordinate. For example, in Plato (c. 428–347 B.C.E.) one can find both praise for the division of labor that engenders expertise in specialized workers (*Republic*) and criticisms of the pretensions of technical specialization (*Apology* and *Gorgias*). Thus, although the term did not exist as such, "management" has often been read back into such preindustrial orders of household, tribe, city-state, military, or church. What distinguishes modern management from traditional political or religious organization and leadership is its greater emphasis on the systematic coordination of means.

Management did not take on its contemporary connotations until the technological, economic, political, and social changes of the Industrial Revolution (c. 1750–1850). Specifically, certain organizational problems arose in the embryonic factory system that led to the genesis of modern management practices and eventually the formalization of management study (Wren 2005). It was also during this era that attitudes to work began to change, although slowly, from ceaseless, futile labor to opportunities for personal wealth and social progress. Central to this transformation were the Renaissance revival of science and reason and the Protestant work ethic with its notion of a worldly "calling" that Max Weber (1930) argued paved the way for market-based capitalist economies.

The modern understanding of management in terms of leading an organization toward a goal through the deployment and manipulation of resources (material, human, financial, and intellectual) was further shaped by classical and nineteenth-century economic theory and the development of technical production elements such as standardization, specialization, and work planning. The emergence of modern technologies and the market economy challenged managers to develop a body of knowledge on how best to administer and utilize human and technological resources. By the middle of the nineteenth century, Robert Owen (1771–1858) and others were developing theories pertaining to the human element of management including worker training, organizational structure, span of control, and the effects of fatigue on performance. By the 1880s, university courses in management were being offered, based in part on the work of Andrew Ure (1778–1857), who developed training programs for managers in the early factory system.

The first comprehensive theories of management appeared around 1920 in the work of scholars such as Henri Fayol (1841–1925), who outlined five functions for managers and synthesized fourteen principles for organizational design and effective administration. Some theorists such as Ordway Tead (1891–1973) applied principles of psychology to management, whereas Elton Mayo (1880–1949) and others approached it from a sociological perspective. In *The Practice of Management* (1954), Peter F. Drucker (b. 1909) presents a contrast to the Fayolian process texts by introducing the notion of "management by objectives," which replaces control from above with self-control and greater worker empowerment in the goal of reaching well-defined objectives.

In *The Managerial Revolution* (1941), James Burnham (1905–1987) sets management theory within a broad historical narrative of political economy and technological change. Burnham saw industrial production coming to be controlled neither by the owners (capitalism) nor the working class (socialism). Rather, a new managerial class was replacing the bourgeois capitalist as a dominant social force, as ever more complex systems of production separated control from ownership. For Burnham, technological progress necessitates a hierarchy of managers among whom direction and coordination of production becomes a highly specialized skill.

In *The Visible Hand* (1977), Alfred D. Chandler Jr. (b. 1918) presents a similar argument but one less oriented toward prophecy. Chandler claims that neither the traditional family firm nor market mechanisms are able to coordinate the increasingly swift and complex flows of goods made possible by technological innovation. Managers of large, multiunit businesses fill this need for coordination, and in so doing assume strong economic and social power, giving rise to managerial capitalism: "In many sectors of the economy the visible hand of management replaced what Adam Smith referred to as the invisible hand of market forces" (p. 1). But while acknowledging the centrality of technology in bringing about increased managerial control, Chandler fails to explore fully the role of scientists and engineers.

The managerial revolution may have held true in heavy industry, but it seems less valid for service and information economies, where bigger and more complex is not always better. Indeed the continual evolution of technological, political, and economic contexts ensures that management theories are constantly being revised. Some of the more recent developments in management thought include operations research, the theory of constraints, reengineering, complexity theory, and information technology–driven theories. A general trend in management thought is toward systems-based, adaptive processes capable of integrating several categories (e.g. human resources, marketing, and production) into a complex, flexible web of organizational administration.

Management as Science

The conceptualizing and ordering of management as a science did not begin in earnest until the nineteenth century. And although Charles Babbage (1792–1871) made significant contributions to management science, Frederick Winslow Taylor (1856–1915) is viewed as the founder of the field. In 1895 Taylor wrote a seminal paper titled "A Piece-Rate System" that developed a set of management techniques designed to stimulate maximum worker productivity and efficiency. This helped fuel the rising emphasis on efficiency and rationality in decision-making that sought the "one best way." Theodore Roosevelt, Gifford Pinchot, and other conservationists spearheaded this movement by preaching a "gospel of efficiency" in natural resource management, which was "an attempt to supplant conflict with a 'scientific' approach to social and economic questions" (Hays 1959, pp. 266–267).

In *The Principles of Scientific Management* (1985 [1911]), Taylor acknowledged the inefficiencies in natural resource use, but argued that wasteful practices in human resource management were just as damaging to the goals of efficiency, productivity, and prosperity. The Industrial Revolution had vastly increased resources and capital and improved technologies, but crude ways of organizing and administering these resources hampered productivity. Taylor set out to prove that the best management is a true science, resting upon a clearly defined foundation of laws, rules, and principles. Furthermore, he sought to show that the fundamental principles of scientific management are applicable to all kinds of human activities, from the simplest individual acts to the work of huge corporations.

Among other organizational techniques, this "true science" involved standardizing measures of productivity and quality; developing time, motion, and method studies; and improving the relationship between mangers and workers. In one instance, Taylor was able to reduce the number of people shoveling coal at Bethlehem Steel Works from 500 to 140 by designing more ergonomic shovels. Taylor believed the credo of rational efficiency would lead to prosperity for all, thus abolishing class hatred, but many labor leaders felt that scientific management meant autocracy in the workplace. In fact, Taylor was questioned at length by Congress in 1911 and 1912 on the grounds that some of his methods treated workers like machines.

Frank Gilbreth (1868–1924) and Lillian Gilbreth (1878–1972) were associates of Taylor, and their studies culminated in laws of human motion from which evolved principles of motion economy. The Gilbreths coined the term *motion study* and used cameras to record motions and improve efficiencies even in domestic chores. Other important pioneers in scientific management included Henry Gantt (1861–1919) and Charles Bedaux (1886–1944). After World War II, scientific management played a key role in boosting economic productivity. Statistical and mathematical techniques were applied to planning and decision analyses. Physics Nobel laureate Patrick Blackett (1897–1974) combined these techniques with microeconomic theory to produce the science of operations research, which has been greatly enhanced by the use of computers.

The work of social scientists such as Elton Mayo uncovered many aspects of human interaction in the workplace that had been ignored by other theorists. Specifically, he noted that worker motivations (e.g., feelings, multiple needs, personal goals) are often outside the bounds of the logical, rational human being posited by scientific management, and that workers think and act not as individuals but as members of formal or informal groups (see also McGregor 1960). This type of work led to the rise of human relations management. The period between 1950 and 1970 witnessed a sevenfold increase in managerial employment. It was during this time that behavioral science became widely applied to management practices by theorists such as Rensis Likert (1903–1981). There is a wide range of contemporary scientific theories of management, and it is clear that the best fit for improving performance depends in part on contextual contingencies.

Indeed in many areas alternatives and complements to scientific management stress the importance of building flexibility into systems in order to accommodate the surprises generated by nature, cognitive limitations, and the pace of global commerce. One example is adaptive management (e.g., Brunner et al. 2005), which is a diverse field developed in the 1970s and based on the incorporation of multiple stakeholders in decision-making processes in order to shift to bottom-up, open-ended management structures. In natural resource management, the underlying realization is that the politics of most problems (even many highly technical ones) cannot be elided by focusing solely on scientific expertise and efficiency. In the business world, the driving factors in the shift away from overly rigid forms of scientific management are the need for flexibility to maintain competitiveness and the realization that many valued outcomes are not readily captured by quantification.

Thus scientific management has from its beginnings been a diverse field that has given rise to equally diverse criticisms. It has been both praised and stigmatized as technocratic, insofar as technocracy can be conceived as an ideological-free pursuit of efficient production and a form of production that excludes the consideration of human values. In natural resource policies, technical management has been argued to impede common-interest solutions (Brunner et al. 2005). In business, although it can lead to greater competitiveness via increased efficiency, scientific management can also rigidify an organization, robbing it of flexibility and creativity.

More generally, Alasdair MacIntyre (1984) criticizes the notion of managerial expertise that derives from the dominant conception of the social sciences as somehow mimicking the natural sciences. For MacIntyre, "What managerial expertise requires for its vindication is a justified conception of social science as providing a stock of law-like generalizations with strong predictive power" (p. 88). He then identifies four sources of systematic unpredictability in human affairs, which he claims undermine the very notion of managerial expertise. He concludes that the concept of managerial expertise, or the idea that anyone can consciously manipulate the social order, is a moral fiction: "Our social order is in a very literal sense out of our, and indeed anyone's, control" (p. 107). What appears to be pragmatic, scientifically managed social control is but the skillful imitation of such control. This does not deny the enormous power exercised by bureaucratic managers, it is just that "the most effective bureaucrat is the best actor" (p. 107).

Nevertheless, regardless of outcomes and the fact that the term has fallen out of use, "'scientific management,' as well as its near synonym, 'Taylorism,' have been absorbed into the living tissue of American life" (Kanigel 1997, p. 6). Indeed, the history of scientific management mirrors the development of science more broadly, having evolved from the ideal of disclosing a single right answer to the reality of uncovering an imbroglio of human values intertwined with artifacts and systems, in which uncertainty and ambiguity are multiplied along with the importance of context and values.

Management as Technology

Parallel with attempts to develop management as a science—and as a science with applications—have been attempts to conceptualize management as a technology. Here the leading theorist has been Peter Drucker, who argues for an identification between management and modern technology. Just as in premodern technology work was more important than the tools with which work was performed—that is, work is the context from which tools receive their meaning—so in modern technology management or the organization of activity is the whole that unifies material resources, human labor, financial capital, and machines. Central to any wealth production is the process of ordering, interrelating, or managing the parts in order to assemble a productive business enterprise, which Drucker identifies as a "*system* of the highest order" (1970, p. 55).

For Drucker, management as technology may also be understood as an extension of biological evolution. Management is an adaptive process that orders (and reorders) different aspects of the world (through productive work); as such management is the most general contemporary expression of the human capacity for purposeful, nonorganic evolution. Tools and technologies are not just givens for management but, like the materials and human beings who make up a productive enterprise, are able to be transformed by management—and then transformed again in response to the changed context that the original transformation produces. Management involves a recursive process in which it takes its own successes and failures into account. "The organization of work, in other words, is . . . the major means of that purposeful and nonorganic evolution which is specifically human" (pp. 48–49).

Related to Drucker's view of management as technology is an argument by intellectual historian Bruce Mazlish (1993) regarding the relation between humans and machines. For Mazlish modern history is characterized by the rejection of four discontinuities: between Earth and the rest of the cosmos (Newtonian mechanics, which used the same laws to explain terrestrial and planetary phenomena), between animals and humans (Darwinian evolution, which argued for a natural development from animals to humans), between the unconscious and rationality (Freudian psychology, which presented reason as tied to the unconscious), and between machines and humans (through the integration of computers and humans). By arguing that human beings are defined by their coevolution with machines, a coevolution they must learn to manage, Mazlish likewise presents management (without using the term) as the fulfillment of technology.

Insofar as this is the case, of course, the science and technology of management must also be brought to bear on science and technology, especially big science or technoscience, which has become a complex enterprise. As first identified by the historian of science Derek J. de Solla Price (1963) and scientist-science administrator Alvin M. Weinberg (1967), science that depends on large-scale funding and coordinates many disciplines to achieve a common goal (such as the Manhattan Project to create the atomic bomb) requires increasingly sophisticated techniques of management. The same goes for macroengineering projects such as the U.S. interstate highway system or the European Channel Tunnel (or Chunnel). When this is the case it can reasonably be argued that the science and technology involved have become manifestations of management.

Management Ethics and Policy

In an influential analysis of how theories of human nature influence managerial practice, Douglas McGregor observed that "the more professional the manager becomes in his use of scientific knowledge, the more professional he must become in his sensitivity to ethical values" (1960, p. 12). Indeed, professionals can expect to be granted professional autonomy by the societies in which they operate only "to the extent that human values are preserved and protected" (p. 14). As the prominence of scientific and technological management has increased, so has the question of the relation between management and ethics—both ethics in management and the management of ethics.

In many instances management ethics is not strongly distinguished from business ethics. As in business ethics, key issues in management ethics include standards of communication, conflict of interest, responsibilities to stockholders, treatment of employees, social and environmental responsibilities, leadership obligations, and more. But because of their managerial roles, managers more than businesspersons or entrepreneurs also have to deal with the ethics of introducing ethics into business operations. One of the central issues in management ethics is thus how to introduce and manage ethics in a corporation or other enterprise that is also being managed for shareholder profit and/or stakeholder interests. One of the key questions for management ethics is thus: What is the proper role for ethics in management? Given the practical orientation of management, this includes: How is ethics best managed?

With regard to managing science and technology, the distinctive forms of scientific research and technological development organizations and processes must also be taken into account. Claude Gelès and colleagues (2000), for instance, argue that because most management texts assume a context of traditional business organizations using repetitive tasks and mass production to make a profit, they are not relevant to the management of scientific laboratories that use exploratory research and creativity to produce new knowledge and technical innovation. To achieve their aim of managing innovation to produce more innovation, science and technology managers need to be aware of the special characters of scientists and engineers, and of institutional resistances to new knowledge and technical innovation. They also need to be aware of the special ethical challenges involved in the scientific production of knowledge associated with temptations to scientific misconduct and the need to promote best practices in the responsible conduct of research.

Finally, because management takes place largely by means of establishing policies, the management of science is intimately related to science policy, especially that type of science policy known as policy for science. Here the work of Weinberg, as a reflective scientist manager of a big science and technology organization (Oak Ridge National Laboratory), provides basic orientation. For Weinberg, it is useful to distinguish internal and external criteria for decision-making in the management of science. Internal criteria focus on whether a particular research program is ripe for pursuit and on the competencies of the scientists involved. External criteria are of three types: scientific merit, technological merit, and social merit. Finally, Weinberg argues that especially in big science, which depends for its existence on financial support from the larger nonscientific community, and because science cannot be presumed to be the summum bonum (supreme good) of a society, "the most valid criteria for assessing scientific fields come from without rather than from within the scientific discipline" (1967, p. 82).

MODELS OF

Management is the process of reaching individual and collective goals by working with and through human and nonhuman resources to improve the world. Managerial values include performance effectiveness (achieving goals), operational efficiency (not wasting resources in the process), sustainable innovation (continually improving outputs and processes), and adding value (as measured by stakeholder responsiveness). Good managers demonstrate sound judgment by balancing these four competing but complementary values.

The four values inherent to some degree at all levels of management are embodied in four management mod-

FIGURE 1

els. Those models focus on rational goals, internal process, human relations, and open systems (Quinn et al. 1995), each of which involves ethical issues that have relevance for the management of science and technology.

Rational Goal Model

The rational goal model, which Frederick Taylor (1856–1915) introduced at the beginning of the twentieth century, stresses the importance of managerial external control that results from the exercise of director and producer role responsibilities in order to employ humans and other tools to engineer optimal productivity (Taylor 1911). Performance effectiveness is achieved through setting goals, speeding productivity, and increasing profits faster than external competitors can and by using time-and-motion studies, financial incentives, and technological power to maximize output.

Three of Taylor's followers—Henry Gantt (1861–1919) and Frank (1868–1924) and Lillian (1878–1972) Gilbreth—expanded the rational goal approach by using new engineering techniques (time and motion studies) that enhanced the ability of technological experts to expand productivity. Time and motion studies provided detailed information about job activities such as grasping, searching, transporting, or assembling and the time it took to complete them in order to measure normal and superior productivity standards.

The strength of this model is that it accounts for managers' providing structure and initiating action. The exclusive and extreme emphasis on the rational goal model, however, imposes fast-paced, robotlike movements on people that were impossible to sustain, and this neglect of individual psychosocial needs in the pursuit of economic returns tends to result in offended individuals and destroy cohesion at the organizational level.

At the microeconomic and geopolitical levels the rational goal model of management was advanced indirectly by Alfred Marshall (1842—1924) and James Burnham (1905—1987), respectively. Marshall was a neoclassical economist who explained how the price and output of a good are determined by both supply and demand curves, such as the price and output of new automobiles that are determined by the demand of the buyers and the supply from the manufacturers, that are like scissor blades that intersect at an optimal point of equilibrium. It is at this point of equilibrium that buyers, sellers, and/or managers could and should rationally optimize their utility values by clearing the external market (see Figure 1).

Burnham's later neoconservative geopolitical works argue that because of the unceasing desire for power among an oligarchy of managerial elites from the three major global "super-states," the struggle for external political control of the world requires a decisive victory by strong-willed U.S. political leadership that exercises an aggressive geopolitical strategy by using all the offensive resources at its disposal. The perceived overreliance on the rational goal model at the microeconomic and geopolitical levels to secure external global control has led to the expected results of offended stakeholders and has destroyed cohesion at those extraorganizational levels as well.

Internal Process Model

The internal process model introduced by Henri Fayol (1841–1925) in the first quarter of the twentieth century stresses the importance of managerial internal control that results from the exercise of the monitor and coordinator role responsibilities in order to exert authority over humans to maintain the stability of hierarchic administration. Operational efficiency is achieved through information management, documentation control, and consolidated continuity and by emphasizing process measurement, smooth functioning of organizational operations, and the maintenance of structural order (Fayol 1916). Fayol described the five functions of management as planning, organizing, commanding, coordinating, and controlling and laid down fourteen principles of good administration, with the most important elements being specialization of labor, unity and chain of command, and the routine exercise of authority to ensure internal control.

Another key exponent of operational efficiency in managing large groups was the sociologist Max Weber (1864–1920), who described and advocated the indispensability of bureaucracy. Weber's ideal bureaucracy included authority, hierarchy, formal rules and regulations, and impersonality in rule application. His ideal bureaucrat neutrally and efficiently manages by the book and follows orders from above even if they go against his or her personal convictions.

When the internal process model is applied to politico-economic control, socialist and communist regulatory infrastructures constrain the negative externalities of the free market but create the risk of stifling technological and politico-economic innovations through overregulation. The strength of this model is that it accounts for managers' maintaining structure and collecting information. The exclusive and extreme emphasis on the internal process model, however, results in stifled progress and neglected possibilities at the organizational and extraorganizational levels.

Human Relations Model

The human relations model, which Elton Mayo (1880–1949) popularized in the second quarter of the twentieth century, stresses the importance of the managerial internal flexibility that results from the exercise of facilitator and mentor role responsibilities in order to improve human relations at work and enhance extraorganizational stakeholder responsiveness. Stakeholder responsiveness is achieved by showing managerial consideration for employees' psychosocial needs to belong, fostering informal group collaboration, and providing recognition at work as well as promoting managerial social responsibility and humane community building in society (Mayo 1933). Mayo's research at the Hawthorne Works demonstrated that management consideration, employee group affiliation, and special recognition motivated can increase productivity.

Peter Drucker (1909–2005), although critical of Mayo's perceived psychological manipulation of employee loyalty, promotes the value of the socially responsible use of managerial power and humane community building. He argues that in a global knowledge society managerial power can and should be applied to the nonprofit sector because that appears to be the primary sector that is focusing on creating socially responsible citizens and giving knowledge workers a sphere in which they can make a positive difference and re-create meaningful communities.

The strength of this model is that it accounts for managers' showing consideration and facilitating supportive interaction with intraorganizational and extraorganizational stakeholders. The exclusive and extreme emphasis on the human relations model, however, creates the risk of slowing production at work and abdicating decision-making authority in society.

Open Systems Model

The open systems model introduced by Paul Lawrence (b. 1933) and Jay Lorsch (b. 1934) in the third quarter of the twentieth century stresses the importance of the managerial external flexibility that results from exercising the innovator and broker role responsibilities in order to adapt continually to changing environmental forces (Lawrence and Lorsch 1967). Sustainable innovation is achieved by cultivating organizational learning cultures, developing cross-functional organizational competencies for continuous creativity, and respecting quality and ecological system limits while negotiating for external resource acquisition, building sustainable entrepreneurial networks, and enabling creative system improvement.

W. Edwards Deming (1900–1993) used statistical quality control to separate special and common causes of variation, fixing the former and accepting the latter to improve production systems continually by narrowing the range of acceptable performance variation over time. Deming's message to managers was that because most performance variations are the result of common causes, that is, fall within a normal range of statistical variation, managers should focus on improving the production system instead of overcontrolling employees.

Paul Shrivastava (b. 1939) focuses on entrepreneurial ecocentric management of sustainable development systems that technologically prevent and/or control pollution of nature and corruption of sociopolitical systems over time. The strength of this model is that it accounts for managers' envisioning improvements and acquiring resources for sustainable system development. The exclusive and extreme emphasis on the open systems model, however, results in disrupted operational continuity and energy wasted on unrealistic change projects.

Ethics of Management

The four management models for handling behavioral complexity have management ethics parallels in handling moral complexity, that is, inclusively balancing the competing moral values of achieving good results, following the right rules, cultivating a virtuous character, and creating supportive contexts (Petrick and Quinn 1997). In effect, the way people manage—make managerial judgments—implicitly and/or explicitly discloses their moral value priorities: the relative emphases they place on results, rules, character, or context in their moral choices. Rational goal "bottom line" managers are naturally disposed to emphasize results-oriented teleological ethics theories; internal process "by the book" managers are naturally disposed to emphasize rule-oriented deontological ethics theories; human relations "bleeding heart" managers are naturally disposed to emphasize character-oriented virtue ethics theories; and open systems "change agent" managers are naturally disposed to emphasize context-oriented situation ethics theories. Nevertheless, just as the balance and inclusiveness of the four management models determine the quality of managerial behavioral complexity judgment, the balance and inclusiveness of the four ethics theories determine the quality of managerial moral complexity judgment as well.

Especially in bringing these ethical issues to bear in the management of science and technology, the economist Adam Smith's (1723–1790) social calculus of adding individual selfish motives to the greater good must be supplemented by the insight that managers often are faced with ethical responsibilities that run counter to their actual or perceived self-interest. Otherwise, management ethics would be synonymous with corporate profit or self-promotion. A case in point would be the uncritical scientific endorsement of genetically modified human foods for global profit without morally considering the harmful effects of genetically modified foods on the health of current and future human generations.

Management ethics involves a complex and inclusive balancing of multiple stakeholder interests, internal and external to organizations, domestically and globally. For example, business managers that focus only on advancing the financial interests of investors while neglecting other stakeholders' interests, such as those of employees, society, and nature, are increasingly criticized for an unduly narrow and short-term managerial ethics perspective. The ability to simultaneously and/or sequentially optimize moral results, rules, character, and context in a sustained way for multiple stakeholders at intraorganizational and extraorganizational levels is becoming the touchstone of sound management ethics and the basis of hope for moral progress in the future.

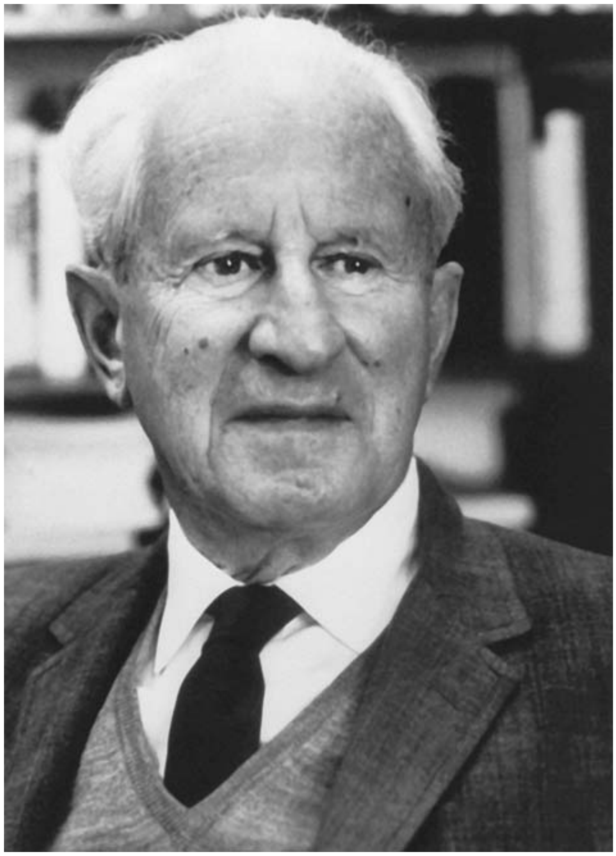
MARCUSE, HERBERT

Herbert Marcuse (1898–1979) was born in Berlin on July 19. After earning a doctorate in literature in 1922, he studied philosophy with Martin Heidegger (1889–1976) in Freiburg from 1928 to 1933. Troubled by Heidegger's affiliation with the National Socialist party, Marcuse joined the philosophers Max Horkheimer (1895–1973) and Theodore Adorno (1903–1969) at the Institute for Social Research in Frankfurt before fleeing to New York in 1934. Marcuse remained for the rest of his life in the United States, where he continued the institute's interdisciplinary work in critical social theory. He died on July 29 in Starnberg, after having suffered a stroke on a trip to Germany. Marcuse synthesized the works of Heidegger, Karl Marx (1818–1883), and Sigmund Freud (1856–1939) into a unique philosophical perspective from which he analyzed the nature of social control and the prospects for liberation in advanced industrial capitalist and communist societies.

Among Marcuse's contributions to critical social theory was his analysis of science and technology as instruments of social and political domination. Echoing Heidegger, Marcuse spoke of the "technological a priori" of scientific-technical rationality that projects nature as potential instrumentality. Technological rationality homogenizes people and nature into neutral objects of manipulation. That rationality is easily co-opted by economic and political power. However, science and technology merely function in the service of social control; they could be transformed to serve different ends, such as freedom, individuality, and creativity.

Marcuse's 1941 article "Some Social Implications of Modern Technology" argued that technological rationality undermines traditional "individual rationality" (autonomy) by employing efficiency as the single standard of judgment. Industrialized societies take advantage of the notion of efficiency to induce people to accept mass production, mechanization, standardization, and bureaucracy. Consequently, Marcuse argued, appeals to enlightened self-interest and autonomy appear progressively quaint and irrational in the face of a technological rationality that makes conformity seem reasonable and protest seem unreasonable.

In the mid-twentieth century political power—including state capitalism, fascism, and state socialism—developed seemingly rational, even pleasurable, means of social control that integrated individuals into a homogeneous society. The result was a "one-dimensional" society that eroded the capacity for individuality, critical thinking, and practical resistance. However, Marcuse maintained that the same impersonal rationality that made individualism unnecessary could be harnessed to realize rather than repress human capacities. Technological rationality could be used as an instrument to foster democracy, autonomy, and individuality. Marcuse was pessimistic about the prospects for that transformation because the technological apparatus tends to incorporate and subsume all opposition. However, despite Marcuse's pessimism regarding the achievement of such a transformation, he maintained that it was in principle possible.



Herbert Marcuse, 1898–1979. Marcuse was a leading 20th-century New Left philosopher in the United States and a follower of Karl Marx. His writing reflected a discontent with modern society and technology and their "destructive" influences, as well as the necessity of revolution. He was considered by some to be a philosopher of the sexual revolution. *(© UPI/Corbis-Bettmann.)*

In his most influential book, *One-Dimensional Man* (1964), Marcuse continued to argue that advanced industrialized societies employ science and technology to serve existing systems of production and consumption but claimed that technological rationality itself required transformation; it could not remain value-neutral if it were to lead to real human liberation. Marcuse also extended his analysis of the role of science and technology in manipulating human needs through advertising, marketing, and mass media. The scientific and technical aspects of a society are used to increase productivity and dominate humans and nature. The result is a carefully managed society that creates a one-dimensional person who willingly conforms to a society that limits freedom, imposes false needs, stifles creativity, and co-opts all resistance.

At the end of *One-Dimensional Man* Marcuse expresses the hope that humans one day will develop technologies for the "pacification of the struggle for existence" that will reduce misery and suffering and promote peace and happiness. Developing those technologies would require a political reversal, not simply more technological advances. A radical break from existing capitalist modes of production is needed to generate a new science and new technology. Science and technology then would become the instruments of liberation, not domination. New technologies would lead to new modes of cooperative production, energy sources, management, and communities; a new science of liberation would serve the interests of freedom and help satisfy genuine human needs. In his later work Marcuse considered the contributions that utopianism, student revolts, feminism, and aesthetic interests might make to the emergence of a new science and technology.

Marcuse was enormously popular in the 1960s and 1970s, and although his fame has been eclipsed since that time by that of Jürgen Habermas (b. 1929) and

French postmodern thinkers, he left an enduring legacy in critical social theory. He created a widely influential framework for analyzing the connections among political economy, science, technology, mass media, and culture in a way that not only identifies social domination and oppression but also attempts to identify the potential for social transformation leading to human liberation.

MARKETING

SEE Advertising, Marketing, and Public Relations.

MARKET THEORY

The market system allows individuals to exchange goods and services voluntarily, based on prices, without knowing one another. For instance, the cup of coffee a person drinks in the morning was brought to that person by thousands of strangers, who cultivated, harvested, processed, manufactured, packaged, shipped, stocked, and sold goods at various stages of production along the way.

One way to appreciate the distinctiveness of market-mediated trade among strangers is to contrast it with other ways in which people transact with one another. The anthropologist Alan Fiske (2004) suggests that all interpersonal transactions can be sorted into four relational models:

- In a communal sharing transaction, such as a family dinner, every member in the relationship is entitled to share in what is available.
- In an authority ranking transaction, such as a decision made in a traditional military unit or a corporation, there is a clear hierarchy, with people lower in the hierarchy deferring to those who are higher up.
- In an equality matching transaction, such as taking turns going through a four-way stop, people operate according to an intuitive sense of balance and fairness.
- In a market pricing transaction, such as buying a used car, people make decisions on the basis of their calculations of the costs and benefits.

The cognitive psychologist Steven Pinker, author of *The Blank Slate* (2002), argues that among these four modes of transactions market pricing is a relatively new phenomenon in the development of the human species:

> Market Pricing is absent in hunter-gatherer societies, and we know it played no role in our evolutionary history because it relies on technologies like writing, money, and formal mathematics, which appeared only recently (Pinker 2002, p. 234).

An important aspect of hunter-gatherer societies is that people belonged to tribes or bands of fewer than 150 people. Everyone knew everyone else, and people expected to interact with one another repeatedly. Small groups with repeated interactions are conducive to establishing trust and confidence in reciprocity, which are requirements for communal sharing and equality matching. When societies become larger and people must interact with strangers, something must replace trust and confidence. Only authority ranking or market pricing can "scale up" to large groups.

Economic historians see the modern market system as having arisen only within the last 300 years. Two features of the modern market system were largely absent until that time. One was flexibility of prices in response to supply and demand. In contrast, ancient and feudal trade took place at prices fixed by custom, authority, and tradition. A second feature of modern markets is that they enable people to work for money and trade for food. Before modern times markets did not have sufficient depth and breadth to allow for specialization and cash crops.

Before 1500 almost all people existed at a subsistence level, living on what they could cultivate. Feudal lords took any excess production and in return provided some public goods, notably protection. As late as 1700 the practice of raising a crop for cash and buying goods and services for money was relatively unknown. Even under late feudalism trade was relatively unimportant, and the terms of exchange were fixed by tradition rather than adjusting to supply and demand. The feedback loop between prices and production did not operate.

Between 1700 and 1850 the market system arose in Western Europe and North America. Better farming techniques allowed people to produce surplus food, giving them something to trade and releasing labor to work in manufacturing. Improvements in transportation, particularly railroads, facilitated specialization and trade. Increasingly, people moved from subsistence farming to a money economy in which they obtained cash for either a crop or physical labor. They then exchanged money for goods and services. Land, labor, and capital became responsive to market conditions.

Adam Smith was the first philosopher to articulate the virtues of the market system fully. In *The Wealth of Nations* (1776) Smith argued that trade was more efficient than self-sufficiency. With trade people can enjoy a wide variety of goods and services while specializing in their labor. In addition, Smith pointed out that the self-interest of producers worked to the benefit of consumers. When consumer demand increases for a good, the price goes up, attracting more producers.

The fact that higher prices induce more production is known as the law of supply. Similarly, a higher price for one good induces consumers to buy less of that good. This is known as the law of demand. Together, the laws of supply and demand determine an equilibrium price and level of output for each good. This impersonal, self-adjusting process is what distinguishes a market economy. In contrast, in a planned economy a bureaucrat determines prices and output levels. In a feudal economy prices are set by custom.

The concept of a market remains counterintuitive in the early twenty-first century. This can be seen in discussions of energy policy, in which it is suggested that the United States could become independent of foreign oil by reducing its domestic consumption and increasing the production of alternative energy. In fact, the world energy market is highly integrated. If the United States reduced its demand for oil, the world oil price would be reduced. However, Americans still would be affected by a disruption in the world supply of oil because such a disruption still would cause the price to rise.

The Ethics of the Market

The market system has ethical virtues in the view of libertarians and utilitarians. The libertarian view is that voluntary exchange among consenting adults is preferable to coercive allocation of resources by government. The utilitarian case for markets, which goes back to Smith, is that market exchanges make people better off.

Markets improve living standards in two ways. First, for any state of knowledge and technology markets achieve an efficient allocation of resources. Flexible prices and competition send signals that accomplish this. Consumers choose the goods and services that satisfy their wants most effectively. Firms choose the inputs and outputs that maximize the value of what is produced. Workers choose the occupations that best apply their talents and interests to social needs.

The second way in which markets improve living standards is through a Darwinian selection of innovative products and processes. Entrepreneurs attempt new techniques, with successful methods surviving and achieving widespread adoption. As unprofitable firms go out of business, failed innovations and obsolete methods fall by the wayside.

The support that markets give to innovation accounts for the high standard of living in the contemporary developed world relative to the past or to the underdeveloped world. The difference is large. Whereas the poorest people in the early 2000s and people who lived 500 ago lived on the equivalent of less than a dollar per day, the average American consumes more than $30,000 in goods and services each year. Market-driven South Korea has a standard of living more than ten times that of communist North Korea.

Feedback between Technological Innovation and Markets

Technological innovation and markets reinforce each other. Markets promote innovation by rewarding success and punishing failure. Technological change broadens markets and makes them more efficient.

Every innovation faces resistance. Scientists may doubt the validity of the theory behind an innovation. Firms are reluctant to discard tried-and-true production methods. Workers in existing industries find their livelihoods threatened by new competition. Consumers may be afraid of new products.

Interest groups that are threatened by new technology attempt to mobilize social institutions to retard innovation. Governments are asked to intervene. For example, some countries in Europe have banned genetically modified food. In the United States opposition to Wal-Mart stores often is driven by store owners and labor unions seeking to stifle competition.

Markets overcome resistance to innovation. The impersonal price system gives its approval to innovations that increase productivity and consumer well-being as firms that adopt the innovations earn profits. Simultaneously, the demise of unprofitable businesses frees resources to be used in more productive ways.

In addition to the ability of markets to foster innovation there is positive feedback from technological innovation to markets. Each improvement in transportation, communication, and trading technology serves to strengthen the market system, increasing the scope of transactions occurring in markets.

The revolution in oceangoing shipping that took place in the fifteenth century helped spur trade, which in turn fostered the transition from feudalism to a market economy. The invention of the steam engine and the railroad lowered shipping costs, enabling cash crops to replace subsistence farming. The internal combustion engine increased the mobility of labor and goods, leading to an increased share of economic activity taking place in the market. Electric motors and labor-saving devices helped release women from household labor and move into market-paid work. In modern times the Internet has increased the breadth of markets, including new possibilities for international trade in white-collar services.

Ethical Concerns with the Market System

There is a long-standing set of ethical concerns with markets. Major problems include inequality, failure to provide public goods, and erosion of cultural traditions.

Markets provide different rewards to different individuals. Those with talent, capital, entrepreneurial instincts, and luck do well. Those who lack valuable talents and/or encounter bad luck do poorly.

Critics of the market system believe that goods and services should be distributed more equally. The socialist thinker Karl Marx (1818–1883) described capitalism not as a neutral system of market pricing but a hierarchical system, with the ruthless capital-owning class exploiting the helpless working class. "From each according to his abilities, to each according to his needs" was Marx's slogan, promising the alternative of communal sharing. However, as anti-Marxists such as Max Weber (1864–1920) and Friedrich Hayek (1899–1992) predicted, large economies could not be made to operate efficiently without markets. Hayek in particular emphasized that the information developed by the price system and individual incentives is much more effective than is central planning.

Critics of inequality tend to view the economy as a zero-sum game, with the success of some individuals necessarily coming at the expense of others. Supporters of the market system view it as a positive-sum game, making it possible for nearly all people to raise their standard of living.

Another area where critics see a zero-sum game is in terms of resource constraints. The argument is that the earth's resources are finite and will be "used up." Economists counter by pointing out that human ingenuity seems boundless. As a result, Jerry Muller comments, "the history of capitalism, as Schumpeter observed, is of finding new ways to make use of formerly insignificant resources. Coal ... petroleum ... uranium ... sand for silicon chips. We may well be at the beginning of the fourth wave of capitalist industrial innovation, the biotechnology revolution" (Muller 2002, p. 391).

Federal Reserve Chairman Alan Greenspan is fond of pointing out that the physical weight of the American gross national product (GDP) is declining, an indication of reduced pressure from economic growth on physical resources. This trend may continue as nanotechnology allows products to be built from raw atoms. Rodney Brooks of the Massachusetts Institute of Technology talks about the possibility of not having to cut down trees and carve wood to make a table but instead simply growing a table with genetic engineering. The technology futurist Ray Kurzweil has suggested in *The Age of Spiritual Machines* (1999) that the information component of GDP is asymptotically approaching 100 percent, which would imply that physical scarcity will never constrain growth.

Another criticism of markets is that they give choices to individuals at the expense of collective purpose. It is argued that there is no overall direction or goal for a market economy. Those who want society to have a common objective see the market as too anarchic. A related criticism of markets is that they fail to pursue cultural ideals: The market may not reward fine art, classical music, or religion.

One strength of the market is that it promotes innovation. However, the market may fail to preserve cultural values and institutions. Occupations made obsolete by market forces represent ways of life that are no longer sustainable. Unique cultural identity may be replaced by homogeneous, anonymous market forces.

Market Imperfections

Economists have found a number of flaws in the market system. The most important are externalities and imperfect information. An externality is a cost or benefit that is not internalized by the market. Pollution is the classic example. The pollution caused by an automobile does not cost its owner anything but the total pollution caused by all automobiles is costly to society. Even though laissez-faire leads to too much pollution, economists still favor market-oriented approaches, including taxes on pollution and tradable pollution "permits." These solutions preserve the flexibility and efficiency of the market while forcing the market to internalize the cost of pollution. Consumers' lack of information provides a rationale for a number of government interventions in the market. For example, government meat inspection helps ensure the safety of meat and regulation of medicines helps protect consumers from harmful or ineffective drugs.

Modern Challenges for the Market System

The market system faces a number of challenges from modern technology. The increased importance of health care and education, the increased role of research and development, the issue of network externalities, and the increased importance of information goods all raise issues for the market.

As human capital increases in importance relative to material resources, health care and education are accounting for an increasing share of the economy. These sectors traditionally have been ones in which government involvement has been extensive.

Health care expenses can soar for the people least able to afford them. Someone who is sick often cannot work. The elderly, who are most likely to have illnesses, are on fixed incomes. Private health insurance may be prohibitively expensive for those with the highest likelihood of needing costly health care. All these issues provide a rationale for government provision of health-care coverage, at least for some segment of the population.
