Reader's Guide

The Reader's Guide is provided to assist readers in locating articles on related topics. It classifies articles into nine general topical categories: (1) Ethical Issues in Survey Research; (2) Measurement; (3) Nonresponse; (4) Operations; (5) Political and Election Polling; (6) Public Opinion; (7) Sampling, Coverage, and Weighting; (8) Survey Industry; and (9) Survey Statistics.

About the General Editor

Paul J. Lavrakas, Ph.D., is a research psychologist (Loyola University of Chicago; 1975, 1977) and currently is serving as a methodological research consultant for several public-sector and private-sector organizations. He served as vice president and chief methodologist for Nielsen Media Research from 2000 to 2007. Previously, he was a professor of journalism and communication studies at Northwestern University (1978–1996) and at Ohio State University (1996–2000). During his academic career he was the founding faculty director of the Northwestern University Survey Lab (1982–1996) and the OSU Center for Survey Research (1996–2000). Prior to that he was a fifth-grade teacher in the inner-city of Chicago (1968–1972) and helped established a social science evaluation research unit for Westinghouse in 1976–1977. Among his publications, he has written two editions of a widely read book on telephone survey methodology (1987, 1993) and served as the lead editor for three books on election polling, the news media, and democracy (1991, 1995, 1999), as well as co-authoring four editions of *The Voter's Guide to Election Polls* (1996, 2000, 2004, 2008). He served as guest editor for a special issue of *Public Opinion Quarterly* on "Cell Phone Numbers and Telephone Surveys" published in December, 2007, and chaired a task force for the American Association for Public Opinion Research (AAPOR) which issued a report in 2008 on this topic (www.aapor.org). Dr. Lavrakas was a co-recipient of the 2003 AAPOR Innovators Award for his work on the standardization of survey response rate calculations, was named a Fellow of the Midwestern Association for Public Opinion Research (MAPOR) in 1995, and was recognized in 2007 with an Outstanding Career Achievement Award by the New York Association for Public Opinion Research (NYAAPOR). He has been elected twice to the AAPOR Executive Council as Program Chair (1997–1999) and Counselor at Large (2008–2010). Dr. Lavrakas was born in Cambridge, Massachusetts, and was educated in the public schools of Birmingham, Michigan. His undergraduate degree is from Michigan State University. His wife of 40 years, Barbara J. Lavrakas, and he live in Connecticut; their son, Nikolas J. Lavrakas, is a resident of Perth, Australia.

Introduction

Survey research is a systematic set of methods used to gather information to generate knowledge and to help make decisions. By the second half of the 20th century, surveys were being used routinely by governments, businesses, academics, politicians, the news media, those in public health professions, and numerous other decision makers. It is not an exaggeration to state that accurate surveys have become a necessary condition for the efficient functioning of modern-day societies, and thus for our individual well-being.

Although there is a rich and expanding body of literature that has been produced mostly in the past half century about the myriad methods that are used by survey researchers, heretofore there has not been a compendium with information about each of those methods to which interested parties could turn, especially those new to the field of survey research. Thus, the purpose of the *Encyclopedia of Survey Research Methods* (*ESRM*) is to fill that gap by providing detailed (although not exhaustive) information about each of the many methods that survey methodologists and survey statisticians deploy in order to conduct reliable and valid surveys.

The Role of Methods and Statistics in the Field of Survey Research

A survey is often contrasted to a census, and the two use many of the same methods. However, whereas a census is intended to gather information about all members of a population of interest, a survey gathers information from only some of the population members, that is, from a sample of the population. Because a survey is more limited in how much information it gathers compared to a census with a comparable scope of variables needing to be measured, a survey is less costly than a census and often is more accurate and timelier. Due to its smaller scope, it is easy to understand why a survey is less costly and timelier than a census, but it may surprise some to learn that a survey can be more accurate than a census. That is the case because a census often is a daunting enterprise that cannot be conducted accurately across an entire population. At far less cost than a census, a survey can sample a representative subset of the population, gain a very high response rate, gather data on the same variables a census measures, and do so much more quickly than a census. Thus, given the finite resources available for information gathering, survey researchers often can allocate those resources much more effectively and achieve more accurate results than those conducting a census on the same topic.

There are two primary defining characteristics of a survey. One is that a sample is taken from the population and the other is that a systematic instrument—most often a structured questionnaire—is used to gather data from each sampled member of, or unit in, the population.

However, the general methods of "surveying" are used in many ways other than their well-recognized manifestations in survey research. At the broadest level, humans are always "sampling" the physical and social environments in which they live, "gathering" information in mostly unstructured ways, and "analyzing" the information to reach decisions, albeit often imperfectly. And although survey research is considered a quantitative approach for gathering information, "surveying" is routinely performed by qualitative researchers, even if many may not think of themselves as using survey methods. That is, qualitative research "samples" some members from a population of interest so as to gather information from or about them. This includes qualitative research that uses content analysis, focus groups, observational methods, ethnographic methods, and other quasi-scientific information-gathering approaches.

Whether the samples drawn for qualitative research are representative, and whether the information-gathering means are reliable, is not the primary issue here. Instead, the issue is that qualitative research relies on "survey methods" even if many who practice it have had no rigorous training in those methods. Also, there are many fields of inquiry in the behavioral sciences that utilize survey methods even if they do not recognize or acknowledge that is what is being done. For example, many psychologists draw samples and use questionnaires to gather data for their studies, even if they do not think of themselves as survey researchers or have not had rigorous training in survey methods. The same holds for many political scientists, economists, sociologists, criminologists, and other social scientists, as well as many public health researchers.

Accuracy Versus Error in Survey Research

The goal of a good survey is to utilize available resources so as to gather the most accurate information possible. No survey researcher should (or can) claim that a survey is entirely without error, that is, that it is perfectly accurate or valid. Instead, what survey researchers realistically can strive for is to gather as accurate information as possible with available resources—information that has the smallest amount of "total survey error." Ideally this will result in an amount of error that is "negligible," that is, ignorable, for the decision-making purposes that the survey is to serve. For example, the senior executives of a corporation do not need to know exactly what proportion of the population is likely to purchase their new product. Rather, they can make a confident decision about whether to proceed with introducing the product on the basis of survey estimates that are accurate within a tolerable (negligible) level of "error."

Broadly speaking, error in surveys takes two forms: variance and bias. Variance refers to all sources of imprecision that may affect survey data. Variance is a random form of error, which can be likened to "noise," and there are many approaches that can be used to reduce its size or to measure its size. Bias is a constant form of error and thus is directional: positive or negative. In some cases, bias leads to survey data that underestimate what is being measured, whereas in other cases, bias leads to overestimates. On occasion, different types of biases cancel out their own separate effects on survey estimates, but often it is very difficult for researchers to know when this has occurred. There are many methods that researchers can use to try to avoid bias, as well as many that can estimate the presence, size, and nature of bias. But all of these methods add costs to survey projects, and in many cases these added costs are great indeed.

In designing a survey, researchers should strive to allocate available resources so as to reduce the impact of likely errors, measure the size of the errors, or both, and then take that knowledge into account when drawing conclusions with the data generated by the survey. To accomplish this, researchers must be well aware of the various survey methods that can be used, and then they must select the ones that are most likely to achieve the most beneficial balance of both these goals. This requires survey researchers to constantly make trade-offs in choosing the "best" methods for their particular survey project. Allocating too many resources for one type of method will limit what can be allocated for other methods. If the first method addresses a source of error that is smaller in size than what will result from another source of error, then the allocation choice will have proven counterproductive in addressing total survey error concerns.

There are numerous types of possible errors that can occur with any survey, and it is the purpose of survey methods to address, and ideally avoid, all of these errors. It has been found useful to categorize these possible errors into a limited number of "types," which logically follow the chronology of planning, conducting, and analyzing a survey. The following sequence of questions summarizes this typology:

1. What is the population that must be studied, and how well will this population be "covered" (represented) by the frame (i.e., list) from which the sample will be drawn? This concerns coverage error.
2. How large will be the sample of frame members chosen for measurement, and what sampling design will be deployed to select these members? This concerns sampling error.
3. Among all the sampled members of the population, how will a high response rate be achieved, and will the nonresponders differ from responders in non-negligible ways on the variables of interest? This concerns nonresponse error.
4. What variables will be measured, and by what means will accurate data be gathered from the responding sample? This concerns specification

error, question-related measurement error, interviewer-related measurement error, respondent-related measurement error, and mode-related measurement error.

5. How will the data be processed, weighted, and analyzed? This concerns adjustment error and processing error.

Rationale for the *Encyclopedia of Survey Research Methods*

There is a considerable amount of existing literature on survey research and the methods that are used to conduct surveys. This exists in book form, in handbook chapters, in journal articles, in published conference proceedings, as well as an expanding body of otherwise unpublished works available via the Internet. The field is growing rapidly, both in the scope of what is known about survey methods and the importance this knowledge plays. However, to date, there has not existed a compendium to which interested parties, especially those without advanced knowledge of survey methods, can turn to learn about the great many topics that comprise the field of survey methodology.

The purpose of the *ESRM* is to fill that gap by being comprehensive in its coverage of the field, although not exhaustive in its explanation of any one topic. By providing more than 600 entries about important topics across the entirety of survey methodology, the encyclopedia serves as a "first place" to turn for those who need to learn about an aspect of survey methodology. The text of the entries in the encyclopedia will provide all the information that many users will need and desire. However, for those who want more information about a particular topic, the cross-referencing associated with nearly all of the entries provides these readers with guidance on where else to turn in the encyclopedia for additional information. And, for those who need still more information on a topic, essentially every entry provides a road map to additional readings.

Content and Organization of the Encyclopedia

The *ESRM* provides information about nearly all types of survey methods and survey errors. The more than 600 entries in the encyclopedia fall out across the following categories, which are listed in full detail in the Reader's Guide:

Ethics. These entries address a wide range of ethical matters that affect survey research, such as confidentiality, anonymity, debriefing, informed consent, voluntary participation, disclosure, and deception. Although addressing ethical issues complicates the methods that survey researchers must use and adds to the costs of surveys, it is critical that the survey research profession earn and maintain credibility and respect through observing strong ethical principles.

Measurement. The measurement entries focus on all nonoperational aspects of data collection, from conceptualization of the questionnaire through data collection and the effects that respondents have on data quality. This includes a wide range of entries covering question-related topics (such as closed-ended question, double-negatives, graphical language, mutually exclusive, question stem, and self-reported measure), interviewer-related topics (such as conversational interviewing, interviewer neutrality, nondirective probing, and standardized survey interviewing), respondent-related topics (such as acquiescence response bias, comprehension, telescoping, nondifferentiation, primacy effect, and satisficing), and mode-related topics.

Nonresponse. The entries on the topic of nonresponse are among the most important in the encyclopedia, as many scholars and practitioners regard nonresponse as the most daunting challenge facing survey research. This set of entries includes ones related to unit nonresponse, item nonresponse, and response outcomes and rates. These entries include incentives, leverage-saliency theory, completion rate, differential attrition, nonignorable nonresponse, missing data, refusal conversion, and tailoring.

Operations. These entries focus on a wide range of operational and technical topics related to the various modes of data collection, but predominantly surveys that are conducted in person (such as computer-assisted personal interviewing, control sheet, field work, and residence rules) and via the telephone (such as answering machine messages, calling rules, Federal Trade Commission (FTC) regulations, number portability, and predictive dialing). This grouping also includes operational entries related to surveys that gather data via interviewers (such as interviewer training, interviewer monitoring, and interviewer debriefing)

Political and Election Polling. This group includes survey methods that are specific to election-related and other types of political polling. These entries include measurement topics (such as approval ratings, convention bounce, leaning voters, and probable electorate), media-related topics (such as election night projections, horse race journalism, and precision journalism) and types of election or political surveys (such as deliberative polls, exit polls, pre-primary polls, and tracking polls).

Public Opinion. The entries in the public opinion grouping focus on a wide range of theoretical matters that affect the understanding of public opinion, with special attention to the methodological issues that are related to each theoretical concept. This set of entries includes agenda setting, knowledge gap, spiral of silence, third-person effect, and trust in government.

Sampling, Coverage, and Weighting. This group covers a large and broad set of entries, many of which are interrelated to sampling, coverage, and weighting, such as address-based sampling, cell phone sampling, coverage error, designated respondent, finite population, interpenetrated design, Neyman allocation, poststratification, quota sampling, replacement, sample size, undercoverage, and zero-number banks.

Survey Industry. The entries in the survey industry grouping include ones describing major survey professional organizations (such as AAPOR, CMOR, and CASRO), major academic-based survey organizations and government-based survey agencies (such as NORC, ISR, Bureau of Labor Statistics, and Statistics Canada), major figures in the history of survey research (such as Elmo Roper, Leslie Kish, Morris Hansen, and George Gallup), major U.S. government surveys (such as the Behavioral Risk Factor Surveillance System, the Current Population Survey, and the National Health Interview Survey), and major survey research periodicals (such as *Public Opinion Quarterly,* the *Journal of Official Statistics,* and the *International Journal of Public Opinion Research*).

Survey Statistics. The survey statistics grouping covers a diverse spectrum of statistical concepts and procedures that survey researchers use to help analyze and interpret the data that surveys generate. These include balanced repeated replication, control group, design-based estimation, hot-deck imputation, margin of error, outliers, perturbation methods, random assignment, sampling variance, test–retest reliability, and Type I error.

Despite the efforts of the editor, the members of the Editorial Board, and the many contributors who suggested new topics for inclusion, not every topic that someone interested in survey methods may seek knowledge about is included in this first edition of the *ESRM.* An encyclopedia such as this is bound to disappoint some who rightly believe that an important topic is missing. The editor and publisher can only hope that no key topic in the field is missing and that few other truly important topics are missing. When there is an opportunity for a second edition, those gaps can be corrected.

Readers will also find some degree of overlap in some of the topic areas. This is believed to be preferable because readers generally will be better helped by encountering too much information on a topic than too little. Similarly, some related topics have been written by contributors who are not fully in agreement with each other about the broader topic area. This too is viewed to be beneficial to readers, as it demonstrates where uncertainties and ambiguities in the field exist in the understanding and the valuing of a specific survey method.

How the Encyclopedia Was Created

A remarkably large number of people made this work possible by contributing to it in many different ways. This includes the editor, our Editorial Board members, editorial and administrative staff at both Sage Publications and The Nielsen Company, and the more than 320 individuals throughout the world who contributed the more than 640 entries that appear in these two volumes.

Due in part to my nearly 30 years of experience as a survey researcher, both as an academic and in the private sector, I was approached by Sage in late 2004 and invited to serve as editor of the encyclopedia. At that time I was employed as chief research methodologist for The Nielsen Company. Sage also asked if Nielsen might serve as "corporate sponsor" for the encyclopedia. I approached Nielsen's chief research officer and readily secured his support for my involvement and the company's endorsement of the venture.

Work on the encyclopedia followed a logical process, whereby (a) the list of entries was assembled; (b) contributors for each entry were identified; (c) individual entries were submitted to the Web-based Sage Reference Tracking (SRT) system; (d) draft contributions were reviewed, edited, and revised as needed; and (e) revised entries were finalized by members of the Editorial Board and me. Sage editors performed additional editing, passed the text along to Sage's production departments, and then I did the final review of the page proofs. Mistakes that remain are mine, and with such a daunting project to manage, there are bound to be at least a few. For these I apologize to the affected contributors and readers.

To build the list of entries, I started by reviewing a comprehensive glossary of methodological survey terms that was assembled for one of my previous publications. Some of these topics were kept and others dropped. Using my own knowledge and experience, I added to this draft list and found that I had approximately 400 topics. I grouped the entries on the list into the categories that were used to organize the Reader's Guide (see groupings described previously). For each of these categories I had chosen Editorial Board members with expertise in that subject area. I circulated the draft list of entries in each category to the Editorial Board member(s) assigned to that category and asked for their input of additional entry titles. This process raised the number of entries on the list to approximately 550. The Editorial Board members and I identified contributors to invite for the majority of these entries. Using Sage's versatile and comprehensive SRT system, email invitations were sent. The vast majority of first invitations were accepted. In some cases, coauthors were proposed by the first author. In many cases where the original invitee could not accept, he or she recommended someone else with expertise in the topic area and that person was invited.

For those entries for which I was unsure whom to invite, I posted a series of emails onto two listserves, inviting qualified contributors to volunteer for the unassigned entries: the American Association for Public Opinion Research listserve, AAPORnet, and the Survey Research Methods Section of the American Statistical Association listserve, SRMSnet. These postings were disseminated further by users of those listserves to their colleagues and to other listserves. This approach, which originally I had not anticipated doing, turned out to be a windfall for the *ESRM*, as it brought out a wide array of international experts in survey research who would not otherwise have had an opportunity to contribute due to my own limitations in heretofore not knowing them well or at all. I cannot thank enough the members of AAPOR and SRMS-ASA, as well the contributors not affiliated with either organization, for their generous efforts to benefit the *ESRM*.

A final source of additional entry titles came from contributors themselves. As they were writing their entries and reviewing the list of entries on the SRT, they would contact me with recommendations for new entries to be added. As these recommendations came in, the Editorial Board and I made a case-by-case decision about whether the suggestion fit the scope of the *ESRM*, and in most cases it did.

Acknowledgments

I would like to begin by thanking Sage Publications for believing that there should be an *Encyclopedia of Survey Research Methods* and that I was a good choice to serve as its editor. Here Lisa Cuevas Shaw, acquisitions editor at Sage, played a major role. I am indebted to Diana Axelsen, the developmental editor at Sage with whom I worked most closely during the final 2 years of the project, for her intelligence, guidance, encouragement, patience, and friendship. I also thank Letty Gutierrez, reference systems manager at Sage, for the numerous occasions that she "fixed" things in the SRT that I was not able to. At the copyediting and production stages, I am especially grateful to the conscientiousness, editing abilities, commitment, and flexibility of Tracy Buyan (production editor), Colleen Brennan (copy editor), and Pam Suwinsky (copy editor). There were many others at Sage who worked hard and intelligently to make this encyclopedia possible, but I am especially thankful to those who created, maintained, and updated the SRT, which provided the Web-based platform that managed almost all the invitations, submissions, reviews, and revisions.

I also am indebted to Jody Smarr, the administrative staff member at The Nielsen Company, who was assigned to work with me during the last 2 years of the project, including the last 13 months after I ended my employment with the company. Ms. Smarr's intelligence, organization, reliability, and calm demeanor will always be remembered and appreciated. I also thank Paul Donato, chief research officer at Nielsen, for committing that the company would be supportive

of the venture and for following through on that commitment without hesitation. As the largest and most-profitable survey research organization in the world, it is highly fitting that Nielsen has served as the "corporate sponsor" of the *ESRM*.

Each and every member of the Editorial Board was central to the success of the project, and I appreciate all that each of them did. They made suggestions of topics to be added to the entry list; they recommended contributors and, many times, encouraged these persons to accept their invitations; they reviewed entries; and they also wrote entries themselves. Michael Link, originally of the Centers for Disease Control and later of Nielsen, helped with the entries in the categories of Ethics and Operations. Linda Piekarski of Survey Sampling International helped with Operations. Edith de Leeuw of Methodika helped with Nonresponse. Dan Merkle of ABC News and Mike Traugott of University of Michigan helped with Election and Political Polling. Carroll Glynn of Ohio State University helped with Public Opinion. Mike Battaglia of Abt Associates, Inc., Trent Buskirk of St. Louis University, Elizabeth Stasny of Ohio State University, and Jeff Stec of CRA International helped with Sampling, Coverage, and Weighting and Survey Statistics. Allyson Holbrook of University of Illinois at Chicago and Peter Miller of Northwestern University helped with Measurement.

Sage and I are also indebted to each of the contributors. Without their expertise, commitment, and belief that the *ESRM* would be a valuable addition to the field of survey research, the project could not have come to fruition. Survey methodologists and survey statisticians are a generous lot. They routinely give of their own time to help the field. They share knowledge freely for the sake of science. They want to make the world a better place, in part through their abilities and interests to use surveys to generate reliable and valid knowledge. There is one researcher, J. Neil Russell, who exemplifies this ethos, who could not be listed formally as a contributor in the *ESRM* because of employment-related reasons but who nevertheless was a coauthor for some of the entries. It is this level of commitment to the field of survey research that all *ESRM* contributors and I are proud to strive for.

A

ABC NEWS/*WASHINGTON POST* POLL

ABC News and *The Washington Post* initiated their polling partnership on February 19, 1981, announcing an 18-month agreement to jointly produce news surveys on current issues and trends. More than 25 years, 475 surveys, and 500,000 individual interviews later, the partnership has proved an enduring one. Their first shared survey—known as the ABC/*Post* poll to viewers of ABC News, and the *Post*/ABC survey to readers of the *Post*—focused on newly elected President Ronald Reagan's tax- and budget-cutting plans. While their work over the years has covered attitudes on a broad range of social issues, ABC and the *Post* have focused their joint polling primarily on politics and elections.

The two organizations consult to develop survey subjects, oversee methodology and research, and write questionnaires; each independently analyzes and reports the resulting data. Sampling, field work, and tabulation for nearly all ABC/*Post* polls have been managed from the start by the former Chilton Research Services, subsequently acquired by the multi-national research firm Taylor Nelson Sofres.

In addition to full-length, multi-night surveys, ABC and the *Post* have shared other polls designed to meet news demands, including one-night surveys (e.g., immediately after the terrorist attacks of September 11, 2001); daily pre-election tracking polls, in which the *Post* joined ABC as of 2000; and a weekly consumer confidence survey, in which the *Post* in 2005 joined an ABC effort ongoing since 1985.

The *Post* has been polling on its own since 1975, ABC since 1979. Their partnership was created by Dick Wald, senior vice president of ABC News, and his friend Ben Bradlee, the *Post*'s editor. Wald pitched the idea at lunch. Bradlee said, "Okay. You have a deal," he recalled. "We just shook hands. There was no contract, no paper, no anything else."

Jeffrey Alderman was longtime director of the survey for ABC, replaced in 1998 by Gary Langer. Barry Sussman directed for the *Post*, replaced in 1987 by Richard Morin, who in turn was succeeded in 2006 by Jonathan Cohen, then ABC's assistant polling director.

The news organizations also conduct polls on their own and with other partners. In 2005, ABC won the first news Emmy Award to cite a public opinion poll, for its second national survey in Iraq, on which it partnered with the BBC, the German network ARD, and *USA Today*. ABC also won the 2006 Iowa/Gallup award and 2006 National Council on Public Polls award for its polling in Iraq and Afghanistan; the *Post* won the 2007 Iowa/Gallup award for its survey focusing on black men in America, a poll it conducted with the Henry J. Kaiser Family Foundation and Harvard University.

Their joint polling nonetheless has been the most consistent feature of both organizations' efforts to cover the beat of public opinion. A search of the Factiva news archive for the 20 years through mid-2007 found 11,266 media references to ABC/*Post* polls, far surpassing references to any of the other ongoing news-sponsored public opinion surveys.

ACCESS LINES

An access line is a telecommunications link or telephone line connecting the central office or local switching center of a telephone company to the end user. Access lines are sometimes referred to as local routing numbers (LRNs), wireline loops, or switched access lines, and they do not include telephone numbers used for wireless services. Access lines provide access to a residence or business over twisted-pair copper wire, coaxial cable, or optical fiber. The Federal Communications Commission reported that as of December 31, 2005, there were approximately 175.5 million switched access lines in the United States. Access lines are normally assigned in prefixes or 1000-blocks classified by Telcordia as POTS ("Plain Old Telephone Service"), and most frames used for generating telephone samples are restricted to POTS prefixes and 1000-blocks.

Approximately two thirds of all access lines connect to a residence, which suggests that two thirds of working numbers in a telephone sample should be residential. Many business access lines are in dedicated prefixes or banks and do not appear in a list-assisted random-digit dialing (RDD) telephone sample. However, since a single business will frequently have multiple access lines, such as rollover lines, direct inward dial lines, fax lines, and modem lines, those access lines that are not in dedicated banks will appear in an RDD sample, substantially increasing the number of ineligible units.

A household also may have more than one access line. Over the years some households added additional access lines for children or home businesses. The increased use of home computers and residential fax machines in the 1990s further increased the number of residences with two or more access lines. Because multiple lines meant multiple probabilities of selection for a household, telephone surveys have regularly included a series of questions designed to determine the number of access lines or telephone numbers in a household. Between 1988 and 2001, the percentage of households with one or more nonprimary lines grew from approximately 2% to 26%. Dedicated computer lines have caused problems for telephone survey researchers, since these lines typically ring but are never answered, resulting in unknown eligibility status. Consequently, survey questions designed to determine the number of access lines have had to be adjusted to determine the number of lines that would ever be answered. Since 2001, the number of residential access lines has been declining. Many households have given up second lines and moved from dial-up Internet service to broadband service. Other households have opted to substitute wireless service for wireline service for some or all of their access lines. Current estimates suggest that, in 2007, 13% of households had only wireless telephone service.

Although an access line usually connects to a business or a residence, it may also connect to a pay phone, fax machine, or modem. Access lines can be used to obtain directory assistance, connect to Internet service providers, and order special programming from a cable or satellite service provider. An access line may not always connect to a specific location or device. Call forwarding allows a telephone call to be redirected to a mobile telephone or other telephone number where the desired called party is located. An access line can also be ported to another access line. Local number portability is the ability of subscribers to keep their existing telephone numbers when changing from one service provider to another. Porting requires two 10-digit numbers or access lines for each telephone number that is switched. One is the original subscriber number and the other is the number associated with the switch belonging to the new carrier. Finally, nascent Voice over Internet Protocol (VoIP) technologies and "virtual" phone numbers allow an access line to connect to either a telephone or computer that may or may not be located at the physical address associated with that access line or switch.

ACQUIESCENCE RESPONSE BIAS

Acquiescence response bias is the tendency for survey respondents to agree with statements regardless of their content.

Acquiescence response bias could influence any question in which the response options involve confirming a statement, but it may be particularly problematic with agree–disagree questions. Although many guides on writing survey questions recommend avoiding agree–disagree questions, such questions are ubiquitous in survey instruments. An agree–disagree question asks respondents to report whether they agree or disagree with a statement. For example, respondents might be asked whether they agree or disagree with the statement, *It is important for the president to be a person of high moral character.* Acquiescence response bias is problematic because the interpretation of an "agree" response is very different if respondents are asked whether they agree or disagree with the posited statement than if they are asked whether they agree or disagree with the statement, "It is not important for the president to be a person of high moral character."

There are a number of explanations for acquiescence response bias. One explanation is that acquiescence response bias occurs partly due to social norms to be polite. Consistent with this, acquiescence response bias is stronger among cultures that put a high value on politeness and deference. Satisficing theory also provides an account for acquiescence response bias. Satisficing theory suggests that although survey researchers hope respondents will answer questions carefully and thoughtfully, respondents may not always be able or motivated to do so. Instead, they may shift their response strategies to minimize effort while providing a satisfactory response to the survey question (known as *satisficing*). One such strategy involves agreeing with assertions made by the interviewer. Satisficing theory also posits that satisficing is more likely when respondents' ability and motivation is low and when question difficulty is high. Thus, acquiescence response bias is likely to be strongest among respondents low in ability and motivation and for questions that are more difficult, a perspective that is supported by research studying acquiescence response bias.

There are also a number of strategies researchers use to avoid or control for acquiescence response bias. One such strategy is to include multiple items to measure a construct of interest, approximately half of which are worded so that the "agree" response indicates one position and the other half worded so that the "agree" response indicates the opposite position. For example, respondents might be asked whether they agree or disagree with the statement, "It is important for the president to be a person of high moral character," and then later asked whether they agree or disagree with the statement, "It is not important for the president to be a person of high moral character." If respondents exhibit acquiescence response bias and agree with both statements, their answers to these two questions cancel each other out.

There are at least three problems with this approach. First, it requires that survey researchers use a large number of redundant questions. This strategy is inefficient and it may be frustrating to respondents. Second, if researchers average responses across questions, this strategy results in "acquiescers" being given scores in the middle of the dimension, and it is not clear that this is appropriate or valid. Finally, as in the case discussed earlier, it sometimes results in respondents being asked whether they agree or disagree with a negative statement (e.g., "It is *not* important . . ."). This may be confusing to respondents, as disagreeing with this statement involves a double negative (respondents are reporting that they disagree that it is not important). This is a particular concern because not all languages treat double negatives in the same way, and agree–disagree questions about negative statements may therefore be particularly confusing for respondents for whom English is not their primary language or if questions are translated into other languages.

Another strategy for dealing with acquiescence response bias in agree–disagree questions involves rewriting all questions so that each question requires respondents to report directly about the dimension of interest. For example, the previous series of questions about the importance of the president's moral character could be rewritten to read, "How important do you believe it is for the president to have a strong moral character: extremely important, very important, somewhat important, a little important, or not at all important?" This strategy also allows researchers to follow experts' recommendations to avoid agree–disagree questions.

Adaptive Sampling

Adaptive sampling is a sampling technique that is implemented while a survey is being fielded—that is, the sampling design is modified in real time as data collection continues—based on what has been learned from previous sampling that has been completed. Its purpose is to improve the selection of elements during the remainder of the sampling, thereby improving the representativeness of the data that the entire sample yields.

Background

The purpose of sampling is to learn about one or more characteristics of a population of interest by investigating a subset, which is referred to as a *sample*, of that population. Typical population quantities of interest include the population mean, total, and proportion. For example, a population quantity of interest might be the total number of people living in New York City, their average income, and so on. From the sample collected, estimates of the population quantities of interest are obtained. The manner in which the sample is taken is called a *sampling design*, and for a sampling design various estimators exist. There is a multitude of sampling designs and associated estimators. Many factors may be considered in determining the sampling design and estimator used. The main objective is to use a sampling design and estimator that yield the most precise and accurate estimates utilizing the resources available. In conventional sampling designs and estimators, the sample is taken without regard to the unit values observed. That is, the observations obtained during sampling are not used in any manner to alter or improve upon future sample selections.

In adaptive sampling, on the other hand, the sampling selections depend on the observations obtained during the survey. In this sense, adaptive sampling designs are adaptive in that, while sampling, the remaining units to be sampled may change according to previously observed units. For design-based sampling, adaptive sampling could be a more efficient design to improve the inference and also increase the sampling yield. For model-based sampling, it has been shown that the optimal sampling strategy should be an adaptive one in general under a given population model.

Adaptive sampling designs have been used in various disciplines, including the ecological, epidemiological, environmental, geographical, and social sciences.

Adaptive Cluster Sampling

Adaptive cluster sampling (ACS) is a subclass of adaptive sampling designs. There has been considerable research within the field of adaptive sampling, utilizing ACS designs and their associated estimators. There are variations of ACS, such as stratified ACS, systematic ACS, ACS without replacement of clusters, and so on. The ACS designs are often more efficient than their conventional counterparts on clustered, or patched, populations. Typically this type of sampling design—ACS—is not only more efficient but also more useful for obtaining observations of interest for rare, hard-to-find, or elusive clustered populations. For example, there are various species of animals known to travel in groups and that are rare, such as whales. Through ACS, more whales may be captured in the sample than through conventional sampling techniques using a comparable final sample size of geographic locations. For surveys focused on elusive or hidden populations, such as individuals who are intravenous drug users, or HIV-positive individuals, ACS can aid greatly in increasing the number of individuals in the survey who meet the desired characteristics.

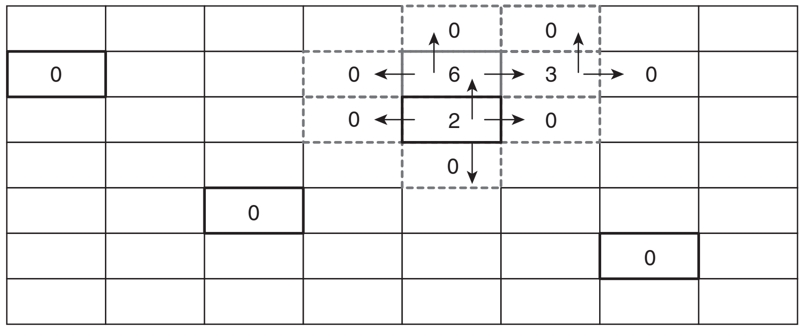

Figure 1 A final sample using ACS design with an initial simple random sample without replacement of size $n = 4$ from a population of size $N = 56$

Before a sampling commences, the condition to adaptively add units into the sample must be defined. Then an initial sample is drawn by some conventional sampling design. For example, for the original ACS, an initial sample is selected by simple random sampling with or without replacement. For stratified ACS, an initial sample is selected by stratified sampling; and for systematic ACS, an initial sample is selected by systematic sampling. With ACS, after the initial sample has been selected, units "in the neighborhood" of units in the sample that meet the predefined condition are added to the sample. If any of the adaptively added units meet the desired condition, then units in their neighborhood are added, and this process continues until no adaptively added units meet the predefined condition.

A neighborhood must be defined such that if unit i is in the neighborhood of unit j, then j is in the neighborhood of unit i. In addition to this restriction, a neighborhood can be defined in many ways, such as by spatial proximity, social relationship, and so on. All units within the neighborhood of one another that meet the predefined condition are called a *network*. Units that are in the neighborhood of units meeting the predefined condition but do not meet the predefined condition are called *edge units*. A network plus its associated edge units are called a *cluster;* thus the name *adaptive cluster sampling*. Only after the entire cluster has been observed is the size of a network containing units meeting the condition known. Often researchers do not desire to sample edge units, as they do not meet the predefined condition; unfortunately, which unit will be on the "edge" of a network remains unknown until after the unit has been observed. In addition, units not meeting the condition, including edge units, are networks of size 1. Figure 1 is an example of a final sample from an ACS, with an initial simple random sample without replacement taken from a forest partitioned into $N = 56$. The objective is to estimate the number of wolves in the forest. The condition to adaptively add neighboring units is finding one or more wolves in the unit sampled. The neighborhood is spatial and defined as north, south, east, and west. The initial sample is of size $n = 4$, represented by the dark bordered units. The units with a dotted border are adaptive added units. The adjacent units with the values 2, 6, 3 form a network of size 3. The units with a dotted border and a value of zero are edge units. The edge units plus the latter network of size 3 form a cluster. The edge units and the other units in the sample with a value of zero are networks of size 1.

In ACS, networks are selected with unequal probability. In typical unequal probability sampling, the probability of units included in the sample is determined before sampling begins. The typical estimators in ACS can be viewed as a weighted sum of networks, where the size of the network and whether the network was intersected in the initial sample is used to calculate the weights. Networks that are also edge units can enter into the final sample by being intersected in the initial sample or by being adaptively added, whereas other networks must be intersected in the initial sample. For the latter reason, the typical estimators do not incorporate edge units not intersected in the initial sample. Some estimators have been derived using the Rao-Blackwell theorem, which can incorporate edge units in the final sample but not in the initial sample.

For various reasons, when taking an ACS, it is often not feasible to sample the entire cluster; for example, because there are too many units to sample, cost-related issues, nonresponse, and so on. For this reason there has been research on estimation of the population quantities of interest in ACS when the entire cluster cannot be sampled, such as a restricted ACS design. A restricted ACS design is similar to a typical ACS design except that sampling stops after a predetermined number of units have been observed in the sample, regardless whether or not an entire network has been sampled. Biased and unbiased estimators have been derived for a restricted ACS design.

Adaptive Web Sampling

Recent research within adaptive sampling is the development of a new class of adaptive sampling designs called adaptive web sampling (AWS). The class of AWS designs is useful for sampling in network and spatial settings. A major distinction between ACS and AWS is that in ACS, units in the neighborhood of a sampled unit meeting a predefined condition are to be automatically adaptively added, whereas in AWS this is not so. In AWS it is possible to assign a probability to adding units adaptively in the neighborhood of units meeting a predefined condition. In the latter sense, AWS may be viewed as more flexible than ACS.

Add-a-Digit Sampling

Add-a-digit sampling is a method of creating a sample of telephone numbers to reach the general public within some geopolitical area of interest. This method is related to directory sampling in that the first step involves drawing a random sample of residential directory-listed telephone numbers from a telephone directory that covers the geographic area of interest. In add-a-digit sampling, the selected directory-listed telephone numbers are not called. Rather, they form the seeds for the list of numbers that will be called. For each directory-listed telephone number drawn from the telephone directory, the last digit of the telephone number is modified by adding one to the last digit. The resulting number is treated as one of the telephone numbers to be sampled. This is the simplest form of add-a-digit sampling. When it was originally devised in the 1970s, it was an important advancement over directory-listed sampling in that the resulting sample of telephone numbers included not only listed numbers but also some numbers that were unlisted residential telephone numbers.

Another practice is to take a seed number and generate several sample telephone numbers by adding 1, 2, 3, 4, 5, and so on to the last digit of the telephone number. However, in the application of this technique, it was found that the higher the value of the digit added to the last digit of the seed telephone number, the less likely the resulting telephone number would be a residential number. Still another method involves drawing the seed telephone numbers and replacing the last two digits with a two-digit random number.

Add-a-digit sampling originated as a method for including residential telephone numbers that are not listed in the telephone directory in the sample. These unlisted numbers are given a zero probability of selection in a directory-listed sample. In add-a-digit sampling, some unlisted telephone numbers will be included in the sample, but it is generally not possible to establish that all unlisted residential telephone numbers have a nonzero probability of selection. Moreover, it is difficult to determine the selection probability of each telephone number in the population, because the listed and unlisted telephone numbers may exhibit different distributions in the population of telephone numbers. For example, one might encounter 500 consecutive telephone numbers that are all unlisted numbers. Because of these and other limitations, add-a-digit sampling is rarely used today. It has been replaced by list-assisted random-digit dialing.

ADDRESS-BASED SAMPLING

Address-based sampling (ABS) involves the selection of a random sample of addresses from a frame listing of residential addresses. The technique was developed in response to concerns about random-digit dialed (RDD) telephone surveys conducted in the United States because of declining landline frame coverage brought on by an increase in cell phone only households and diminishing geographic specificity as a result of telephone number portability. The development and maintenance of large, computerized address databases can provide researchers with a relatively inexpensive alternative to RDD for drawing household samples. In the United States, address files made available by the U.S. Postal Service (USPS) contain all delivery addresses serviced by the USPS, with the exception of general delivery. Each delivery point is a separate record that conforms to all USPS addressing standards, making the files easy to work with for sampling purposes.

Initial evaluations of the USPS address frame focused on using the information to reduce the costs associated with enumeration of primarily urban households in area probability surveys or in replacing traditional counting and listing methods altogether. These studies showed that for a survey of the general population, the USPS address frame offers coverage of approximately 97% of U.S. households. The frame's standardized format also facilitates geocoding of addresses and linkage to other external data sources, such as the U.S. Census Zip Code Tabulation Areas data. These data can be used to stratify the frame for sampling target populations.

Use of ABS in conjunction with the USPS address frame does have some drawbacks. Researchers cannot obtain the address frame directly from the USPS but must purchase the information through private list vendors. The quality and completeness of the address information obtained from these vendors can vary significantly based on (a) how frequently the company updates the listings, (b) the degree to which the listings are augmented with information from other available databases, and (c) if the company purges records based on requests from householders not to release their information. Moreover, vendors differ in their experience with and ability to draw probability samples from the USPS list. This can be problematic for researchers who do not wish to draw their own samples and tend to rely upon vendor expertise for this task.

Another drawback is that coverage in rural areas tends to be somewhat lower than in urban areas. Additionally, in some rural areas, the USPS files contain simplified (i.e., city, state, and zip code only) listings rather than full street addresses. The percentage of these types of addresses in the database is declining, however, as local governments adopt emergency 911 protocols, which require that all households be identified with a street address. Therefore, over time, simplified address designations are expected to be replaced by full street address information. Another potential issue is that the USPS address frame contains post office (P.O.) boxes and multi-drop addresses (i.e., multiple persons associated with the same address), which may be problematic for both in-person and telephone surveys in which a street address is required to locate the household or to identify a telephone number associated with the household. Such addresses may be less problematic for mail surveys, where the initial goal is to ensure that the mailed questionnaire is delivered to the sampled household.

Households with multiple mailing addresses (e.g., a street address and a residential P.O. box) may also induce selection multiplicities. Research suggests that in some localities a fairly large percentage of households with residential P.O. boxes may also have mail delivered to a street address. Inclusion of P.O. boxes may be necessary, however, to ensure coverage of all households.

Some of the first tests of ABS as an alternative to RDD for general population surveys were conducted by the Centers for Disease Control and Prevention for use on the Behavioral Risk Factor Surveillance System (BRFSS), a large RDD health survey. Two rounds of testing during 2005 and 2006 were conducted with households sampled from the USPS address frame, first using mail surveys, then later utilizing mail surveys with telephone survey follow-up of nonrespondents (a mixed-mode approach). In both instances, the mail survey and mixed-mode approaches produced significantly higher response rates than those obtained in the RDD surveys in states where the RDD response rate was below 40%. The ABS approach also provided access to households with only cell phones, and to a smaller degree, to households with no telephone coverage in percentages that corresponded with other national estimates for the proportional size of these groups. Moreover, the mail survey cost less to conduct than the RDD survey; the mixed-mode approach was cost neutral.

While ABS appears to be an effective sampling frame for conducting mail surveys of the general population, its true potential may be in facilitating mixed-mode surveys. Cross-referencing USPS addresses with other public databases yields telephone numbers for half to two thirds of the addresses. Moreover, ABS may facilitate use of other more cost-effective data collection modes, such as Internet or Web surveys or interactive voice response (IVR). Households could be sampled through ABS, then provided a link to a Web site, given the telephone number for an IVR survey, mailed a hard-copy questionnaire, or any combination of these approaches. Resources permitting, face-to-face surveys could also be added to this mix, particularly since use of the USPS address frame was initially tested as a means of identifying households for such surveys. ABS has the potential, therefore, to serve as a sampling base for a wide variety of single or multi-mode survey designs.

Advance Contact

Advance contact is any communication to a sampled respondent prior to requesting cooperation and/or presenting the respondent with the actual survey task in order to raise the likelihood (i.e., increase the response propensity) of the potential respondent cooperating with the survey. As explained by Leverage-Saliency Theory, a respondent's decision to participate in research is influenced by several factors, including his or her knowledge of and interest in the survey research topic and/or the survey's sponsor. A researcher can improve the likelihood of a respondent agreeing to participate through efforts to better inform the respondent about the research topic and sponsor through the use of advance contact. Factors in considering the use of advance contacts are (a) the goals of the advance contact and (b) the mode of contact.

The goals of advance contact should be to educate and motivate the respondent to the survey topic and the sponsor in order to improve the likelihood of cooperation with the survey task. The cost and additional effort of advance contact should be balanced against the cost effects of reducing the need for refusal conversion and lessening nonresponse. The first goal of educating respondents is to help them better understand or identify with the topic and/or the sponsor of the research through increasing awareness and positive attitudes toward both. Respondents are more likely to participate when they identify with the research topic or sponsor. Additionally, it is an opportunity to inform the respondent of survey dates, modes of survey participation (e.g., "Watch your U.S. mail for our questionnaire that will be arriving in a first-class [*color and size description of mailer*] around [*anticipated arrival date*]"), and contact information to answer questions or concerns (e.g., "Feel free to contact us toll-free at [*contact number*] or via the Web at [*Web site address*]"). The second goal is to motivate the respondent to participate in the research. This can be done through persuasive messages and appeals to the respondent, such as "Please participate so that your views are represented and represent your community," "This research will help direct money to health care programs in your area," and "This is your chance to make a difference," and so on. Additionally, advance contact is an opportunity to offer or mention incentives (if offered) that the respondent will receive. Research has shown significant improvements in response rate by combining noncontingent cash incentives with advance contact, though the researcher must balance this with research cost and impact to sample representation.

Once the goals of the advance contact have been established, the mode(s) of contact should be selected. The research may select from one or a combination of direct (mail, phone, and email) and indirect (paid advertising, community partnerships, and promotions or special events) modes of advance contact.

A direct mode of advance contact can be via mail or email. A mailed letter or postcard or email (if such an address is available, e.g., when sampling from a membership list) can be used prior to the actual questionnaire being sent or administered to the respondent. Advance mailing can also be a series of contacts that take the form of promotional brochures or flyers that highlight different aspects of the research and/or sponsor. An example used by Nielsen Media Research is the use of mailed brochures highlighting the measurement of the size of the audience for "great moments in television history" (e.g., the first appearance of the Beatles on *The Ed Sullivan Show*) prior to a request to participate in a television viewing survey. Although not used often, a "warm-up" telephone contact (including leaving answering machine messages) also can be used for advance contact.

An indirect mode of advance contact takes the approach of a marketing or public awareness campaign using various forms of communication, including paid advertising in the mass media, community partnerships, and promotions and special community events. Paid (or donated) advertising media can take the form of location-specific media (e.g., billboards, bus or train shelters and benches, flyers) and print and electronic mass media (Internet, magazine, newspaper, radio, and television) such as a public service announcement. Researchers can utilize community partnerships with neighborhood associations or clubs, churches, synagogues, schools, and so on and use a word-of-mouth campaign to spread awareness of research and gain the sponsorship or approval of community leaders. Finally, advance contact can take the form of promotions and special events, such as a booth at a community fair or festival.

ADVANCE LETTER

Advance letters (sometimes referred to as "prenotification" letters) are a means of providing potential respondents with positive and timely notice of an impending survey request. The letters often address issues related to the purpose, topic, and sponsor of the survey and a confidentiality promise. In some surveys, advance letters include a token cash incentive. Letters should be sent by first-class mail and timed to arrive only days to a week ahead of the actual survey contact. They also may be accompanied by other informational materials, such as study-related pamphlets, which are typically designed to address questions about survey participation frequently asked by respondents and, in the case of ongoing or longitudinal surveys, provide highlighted results from previous administrations of the survey.

Long used in survey research efforts, advance letters require only that a mailable address be associated with the sampled unit, regardless of whether that unit is a dwelling, telephone number, or name on a listing. Advance letters are used in conjunction with nearly all survey modes, including face-to-face, telephone, mail, and some Web-based surveys. For example, with random-digit dialed (RDD) telephone surveys, sampled telephone numbers are often cross-referenced with electronic telephone directories and other commercially available databases to identify addresses. In a typical RDD sample, addresses can usually be identified for 50–60% of the eligible telephone numbers. Unfortunately, advance letters cannot be used with survey designs when an identifiable address cannot be determined, such as when respondents in the United States are sampled from a frame of cellular telephone numbers or email addresses. Typically, such frames do not include mailable address information.

In terms of content, most of the research literature and best practice recommendations suggest that an advance letter be brief, straightforward, simple, and honest, providing general information about the survey topic without too much detail, especially if the topic is sensitive. The letter should build anticipation rather than provide details or conditions for participation in the survey. Highlighting government sponsorship (e.g., state), emphasizing confidentiality of the data, expressing advance appreciation, and supplying a toll-free telephone number are typically seen as desirable features. Advance letters can also be used to adjust a variety of other influences known to affect survey participation, including use of official stationery of the sponsoring organization to convey legitimacy; having the letter signed by a person in authority; personalizing the name (when available) and address of the sample household and salutation of the letter to convey the importance of the survey; and providing basic information about the nature of the survey questionnaire to educate the household with regard to the task being requested. Additionally, by alerting a household in advance to an upcoming survey request, the letter can be consistent with the norms of politeness that most unannounced contacts from "salespersons" (or even criminals or scam artists) often violate. Furthermore, advance letters can have a positive effect on the interviewers conducting surveys, enhancing their own confidence in seeking a household's participation in a survey.

Postcards are sometimes used in place of actual letters and are considerably less expensive to produce. They also appear, however, less formal and "official" than a letter might; they are more difficult to personalize; they can include less information about the survey than might be included in a letter; and no incentive can be sent with them (nor should one even be mentioned).

Some researchers have argued that it takes only a few seconds to look at a postcard, flip it over, and lay it aside—too short a time for the information to register in the respondent's long-term memory. In addition to being able to enhance a letter over a postcard with more visual and trust-inducing elements, a letter's envelope has to be opened, the letter extracted, reviewed, and then posted, stored, or disposed of, thus increasing the likelihood of the householder's registering it in long-term memory.

Effectiveness and Cost

The effectiveness of advance letters varies with such factors as the length of the letter, the organization on the letterhead, the time lag between mailing and survey contact, and the person to whom the letter is addressed. Particularly germane to the last point, studies indicate that, in about half of households, all the mail is sorted by a single individual, and that 60% discard some mail without opening it, but that this rarely happens to letters addressed to specific household members. Advance letters tend, therefore, to be less effective if their length dissuades people from reading them, if they are not opened and read, if they are read too long prior to contact to recall, and if their sponsorship discounts the value of what is read.

Advance letters can also be accompanied by an incentive (monetary or nonmonetary) to further encourage survey participation. Prepaid cash incentives tend to have the greatest impact on survey participation. Letters can be used, however, to offer a promised incentive, that is, one that is to be provided after completion of a specified task, such as completing an interview. If a noncontingent (pre-paid) incentive is sent in the advance letter, its value should be less than the value of any incentive that is used later in the survey. Past research shows that even $1 or $2 sent in an advance letter will markedly increase the cooperation rate when actual survey contact is made.

The promise of advance letters is that they can increase survey participation, conversely reducing the potential size of nonresponse-related total survey error. For instance, when used in conjunction with RDD telephone surveys, advance letters often have been found to increase response rates by at least 5 percentage points and some times by twice that much. Advance letters can, however, have a heterogeneous impact on subgroups, disproportionately raising participation rates among some groups but not others. This is a problem with many of the techniques developed to reduce nonresponse, particularly those that focus on or are applicable only with a subset of sample members. For instance, in the case of RDD surveys, advance letters can only be used with the subset of respondents for whom an address can be identified; these are disproportionately those respondents who are more likely than average to cooperate in the first place. Likewise, studies have shown that some subgroups are less likely to remember seeing an advance letter sent to their home, in particular, racial minorities, those ages 18 to 34, and those in households with three or more adults. Because survey bias is a function of both the level of nonresponse and the differences between respondents and nonrespondents on measures of importance to the particular survey, improving response rates alone is not enough to guarantee improvement in data quality. Case in point: if efforts to improve participation levels actually exacerbate the distinctions between those who tend to participate in a survey and those who do not, the gains in data quality from reducing nonresponse could actually be offset (or worse, overtaken) by a widening gap between participants and nonparticipants. Researchers should focus, therefore, on reducing overall nonresponse error rather than on simply raising response rates.

In terms of costs, advance letters have been shown in some instances to "pay for themselves." Some studies have shown that the differential cost of obtaining a fixed number of completed interviews from address-matched samples was more than twice as high when advance letters were *not* used, compared to when they were used. In an era of declining survey participation, the fact that this nonresponse-reducing technique often is cost neutral (or nearly so) is welcomed by researchers who are increasingly under pressure to minimize survey costs.

A final consideration: it is impossible to state with certainty that this technique would be effective in reducing nonresponse error in all survey contexts. Researchers are encouraged, therefore, to evaluate the use of advance letters thoroughly within their particular research context to determine whether the gains from the reduction of nonresponse error outweigh the costs or potential for survey bias.

Agenda Setting

Agenda setting refers to the media effects processes that lead to what are perceived as the most important problems and issues facing a society. It is an important component of public opinion, and thus measuring it accurately is important to public policy deliberation and formation and to public opinion research.

The power to set the public agenda—determining the most important problems for discussion and action—is an essential part of any democratic system. This is so because agenda control is a fundamental lever of power and it is necessary to achieve citizen desires. If democracy is to be a meaningful concept, it must include the right of citizens to have their preferred agenda of topics taken up by policymakers. Leaders who ignore the topics that citizens consider important are not representing the people adequately.

Concepts

Popularized in the mass communication and public opinion literature, agenda setting has for many years been nearly synonymous with studying public issues in a public opinion context. In the study of public opinion, *agenda setting* refers to a type of media effect that occurs when the priorities of the media come to be the priorities of the public. Broadly speaking, the agenda-setting process has three parts:

1. *Public agenda setting* examines the link between issues portrayed in the mass media and the issue priorities of the public.
2. *Policy agenda setting* studies are those examining the activities of public officials or legislatures, and sometimes the link between them and media content.
3. *Media agenda setting* examines the antecedents of media content that relate to issue definition, selection, and emphasis. This can typically include the individual and organizational factors that influence decision making in newsrooms and media organizations generally.

Agenda setting deals fundamentally with the importance or salience of public issues as measured in the popular public opinion polls. Issues are defined similarly to what the polls measure—the economy, trust in government, the environment, and so on—and this ensures comparability to the polling data. The innovation of conceptualizing all the complexity and controversy of a public issue in an abstract manner makes it possible to study issues over long periods of time. But it also tends to produce studies that are quite removed from the very things that made the issues controversial and interesting. Removing details also removes most conflict from the issue. What is left is really just the topic or shell of the issue, with very little content.

Most of the early agenda-setting research focused on the correspondence of aggregate media data and aggregated public opinion data. The rank-order correlations among the two sets of agendas measured the agenda-setting effect. This trend continues to the present day. While it is important to try to understand the connections between media and social priorities, agenda-setting research as it is presently constituted does not do a very good job of explaining how social priorities are really determined. This is so because most agenda-setting research focuses on media as the prime mover in the process and not on the factors that influence the production of media content. Real-world cues are for the most part absent from most agenda-setting studies. Fortunately, new techniques in the analysis of survey data can help revitalize this research tradition. For example, it is becoming easier now to add the respondent's geographical location to survey data. Once one knows the respondent's location, it is possible to append a variety of corresponding contextual or community-level data such as local unemployment rates, taxation levels, housing prices, neighborhood crime rates, and so on. Such contextual data analyzed along with public opinion data using multi-level modeling can help make agenda-setting studies more realistic and inclusive of real-world variables that affect public opinion. Local information about media markets and newspaper circulation areas can also be used in the same way. The key point is that it is important in analysis of agenda-setting effects to make certain that media attention to the problem—and not background conditions—is the real cause.

Background

A famous case study of agenda setting that was developed by Christopher Bosso illustrates this concern with identifying the correct independent and control variables in agenda-setting research. In the case of the Ethiopian famine in 1984, the problem had been at a severe level for some time. Some BBC journalists traveling in Africa filmed sympathetic reports of starving Ethiopians and interested a major American television network in them because of the personal interest of one news anchor. American television news aired the British footage and attracted tremendous interest and more coverage by the other networks and eventually the world. The Ethiopian famine became the subject of worldwide headlines and media attention, from which followed a number of very high-profile food relief efforts and other innovations in fundraising in a global attempt to solve the problem. Of course, the problem had existed long before the media spotlight focused on the problem and continued long after the media tired of the story and moved on. While the audience might conclude that the problem was solved, it was not. But the abrupt spike of interest, as measured by public opinion polls, and subsequent decline and its lack of correlation with the real-world conditions is a classic example of media agenda setting as a unique force, operating by its own logic and according to its own principles. In this case, media acted as a giant searchlight, highlighting an issue for a while, creating considerable interest, and then growing bored of the story and moving on to new problems. The attention of the public often follows. In this case, real-world conditions were not sufficient to explain the public agenda. In fact, the problem is incomprehensible without understanding the media processes.

Political scientist Anthony Downs described this process as the "issue-attention cycle." This model describes a series of stages that certain kinds of long-term chronic problems may go through. The process begins with a pre-problem stage in which the issue exists and experts are aware of it but it has not had much media attention. In stage 2, there is an "alarmed discovery" of the problem accompanied by intense optimism about solving the problem once and for all. This optimism cools considerably by stage 3, in which the true dimensions and costs of the problem become well understood by the public, particularly the nature of the trade-offs and sacrifices that would be required. As Downs explained, a majority of people are likely benefiting from existing conditions and may feel threatened by the kind of fundamental changes that might be needed to overcome many long-standing issues. In the fourth stage there is a general decline of public interest in the problem, accompanied by feelings of discouragement, fear, or boredom. The issue finally settles into a kind of permanent post-problem fifth stage, in which public interest stabilizes at a level well below the peak interest period but higher than it was at the beginning of the cycle. According to Downs's account of the process, sometimes issues stabilize at a level higher than the previous pre-problem stage, but they typically do not regain center stage again for any prolonged period of time.

Not all types of issues are suitable for the cycle of attention described by Downs. Issues likely to receive this type of treatment are those that do not affect the majority of people. The problem is typically caused by power or status arrangements that provide benefits to the majority of people. The final characteristic is that the problem has little or no inherently exciting qualities. In other words, many common social problems such as poverty, racism, transportation, crime, addiction, and unemployment are candidates for this treatment.

As late as the 1980s, the agenda-setting model in mass communication largely meant empirical generalizations based on survey data and content analysis and a set of process variables that included "need for orientation," time lags, topic interest, and media exposure. In the late 1980s, an innovative research program by political psychologists Shanto Iyengar and Donald Kinder used cognitive concepts to reinvent the agenda-setting model, primarily relying mainly on careful experimental methods, although some of their evidence also involved survey data. This work put the agenda-setting model on a firm theoretical footing grounded in social cognitive theory. This led the way to substantial innovation in process terms, as well as work on media priming and media framing, emphasizing different aspects of public issues and the ways they are discussed in public discourse and understood by the public.

In recent years, Maxwell McCombs and his students have continued to develop the agenda-setting model, primarily through efforts to extend the original conceptualization and methods to what they call "second-level agenda setting" or sometimes "attribute agenda setting." This extension of the McCombs agenda-setting tradition attempts to fold the work of media priming and elements of issue framing into his original version of agenda setting. Theoretical benefits of such a project are unclear.

A final consideration is the impact of new media and personalized systems of communication on the future of agenda setting. This is an important consideration, because agenda setting dates from the mass communication era. One distinctive feature of the mass communication system during the past decade has been the proliferation of channels through which news flows and that audiences use to become informed. The rich variety of outlets, including multiple channels of cable and satellite television, newspapers, and online sources, makes studying the news agenda no longer the simple process that it used to be. In his original 1972 study, McCombs could analyze the newspaper reports in one city and represent the media agenda to which that community had been exposed. This is impossible today, given the wide range of available communication outlets. In addition to increased diversity of channels of communication, a person's media use can be readily customized to an unprecedented degree.

Looking Forward

Studying agenda setting in the new information environment where "Search Is Everything" will be increasingly challenging. One way to address this issue is to focus more research attention on the political economy of search engines that are delivering news to many people and the agenda-setting power of their methods to determine who sees what news. Search engines operate via proprietary algorithms that they apply to the portion of the Internet that they are able to map and index. When a user enters a topic into a search engine, the search engine returns a prioritized list—an agenda—of results. Unfortunately, how this agenda is set is anything but transparent. In fact, search results vary, sometimes dramatically, from search engine to search engine based on the nature of the formulae used to find the results and prioritize them. Most search engines collect fees from clients who want their search terms to appear higher on the prioritized order of results. Some disclose that a given site's result is a "sponsored link," but this is not a universal practice. In other words, commercial interests often buy the answer to a given search. Search results can also be influenced without anyone making a payment directly to a search engine. Results are "gamed" by firms known as *optimizers*, which collect fees in exchange for figuring out ways to move certain results higher on the list. They do this through painstaking attempts to learn key elements of the algorithms used to determine the agenda order and then making sure their clients' sites meet these criteria.

In an information environment that increasingly depends on search technology, the political economy of search is an understudied but key component of what the public knows and thinks is important: the public agenda. In today's fracturing media environment, consumers and citizens rely increasingly on standing orders for customized information that meets certain specifications. How that information is searched and delivered will be an increasingly significant issue for political and commercial interests as well as public opinion researchers seeking to understand the public's priorities. A challenge to survey researchers will be to understand this process and use it to design studies that incorporate an up-to-date understanding of the media system. This can help assure the relevance of the agenda-setting model for years to come.

Aided Recall

Aided recall is a question-asking strategy in which survey respondents are provided with a number of cues to facilitate their memory of particular responses that are of relevance to the purpose of the study. Typically such cues involve asking respondents separate questions that amount to a list of subcategories of some larger phenomenon. The purpose of listing each category and asking about it separately is to assist the respondent by providing cues that will facilitate memory regarding that particular category.

Applications

This question technique is most appropriate when the researcher is most concerned about completeness and accuracy and more worried about underreporting answers than in overreporting. Aided recall question strategies structure the range of possible answers completely and simplify the task for the respondent. They also simplify the investigator's work in gathering and analyzing the data, since no recording or coding of open-ended protocols is required, according to Seymour Sudman and Norman Bradburn in their classic volume, *Asking Questions.*

While it might seem most natural to ask respondents to self-nominate events to be recalled or criteria that they will use in decision making, they may easily forget or overlook relevant answers. This can occur for many reasons. The respondent might not take the time to think the answer through carefully and completely. The respondent might think that certain potential aspects of his or her answer are not relevant or appropriate and so are omitted. Respondents might not want to take the time needed to respond to the questions or could be hurried along by an interviewer. Difficult or time-consuming tasks might encourage respondents to satisfice—that is, to report what comes to mind as the first acceptable answer or use other mental shortcuts—rather than optimizing their answers by making them as complete and thoughtful as possible. When forgetting seems particularly likely, aided recall questions should be used, as recommended by Sudman and Bradburn.

Aided recall questions are common in the survey literature. An example will help to clarify the strategy, as will a contrast to *unaided* recall. To ask respondents about where they typically obtain public affairs information, one might simply ask a broad, open-ended question and attempt to code the responses until the respondent had been thoroughly probed and had nothing else to say. This would be an example of unaided recall. The respondent would be given no clues to limit or steer the scope of the inquiry and would have to conduct a thorough information search of his or her own memory to think of possible answers as well as to screen them in terms of appropriateness. If the respondent answered by mentioning radio, television, and newspapers, the interviewer might probe further by asking if there were any other sources. Uncertain of how detailed to make the answer, at that time the respondent might mention magazines. The person might not have thought that online sources of information were appropriate or may simply not think of them at the time. Another possibility is that an additional interviewer probe might have elicited online sources.

A variation on this general topic domain using an aided recall strategy might ask about what sources the respondent used for public affairs information in the past week and then might proceed to list a number of such sources. By listing each source explicitly and asking whether or not the respondent used it, the survey designer is enhancing completeness and prompting the respondent to think of the meaning of the topic in the same way. In this way there is less opportunity for the respondent to overlook possible categories, but he or she may feel under more pressure to agree to more categories for fear of appearing uninformed. Sources that might be mentioned in the answer include daily and weekly newspapers, news magazines, local and national on-air television, cable-only television networks such as CNN, CNBC, and FOX, and the various channels of C-SPAN. They might also include various popular online sources of news such as Yahoo.com, MSN.com, Google News, and *The New York Times* Web site, as well as interpersonal channels of communication such as friends, coworkers, and family members. In addition to all of these clearly specified information channels, one should also probe for other responses not listed.

Simpler variations on aided recall include listing some examples of the kind of general responses that are anticipated or showing respondents a card containing a list of possible responses and asking them to indicate which ones apply to their situation. This information ensures that respondents do not forget to consider items of particular importance to the purposes of the question. To ensure the meaningfulness of such questions, the list of items from which respondents choose must be complete. Such completeness can be guided by theoretical concerns and literature and verified by pretesting. Such questions can only be as valid as the completeness of the list. The order in which items on the list are presented to the respondents also is an important issue; ideally this should be varied systematically or randomly across respondents. Very long lists should be avoided, as they can make respondents feel that they need to respond positively to at least some of the items. Sudman and Bradburn suggest that when lists become long, questionnaire designers should consider a system of screening questions.

In general, the aided recall question strategy will yield higher estimates of what is measured compared to unaided recall items. However, the list tends to convey to the respondent at least implicit expectations for positive responses to something on the list. While aided recall questions are helpful when underreporting is likely to be an issue, they can lead to overreporting. They are thus inappropriate in situations in which overreporting is likely to be a problem, or at least they need to be used with other tools that will help limit overreporting, such as screening questions. Roger Tourangeau, Lance Rips, and Ken Rasinski's book, *The Psychology of the Survey Response*, provides extensive relevant discussions of the theoretical issues related to these problems of memory and the survey response.

Aided Recognition

Within the context of survey research, aided recognition is a form of aided recall in which a survey respondent is asked if she or he was aware of something prior to being asked about it in the survey questionnaire. The stimulus that the respondent is asked about typically is the name of a company or of a product or service. In some cases, other than in telephone surveys, a picture can be shown as the stimulus. In telephone, Internet, and in-person surveys, audio can serve as the stimulus for the respondent.

The common form for measuring aided recognition is to use a closed-ended survey question along the following lines:

> Before today, have you ever heard of _____?

The respondent is asked to simply answer "Yes" or "No." Sometimes a respondent is uncertain and says so to the interviewer. Thus the questionnaire can be precoded with an "Uncertain/Maybe/etc." response that is not read to the respondent but that an interviewer can code if the respondent volunteers such.

Aided recognition is often used in branding studies as a measure of people's awareness of a company brand. Typically this is done by mixing the name of the brand that is the primary focus of the survey with the names of competitors in series of separate items. In this way, the survey can show how recognition levels compare across brands. It often is prudent to include at least one "bogus" brand name in the list of brands asked about to measure the baseline level of "Yes" saying among respondents, which is a form of acquiescence response bias. If a series of aided recognition items is asked, it also is prudent to use either a random start or a random order in presenting the items in the series to different respondents.

Aided recognition questions must be asked *after* any unaided recall questions are asked on the same topic; otherwise the aided recognition questions will bias answers to the unaided recall questions. Subsequent to the positioning of unaided recall and aided recognition questions within a questionnaire, branding studies often include image questions about the brand to get more information on the valence (positive or negative) associated with the brand. Logic dictates that any respondent who is not able to mention the brand under the unaided recall questions or to recognize the brand under the aided recognition questions is not asked any of the image questions.

Algorithm

Algorithm is a computer science term for a way of solving a problem, and it also refers to the instructions given to the computer to solve the problem. The study of algorithms is central to computer science and is of great practical importance to survey data analysis because algorithms are used in statistical programs.

An algorithm can be thought of as any step-by-step procedure for solving a task. Imagine five playing cards face down on a table and the task of sorting them. Picking them up one at a time with the right hand and placing them in the left hand in their proper

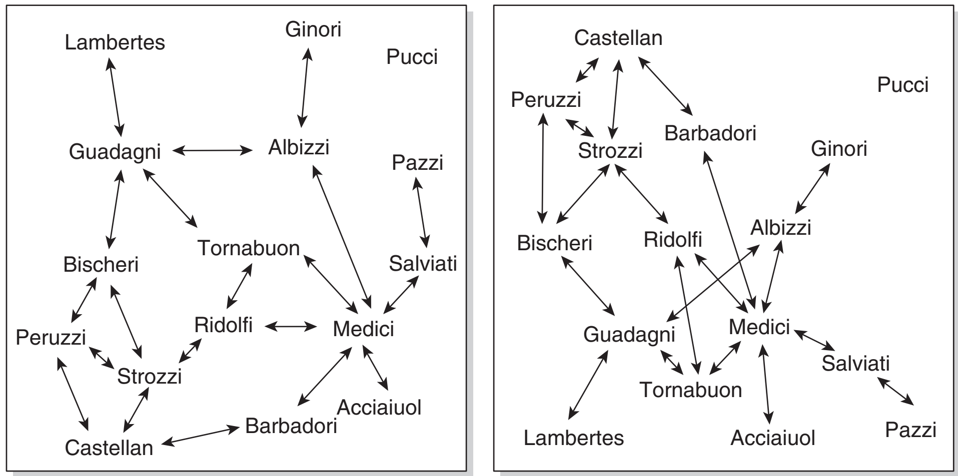

Figure 1 Two possible depictions of the same network data

place would be one way to solve this task. This is an algorithm, called *insertion sort* in computer science.

It is worth noting the subtle distinction between the concept of algorithm and the concept of a *method* or of a *technique.* For example, a method would be least squares; matrix inversion would be a technique used therein; and LU decomposition and Strassen's algorithm would be alternative algorithms to accomplish matrix inversion. A single data analysis method may use more than one algorithm.

It is impossible to write statistical software without using algorithms, so the importance of algorithms to survey data analysis is assured. However, user-friendly statistical software packages eliminate the need for end users to construct their own algorithms for most tasks. Nonetheless, at least a basic understanding of algorithms can be useful to survey researchers. For example, maximum likelihood methods can use an initial estimate as a starting point, and in some cases failure to converge may be remediated by trivially altering the initial estimate. Without some familiarity of the underlying algorithm, a researcher may be stuck with a nonconverging function.

Another setting where some knowledge of algorithms is useful is shown in Figure 1, which illustrates two possible depictions of the exact same network data. The left panel uses the multi-dimensional scaling algorithm and the right uses simulated annealing. The data are identical, which may be verified by observing who is connected to whom, but the appearance of the graphs is different. Algorithms are important here, because interpretation of the network data is affected by the appearance of the graph, which is affected in turn by the choice of algorithm. Whereas in many cases different algorithms will produce the same result but differ in speed (i.e., computing time), in this case different algorithms produce different results.

The term *algorithm* is sometimes used more broadly to mean any step-by-step procedure to solve a given task, whether or not a computer is involved. For instance, matching historical records from more than one archival source can be done by hand using an algorithm. Moreover, it is not only the analysis of survey data that uses algorithms, but also in many cases in the collection of the data an algorithm may be used to select clusters in a complex sample survey design.

Alpha, Significance Level of Test

Alpha is a threshold value used to judge whether a test statistic is statistically significant. It is chosen by the researcher. Alpha represents an acceptable probability of a Type I error in a statistical test. Because alpha corresponds to a probability, it can range from 0 to 1. In practice, 0.01, 0.05, and 0.1 are the most commonly used values for alpha, representing a 1%, 5%, and 10% chance of a Type I error occurring (i.e., rejecting the null hypothesis when it is in fact correct). If the *p*-value of a test is equal to or less than the chosen level of alpha, it is deemed statistically significant; otherwise it is not.

The typical level of alpha is 0.05, but this is simply a custom and is not based on any statistical science theory or criteria other than conventional practice that has become the accepted standard. Alpha levels of 0.1 are sometimes used, which is a more lenient standard; alpha levels greater than 0.1 are rarely if ever used. All things being equal, standard errors will be larger in smaller data sets, so it may make sense to choose 0.1 for alpha in a smaller data set. Similarly, in large data sets (hundreds of thousands of observations or more), it is not uncommon for nearly every test to be significant at the alpha 0.05 level; therefore the more stringent level of 0.01 is often used (or even 0.001 in some instances). In tabular presentation of results, different symbols are often used to denote significance at different values of alpha (e.g., one asterisk for 0.05, two asterisks for 0.01, three asterisks for 0.001). When *p*-values of tests are reported, it is redundant also to state significance at a given alpha.

Best practice is to specify alpha before analyzing data. Specifying alpha after performing an analysis opens one up to the temptation to tailor significance levels to fit the results. For example, if a test has a *p*-value of 0.07, this is not significant at the customary 0.05 level but it meets what sometimes is referred to as "marginal" significance at the 0.1 level. If one chooses a level of alpha after running the model, nothing would prevent, in this example, an investigator from choosing 0.1 simply because it achieves significance. On the other hand, if alpha is specified a priori, then the investigator would have to justify choosing 0.1 as alpha for reasons other than simply "moving the goalposts." Another reason to specify alpha in advance is that sample size calculations require a value for alpha (or for the confidence level, which is just 1 minus alpha).

Note that if 20 statistical models are run, for example, then one should expect one of them to produce a significant result when alpha is set at 0.05, merely by chance. When multiple tests are performed, investigators sometimes use corrections, such as the Bonferroni correction, to adjust for this. In and of itself, specifying a stringent alpha (e.g., 0.01 or 0.001) is not a guarantee of anything. In particular, if a statistical model is misspecified, alpha does not change that.

Only models in which a given alpha is satisfied tend to reach consumers, who tend to be exposed to scientific studies via referred journal articles. This phenomenon is known as "publication bias." The reader of a study may find it persuasive because the *p*-value is smaller than alpha. The persuasion derives from the small likelihood (alpha) of the data having arisen by chance if the null hypothesis is correct (the null hypothesis is therefore rejected). But even at a small level of alpha, any given result may be likely by sheer chance if enough models have been run, whether or not these models are reported to the reader. Even an arbitrarily small alpha is meaningless as a probability-based measure if many models are run and only the successful ones revealed. A small level of alpha, taken by itself, is therefore not an indicator that a given piece of research is persuasive.

Statistical models are sometimes used for purely descriptive purposes, and in such contexts no level of alpha need be specified.

Alternative Hypothesis

An alternative hypothesis is one in which a difference (or an effect) between two or more variables is anticipated by the researchers; that is, the observed pattern of the data is not due to a chance occurrence. This follows from the tenets of science, in which empirical evidence must be found to refute the null hypothesis before one can claim support for an alternative hypothesis (i.e., there is in fact a reliable difference or effect in whatever is being studied). The concept of the alternative hypothesis is a central part of formal hypothesis testing.

Alternative hypotheses can be nondirectional or directional. If nondirectional, an alternative hypothesis is tested with a two-tailed statistical test and is stated in words to the effect that "A differs from B." If directional, an alternative hypothesis is tested with a one-tailed statistical test and is stated in words to the effect that "A is greater than B" or "B is greater than A." (The null hypothesis is stated in words to the effect that "A equals B.")

An example in survey research would be a split-half experiment that is used to test whether the order of two question sequences within a questionnaire affects the answers given to the items in one of the sequences, for example, in crime surveys where both fear of crime and criminal victimization experience are measured. In this example, a researcher could venture a directional alternative hypothesis that greater levels of fear would be reported if the fear items followed the victimization items, compared to if they preceded the victimization items. Half the respondents would be randomly assigned to receive one order (fear items, then victimization items), and the other half would receive the other order (victimization items, then fear items). The null hypothesis would be that the order of these question sequences makes no difference in the answers given to the fear-of-crime items. Thus, if the null hypothesis is true, the researcher would not expect to observe any reliable (i.e., statistically significant) difference in levels of fear reported under the two question-ordering conditions. In contrast, if the directional alternative hypothesis is true (i.e., if results indicate significantly greater fear being reported when the fear items follow the victimization items than when they precede them), then the null hypothesis is rejected and support is accorded to the alternate hypothesis.

Another way of understanding the alternative and null hypotheses in survey research is to think about the crime survey example and the confidence intervals that can be calculated around the fear-of-crime measures in the two conditions. The null hypothesis would be that the 95% confidence intervals for the fear measures under the two question orders would overlap and thus not be reliably (significantly) different from each other at the .05 (alpha) level. A directional alternative hypothesis that states that reported fear of crime would be higher when the victimization items precede the fear items would be that (a) the confidence intervals would not overlap and that (b) the lower limit of the confidence interval for the fear items when the victimization items precede them would exceed the upper limit of the confidence interval for the fear items when the victimization items follow them.

Supporting an alternative hypothesis when it is in fact false is termed a *Type I error*. Failing to support an alternative hypothesis when it is in fact true is termed a *Type II error*.

American Association for Public Opinion Research (AAPOR)

The American Association for Public Opinion Research (AAPOR) is the principal professional association for survey researchers in the United States. Organized shortly after World War II, AAPOR develops and promotes ethical principles to guide survey research, advances its methodology, and attempts to further an understanding of appropriate practice both for researchers and the general public. Its ethical code and its enforcement have evolved with changing technology and new applications of survey research.

Founding of AAPOR

The redeployment of U.S. industrial power to the production of consumer goods after World War II stimulated interest in a wide variety of survey applications, particularly market and media research. The economy needed mass media to sell the output of mass production, and survey research made the marketing process efficient.

Harry Field, who had founded the National Opinion Research Center (NORC) at the University of Denver in 1941, saw the war's end as an opportunity to assemble the diverse strands of survey research. He organized a national conference to open on July 29, 1946. The site was Central City, Colorado, 42 miles of winding mountain road from downtown Denver and 8 hours by reciprocating-engine airliner from New York City. Field invited 264 practitioners, and 73 attended. Don Cahalan, who coordinated the event, classified the attendees: 19 from media, 18 academics, 13 commercial researchers, 11 from nonprofits, 7 government employees, 3 from advertising agencies, and 2 others.

A key session on technical and ethical standards in public opinion research was led by George Gallup, Clyde Hart of the Office of Price Administration, Julian Woodward of Elmo Roper's organization, and Field. In a paper that Paul Sheatsley would later describe as "remarkably prescient," Woodward foresaw expanded use of polls to provide feedback for elected officials and to test public knowledge. Competition among polls would create pressure to minimize costs, but because such polls would play an important role in public service by providing a continuing referendum on policy and consumer issues, they would require standards of quality that would "justify the responsibilities which will increasingly be theirs."

After 3 days of discussion, the conference decided that a second meeting should be held in 1947. Harry Field was to lead it, but he died in a plane crash in France only a month later. Clyde Hart became director of NORC and organizer of the second conference.

For the second meeting, Hart and the sponsoring committee chose Williamstown, Massachusetts, in the northwest corner of the state. Julian Woodward assembled a program that drew 194 participants.

While the Central City meeting had envisioned an international confederation of existing survey research organizations, the Williamstown meeting took the unexpected step of forming a membership organization instead. A constitution was drafted, and the name "American Association for Public Opinion Research" was approved after assurances were made that an international organization would be formed the next day. Since that time, AAPOR and the World Association for Public Information Research (or WAPOR) have combined their meetings in even-numbered years.

Clyde Hart was elected by acclamation, and, in a secret ballot, Elmo Wilson, research director for CBS, was named vice president. Wilson's election as president the following year began the AAPOR tradition of alternating the presidency between the commercial and academic sectors. A 1951 revision of the constitution provided for the vice president to ascend automatically to the presidency.

Mission of AAPOR

One function of a professional association is to codify the profession's self-definition by setting standards of ethics and technical competence. When AAPOR was founded, the main technical debate was between the advocates of quota sampling and those who preferred probability sampling. It quickly became clear that setting rules of scientific orthodoxy was not practical, but there was support for setting moral standards, particularly regarding transparency in research methods.

The other key aspect of professionalism is advancement of the profession's body of knowledge. The constitution adopted at Williamstown provided for the "dissemination of opinion research methods, techniques and findings through annual conferences and an official journal and other publications." *Public Opinion Quarterly* had been started in 1937 at Princeton University, and AAPOR designated it the official journal of the association, paying a fee to have its conference proceedings published there. In 1968, the journal was acquired by Columbia University, and title was transferred to AAPOR in 1985.

Evolution and Application of the AAPOR Code

Several years passed without the association having to face a specific case or controversy. That ended in 1955, when Walter Reuther, president of the United Auto Workers, filed a complaint alleging biased questions in a survey of General Motors employees. The Standards Committee of AAPOR shied away from dealing with the issue and sent a summary of the case to the membership so that "each is free to make his own evaluation."

Sidney Hollander, in his 1992 history of the Standards Committee, found the next critical point to occur in 1957, when members became concerned about a conflict between their duty to maintain the confidentiality of survey respondents and possible demands for their names as legal evidence. Researchers would have a stronger case if respondent anonymity could be specified as a professional standard.

That need opened the door to the development of a formal code. Different versions were presented to the 1958 and 1959 meetings without success; finally a code was adopted at the 1960 annual meeting with responsibility for enforcement assigned to the Executive Council.

The standards became more specific in 1967 with the adoption of disclosure requirements—key pieces of information that should be revealed about any poll, for example, sample size, dates of interviewing, question wording, method of data collection, and identity of the sponsor of the survey. A test case arose in 1974 when survey findings supporting the Nixon administration were released without identifying the sponsor, which turned out to be the Republican National Committee. No action was taken because AAPOR lacked defined procedures for enforcing its rules.

That flaw was repaired under the leadership of California pollster Mervin Field during his tenure as Standards chair in 1974–1975. A detailed procedure was worked out to provide formal hearings, right of reply, and protection of the anonymity of accusers. In its first application, the procedure led to a finding that Opinion Research Corporation, in a survey report used to oppose establishment of a federal consumer advocacy agency, had made interpretations unsupported by the publicly released data.

One effect was to give journalists a tool to extract information from reluctant pollsters. Survey researchers could not hide behind confidentiality obligations to their clients if to do so would conceal a violation of good practice. The code, which every member signs, contains this language: "If we become aware of the appearance in public of serious inaccuracies or distortions regarding our research, we shall publicly disclose what is required to correct these inaccuracies or distortions . . . ."

A person need not be a member of AAPOR to lodge a complaint, nor does AAPOR limit its investigations to members. From 1975 to 1997, the organization used publicity as a sanction in the form of a press release issued after a council finding. The organization fell relatively silent after 1997, continuing to investigate complaints of code violations but imposing sanctions by private letter of censure with no public announcement.

Much of the recent effort at enforcing standards has been directed at pseudo-polls used to cover generation of marketing leads, develop voter lists, or disseminate political falsehoods. The organization also turned its attention to education and promotion, hiring its first full-time public relations specialist in 2007.

Annual AAPOR Conference

The annual conference has traditionally included a plenary session on a current topic of broad interest, an address by the current president, formal paper presentations organized by topic with discussants, round table discussions, teaching sessions, and informal networking. In the early days, conference organizers favored university settings for the sake of economy, but as the organization grew, resort hotels became the standard choice. Further growth, with conference attendance approaching 1,000, drew the meetings to metropolitan areas. By the early 21st century, AAPOR had become an organization of more than 2,000 members with annual revenue of nearly $1 million.

American Community Survey (ACS)

The American Community Survey (ACS) is an ongoing national survey conducted by the U.S. Census Bureau. Part of the federal decennial census program, the ACS was designed to replace the long form or sample portion of the decennial census, starting in 2010. By conducting monthly surveys of a sample of the U.S. population, the ACS collects economic, social, and housing information continuously rather than every 10 years. The ACS does not replace the decennial enumeration, which is constitutionally mandated for apportioning congressional seats. It is expected that the ACS program will improve the quality of the decennial census, because the elimination of long-form questions should increase response and allow more focused nonresponse follow-up.

Eventually, the ACS will supply data for the same geographic levels that have traditionally been available from the census long form, including sub-county areas such as census tracts and block groups. The ACS sample sizes are not large enough to support annual releases for all geographic areas. For smaller areas, the ACS data are averaged over multiple years. Annual data are available for populations of 65,000 or more. Annual estimates from the 2005 ACS were released in 2006. Three-year averages will be released for areas with 20,000 or more people, and 5-year averages will be available for the remaining areas. Three-year averaged data will be available starting in 2008, and the 5-year averaged data will first be available in 2010. After 2010, data for all geographic data will be updated annually, using the rolling 3- or 5-year averages for the smaller areas.

The Census Bureau has conducted ACS tests in select counties since the mid-1990s. In 2005, the housing unit sample was expanded to its full size, which includes all U.S. counties and equivalents, the District of Columbia, and Puerto Rico. The ACS was expanded to include group quarters facilities in 2006. As an ongoing program, funding for the American Community Survey must be approved by Congress annually as part of the federal budget process. Current ACS implementation plans could change in the future if funding is not approved.

Content

Recent versions of the ACS questionnaires have included the same general subjects as the 2000 long form, asking more than 20 housing questions and more than 30 population questions about each household member. The population questions include the six basic demographic questions from the 2000 census short form (name, relationship to householder, age, sex, Hispanic identity, and race). ACS questions cover subjects such as ancestry, language use, education, occupation, veteran status, income, and housing costs. The content remained the same for the 2005 and 2006 surveys and is planned to remain the same for 2007.

The content of the American Community Survey is determined through a formal process managed by the Census Bureau and the federal Office of Management and Budget (OMB). The Census Bureau and OMB restrict ACS content to include only questions that are necessary for a specified federal purpose, such as a regulation that requires use of the subject data. Because the ACS is a continuous survey, changes to the survey can result in inconsistent data trends. Content changes are minimized and cannot be made more than once per year. Content modifications require extensive testing. Census Bureau staff and other subject experts review content test results and make recommendations to the OMB, which makes final content decisions.

Sample Design and Selection

The American Community Survey is stratified so that housing units and group quarters facilities are sampled separately. On average, sample rates for both populations are targeted to be 2.5% per year. Approximately 250,000 housing unit addresses are selected in each month, or 3 million per year. The ACS selects addresses from the Census Bureau's Master Address File (MAF). The MAF is a list of housing units and group quarters facilities in the United States. Because the completeness of the sample frame is so important to the ACS sample process, the MAF file is reviewed and updated on an ongoing basis. To update the MAF, the Census Bureau uses information from the U.S. Postal Service and from local governments.

For each ACS sample year, there are two phases for selecting the addresses. The first phase takes place a few months prior to the sample year, and a supplemental phase takes place early in the sample year. The supplemental phase allows for the inclusion of addresses that have been added since the first phase. The ACS allocates addresses to subframes to ensure that no address can be chosen more than once during a 5-year period.

The ACS intends to provide reliable data for local areas of varying sizes. The ACS staff must also intensely protect the confidentiality of respondents. In order to meet the reliability and confidentiality standards and still report data for very small areas, the Census Bureau employs differential sample rates. In this process, the sample is stratified so that addresses in smaller geographic areas have a higher probability of selection than those in larger areas.

Data Collection and Processing

ACS surveys are administered using three collection modes: mail, telephone, and in person. Addresses that are determined to be incomplete are also assigned for in-person collection. The large majority of households are contacted first through the mail. The mail-out process begins with a pre-survey letter that notifies the recipients that they will receive a survey. Next the complete survey packet is sent, including a cover letter, the questionnaire, instructional guidance, and a return envelope. A reminder postcard is sent to all mail recipients several days after the survey packet. After a number of weeks, if questionnaires are not returned, the Census Bureau will send another survey packet. The ACS typically has maintained very high mail-back response rates.

Respondents who return incomplete surveys or do not mail back surveys after a designated amount of time will be contacted by telephone. Using a computer-assisted telephone interview (CATI) process, Census Bureau interviewers will attempt to complete the survey on the phone.

Surveys that are not completed by mail or telephone will become eligible for in-person data collection through a computer-assisted personal interview process (CAPI). Because of the high costs of in-person data collection and the difficulty in reaching persons who have not responded during other phases, not all of these nonresponse cases will be chosen for personal interview. The ACS selects a subsample of nonrespondents for the CAPI phase. The responses from the nonresponse follow-up are weighted up to account for the nonrespondents who are not contacted.

Currently, standard ACS questionnaires are produced in English and in Spanish. English forms are mailed to homes in the United States, and Spanish forms are mailed to homes in Puerto Rico. ACS questionnaires include phone numbers that recipients can call for assistance in filling out the questionnaire. English forms include these phone assistance instructions in both English and Spanish. Persons in the United States may request the Spanish language form.

Sources of Survey Error in the ACS

A sample-based survey, the ACS will have sampling and nonsampling error. Sampling error is the random error that occurs when the survey is conducted for a sample of the universe rather than for all members of the universe. Sampling errors are often described using standard errors and margins of error. ACS data are published with margins of error at the 90% confidence level.

The ACS is also subject to nonresponse error through both unit and item nonresponse. *Unit nonresponse* occurs when recipients do not return their ACS forms or mail back blank forms. *Item nonresponse* occurs when certain questions are not answered. Compared to other surveys, the ACS has maintained relatively low levels of both unit and item nonresponse. One reason for the high response rates is that, like decennial census, persons who are selected for the ACS are required by law to participate. Another contributing factor to the high response rates relates to fact that the ACS is an ongoing operation. Unlike the decennial census and other less frequent surveys, the ACS maintains a regular staff of professional interviewers who receive in-depth training on how to gain cooperation and collect information during the telephone and in-persons phases.

General ACS Considerations

Users will find that there a number of things to keep in mind when using ACS data, especially when making comparisons to decennial census data. Users need to adjust to the multi-year averages as well as to the higher rates of sampling error. While the 2000 census long form was sent to 1 in 6 housing units, the ACS will be sent to about 1 in 8 households in a 5-year period. Thus, to provide the more frequent data updates, there has been a trade-off in the size of the samples. When comparing data, only statistically significant changes should be considered. The Census Bureau publishes instructions for users on how to apply statistical tests when trying to measure change over time.

Because the ACS is conducted monthly, annual ACS data essentially reflect an average throughout the year. In contrast, the decennial census reflected a particular point in time (traditionally April of the census year). This consideration is particularly important when comparing data for areas that have seasonal population fluctuations, such as college towns or resort areas.

The ACS also employs different residency rules than the decennial census. While the decennial census counts people in their usual place of residence (where they spend the majority of the year), the ACS includes people who have lived in the sample residence for most of the past 2 months.

Questions about concepts such as income and mobility are also conducted differently with the ACS. While the decennial census asks for income amounts for the prior year; the ACS asks for income over the past 12 months. In the 2000 census, respondents were asked if they lived in the housing unit on April 1, 1995. The ACS question asks whether the resident lived in the unit 1 year ago.

The ACS is designed to provide information about the characteristics of U.S. populations, but it is not designed to provide annual updates to the decennial census total population or housing unit counts. The official responsibility for updating population estimates falls under the Census Bureau's Population Division, which produces annual estimates of the total population and population by age, sex, race, and Hispanic identity. The estimates are produced for the nation, states, and for all U.S. counties and county equivalents. To estimate the population, the Census Bureau uses the components-of-change approach, which estimates change from the 2000 decennial census base counts. The components of population change are births, deaths, and migration. To estimate the components of change, the Census Bureau uses sources such as birth records, death certificates, and Internal Revenue Service (IRS) data. Using weighting procedures, the ACS data are controlled to the population (by age, sex, race, Hispanic identity) and housing unit estimates from the Census Bureau's annual population estimate program.

For the 2005 ACS, group quarters were not sampled because of budget restrictions. Thus, the published data contain only the household population. Some data users did not understand these universe differences and made direct comparisons to decennial data that represented the total population.

Although there are a number of considerations for ACS data users, when used properly, the ACS supplies reliable and timely information to help users make better decisions. Many of these issues should be worked out over time as more information is released and data users become more familiar with the data limitations.

American Statistical Association Section on Survey Research Methods (ASA-SRMS)

The Section on Survey Research Methods (SRMS) is a formal section of the American Statistical Association (ASA) that is devoted to encouraging research and the advancement of knowledge in all aspects of survey research. The goals of the SRMS are to promote the improvement of survey practice and the understanding of survey methods in both theoretical and applied research. In 2006, the SRMS was the third-largest section in the ASA, with approximately 1,300 members. All sections of the ASA require that their members first join the ASA.

The SRMS has a relatively short history. In 1974, a group of members of the ASA recognized a need to coordinate and facilitate the study of survey research distinct from other statistical activities. To accomplish this goal, they formed a subsection within the existing Social Statistics Section of the ASA specifically for this purpose. The subsection evolved quickly. It petitioned the ASA to become a full section in 1976, and the petition was approved in 1977 by a vote of the ASA membership. The SRMS began operation as a full section of the ASA in January 1978. In 1990, Irene Hess describes these events and the researchers who helped create the SRMS in an article in *The American Statistician.*

Since its inception as a subsection, the SRMS has identified and fostered research in some areas of special interest to its members. These areas include (a) foundations of sampling; (b) design and execution of sample surveys; (c) nonsampling errors; (d) data collection methods; (e) questionnaire design, evaluation, and testing; (f) analysis and presentation of survey data; (g) education of the public and students on the importance of scientific survey research; (h) publication and dissemination of survey research findings; (i) ethics related to the conduct of survey research; (j) appropriate methods of dealing with respondents and potential respondents; and (k) standards for survey practice.

Disseminating information on survey methods is one of the main functions of the SRMS. The SRMS has been active in a number of ways to disseminate information on survey research methods to a wide audience within the ASA, in the scientific community, and among the public. One approach has been to stimulate the preparation of articles and reports dealing with survey methodology under its auspices. Another approach has been to foster liaisons with persons and organizations publishing papers and monographs on topics of interest in survey methodology. A third approach has been to sponsor topic-oriented workshops, short courses, and conferences of interest to survey researchers.

One of the first such efforts was undertaken in 1976 when the SRMS was still a subsection. A brochure called *What Is a Survey?* was developed and quickly became a key piece of the dissemination effort. The brochure was published several times and was translated into several languages. The brochure was later developed into a series covering specific topics and is still widely used. It is currently available on the SRMS Web site.

The SRMS has also been very active in sponsoring international conferences on specific survey research methods. The first international conference that led directly to an edited monograph was the International Symposium on Survey Methods, cosponsored by ASA Ottawa Chapter, Statistics Canada, and Carleton University in 1980. In 1986, the international conferences sponsored by the SRMS became a continuing series. An international conference has been held every 2 years or so, and nearly all of these conferences resulted in edited monographs of the invited papers. The topics of the conferences have included Panel Samples, Telephone Sampling, Survey Measurement and Process Quality, Business Surveys, Computer Assisted Data Collection, Nonresponse, and Methods for Testing and Evaluating Survey Questionnaires. Nearly all of these conferences were cosponsored by the American Association of Public Opinion Research and the International Association of Survey Statisticians.

At many of the international conferences and the annual Joint Statistical meetings, short courses and tutorials are sponsored by the SRMS. The short courses are presented by survey researchers who are experts in the field and many have recently published books. Topics of the short courses have covered a wide range of methods issues, from questionnaire design to variance estimation with complex samples.

In a more recent and highly effective dissemination effort, the SRMS has scanned all the papers that were prepared for the *Proceedings of the Survey Research Methods Section of the American Statistical Association*. Access to all *Proceedings* papers published by the SRMS going back to 1978 can be obtained without charge from the SRMS Web site. This has been found to be a great benefit to the SRMS members and the survey research community at large.

The SRMS also established and distributes a newsletter for its members. The newsletter provides a forum for keeping SRMS members aware of the activities and concerns of the section as well as informing members of upcoming events, training opportunities, and awards.

Another approach that the SRMS has used to promote interest in survey methods is to award scholarships to students and to honor those who have made important contributions to survey research. For example, the SRMS offers Student Travel Awards to several doctoral students to support their attendance at the ASA annual meeting and attendance at an SRMS short course. In conjunction with other sections of the ASA, the SRMS annually has a competition open to students and postgraduates in survey methodology and related fields, and the winners are given awards to support their attendance at the ASA annual meeting.

Analysis of Variance (ANOVA)

Analysis of variance (ANOVA) is a statistical technique that is used to compare groups on possible differences in the average (mean) of a quantitative (interval or ratio, continuous) measure. Variables that allocate respondents to different groups are called *factors;* an ANOVA can involve one factor (a one-way design) or multiple factors (a multi-way or factorial design). The term *analysis of variance* refers to the partitioning of the total variation in the outcome variable into parts explained by the factor(s)—related to differences between groups, so-called explained or between variation—and a part that remains after taking the factor(s) into account, the so-called unexplained, residual, or within variation.

Consider a one-factor example in which the target population contains respondents from four different ethnic backgrounds (e.g., Chinese, Japanese, Korean, Vietnamese) and the research question is whether these ethnic groups have different average incomes. The null and alternative hypotheses for this example tested with the ANOVA are H_0: $\mu_1 = \mu_2 = \mu_3 = \mu_4$ and H_A: not all μ_j equal, where μ_j $(j = 1, \ldots, 4)$ denote the population mean incomes for the ethnic groups. The test statistic, denoted by F and following an F-distribution, is based on the ratio of the between variation (the variation between the sample group means) and the residual (within groups) variation. A statistically significant result is obtained if the former is large compared to the latter. The conclusion that can be drawn from a significant result is that the mean incomes for the ethnic groups are not all four equal. Of note, no causal conclusions can be made, since this is a nonexperimental study.

In a factorial design, for instance, by the inclusion of gender as a second factor in the previous example hypotheses about main and interaction effects can be tested. A significant main effect of gender implies that the marginal mean incomes of men and women (irrespective of the four ethnic groups) differ. A significant interaction effect of gender and ethnicity on income implies that the differences in mean income between men and women are different among the four ethnic groups.

Some important assumptions underlying the ANOVA are independence of observations and approximately normally distributed residuals, as well as approximately equal residual variances in the subgroups.

Note that the practical conclusions that can be drawn from an ANOVA are somewhat limited. The null hypothesis "all means are equal" is evaluated against the rather uninformative alternative hypothesis stating nothing more than "not all means are equal." Rejecting the null hypothesis in an ANOVA does not inform the researcher about which pairs of means differ from each other. Therefore, an ANOVA is often followed by pair-wise comparisons to further investigate where group differences are found. Since several tests are performed in such a case, the alpha level used per comparison is usually corrected to protect for an increased Type I error probability (post-hoc corrections). Several correction methods are developed, but unfortunately it is not always clear which method should be preferred. Another approach for further investigation of differences between specific means or investigation of a specific structure in the group means is contrast testing.

A second limitation of ANOVA is that directional testing is not possible. An exception is when the ANOVA is applied to a two-mean hypothesis; the ANOVA is then equivalent to the independent samples *t* test. However, it is regularly seen that researchers have specific expectations or theories in terms of the order of the population means. For instance, in a four-group ANOVA the actual hypothesis the researcher is interested in may be: $\mu_1 < \mu_2 < \mu_3 < \mu_4$.

ANONYMITY

Anonymity is defined somewhat differently in survey research than in its more general use. According to the *American Heritage Dictionary*, anonymity is the quality or state of being unknown or unacknowledged. However, in survey research, the concept is more complex and open to interpretation by the various organizations that conduct surveys.

In the form closest to the standard definition, *anonymity* refers to data collected from respondents who are completely unknown to anyone associated with the survey. That is, only the respondent knows that he or she participated in the survey, and the survey researcher can not identify the participants. More often, anonymity refers to data collected in surveys in which the respondents are de-identified and all possible identifying characteristics are separated from the publicly available data. Many survey research organizations provide data and data summaries to individuals outside their organizations. These data are considered anonymous if those outside the survey organization cannot identify the survey participants.

However, for many surveys defined as anonymous, the survey organization could, if needed, identify the respondents. For example, in a survey that uses pure random-digit dial procedures, limited information about the respondent is available to the survey organization. Through the use of various databases, the organization could possibly determine the household associated with the telephone number. Survey organizations would rarely do that.

Survey researchers have developed a number of procedures for designing anonymous surveys. For example, many surveys conducted in classrooms or other gathered events use unnumbered questionnaires and do not contain questions that could identify respondents. For some classroom surveys, identifying information is collected on a sheet separate from the questionnaire.

A procedure sometimes used in postal surveys is to include a return postcard along with return envelope. The unnumbered questionnaire is returned in the envelope, and the postcard is sent separately to let the researchers know that the questionnaire has been returned.

Survey researchers have developed many techniques for conducting completely anonymous surveys. For example, Internet surveys offer multiple methods for anonymous participation. Some surveys may not require authentication to access the survey. Invitations are sent to potential participants but with no control over who participates nor how often. A more sophisticated recruitment method is to completely separate the database used for authentication from the database that contains the survey responses. Another method is for one organization to send the recruiting requests and a second to collect the data.

A similar method can be used for telephone surveys. The telephone numbers can be stored in a database that has no direct link to the survey responses. This method can be used with random-digit dial telephone number samples to further separate the identifying information from the survey responses.

However, the procedures for ensuring anonymity can conflict with other important survey quality control procedures. For example, sending unnumbered paper questionnaires with postcards in postal surveys allows respondents to return the questionnaires but not the postcard. As a result, follow-up requests cannot be limited to nonrespondents only. Respondents who did not return the postcards may believe their first questionnaire did not reach the survey organization and respond a second time.

A similar problem that leads to inappropriate follow-up requests occurs with Internet surveys that do not use authentication. These surveys are open to anyone with Internet access. While some limitations can be applied to prevent unauthorized access, they are minimally effective. The survey data and results are harmed if those not selected for the sample are included in the survey data or respondents participate more than once.

Many survey organizations conduct random checks on survey interviewers to determine whether the interview was conducted and/or was conducted correctly. Survey procedures that ensure anonymity simultaneously prevent these important procedures for verification and monitoring survey quality.

Anonymity is important for the success of surveys under certain conditions. Anonymity can help to protect privacy so that respondents can reveal information that cannot be identified to them. When the survey poses exceptional risks for participants, anonymity may improve cooperation. When a survey asks especially sensitive questions, anonymity will likely improve reporting of stigmatizing behaviors or unpopular attitudes and opinions. Surveys of sexual behaviors, illegal drug use, excessive alcohol use, illegal activities such as tax evasion, and other possibly stigmatizing activities can benefit from providing anonymity to the respondents.

Some participants would be reluctant to discuss attitudes and opinions on such topics as race, politics, and religion unless they believed their responses could not be identified to them. Similarly, respondents have a reduced impetus to provide socially desirable responses in anonymous surveys. For example, respondents may be more willing to admit to negative attitudes toward minority groups if the survey is anonymous.

For these surveys, the risk of exposure or harm to respondents needs to be balanced against the loss of quality control procedures needed to ensure survey integrity. Little empirical evidence is available to indicate the overall importance of anonymity to survey cooperation and survey quality, but survey researchers regularly attempt to use procedures that can ensure anonymity in data collection.

Answering Machine Messages

Telephone answering machines are devices that automatically answer telephone calls and record messages left by callers when the party called is unable to answer. Within households such devices are often used as "virtual secretaries" to screen unwanted calls or to facilitate communication while away from home. The first automated answering machines became available in the late 1930s in Europe, and the first commercial answering machine was sold in the United States in 1960. It was not, however, until the advent of digital technology in the early 1980s that ownership of telephone answering machines became widespread. Ownership in the United States has increased significantly since then, with more than 70% of households owning a telephone answering machine in 2006. Compared with people who do not have answering machines, owners of these devices typically have higher levels of education and incomes and are more likely to live in households of two or more adults.

Increased ownership of telephone answering machines and their use to screen calls pose a threat to the representativeness of samples in telephone surveys, particularly those based on random-digit dialed designs. More than half of the people who own answering machines say that they or someone else in their household uses the device to screen incoming telephone calls on at least an occasional basis. Households that screen calls are likely to have high family incomes, to be located in suburban or urban areas, and to include young adults with high levels of education. Yet, despite the increased use of answering machines for call screening, many researchers found that households with answering machines can be reached by telephone for survey calls, albeit often after multiple attempts. Fewer than 5% of households appear to screen all of their telephone calls with an answering machine, and when reached, answering machine owners tend to be just as willing to complete surveys as are those without answering machines. Contact with households with answering machines tends to be most successful when calls are made on Saturdays before noon, on Sundays, or on weekdays after 6:00 p.m.

People are not uniform, however, in how they use telephone answering machines. People with on-the-go lifestyles tend to use telephone answering machines to stay in contact and facilitate communication. This finding led some researchers to hypothesize that scripted messages left on such devices may prepare the household for a later call or even encourage a prospective respondent to return the call free of charge to complete the interview. If successful, such an approach would help to reduce the level of nonresponse in telephone surveys.

However, empirical research on the effectiveness of leaving messages on answering machines to improve survey participation is mixed. For surveys that involve a list of sample members whose names are known, leaving messages can be effective at improving survey participation. Such messages appear to work best if the message is tailored to include the sample member's name. Several random-digit dialed telephone surveys conducted in the early 1990s also showed that leaving messages on telephone answering machines could significantly improve response rates by 3 to 4 percentage points. However, more recent studies conducted at the state and national levels using random-digit dialed sample designs found no difference in the contact or completion rates of households that were left a message and those that were not. The strategy does not appear effective for two reasons. First, the percentage of households with which this technique can be used is limited, since messages can be left only at households with answering machines that are set to receive messages. Although telephone answering machines are in more than 70% of households, not all of these machines are ready to receive messages every time a survey call is made. Second, only a small percentage of respondents within households hear the message and are positively influenced to participate in the survey. It may be that people in households with multiple adults or teenagers sort through and listen to telephone messages in much the same way they sort through mail: one person tends to sort and screen for the rest of the household. It is likely that one person (perhaps simply the first person home each day) will listen to all of the telephone messages and relay to others in the household what is deemed to be important information. Unsolicited calls from researchers are probably not at the top of that priority list. As a result, with the exception of the person who sorts the messages, probably few other adults in the household hear them.

In addition, leaving messages on telephone answering machines has real costs. Leaving messages takes interviewer time, both to listen to the greeting on the answering machine and message and to leave the notice about the survey. This added time increases costs and does not appear to produce positive returns in the form of either lower nonresponse rates or less interviewer labor.

Approval Ratings

Approval ratings are a particularly versatile class of survey questions that measure public evaluations of a politician, institution, policy, or public figure as well as judgments on public issues. This type of question was first developed by the Gallup Organization in the late 1930s to measure public support for the U.S. president. Today, the presidential job approval question is believed to be the single most frequently asked question in political surveys. Many members of the political community, journalists, and academics consider the job approval question to be among the most reliable and useful barometer of a president's public standing.

Basic Question Format

While versions of the job approval question were asked by George Gallup in the late 1930s, the modern form of the presidential approval question was finally adopted by Gallup in the mid-1940s, according to the Gallup Organization. Since then, the Gallup wording remains unchanged, giving journalists and academics an historic record of public evaluations of their presidents for more than 60 years.

The basic form reads: *Do you approve or disapprove of the way (*name of president*) is handling his job as president?* Some polling organizations use slightly different wording, but most have adopted the Gallup language, in part so they can compare the results with Gallup's historic data without having to worry about the effect of wording differences. A variation of the question is frequently used to measure a president's performance in specific domains, as with this trend question asked by *The Los Angeles Times*: *Do you approve or disapprove of the way George W. Bush is handling the war on terrorism?*

The question's basic format is easily altered to evaluate the performance of other public officials or institutions, such as Congress, individual members of a president's cabinet, or state and local officials, as well as other prominent leaders. It also is a useful measure of public attitudes toward government programs or policies and frequently is used to measure attitudes toward a range of nonpolitical issues, such as this question by *USA Today* and Gallup: *Do you approve or disapprove of marriage between blacks and whites?*

Polling organizations often include language that measures the intensity of approval or disapproval, as with this approval question asked in 2005 by the Pew Center for the People and the Press: *There is now a new Medicare law that includes some coverage of prescription drug costs. Overall, would you say you strongly approve, approve, disapprove, or strongly disapprove of the way Medicare will now cover prescription drug costs?* These strength-of-support measures allow survey respondents to indicate a degree of approval or disapproval, and thus are more sensitive to change in public attitudes. For example, declining public support for elected officials is often first seen as a decline among those who strongly approve of him or her and a comparable increase in those who somewhat support the official, with little or no decline in the overall support.

Presidential Approval Ratings

President George W. Bush has the distinction of having the highest as well as one of the lowest overall job approval ratings in Gallup polls of any president in the modern era. In an ABC survey conducted 4 weeks after the terrorist attacks of September 11, 2001, Bush recorded a 92% job approval rating, the highest job performance rating ever achieved by an American president in a major national poll. Other polling organizations also recorded historic highs for Bush in this time period. Coincidentally, Bush's father, George H. W. Bush, achieved the second-highest job approval rating in Gallup surveys, 89%, in February 1991, after the quick Allied victory in the Gulf War. Both numbers stand as striking illustrations of the power of the presidential job rating to measure *rally effects* in American politics, that is, the tendency of the public to rally behind their leader in times of national crisis. In a survey conducted by *The Washington Post* and ABC News the week before the 9/11 terrorist attacks, George W. Bush's job approval rating stood at 55%, 35 percentage points below his approval rating in a *Post*/ABC survey 2 weeks after the attacks.

As these numbers suggest, times of war and national crisis have produced sharp spikes in presidential approval. Other presidents with high job approval ratings in Gallup polls include Franklin Delano Roosevelt, who had an 84% approval rating in January 1942, after the Japanese attacked Pearl Harbor and Germany declared war on the United States. Harry S Truman had an overall job approval rating of 87% in June 1945, after the end of World War II in Europe and just before Japan surrendered. (The Gallup question, however, was slightly different in that it asked whether people approved or disapproved of the way Roosevelt *is handling his job as President today*. The word *today* was dropped three years later.)

Truman also has the distinction of being the president with the lowest job approval rating ever recorded by Gallup: 22% in February 1952, a consequence of public dissatisfaction with the Korean War. At the climax of the Watergate scandal in the summer of 1974, Richard Nixon's approval rating was 24%, while George W. Bush matched Nixon's low in a Reuters-Zogby survey in October 2007. Scandal does not automatically send a president's job approval rating plummeting. Most political observers expected that President Bill Clinton's job approval rating would collapse after details of his affair with White House intern Monica Lewinsky were revealed. In fact, his approval rating dropped insignificantly, if at all, in most public polls and quickly rebounded; whatever his failings as a person, the public continued to give Clinton high marks for his on-the-job performance as president.

Retrospective Judgments

Approval questions sometimes are used to measure the public's retrospective judgments. *USA Today* and Gallup asked this question in 1995 on the 50th anniversary of the end of World War II: *As you may know, the United States dropped atomic bombs on Hiroshima and Nagasaki in August 1945 near the end of World War II. Looking back, would you say you approve or disapprove of using the atomic bomb on Japanese cities in 1945?* Such a format has provided an interesting view of the American public's retrospective judgment of its presidents. When Gallup asked the public in 2002 if they approved or disapproved of the job done by each of the presidents in the post–World War II era, President John F. Kennedy topped the list with 83% approval, followed by Ronald Reagan (73%), and Jimmy Carter (60%).

The retrospective approval question is regularly asked by Gallup. The results over time suggest that an elected official's job approval rating can change significantly even after he or she leaves office. In 2002, Gallup found that 69% of the public approved, in retrospect, of the job that George H. W. Bush had done as president. But in 2006, the elder Bush's job rating had declined from 69%, third-highest behind Kennedy and Reagan, to 56%. Conversely, President Clinton's retrospective job approval rating increased from 51% in 2002 to 61% four years later.

Question Order Effects

Pollsters have found that job approval questions can be particularly sensitive to question order effects. For example, the overall job approval rating of Congress can be significantly different if the question is asked in a survey before or after a series of questions that ask people to evaluate how effective lawmakers were in dealing with a set of controversial issues. Presidential approval ratings tend to be higher when the question is asked first in a survey compared to when they are asked later in the survey after various policy issues and evaluations. That is why the presidential job approval rating and other approval questions typically are asked near or at the beginning of a survey.

AREA FRAME

An area frame is a collection of well-defined land units that is used to draw survey samples. Common land units composing an area frame include states, provinces, counties, zip code areas, or blocks. An area frame could be a list, map, aerial photograph, satellite image, or any other collection of land units. Area frames play an important part in area probability samples, multi-stage samples, cluster samples, and multiple frame samples. They are often used when a list of ultimate sampling units does not exist, other frames have coverage problems, a geographically clustered sample is desired, or a geographic area is the ultimate sampling unit.

Plot and Grid Area Frames

There are two types of area frames: grid frames and plot frames. The distinction between a grid and plot frame is based on the analytical goal of the survey rather than the structure of the frame. *Plot frames* contain ultimate sampling units that are observed in their entirety, whereas *grid frames* contain land units that will be further divided and sampled at further stages.

Plot frames are often used in agricultural and environmental surveys in which measurements are taken on a piece of land. For example, consider a survey designed to estimate pollutants in a stream. After obtaining a map of the stream, one could partition the stream into 3-foot-by-3-foot square plots. If a sample of plots is selected and the pollutants in each sample plot are measured, then the map of 3-foot-by-3-foot square plots is a plot frame, because the entire plot is enumerated.

Sometimes is it desirable to select a sample of units within geographic areas. In grid frames, geographic clusters of sample units compose the frame. The geographic clusters are first sampled. Then a sample is selected from units within the sampled clusters.

Use of Area Frame in Multi-Stage Sampling

Grid area frames play a central role in multi-stage sampling. At every stage of selection except the final stage, a different area frame is used. For example, consider a survey designed to estimate the median income of all households in a city. In the United States, one possible area frame for the first stage of sample is a list of all census tracts. After selecting a set of tracts, one could construct a second area frame of all census blocks within the selected tracts. Blocks that are not in selected counties are not considered a part of the sampling frame because they do not have a chance of selection.

Before selecting the final stage of households in sample blocks, a list of households within the blocks needs to be built. Field staff often perform this role by listing all households within the selected blocks; although the list of addresses could be obtained from an administrative list. In the final stage of sampling, the list of housing units is an example of a list frame rather than an area frame. However, sometimes geographically clustered lists built from a field enumeration are referred to as an area frame.

Reasons to Use Area Frames

When a satisfactory list frame is not available, an area frame may be the best alternative. For example, consider a survey of homeless adults in a large city. In the absence of a list of homeless people in the city, one could construct an area frame of city blocks that would cover the entire population. In such a case one might also want to use a second frame of people staying in a homeless shelter to supplement the area frame.

Sometimes area frames are used to enhance an imperfect frame. For example, a national survey of households might use a frame of telephone numbers supplemented by an area frame. The sample drawn from the telephone list will not cover households without telephone service. However, constructing the entire survey from an area frame may be too expensive. Thus some surveys use an area frame to enhance a frame with known coverage deficiencies.

For surveys involving personal interviews, geographic clustering provides a way to reduce field costs. For example, it is more efficient to interview four different households in the same city block than four different households spread out in a large area. Selecting a multi-stage sample from area frames is the most common way to obtain a geographically clustered sample.

Finally, plot area frames are used when the geographic area is of interest. For example, area frames are widely used in measuring the coverage of address lists. To do so, a sample of geographic areas is selected from a plot area frame. Then, field staff lists all the addresses in the sample areas, which are then compared to the list frame to measure coverage.

Area Frame Construction

In many cases it is possible to enhance an area frame with a wealth of auxiliary data that can be used in stratification, allocation, and sampling. Accurate estimates of the estimated measure of each geographic unit's size is of particular importance in the case of area probability sampling.

Area frames should cover the entire population and partition it into mutually exclusive geographic units. Indeed, the best frames have well-defined boundaries because poorly defined boundaries are likely to lead to coverage problems. For surveys that make estimates based on political boundaries such as counties or cities, some tradeoff usually has to be made between visible geographic boundaries and "invisible" political boundaries.

Besides being clearly defined with visible boundaries, area frames should be up-to-date and accurate. Changes in the political geography such as city annexations as well as changes in the physical geography such as changing rivers, tree rows, and roads should be reflected in the area frame boundaries. Out-of-date boundaries can cause confusion in the field, increasing cost, coverage bias, and coverage variance.

Last, each unit in the area frame should be unique. For example, an area frame of counties must also include the state name, otherwise there would be no way of differentiating Montgomery County, Alabama, from Montgomery County, Maryland.

AREA PROBABILITY SAMPLE

An area probability sample is one in which geographic areas are sampled with known probability. While an area probability sample design could conceivably provide for selecting areas that are themselves the units being studied, in survey research an area probability sample is usually one in which areas are selected as part of a clustered or multi-stage design. In such designs, households, individuals, businesses, or other organizations are studied, and they are sampled within the geographical areas selected for the sample. An example of a survey that uses area probability sampling in the United States is the Current Population Survey (CPS).

Terminology

There are several terms that are used in relation to area probability sampling that are not frequently used except in area probability and other multi-stage sampling designs. In area probability samples, the units formed for selection at the first stage are called *primary sampling units* (PSUs) and those for the second stage of selection are called *secondary sampling units* (SSUs). The units that are actually selected at these stages are called, respectively, *primary* and *secondary selections*. If there are more than three stages, the units for the third stage may be called *tertiary selection units* or *third-stage selection units*. The final unit to be selected is called the *ultimate sampling unit*.

PSUs, SSUs, and perhaps other units are often selected using probability proportional to size (PPS) methods. In these cases, each selection unit is assigned a measure of size (MOS). The MOS usually represents the size of the study population found in the unit. The MOS may be known or estimated or may be a function such as the square root of the population total or a composite (e.g., the sum of the total number of males plus 1.5 times the total number of females).

Reasons for Using Area Probability Designs

Many considerations can affect the choice of an area probability design for a study. One reason to use this approach could be that there is no available satisfactory list of the study population that can serve as a sampling frame. In other cases, the researchers may desire to use data about the areas as correlates in analysis of other data collected from persons or establishments. Often the choice is driven by the fact that the data being collected are best obtained (or can only be obtained) through personal contact with, or observation of, members of the population being studied. For example, (a) questionnaire items may require that the respondent be presented with visual cues as can be done in face-to-face interviewing; (b) the study requires that medical specimens be taken or anthropometric measurements be made; (c) the data collection involves observing behaviors, situations, or the physical environment.

If personal contact is required, cost considerations may make a clustered or multi-stage area probability sample design the most efficient, if not the only feasible design. For instance, if the survey is to collect data through personal contact with 3,000 adults in the United States, a simple random sample (or other unclustered design), even if possible, would be prohibitively expensive. An example of a more affordable design would be collecting data on 30 adults in each of 100 relatively compact areas such as metropolitan areas, counties, cities, towns, or similar administrative areas.

Disadvantages of Area Probability Samples

There are two major disadvantages to using an area probability sample: (1) the increase in variance, often called a design effect (*deff*) that comes from the use of multi-stage or clustered designs, and (2) the increased cost that is mostly associated with using in-person data collection (although not all studies with area probability sample designs use in-person data collection).

The design effect due to clustering arises from the fact that the units of observation in the study, be they individuals, households, or businesses, are not selected independently, but rather their selection is conditional on the cluster (in this case a geographic area) in which they are found being selected. In area probability sampling, the design effect of clustering can be small for some variables (estimates of gender and age, and some attitudinal measures), moderate for others (economic variables), and substantial for others (estimates of the prevalence of racial or ethnic groups).

The increased cost can come from having to have interviewers visit homes or businesses, but it can also come from the sampling process itself if part of the sampling frame must be developed by having field workers travel to selected areas and compile lists of addresses.

Procedures for Designing and Selecting Area Probability Samples

The first step in designing an area probability is defining the study population in geographic terms (e.g., adults living in the United States; students attending charter schools in the state of New York; or registered voters in the Mexican state of Zacatecas). The second step is to find or develop a sampling frame or frames, since the process often involves finding or developing a frame for each stage of selection. The frames should comprise lists of the sampling units at each stage, with all the information needed to stratify and implement the selection plan. The initial list may not correspond exactly to the sampling units that will be defined, but it should contain the information needed to create the frame once the sampling units are defined. For example, a list of counties or cities could be used to compile a frame of PSUs, some of which would include multiple counties or cities.

Since the size of the sampling units is important for selecting the sample in most area probability designs, data about the size of each PSU should be available. In addition, geography and economic and demographic measures may be needed. In most countries there will be lists available from government agencies that will serve as a frame for the PSUs. Constructing frames for the subsequent stages of selection may require more work, and depending on study needs, will call for creativity.

The next several steps involve defining sampling units and the strata within which they are to be sampled. What geographic areas will comprise the PSUs, SSUs, and other sampling units? Attention should be paid to the size of the units. As a rule of thumb, an area probability sample should have a minimum of 30 to 50 PSUs; a hundred or more are preferred for large studies. If the PSUs are too large, the sample may not be able to include a desirable number of selections. On the other hand, small PSUs may be more homogeneous than desired. A good approach is to have PSUs large enough that sampling the SSUs and subsequent units can introduce heterogeneity into the sample within each PSU.

After defining the PSUs, at least in general terms, strata are defined. Part of the stratification process involves defining "certainty selections," that is, PSUs that are large enough that they are certain to be selected. Each certainty PSU becomes its own stratum. One can think of certainty selections in terms of a sampling interval for systematic selection. To this end, define the interval (I) as the sum of the MOS for all PSUs in the population (MOSTOT) divided by the number of PSUs to be selected (n_PSU):

$$I = MOSTOT/n\_\text{PSU}.$$

Thus, any PSU with an MOS at least as large as I would be certain to be selected. If there are certainty selections, then it is advisable to set the cutoff for designating a PSU as a certainty selection as a fraction of I (perhaps 0.8 times I). The reason for this is that once the certainty PSUs are removed from the population, the sum of the MOS becomes smaller, and possibly additional PSUs will become large enough to be certainty selections: the sum of the remaining MOS can be designated MOSTOT* and the number of PSUs to be selected after the certainty selections are made as n_PSU_noncert. If one calculates a new sampling interval $I^* = \text{MOSTOT}^*/n\_\text{PSU\_noncert}$, it is possible that there will be new certainty selections the MOS for which is equal to or greater than I^*. Setting the certainty cutoff as a fraction of I usually avoids the problem of having to go through several iterations of removing certainty PSUs from the pool.

Once all certainty selections have been defined, the other PSUs on the frame are grouped into strata. As for any study, the strata should be related to study objectives, especially if subgroups of the population are to be oversampled. Area probability samples are often stratified geographically. The number of strata for the first stage is limited by the number of primary selections to be made. To estimate sampling variance, each stratum should be allocated at least two primary selections. Some deeply stratified designs call for one selection per stratum, but in such a design, strata will have to be combined for variance estimation.

The process just described for PSUs is then repeated for SSUs, third-stage units, and so on. It is only necessary to define SSUs within PSUs that are actually selected for the sample. SSUs within certainty PSUs are treated as primary selections for estimating sampling error (the certainty PSUs are treated as strata). The selection of units within PSUs depends on the purposes of the study. Oversampling may be accomplished through the use of stratification or giving extra weight when creating the MOS to the group(s) to be oversampled. If no oversampling is desired, it is possible, by using PPS at all stages, to have nearly equal probabilities of selection for the ultimate sampling units.

The sampling frames at the final or next-to-final stages often require substantial field labor. For example, field workers may have to visit the sampled areas and make lists, based on visual inspection, of dwelling units or businesses. In addition to taking the cost of listing into account, area probability sample designs must be flexible in case MOS at the later stages are substantially incorrect—whole blocks may have been destroyed by natural disasters or to make way for new construction, or the new construction may have taken place and the area contains many more dwellings or businesses than were anticipated. If an area has grown substantially, it may have to be subdivided before listing—essentially adding another stage of sampling.

Hypothetical Example of an Area Probability Design

In the United States, many large ongoing surveys operated or funded by the federal government use area probability designs. These include surveys of households or individuals as well as studies of businesses and other establishments. The subject areas of these surveys range from labor force participation to health status to energy consumption and other topics. Rather than try to examine the details of such sample designs, what follows is a hypothetical (generic) example of a sample design for a survey in which adults living in households comprise the target population and in-person data collection is required. Although there could be more stages of sampling, this example deals with four: (1) at the first stage, PSUs will be defined as "large" geographic areas; (2) in the second stage, somewhat smaller geographic areas will be defined as SSUs; (3) the third-stage units will be households identified within the SSUs; and (4) the fourth-stage (in this case ultimate) units will be adults identified within households.

If the survey were conducted in the United States, the PSUs very likely would be defined as metropolitan areas or counties. (Larger units, such as states, would probably be inefficient for most surveys.) The sampling frame, a list of all PSUs, would be stratified, possibly using a combination of variables such as region of the country, population density, economic and demographic characteristics. The stratifying variables would depend in part on whether the design was a general purpose one (to be used for many, perhaps unrelated studies) or a more specific one (such as for a study of a particular ethnic group).

SSUs in the United States might comprise areas defined for the U.S. Decennial Census, such as tracts, block groups, or blocks. The sampling frame for the SSUs would probably be electronic or other lists of these units obtained from the U.S. Census Bureau. The frame of SSUs should be stratified within each PSU; often the stratifying variables are similar to those used in sampling PSUs.

To create sampling frames of households within the SSUs, lists of dwellings or addresses are compiled, possibly by having field workers record the addresses on forms or enter them on portable computers. It is also possible to define sets of addresses based on postal delivery files or other administrative lists. These lists (whether created by study staff or obtained from postal or other administrative records) may be incomplete; thus, procedures need to be devised so that dwellings not on the list have a chance of being selected. One such method is the *half-open interval method*, in which unlisted units within a certain interval are given a known chance of selection.

The list of addresses or dwellings comprises the sampling frame for selecting households. However, at this point the study usually introduces two-phase sampling, since the list must be screened to determine if the dwellings identified on the list contain eligible households. This screening might be done on all units listed or on a subsample. For this example, we will assume that all listed units are screened. Examples of addresses that would not be eligible for this hypothetical survey include apparent dwellings that are actually businesses; vacant or uninhabitable structures; dwellings for which the group of people living there do not meet the definition of a household (for example a halfway house for recovering alcoholics or inmates close to being released from prison); or dwellings that do not contain an adult.

For this hypothetical example, the study will attempt to conduct interviews at all dwellings that contain households with adults; this is a likely scenario since it can reduce nonresponse if the interview is attempted at the same time as the household is screened. At this point, the design might call for attempting to interview (or otherwise collect data about) all adults in the household or for random selection of one adult to be interviewed.

Attenuation

Attenuation is a statistical concept that refers to underestimating the correlation between two different measures because of measurement error. Because no test or other measurement of any construct has perfect reliability, the validity of the scores between predictor and criterion will decrease. Hence, when correlating scores from two survey instruments, the obtained correlation may be substantively lower if the score reliabilities from both instruments are suspect. Therefore, Charles Spearman proposed the following "correction for attenuation" formula, estimating the correlation between two measures if the scores on both had perfect reliability:

$$r_{xyc} = \frac{r_{xy}}{\sqrt{r_{xx} * r_{yy}}}.$$

In this formula, r_{xyc} is the correlation between the predictor (x) and the criterion (y) corrected for attenuation; r_{xy} is the correlation between the predictor and criterion scores; r_{xx} is the reliability of the predictor scores; and r_{yy} represents the reliability of the criterion scores.

Suppose the correlation between scores on self-esteem and anger scales is .30. If the reliability (e.g., Cronbach's alpha) of the scores from the self-esteem inventory is .80 and the reliability of the scores from the anger inventory is .90, then the correction for attenuation would be equal to the following:

$$.35 = \frac{.30}{\sqrt{.80 * .90}}.$$

Because the reliabilities of the scores from the self-esteem and anger scales are high, there is little correction. However, suppose the score reliabilities for the anger and self-esteem inventories are extremely low (e.g., .40). The correction for attenuation would escalate to .75. If the square root of the product of the reliabilities were less than .30, then the correction for attenuation would be greater than 1.0!

However, rather than correcting for score unreliability in both measures, there are times in which one would correct for score unreliability for either the predictor or criterion variables. For example, suppose the correlation between scores from a job interview (x) and from a personnel test (y) is equal to .25, and assume that the reliability of the personnel test is .70. If one corrected only for the score unreliability of the criterion, then the following equation would be used:

$$r_{xyc} = \frac{r_{xy}}{\sqrt{r_{yy}}}.$$

In this case, the correction for attenuation would equal .30. One could also use a similar equation for correcting the predictor variable. For example, suppose the correlation between scores from a personnel test (x) and the number of interviews completed in a week (y) is equal to .20 and the score reliability of the personnel test is .60. The correction for attenuation would equal .26, using the following equation for correcting only for the score reliability of the predictor variable:

$$r_{xyc} = \frac{r_{xy}}{\sqrt{r_{xx}}}.$$

Paul Muchinsky summarized the recommendations for applying the correction for attenuation. First, the corrected correlations should neither be tested for statistical significance nor should they be compared with uncorrected validity coefficients. Second, the correction for attenuation does not increase predictive validity of test scores. Donald Zimmerman and Richard Williams indicated that the correction for attenuation is useful given high score reliabilities and large sample sizes. Although the correction for attenuation has been used in a variety of situations (e.g., meta-analysis), various statisticians have suggested caution in interpreting its results.

ATTITUDE MEASUREMENT

Researchers from a variety of disciplines use survey questionnaires to measure attitudes. For example, political scientists study how people evaluate policy alternatives or political actors. Sociologists study how one's attitudes toward a social group are influenced by one's personal background. Several different methods, including multi-item measures, are used to measure attitudes.

Question Format

People hold attitudes toward particular things, or *attitude objects*. In question format, an attitude object is presented as the stimulus in an attitude question, and respondents are asked to respond to this stimulus. Consider the following question:

> Do you approve, disapprove, or neither approve nor disapprove of the way the president is handling his job?

The attitude object in this question is the president's handling of his job. The respondents must consider what they know about how the president is handling his job and decide whether they approve, disapprove, or neither approve nor disapprove. Another possible closed-ended format is to turn the question into a statement, and ask the respondents whether they agree or disagree with a declarative statement, for example, *The president is doing a good job.* However, some research indicates that the agree–disagree format produces "acquiescence bias" or the tendency to agree with a statement regardless of its content. Yet another closed-ended format is to ask the respondents to place themselves on a continuum on which the endpoints are labeled. For example, one could ask, *How do you feel the president is handling his job?* and ask the respondents to place their opinions on a scale, from 0 being poor to 10 being excellent.

Researchers measuring attitudes must decide how many scale points to use and how to label them. Five to seven scale points are sufficient for most attitude measures. Assigning adjectives to scale points helps define their meaning, and it is best if these adjectives are evenly spaced across the continuum.

Sometimes a researcher wants to understand the preferences of respondents in more depth than a single closed-ended question will allow. One approach for this purpose is to ask the question in an open-ended format such as, *If the Democratic Party were a person, what traits would you use to describe it?* Here, the Democratic Party is the attitude object or stimulus. An advantage of the open format is that the answers are not limited to the researchers' own categories. The answers to such a question will provide insights into whether or not the respondent holds positive, negative, or conflicted attitudes toward the attitude object (the Democratic Party, in this example). However, open-ended responses can be very time consuming to code and analyze. Alternatively, one can list a series of attributes and ask the respondent to rank them. This is easier to analyze but can be cognitively complex if respondents are asked to rank too many items.

Two other important considerations for the response options are whether or not to include a "No opinion" option and/or a middle option. Research suggests that more respondents will use both of these options when they are explicitly offered than when it is left up to respondents to volunteer such responses on their own. Research has also shown that many respondents are willing to offer opinions on obscure or fictitious issues, especially when a "no opinion" option is not offered as an explicit response choice. However, other research suggests that an explicit "no opinion" option may encourage individuals who do have attitudes to not report them. In some measurement contexts, using a middle response choice that conveys a position of noncommitment toward the attitude object makes sense. However, those who have less intense feelings or views about an issue are disproportionately influenced by the inclusion of a middle option. For this reason, the middle option is sometimes omitted, and attitude strength instead is measured with a separate question.

Multi-Item Scales

Another way to measure attitude strength is by using multi-item scales. All scaling procedures require the creation of a pool of items from which a respondent is asked to select a final set according to some criteria. For example, Thurstone scaling first requires a set of judges to rate or compare several statements on a continuum from unfavorable to favorable toward the attitude object. The judges' scores for each statement are then averaged to align the statements along the attitude continuum. These average scores from the judges become the scale values for each statement. Next, the statements are administered to the respondents. The respondents are asked whether they agree with the statements. The respondents' score is then a function of the scale values for the statements that the respondents agreed with.

Guttman scaling is similar, except that it requires an assumption about the pattern of responses that is rarely met in practice. The assumption is that the data set associated with a Guttman scale has a cumulative structure, in the following sense: For *any* two persons in the observed sample, one of them would exhibit all the manifestations of the trait that the other person would, and possibly additional ones. That is, there would be no two persons in the sample with one person higher than the other in one variable but lower than the other in another variable.

Thurstone and Guttman approaches require a significant amount of developmental work. In contrast, Likert scales are much easier to construct. Typically, the researcher selects the statements that correlate the strongest with the sum of the responses to all the statements. The final scale is administered by asking the respondents to respond to the selected statements using a traditional 5- or 7-point agree–disagree response scale. The respondent's attitude is then represented by the sum of the responses to the individual statements or some weighted combination of responses. Although multi-item scales increase the reliability of a measure, thereby reducing measurement error, a disadvantage is that they can seem redundant to some respondents.

Evaluating and Refining Attitude Measures

All attitude questions should be carefully constructed regardless of the format that is used to measure them. The questions should be pretested, using techniques such as cognitive interviewing to ensure that respondents are interpreting the questions as intended. Split-half experiments also can be useful for pretesting alternative versions of a question. It is important to pretest attitude measures in a realistic situation since it is known that attitude questions can be sensitive to the context in which they are asked.

ATTITUDES

Attitudes are general evaluations that people hold regarding a particular entity, such as an object, an issue, or a person. An individual may hold a favorable or positive attitude toward a particular political candidate, for example, and an unfavorable or negative attitude toward another candidate. These attitudes reflect the individual's overall summary evaluations of each candidate.

Attitude measures are commonplace in survey research conducted by political scientists, psychologists, sociologists, economists, marketing scholars, media organizations, political pollsters, and other academic and commercial practitioners. The ubiquity of attitude measures in survey research is perhaps not surprising given that attitudes are often strong predictors of behavior. Knowing a person's attitude toward a particular product, policy, or candidate, therefore, enables one to anticipate whether the person will purchase the product, actively support or oppose the policy, or vote for the candidate.

What Is an Attitude?

An *attitude* is a general, relatively enduring evaluation of an object. Attitudes are *evaluative* in the sense that they reflect the degree of positivity or negativity that a person feels toward an object. An individual's attitude toward ice cream, for example, reflects the extent to which he or she feels positively toward ice cream, with approach tendencies, or negatively toward ice cream, with avoidance tendencies. Attitudes are *general* in that they are overall, global evaluations of an object. That is, a person may recognize various positive and negative aspects of ice cream, but that person's attitude toward ice cream is his or her general assessment of ice cream taken as a whole. Attitudes are *enduring* in that they are stored in memory and they remain at least somewhat stable over time. In this way, attitudes are different from fleeting, momentary evaluative responses to an object. Finally, attitudes are specific to particular objects, unlike diffuse evaluative reactions like moods or general dispositions.

Given this conceptualization, attitudes are most commonly measured by presenting respondents with a bipolar rating scale that covers the full range of potential evaluative responses to an object, ranging from extremely negative to extremely positive, with a midpoint representing neutrality. Respondents are asked to select the scale point that best captures their own overall evaluation of a particular attitude object.

In the National Election Studies, for example, respondents have often been asked to express their attitudes toward various groups using a "feeling thermometer" ranging from 0 (very cold or unfavorable) to 100 (very warm or favorable), with a midpoint of 50 representing neither warmth nor coldness toward a particular group (e.g., women). By selecting a point on this scale, respondents reveal their attitudes toward the group.

How Are Attitudes Formed?

At the most general level, attitudes can be formed in one of three ways. Some attitudes are formed primarily on the basis of our cognitions about an object. For example, we may believe that a particular brand of laundry detergent is reasonably priced, removes tough stains, and is safe for the environment. On the basis of these and other beliefs, we may come to hold a positive attitude toward the detergent. This attitude would be cognitively based.

In contrast, some attitudes are based on few or no cognitions. Instead, these attitudes are based primarily on our affective reactions to an object. Instead of deriving our attitude toward a laundry detergent from our beliefs about its various attributes, for example, we may form an attitude toward it on the basis of the feelings that we associate with the detergent. An advertisement for the detergent that makes us laugh, for example, may leave us feeling positive toward the detergent, even though the advertisement conveyed no substantive information about the detergent.

Attitudes can also be derived from our past behaviors. Sometimes this occurs through self-perception processes. In much the same way that we often infer other people's attitudes from the behaviors they perform, we sometimes look to our own behavior to determine our attitudes. When asked about our attitude toward a particular laundry detergent, for example, we may canvass our memory for relevant information. One thing that we may recall is our past behavior regarding the detergent. We may remember, for example, that we have purchased the detergent in the past. On the basis of this behavior, we may infer that we hold a positive attitude toward the detergent, even if we know nothing else about the product.

In addition to these self-perception processes, there is another way in which our past behavior can influence our attitudes. Instead of inferring our attitudes from our past behavior, we sometimes modify our attitudes to bring them into line with behaviors we have performed. This occurs because, in general, people prefer to exhibit consistency. In fact, according to cognitive dissonance theory, people are very uncomfortable when they recognize an inconsistency among their cognitions, and they are highly motivated to reduce this discomfort. For example, the knowledge that we have performed a behavior that is incongruent with our attitude often produces a state of tension. Resolving this tension requires that we eliminate the inconsistency. Because the behavior has already been performed, it is often easiest to do this by changing the attitude to bring it into line with the behavior. And indeed, a large body of evidence suggests that people often do change their attitudes to make them more consistent with past behaviors.

Why Do People Hold Attitudes?

Attitudes are ubiquitous—we hold them toward people, places, and things, toward concepts and ideas, and toward the vast array of stimuli in our environment. Why do we store these evaluations in memory? Attitudes are believed to serve a number of important psychological functions. Perhaps the most fundamental of these is a "utilitarian" function. Attitudes enable us to efficiently and effectively obtain rewards and avoid punishment by summarizing the positive or negative connotations of an object, guiding our behavior regarding the object. In the absence of attitudes stored in memory, we would be required to appraise an object every time we encountered it to assess its evaluative implications and decide whether to approach the object or avoid it. This process would overwhelm our cognitive capacity and would severely limit our ability to act swiftly and decisively in situations that require immediate action.

The attitudes we hold sometimes serve other psychological functions as well. For example, some of our attitudes enable us to affirm central aspects of our self-concept by expressing our core values. Support for a particular affirmative action policy may enable an individual to express the central role that egalitarianism plays in his or her worldview. In this case, the policy attitude could be said to serve a "value-expressive" function. Other attitudes enable us to enjoy smooth social interactions with important others, serving a "social-adjustive" function. For example, holding a positive attitude toward environmental conservation may make it easier for us to get along with close friends who hold pro-environment attitudes. Still other attitudes serve an "ego-defensive" function, helping shield people from recognizing unpleasant aspects of themselves. For example, instead of acknowledging our own unacceptable impulses or feelings of inferiority, we may project these qualities onto out-groups. In this case, our negative attitudes toward the members enable us to distance ourselves from these negative qualities, protecting our self-image.

What Do Attitudes Do?

Attitudes are tremendously consequential. In fact, their influence can be detected almost immediately upon encountering an attitude object. Psychophysiological evidence reveals that almost instantly, the objects that we encounter are categorized according to our attitudes toward them—things that we like are differentiated from things that we dislike. This occurs even when we are not actively attending to the evaluative connotations of an object.

Once an attitude has been activated, it systematically influences thought and behavior. For example, attitudes often bias our judgments and shape our interpretations of events. This explains how supporters of two different political candidates can watch the very same debate and can come away convinced that his or her own candidate was clearly victorious. In this case, their pre-existing attitudes toward the candidates colored their interpretation of the debate performances.

And of course, attitudes motivate and guide behavior. For example, people's attitudes toward recycling are strongly predictive of whether or not they actually engage in recycling behavior. Attitudes toward particular consumer products powerfully shape people's purchasing decisions. And attitudes toward political candidates are excellent predictors of voting behavior.

Indeed, attitudes have been shown to predict behavior toward a diverse range of objects.

An Important Caveat

It is important to note, however, that attitudes do not always exert such powerful effects. In fact, attitudes sometimes appear to have negligible influence on thought and behavior. Recently, therefore, a central focus within the attitude literature has been on identifying the conditions under which attitudes do and do not powerfully regulate cognition and behavior. And indeed, great strides have been made in this effort.

It has been established, for example, that attitudes influence thought and behavior for some types of people more than others, and in some situations more than others. More recently, attitude researchers have determined that some attitudes are inherently more powerful than others. These attitudes profoundly influence our perceptions of and thoughts about the world around us, and they inspire us to act in attitude-congruent ways. Further, these attitudes tend to be tremendously durable, remaining stable across time and in the face of counter-attitudinal information. Other attitudes do not possess any of these qualities—they exert little influence on thought and behavior, they fluctuate over time, and they change in response to persuasive appeals.

The term *attitude strength* captures this distinction, and it provides important leverage for understanding and predicting the impact of attitudes on thought and behavior. That is, knowing an individual's attitude toward a particular object can be tremendously useful in predicting his or her behavior toward the object, but it is just as important to know the *strength* of the attitude.

Fortunately, several attitudinal properties have been identified that differentiate strong attitudes from weak ones, enabling scholars to measure these properties and draw inferences about the strength of a given attitude (and therefore about its likely impact on thought and behavior). For example, strong attitudes tend to be held with great certainty, based on a sizeable store of knowledge and on a good deal of prior thought, and considered personally important to the attitude holder. Thus, measures of attitude certainty, attitude-relevant knowledge, the extent of prior thought about the attitude object, and attitude importance offer valuable insights regarding the strength of individuals' attitudes.

Ambivalence is another important component of attitude strength. Sometimes people simultaneously experience both positive and negative reactions toward an object, producing an uncomfortable state of evaluative tension. Ambivalent attitudes tend to be weaker than univalent attitudes, so assessing ambivalence toward an attitude object can be very useful. Furthermore, on bipolar evaluative measures, people who have highly ambivalent attitudes often select the scale midpoint, rendering them indistinguishable from people who are neutral toward an object. Directly asking people how conflicted or how torn they feel about the attitude object or asking people for separate reports of their positivity and negativity toward the attitude object enable researchers to differentiate among these two groups of respondents.

Response latencies (i.e., the length of time it takes a person to answer an attitude question) can also reveal something about the strength of peoples' attitudes: attitudes that spring to mind and can be expressed quickly tend to be stronger than those that require deliberation. Increasingly, survey researchers have begun measuring the latency between the conclusion of an attitude question and the start of respondents' attitude response in an effort to capture differences in attitude accessibility. Because they do not involve additional survey items, response latencies have the potential to provide an efficient and cost-effective index of attitude strength. However, differences in survey response latency can be due to factors other than attitude accessibility. Furthermore, attitude accessibility is only one of several key strength-related attitude properties, and these properties are not always highly correlated. Thus, accessibility alone provides an imperfect index of attitude strength and whenever feasible, additional strength-related attitude properties (e.g., importance, certainty) should also be measured.

ATTITUDE STRENGTH

Attitude strength refers to the extent to which an attitude is consequential. Compared to weak attitudes, strong attitudes are more likely to remain stable over time, resist influence, affect thought, and guide behavior.

Researchers have identified several attributes related to attitude strength. Several frequently studied attributes are well suited for survey research because they can be assessed directly using a single self-report survey item. For example, *attitude extremity* can be conceptualized as the absolute value of an attitude score reported on a bipolar scale that is centered at zero and ranges from strongly negative to strongly positive. *Attitude importance* is the significance people perceive a given attitude to have for them. *Attitude certainty* refers to how sure or how confident people are that their attitude is valid. Each of these attributes can be measured with straightforward questions, such as, *To what extent is your attitude about X positive or negative?; How important is X to you personally?;* and *How certain are you about your attitude about X?* Recent research suggests that attitude strength also is related to the extent that individuals subjectively associate an attitude with their personal moral convictions.

Other attributes can be assessed directly, with self-report survey items, or indirectly, with survey measures that allow researchers to infer the level of the attribute without relying on people's ability to introspect. For example, knowledge is the amount of information people associate with an attitude. Knowledge often is assessed by quizzes or by asking people to recall and list facts or experiences they relate to the attitude object. In a similar way, ambivalence, or the extent that people feel conflicted about a target, can be measured by asking people to list both positive and negative thoughts about the attitude object.

Most attitude strength research has assessed the association between attributes and characteristics of strong attitudes. Much less is known about how strength-related attributes relate to each other. Existing evidence, however, suggests that attitude attributes are best conceptualized as distinct constructs rather than as indicators of a single latent construct. Correlations between attributes typically range from low to only moderately positive.

Moreover, attributes often have different antecedents and consequences. For example, attitude importance, but not attitude certainty, about political policies has been found to predict whether people voted in the 1996 U.S. presidential election. In contrast, attitude certainty, but not attitude importance, has been found to predict whether people were willing to accept a nonpreferred candidate in the election.

ATTRITION

Unit nonresponse is a problem for any type of survey; however, unit nonresponse in panel studies can be a more severe problem than in cross-sectional studies.

Like cross-sectional studies, panel studies are subject to nonresponse at the initial wave. In addition, attrition—which is unit nonresponse after the initial wave of data collection—can occur at each subsequent wave.

A framework for understanding attrition in panel studies divides the participation process into three conditional steps: (1) location, (2) contact given location, and (3) cooperation given contact; this process cycle is repeated at each wave. Attrition thus occurs because of a failure to relocate or recontact an eligible sample unit after the initial wave of data collection, and because of noncooperation (i.e., a refusal to participate again in the survey) or the inability to participate again.

The accumulation of attrition over several waves can substantially reduce the number of sample units, thereby reducing statistical power for any type of analysis, both cross-sectional and longitudinal. However, attrition may also introduce nonresponse bias in the survey estimates. Differential or selective attrition occurs when the characteristics of the sample units who drop out of the panel because of attrition differ systematically from the characteristics of sample units who are retained in the panel study.

Distinguishing between initial wave nonresponse and attrition is important because the reasons for attrition may be different from the reasons for nonresponse in the initial wave of a panel study or in cross-sectional studies, in general. Contrary to cross-sectional studies where sample units' judgments about participating in the survey are largely made during the brief interactions they have with survey interviewers when the request is formulated, sample units in panel studies with repeated survey requests and contacts in between data collection points have more information about the nature of the request being made and will be influenced by their personal survey experience in the initial wave or other previous waves. In addition, in the case of a panel study, and once the initial wave has been conducted, the interviewers are better informed than in the initial wave to select the best approach to successfully locate, contact, and convince sample units to participate in additional waves of the panel study.

There are two main strategies that survey researchers use to address attrition. The first is to reduce attrition rates by maximizing sample retention; the second is to develop post-survey adjustments to correct for the biasing effects of attrition. These two strategies are not mutually exclusive, and they often are used together.

The main goal of panel management or panel maintenance is to maintain participation of all sample members in the panel study after the initial wave. The specific techniques to reduce attrition in panel studies are focused on locating the sample unit and establishing sufficient rapport with the sample units to secure their continued participation. Panel studies can keep contact with the sample units and keep them interested in participating in the panel study by adopting a good panel maintenance plan and employing techniques of tracking and tracing. Acquiring detailed contact information, the organization of contact efforts, hiring skilled interviewers, and retaining staff over time are important components of a good panel maintenance plan. Tracking procedures aim to maintain contact with sample units in the period between waves in order to update addresses between interviews so that a current or more recent address is obtained for each sample unit prior to conducting the interview. Tracking procedures are adopted in an attempt to find the missing sample units and are used at the point of data collection when the interviewer makes his or her first call, discovers the sample member has moved, and tries to find a new address or telephone number.

The second approach to addressing attrition is to calculate adjustment weights to correct for possible attrition bias after the panel study has been conducted. Since nonresponse may occur at each successive wave of data collection, a sequence of nonresponse adjustments must be employed. A common procedure is first to compute adjustment weights for nonresponse in the initial wave. At Wave 2, the initial weights are adjusted to compensate for the sample units that dropped out because of attrition in Wave 2; at Wave 3, the Wave 2 weights are adjusted to compensate for the Wave 3 nonrespondents; and so on. Adjustment weighting is based on the use of auxiliary information available for both the sample units that are retained and the sample units that dropped out because of attrition. However, for the second and later waves of a panel study, the situation to find suitable auxiliary information is very different than in cross-sectional studies or in the initial wave because responses from the prior waves can be used in making the adjustments for nonresponse in subsequent waves.

Audio Computer-Assisted Self-Interviewing (ACASI)

Audio computer-assisted self-interviewing (ACASI) is a methodology for collecting data that incorporates a recorded voice into a traditional computer-assisted self-interview (CASI). Respondents participating in an ACASI survey read questions on a computer screen and hear the text of the questions read to them through headphones. They then enter their answers directly into the computer either by using the keyboard or a touch screen, depending on the specific hardware used. While an interviewer is present during the interview, she or he does not know how the respondent answers the survey questions, or even which questions the respondent is being asked.

Typically the ACASI methodology is incorporated into a longer computer-assisted personal interview (CAPI). In these situations, an interviewer may begin the face-to-face interview by asking questions and recording the respondent's answers into the computer herself or himself. Then in preparation for the ACASI questions, the interviewer will show the respondent how to use the computer to enter his or her own answers. This training may consist solely of the interviewer providing verbal instructions and pointing to various features of the computer but could also include a set of practice questions that the respondent completes prior to beginning to answer the actual survey questions. Once the respondent is ready to begin answering the survey questions, the interviewer moves to a place where she or he can no longer see the computer screen but where she or he will still be able to answer questions or notice if the respondent appears to be having difficulties and to offer assistance as needed.

ACASI offers all the benefits of CASI, most notably: (a) the opportunity for a respondent to input her or his answers directly into a computer without having to speak them aloud to the interviewer (or risk having them overheard by someone else nearby); (b) the ability to present the questions in a standardized order across all respondents; (c) the ability to incorporate far more complex skip routing and question customization than is possible for a paper-based self-administered questionnaire; and (d) the opportunity to eliminate questions left blank, inconsistent responses, and out-of-range responses. In addition, the audio component allows semi-literate or fully illiterate respondents to participate in the interview with all of the same privacy protections afforded to literate respondents. This is significant, because historically, in self-administered surveys it was not uncommon for individuals who could not read to either be excluded from participation in the study altogether or to be included but interviewed in a traditional interviewer-administered manner, resulting in the potential for significant mode effects.

Evidence from several large-scale field experiments suggests the ACASI methodology reduces socially desirable responding compared to both interviewer-administered and solely text-based self-administration methods for sensitive topics, including use of illicit drugs, sexual behaviors, and abortion. ACASI also allows for increased standardization in the presentation of the survey questions because a pre-recorded voice is utilized to administer the survey questions. As a result, each respondent hears all introductory text, questions, and response categories read in exactly the same way. Thus, the natural variation caused by differences in interviewers' reading skills, pace, and/or vocal quality is eliminated.

AURAL COMMUNICATION

Aural communication involves the transmission of information through the auditory sensory system—the system of speaking and hearing. It usually encompasses both verbal communication and paralinguistic communication to convey meaning. Aural communication can be used to transmit information independently or in combination with visual communication. When conducting surveys, the mode of data collection determines whether information can be transmitted aurally, visually, or both. Whether survey information is transmitted aurally or visually influences how respondents first perceive and then cognitively process information to provide their responses.

Aural communication relies heavily on verbal language when information is transmitted through spoken words. Additionally, paralinguistic or paraverbal communication, in which information is conveyed through the speaker's voice, is also an important part of aural communication. Paralinguistic communication can convey additional information through voice quality, tone, pitch, volume, inflection, pronunciation, and accent that can supplement or modify the meaning of verbal communication. Paralinguistic communication is an extremely important part of aural communication, especially in telephone surveys, where visual communication is absent.

Since aural and visual communication differ in how information is presented to survey respondents, the type of communication impacts how respondents initially perceive survey information. This initial step of perception influences how respondents cognitively process the survey in the remaining four steps (comprehension, retrieval, judgment formation, and reporting the answer). Whereas telephone surveys rely solely on aural communication, both face-to-face and Internet surveys can utilize aural and visual communication. Face-to-face surveys rely extensively on aural communication with the occasional use of visual communication by utilizing show cards or other visual aids. In contrast, Web surveys use mostly visual communication but have the potential to incorporate aural communication through sound files, a practice that is still fairly uncommon and generally only used to transmit information to respondents. Paper surveys do not utilize any aural communication.

The influence that aural communication has on perception and cognitive processing of information can contribute to effects between modes that rely primarily on aural communication and modes that rely primarily on visual communication. For example, aural transmission of information makes higher demands on memory capacity than visual transmission because respondents must remember information communicated to them without a visual stimulus to remind them. Additionally, in aural communication, the flow or pace is usually controlled by the interviewer, so the respondent may have more pressure to respond quickly rather than being able to fully process the information at his or her own pace. Because of these influences of aural communication on processing time and memory, surveyors often shorten questions and limit the amount of information respondents need to remember at one time in telephone surveys where aural communication cannot be supplemented by visual communication. However, this design difference can impact whether data from telephone surveys can be combined with or compared to data collected using primarily visual communication, where longer and more complex questions and sets of response options are often used.

AUXILIARY VARIABLE

In survey research, there are times when information is available on every unit in the population. If a variable that is known for every unit of the population is not a variable of interest but is instead employed to improve the sampling plan or to enhance estimation of the variables of interest, it is called an *auxiliary variable*.

Ratio and Regression Estimation

The term *auxiliary variables* is most commonly associated with the use of such variables, available for all units in the population, in ratio estimation, regression estimation, and extensions (calibration estimation).

The ratio estimator is a widely used estimator that takes advantage of an auxiliary variable to improve estimation. If x is the auxiliary variable and y is the variable of interest, let X and Y denote the population totals for x and y and let $\hat{X}$ and $\hat{Y}$ denote unbiased estimators of X and Y. Then the ratio estimator $\hat{Y}_R$ of Y is given by

$$\hat{Y}_R = \frac{\hat{Y}}{\hat{X}}X.$$

$\hat{Y}_R$ improves upon $\hat{Y}$ provided that the correlation between x and y exceeds one-half of $S_x/\bar{X}$ divided by $S_y/\bar{Y}$ where $S_x, S_y, \bar{X}$, and $\bar{Y}$ are respectively the standard errors for x and y and the population means for x and y. The ratio estimator takes advantage of the correlation between x and y to well estimate Y/X by $\hat{Y}/\hat{X}$ and further takes advantage of X being known.

A more flexible estimator than the ratio estimator also taking advantage of the auxiliary variable x is the regression estimator:

$$\hat{Y}_{Reg} = \hat{Y} + \hat{b}(X - \hat{X}),$$

where $\hat{b}$ is the estimated slope of y on x from the sample data. The regression estimator can be extended to make use of a vector, X, of auxiliary variables rather than a single one.

In the case of stratified sampling, the ratio and regression estimators have a number of variants. In the case of ratio estimation, the separate ratio estimator does ratio estimation at the stratum level and then sums across strata, whereas the combined ratio estimator estimates $\hat{X}$ and $\hat{Y}$ across strata and then takes ratios.

Unequal Probability Sampling

In unequal probability sampling, the auxiliary variable x is termed a measure of size. The probability of selecting a unit is proportional to its measure of size. For example, in a survey of business establishments, the measure of size might be the number of employees or the total revenue of the establishment, depending on the purpose of the survey and the auxiliary information available. There are numerous sampling schemes for achieving selection probabilities proportional to the measure of size, one being unequal probability systematic sampling. Under general conditions, these schemes are more efficient than equal probability sampling when there is substantial variability in the size of the units in the population.

Stratification

It is often advantageous to divide a population into homogeneous groups called *strata* and to select a sample independently from each stratum. Auxiliary information on all population units is needed in order to form the strata. The auxiliary information can be a categorical variable (e.g., the county of the unit), in which case the categories or groups of categories form the strata. The auxiliary information could also be continuous, in which case *cut points* define the strata. For example, the income of a household or revenue of an establishment could be used to define strata by specifying the upper and lower limits of income or revenue for each stratum.

Post-Stratification

If specific auxiliary information is not used in forming strata or as a measure of size, it can still be used to adjust the sample weights to improve estimation in a process called *post-stratification.*

BALANCED QUESTION

A balanced question is one that has a question stem that presents the respondent with both (all reasonably plausible) sides of an issue. The issue of "balance" in a survey question also can apply to the response alternatives that are presented to respondents. Balanced questions are generally closed-ended questions, but there is nothing inherently wrong with using open-ended questions in which the question stem is balanced.

For example, the following closed-ended question is *unbalanced* for several reasons and will lead to invalid (biased) data:

> Many people believe that American troops should be withdrawn from Iraq as soon as possible. Do you Strongly Agree, Agree, Somewhat Agree, or Strongly Disagree?

First, the question stem presents only one side of the issue in that it notes only one position taken by some people in the general public. Second, the response alternatives are not balanced (symmetrical), as there are three "agree" choices and only one extreme "disagree" choice. Third, the four response alternatives have no true midpoint; this is a further aspect of the asymmetrical (unbalanced) nature of the response alternatives.

In contrast, a balanced version of this question would be as follows:

> Some people believe that American troops should be withdrawn from Iraq as soon as possible, whereas other people believe that they should remain in Iraq until the country is more stable. What is your opinion on whether the troops should be withdrawn as soon as possible? Do you Strongly Agree, Somewhat Agree, Somewhat Disagree, or Strongly Disagree?

This wording is balanced because it poses both sides of the issue. It also has a symmetrical set of response alternatives, with two choices for "agree" and two similarly worded choices for "disagree." Furthermore, it has a true midpoint, even though that midpoint does not have an explicit response alternative associated with it. If the researchers wanted to add a fifth response option representing the midpoint, they could add, "Neither Agree nor Disagree" in the middle.

In writing survey questions, researchers can further balance them by using randomized variations of the ordering of the wording in the question stem and in the ordering of the response choices. In the second example presented here, one version of the stem could be worded as shown and a second version could have the information reversed, as in, *Some people believe that American troops should remain in Iraq until the country is more stable, whereas other people believe that they should be withdrawn from Iraq as soon as possible*. The response alternatives could also be randomly assigned to respondents so that some respondents received the four response choices shown in the second example, and the other half of the respondents could be presented with this order of response choices: Strongly Disagree, Somewhat Disagree, Somewhat Agree, or Strongly Agree.

Balanced Repeated Replication (BRR)

Balanced repeated replication (BRR) is a technique for computing standard errors of survey estimates. It is a special form of the *replicate weights technique*. The basic form of BRR is for a stratified sample with two primary sampling units (PSUs) sampled with replacement in each stratum, although variations have been constructed for some other sample designs. BRR is attractive because it requires slightly less computational effect than the jackknife method for constructing replicate weights and it is valid for a wider range of statistics. In particular, BRR standard errors are valid for the median and other quantiles, whereas the jackknife method can give invalid results.

A sample with two PSUs in each stratum can be split into halves consisting of one PSU from each stratum. The PSU that is excluded from a half-sample is given weight zero, and the PSU that is included is given weight equal to 2 times its sampling weight. Under sampling with replacement or sampling from an infinite population, these two halves are independent stratified samples. Computing a statistic on each half and taking the square of the difference gives an unbiased estimate of the variance of the statistic. Averaging this estimate over many possible ways of choosing one PSU from each stratum gives a more precise estimate of the variance.

If the sample has L strata there are 2^L ways to take one PSU from each stratum, but this would be computationally prohibitive even for moderately large L. The same estimate of the variance of a population mean or population total can be obtained from a much smaller set of "splittings" as long as the following conditions are satisfied:

1. Each PSU is in the first half in exactly 50% of the splittings.
2. Any pair of PSUs from different strata is in the same half in exactly 50% of the splittings.

A set of replicates constructed in this way is said to be in *full orthogonal balance*. It is clearly necessary for these conditions that the number of splittings, R, is a multiple of 4.

An important open question in coding theory, the *Hadamard conjecture*, implies that a suitable set of splittings is possible whenever R is a multiple of 4 that is larger than L. Although the Hadamard conjecture is unproven, sets of replicates with full orthogonal balance are known for all values of R that are likely to be of interest in survey statistics. The construction is especially simple when R is a power of 2, which results in at most twice as many replicates as necessary.

All sets of replicates with full orthogonal balance give the same standard errors as the full set of 2^L replicates for the estimated population mean or population total, and thus it does not matter which set is chosen. For a statistic other than the mean or total, on the other hand, different sets of replicates in full orthogonal balance will typically not give exactly the same standard error. The difference is usually small, and analyses often do not report how the set of replicates was constructed.

One disadvantage of the BRR approach is that a half-sample increases the risk of small-sample computational difficulties such as zero cells in tables. A variant called Fay's method multiplies the sampling weights by $2 - \rho$ and ρ rather than 2 and 0, thus including all observations in all the computations. Fay's method retains the wide validity of BRR and has better small-sample performance. Fay's method is usually available in software that supports BRR replicate weights.

The other disadvantage of BRR is that it applies only to a specialized set of designs. This disadvantage is more difficult to avoid. There are variants of BRR that apply to designs for which the number of PSUs per stratum is fixed and small, but greater than 2. There are also variants that allow for a few strata to have extra or missing PSUs due to design imperfections. Methods for constructing these variants of BRR are typically not available in standard survey software.

Bandwagon and Underdog Effects

Bandwagon and underdog effects refer to the reactions that some voters have to the dissemination of information from trial heat questions in pre-election polls. Based upon the indication that one candidate is leading and the other trailing, a *bandwagon effect* indicates the tendency for some potential voters with low involvement in the election campaign to be attracted to the leader, while the *underdog effect* refers to the tendency for other potential voters to be attracted to the trailing candidate.

Background

Bandwagon and underdog effects were a concern of the earliest critics of public polls, and the founders of polling had to defend themselves against such effects from the start. The use of straw polls was common by the 1920s, and by 1935 a member of Congress had introduced an unsuccessful piece of legislation to limit them by constraining the use of the mails for surveys. A second piece of legislation was introduced in the U.S. Senate after the 1936 election, following on the heels of an editorial in *The New York Times* that raised concerns about bandwagon effects among the public as well as among legislators who saw poll results on new issues (even while the *Times* acknowledged such effects could not have been present in the 1936 election). A subsequent letter to the editor decried an "underdog" effect instead, and the debate was off and running.

In 1937, a scholarly article by Claude E. Robinson presented a defense of the polls that focused on two claims that he disputed empirically. One claim was that the release of the polling data depressed turnout; Robinson argued that turnout had steadily increased from 1924, when the straw polls came to prominence, until the 1936 election. And the second claim concerned the bandwagon effect. Robinson argued that it was too soon to judge that such an effect occurs, because the data did not show any clear demonstration of it; among the multiple instances he cited was the fact that in 1936 Republican candidate Alf Landon's support actually dropped after the release of the 1936 *Literary Digest* results showing Landon in the lead.

George Gallup and S. F. Rae, in 1940, addressed the issue just before the next presidential election, again citing empirical data from multiple states and discussing reactions to presidential candidates and issues in national surveys. They concluded that there were no demonstrable effects while holding out the possibility that additional research might produce evidence in the future. Their approach is interesting in that it discusses alternative research designs that could shed light on the phenomenon. One was the possibility of panel designs for surveys, and the other was the use of experiments, although they warned against using college students as subjects and of issues of external validity associated with unrealistic settings or issues to be evaluated.

The concepts themselves require some definition and specification in order to understand why research on their existence was limited and inconclusive for such a long time, allowing the public pollsters to defend themselves so well. Even when research designs became more refined, the magnitude of effects that could be demonstrated appeared to be relatively small, not enough to affect most elections but with the potential for an impact on close ones. In one sense, both bandwagon and underdog effects reflect a simple stimulus–response model. A potential voter has an initial predisposition, either toward a candidate or to abstain. After exposure to polling information disseminated through the media (newspapers and radio in the 1930s and all kinds of media now), the individual's preference shifts toward one or another candidate, based upon whether the candidate is leading or trailing in the polls. So the first implication of assessing such effects with a survey design is that there should be measurements of preferences over time, preferably with a panel design as suggested by Gallup and Rae. But such panel designs have rarely been present in survey research on underdog and bandwagon effects.

Limitations

A second consideration is that the likely size of the effects is small. This is due to the fact that as Election Day approaches and preferences crystallize, it is the strongest partisans who are most likely to participate. And their preferences are the most stable in the electorate. As a result, there is a relatively small proportion of the likely electorate, as opposed to the entire registered or voting age population, that could be subject to such effects. This implies that very large sample sizes are needed to detect such effects with confidence.

A third consideration is that these two effects do not occur in isolation, and as a result they may offset each other because they reflect responses in opposing directions. This represents another difficulty in searching for their occurrence in single cross-sectional surveys. This in fact was the main point of evidence and source of refutation of bandwagon and underdog effects used by the public pollsters in the early defense of their work. Given the historical record of accuracy of the major public pollsters, with an average deviation from the final election outcome of about 2 percentage points (excluding the 1948 election), the differences between final pre-election poll estimates at the national level and the popular vote for president have been very small.

It should also be noted that the full specification of models that predict candidate preference involve a large number of factors, a further complication for isolating published poll results as a cause. For all of these reasons, researchers interested in these phenomena turned to alternative designs involving variations on experiments. The experimental approach has a number of advantages, including isolating exposure to poll results as the central causal factor when randomization of subjects to various treatment groups and a control group is used to make all other things equal. An experimental design can also assess temporal order as well, verifying that candidate preference occurred (or changed) after exposure to the poll results. A well-designed experimental study will require many fewer subjects than the sample size for a survey-based design. At the same time, the kind of subjects used in many experiments, such as college undergraduates, can raise questions about the external validity of the results. And the nature of questioning and the kinds of stimuli used can as well.

Research

Michael Traugott's 1992 comprehensive review of research on bandwagon and underdog effects found mixed results, probably because the research designs suffered from many of the limitations previously discussed. Virtually all of the experiments were conducted with undergraduate students in a campus setting. They tend to demonstrate effects of exposure to information about the relative standing of candidates in polls, but the subjects were essentially new or beginning voters who tended not to have strong partisan attachments or a history of voting.

In one of the few surveys with a panel design, a 1976 study found that perceptions of the electorate's reactions to Gerald Ford and Jimmy Carter did have an effect on respondents' preferences, especially among those who were ambivalent about the candidates or uncertain of their own choices. Researchers who study the presidential nominating process focus on candidate "momentum" that builds during the primaries and caucuses, a particular form of a bandwagon effect that affects partisans rather than the general electorate. And a panel study conducted before and after Super Tuesday during this phase of the 1988 election showed that contagion was a more powerful explanation for growing support for George H. W. Bush than a desire to support the winner.

In a more elaborate panel conducted by Paul J. Lavrakas and his colleagues during the 1988 election campaign, which also included an imbedded experimental administration of question wordings, both underdog and bandwagon effects were observed. In a pre-election survey, a random half of the sample was given information about the current poll standing of George H. W. Bush and Michael Dukakis while a control group was not. There was an interaction of support levels for each candidate with level of education. Among those with less than a high school education, there was an increase in uncertainty about their preferences but no movement toward one candidate or the other. Among those with a high school education, there was no change in certainty about who they would vote for; but there was an underdog effect when exposed to the current poll standings showing Bush ahead of Dukakis. And those with the highest levels of education showed no change in certainty or candidate preference upon exposure to poll results.

A Canadian study with a similar design focused on two political issues rather than candidate choice, and it detected bandwagon effects of approximately 5 to 7 percentage points. This is the equivalent of conducting two experiments simultaneously, using abortion and Quebec sovereignty as the issues and a statement about poll results and the nature of change in them as stimuli; the bandwagon effect was present in each.

In conclusion, with additional attention devoted to specification of the bandwagon and underdog concepts and a deeper understanding of the conditions needed to demonstrate their presence, the results of recent research indicate that bandwagon and underdog effects can be produced under a variety of conditions. The strongest support for their presence comes from carefully designed experiments. While there may be issues of external validity associated with those conducted in the laboratory, those that are grounded in representative samples of adults or registered voters seem more compelling. The renewed interest in this area of the study of media effects, coupled with more sophisticated survey methodology, suggests that further research on this topic will be fruitful.

Behavioral Question

Behavioral questions are survey questions that ask about respondents' factual circumstances. They contrast with attitude questions, which ask about respondents' opinions. Typical behavioral questions target the respondent's household composition, sources of income, purchases, crime victimizations, hospitalizations, and many other autobiographical details. The Current Population Survey (CPS), for example, asks:

> *Have you worked at a job or business at any time during the past 12 months?*

Similarly, the National Crime Survey (NCS) includes the following behavioral item:

> *During the last 6 months, did anyone steal things that belonged to you from inside ANY car or truck, such as packages or clothing?*

Although these examples call for a simple "Yes" or "No" response, other behavioral items require dates (*When was the last time you . . .* ?), frequencies (*How many times during the last month did you . . .* ?), amounts (*How much did you pay for . . .* ?), and other data. The CPS and NCS examples concern the respondents' behavior in a loose sense, but other questions are less about behavior than about existing or past states of affairs. For example, the following question, from the National Health Interview Survey (NHIS), is more difficult to peg as a behavioral matter:

> *How much do you know about TB—a lot, some, a little, or nothing?*

For questions such as this, "factual question" may be a better label than "behavioral question."

Because behavioral questions often probe incidents in the respondents' pasts, such as jobs and burglaries, they place a premium on the respondents' memory of these incidents. Inability to recall relevant information is thus one factor that affects the accuracy of responses to such questions. Questions about events that took place long ago, that are unremarkable, or that can be confused with irrelevant ones are all subject to inaccuracy because of the burden they place on memory.

People's difficulty in recalling events, however, can lead them to adopt other strategies for answering behavioral questions. In deciding when an event happened, for example, respondents may estimate the time of occurrence using the date of a better-remembered neighboring event ("The burglary happened just after Thanksgiving; so it occurred about December 1"). In deciding how frequently a type of event happened, respondents may base their answer on generic information ("I usually go grocery shopping five times a month"), or they may remember a few incidents and extrapolate to the rest ("I went grocery shopping twice last week, so I probably went eight times last month"). These strategies can potentially compensate for recall problems, but they can also introduce error. In general, the accuracy of an answer to a behavioral question will depend jointly, and in potentially complex ways, on both recall and estimation.

Answers to behavioral questions, like those to attitude questions, can depend on details of question wording. Linguistic factors, including choice of words, grammatical complexity, and pragmatics, can affect respondents' understanding of the question and, in turn, the accuracy of their answers. Because behavioral questions sometimes probe frequencies or amounts, they can depend on the respondents' interpretation of adverbs of quantification, such as *usually, normally*, or *typically* (*How often do you usually/normally/typically go grocery shopping each month?*) or quantifiers of amounts, such as *a lot, some*, or *a little* (as in the NHIS example). Similarly, answers to these questions are a function of respondents' interpretation of the response alternatives. Respondents may assume, for example, that the response options reflect features of the population under study and base their response choice on this assumption.

Behavioral Risk Factor Surveillance System (BRFSS)

The Behavioral Risk Factor Surveillance System (BRFSS) was developed in 1984 as a state-based system designed to measure behavioral risk factors associated with chronic diseases and some infectious diseases. The BRFSS is the world's largest ongoing, random-digit dialing telephone survey on health of adults ages 18 years or older. The survey is administered by the health departments in the 50 U.S. states, the District of Columbia, Puerto Rico, Guam, and the Virgin Islands. The target population is noninstitutionalized adults ages 18 years or older; however, BRFSS has also been used to collect information about children in the households. A large number of interviews (estimated at 350,000) are conducted annually, facilitating the development of local, state, and national estimates of health conditions and risk behaviors.

Participating areas use a standard core questionnaire of about 75 questions. In addition, states can elect to add their own questions or one or more optional standardized modules. In 2006, BRFSS offered 20 of these optional modules, which vary in number of questions and topic and averaged about six questions per module. The number of state-added questions also varies each year, with some states adding as many as 50. All information is self-reported. The core interview takes about 20 minutes to complete.

BRFSS data are collected by each state or territory with support from the Centers for Disease Control and Prevention (CDC). CDC helps to coordinate activities by the states and CDC-based programs, monitors and enforces standardized data collection protocols, ensures the validity and reliability of the data, assists the states in developing new methods and approaches to data collection, and provides BRFSS data files for public use. Because the states are responsible for conducting the survey, multiple contractors are involved. Standardization is achieved through the use of common training and interviewing protocols.

A stratified sample design is used, which facilitates production of estimates for 54 states and territories and for selected local areas. The Selected Metropolitan/Micropolitan Area Risk Trends (SMART-BRFSS) project uses BRFSS to develop estimates for selected metropolitan and micropolitan statistical areas (MMSAs) with 500 or more respondents. Data from the core survey in each state and territory are combined to produce national estimates.

BRFSS data are also used for rapid response surveillance during health emergencies. In the wake of the September 11, 2001, terrorist attacks in New York and Washington, D.C., BRFSS was used to monitor the mental health status of residents in the most affected areas. During the 2004–05 influenza season, when the supply of available influenza vaccine to the United States was cut nearly in half, the BRFSS was used to monitor influenza vaccination coverage during the season, providing national, state, and local health officials with critical information needed to make vaccine redistribution decisions and to inform public health messages encouraging vaccination among people in high-priority groups.

Procedures for maximizing response rates include online standardized interviewer training (required for all BRFSS interviewers), thorough pretesting of the survey questions, toll-free telephone numbers for participants, automated review of key quality indicators (e.g., response rates, refusal rates, percentage of key items with missing data, distribution of respondents by sex and age), and flexible calling schedules. BRFSS is conducted in English and Spanish.

New methodological approaches are tested extensively and regularly to ensure that the BRFSS continues to thrive as one of the leading public health surveillance systems in the world in the face of mounting technological, social, and legal barriers to telephone surveys. This research aims to (a) expand the utility of the surveillance system by developing special surveillance projects, including rapid response surveillance, follow-up surveys, and stand-alone surveillance; (b) identify, monitor, and address potential threats to the validity and reliability of BRFSS data (e.g., changes in telecommunications technologies, legal and privacy restrictions, and changes in social behaviors that might affect survey participation); and (c) develop and conduct innovative pilot studies designed to improve BRFSS's methods and to shape the future direction of the system (e.g., multiple modes of survey administration, address-based sampling, and on-phone interpreters to expand the number of languages in which BRFSS is offered). In addition, BRFSS is exploring the possibility of incorporating households that have only cell phones into the BRFSS sample and collecting physical measures from selected respondents to improve the accuracy of the survey estimates.

Strengths of the BRFSS include the high quality of state and local data, which are available for public health planning. The large state sample sizes, averaging 6,000 completed interviews per state annually, permit analysis of data on population subgroups within a state and development of local estimates for some areas. Data have been collected for many years, so trend data exist for each state or territory and for the nation. BRFSS also facilitates surveillance capacity building within a state or territory. BRFSS provides a basis on which states can develop and expand their data collection and analysis capabilities. The current BRFSS program extends beyond data collection to include a series of committees, workgroups, and conferences that are built around the surveillance effort to help to integrate national, state, and local programs.

Behavior Coding

Behavior coding concerns the systematic assignment of codes to the overt behavior of interviewer and respondent in survey interviews. The method was developed by Charles Cannell and his colleagues at the University of Michigan in the 1970s. Behavior coding is a major tool used to evaluate interviewer performance and questionnaire design. Behavior coding is sometimes referred to as "interaction analysis," although interaction analysis is usually more specifically used in the sense of applying behavior coding to study the course of the interaction between interviewer and respondent.

The three main uses of behavior coding are (1) evaluating interviewer performance, (2) pretesting questionnaires, and (3) studying the course of the interaction between interviewer and respondent.

Evaluating Interviewer Performance

The use of behavior coding to evaluate interviewer performance primarily concerns how the interviewer reads scripted questions from the questionnaire. Typical codes include "Reads question correctly," "Reads question with minor change," "Reads question with major change," "Question incorrectly skipped," and "Suggestive probe." Usually the number of different codes for the purpose of evaluating interviewer performance ranges from five to 15.

Evaluating interviewer performance is usually part of the main field work. To this end, the interviews from the actual survey are audio-recorded. A sufficiently large sample of interviews from each interviewer is drawn (preferably 20 or more of each interviewer) and subjected to behavioral coding. Results may be in the form of "Interviewer X reads 17% of the questions with major change." These results are used to give the interviewer feedback, retrain him or her, or even withdraw him or her from the study.

Pretesting Questionnaires

If a particular question is often read incorrectly, this may be due to interviewer error, but it may also be a result of the wording of the question itself. Perhaps the question has a complex formulation or contains words that are easily misunderstood by the respondent. To prevent such misunderstandings, the interviewer may deliberately change the formulation of the question.

To gain more insight into the quality of the questions, the behavior of the respondent should be coded too. Typical codes for respondent behavior include "Asks repetition of the question," "Asks for clarification," "Provides uncodeable response" (e.g., "I watch television most of the days," instead of an exact number), or "Expresses doubt" (e.g., "About six I think, I'm not sure"). Most behavior coding studies use codes both for the respondent and the interviewer. The number of different codes may range between 10 and 20.

Unlike evaluating interviewer performance, pretesting questionnaires by means of behavioral coding requires a pilot study conducted prior to the main data collection. Such a pilot study should reflect the main study as closely as possible with respect to interviewers and respondents. At least 50 interviews are necessary, and even more if particular questions are asked less often because of skip patterns.

Compared to other methods of pretesting questionnaires, such as cognitive interviewing or focus groups, pretesting by means of behavior coding is relatively expensive. Moreover, it primarily points to problems rather than causes of problems. However, the results of behavior coding are more trustworthy, because the data are collected in a situation that mirrors the data collection of the main study. Moreover, problems that appear in the actual behavior of interviewer and respondent are real problems, whereas in other cases, for example in cognitive interviewing, respondents may report pseudo-problems with a question just to please the interviewer.

Interviewer–Respondent Interaction

If one codes both the behavior of interviewer and respondent and takes the order of the coded utterances into account, it becomes possible to study the course of the interaction. For example, one may observe from a pretesting study that a particular question yields a disproportionately high number of suggestive probes from the interviewer. Such an observation does not yield much insight into the causes of this high number. However, if one has ordered sequences of codes available, one may observe that these suggestive probes almost invariantly occur after an uncodeable response to that question. After studying the type of uncodeable response and the available response alternatives in more detail, the researcher may decide to adjust the formulation of the response alternatives in order to decrease the number of uncodeable responses, which in turn should decrease the number of suggestive probes.

In contrast, if the researcher merely looked at the sheer number of suggestive probings, he or she might have decided to adjust the interviewer training and warn the interviewers not to be suggestive, especially when asking the offending question. This may help a bit, but does not take away the cause of the problem.

As the previous example shows, interviewer–respondent interaction studies are focused on causes of particular behavior, that is, the preceding behavior of the other person. Because the researcher does not want to overlook particular causes, each and every utterance in the interaction is usually coded and described with some code. Hence, the number of different codes used in these studies can be quite high and exceeds 100 in some studies.

Behavior Coding Procedures

Recording Procedures

In a few cases, interviews are coded "live" (during the interview itself), sometimes by an observer, sometimes even by the interviewer herself. A main reason for live coding is that one does not need permission of the respondent to audio-record the interview. Another advantage is that results are quickly available, which can be especially useful in case of pretesting questionnaires.

In most studies, however, the interview is first audio-recorded. More recently, in the case of computer-assisted interviewing, the interview is recorded by the computer or laptop itself, thus eliminating the need for a separate tape recorder. Coding audio-recorded interviews is much more reliable than live coding, because the coder can listen repeatedly to ambiguous fragments.

If interviews are audio-recorded, they are sometimes first transcribed before coding. Transcripts yield more details than the codes alone. For example, if a particular question is often coded as "Read with major change," the availability of transcripts allows the researcher to look at the kind of mistakes made by the interviewer. Transcripts also make semi-automatic coding possible; a computer program can decide, for example, whether or not questions are read exactly as worded.

Full Versus Selective Coding

In interviewer-monitoring studies, it may be sufficient to code the utterances of the interviewer only; moreover, the researcher may confine himself to particular interviewer utterances, like question reading, probing, or providing clarification. Other types of utterances—for example, repeating the respondent's answer—are neglected. In pretesting studies, it is sometimes decided to code only behavior of the respondent. Also, in interaction studies, the researcher may use a form of such "selective" coding, neglecting all utterances after the answer of the respondent (e.g., if the respondent continues to elucidate the answer, this would not be coded). Alternatively, each and every utterance is coded. Especially in the case of interaction studies, this is the most common strategy.

All these procedural decisions have time and cost implications. Selective live coding is the fastest and cheapest, while full audio-recorded coding using transcriptions is the most tedious and costly but also yields the most information.

BENEFICENCE

The National Research Act (Public Law 93348) of 1974 created the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research, which, among other duties, was charged with the responsibility of identifying, articulating, and fully explaining those basic ethical principles that should underlie the conduct of biomedical and behavioral research involving human subjects throughout the United States. The commission's findings have been detailed in a 1979 document typically referred to as "The Belmont Report" in recognition of the Smithsonian Institute satellite site where it was drafted, the Belmont Conference Center in Elkridge, Maryland. The Belmont Report identified three basic ethical principals for the conduct of research, and one of these is *beneficence*. (The other identified principles are *justice* and *respect for persons*.) The Belmont Report clearly states that the principle of beneficence has its roots in the long-standing ethical guidelines of the medical profession's Hippocratic Oath generally and, in particular, its maxims instructing physicians to "never do harm" while acting "according to [one's] ability and [one's] judgment."

From these ideas, three more fully articulated notions have been derived. First is the principle that researchers are obligated, not merely encouraged or expected, to take all reasonable steps to avoid inflicting foreseeable harm upon research participants. Second is that researchers are obligated to work toward maximizing the benefits that research subjects might experience from participation in a research program. This does not mean that it is required that a research program provide direct benefits to its research subjects, however. Similarly, investigators are obligated to attempt to maximize anticipated longer-term benefits that society or people in general might realize as a consequence of the study. Finally, beneficence incorporates the idea that exposing research participants to risk is justifiable. The reality that research is a human enterprise, one that relies upon the individual abilities and judgments of researchers acting within the frameworks of existing knowledge and cultural norms, is recognized. As such, it is ethically acceptable and permissible for research to possess or encompass potential for a protocol or well-meaning actions taken by an investigator to result in harm to participants; typically some level of risk is appropriate, and it is a judgment call as to what that risk level can and should be. To summarize, beneficence represents the process of balancing the trade-off between the potential benefits and the justifiable risk of potential harms associated with participation in research, and it is manifest in investigator efforts to minimize risks while maximizing potential benefits to the individual participant and/or society as a whole.

The term *risk* refers to both the likelihood of some type of harm being experienced by one or more research participants and the extent or severity of that harm in the event that harm is experienced. Therefore, assessments of the risks associated with a research project may take account of the combined probabilities and magnitudes of potential harms that might accrue to research participants. Furthermore, though one proclivity may be to think of harm as physical insults (such as pain, discomfort, injury, or toxic effects of drugs or other substances), the nature of potential harms can be wide and varied. Indeed, while the potential for physical harms typically is virtually nonexistent in survey research, other categories of potential harms frequently are relevant. These other categories include:

- Psychological and emotional harms (e.g., depression, anxiety, confusion, stress, guilt, embarrassment, or loss of self-esteem)
- Social or political harms (e.g., "labeling," stigmatization, loss of status, or discrimination in employment)
- Economic harms (e.g., incurring actual financial cost from participation), and
- Infringements of privacy or breaches of confidentiality (which, in turn, may result in psychological, emotional, social, political, or economic harms)

It is the principle of beneficence, along with the principles of justice and respect for human subjects, that stands as the foundation upon which the government-mandated rules for the conduct of research (Chapter 45, Subpart A, Section 46 of the Code of Federal Regulations) have been created under the auspices of the U.S. Department of Health and Human Services, Office of Human Research Protections.

Bias

Bias is a constant, systematic form or source of error, as opposed to *variance*, which is random, variable error. The nature and the extent of bias in survey measures is one of the most daunting problems that survey researchers face. How to quantify the presence of bias and how to reduce its occurrence are ever-present challenges in survey research. Bias can exist in myriad ways in survey statistics. In some cases its effect is so small as to render it ignorable. In other cases it is nonignorable and it can, and does, render survey statistics wholly invalid.

Overview

Survey researchers often rely upon estimates of population statistics of interest derived from sampling the relevant population and gathering data from that sample. To the extent the sample statistic differs from the true value of the population statistic, that difference is the error associated with the sample statistic. If the error of the sample statistic is systematic—that is, the errors from repeated samples using the same survey design do not balance each other out—the sample statistic is said to be biased. Bias is the difference between the average, or expected value, of the sample estimates and the target population's true value for the relevant statistic. If the sample statistic derived from an estimator is more often larger, in repeated samplings, than the target population's true value, then the sample statistic exhibits a *positive bias*. If the majority of the sample statistics from an estimator are smaller, in repeated samplings, than the target population's true value, then the sample statistic shows a *negative bias*.

Bias of a survey estimate differs from the error of a survey estimate because the bias of an estimate relates to the systematic and constant error the estimate exhibits in repeated samplings. In other words, simply drawing another sample using the same sample design does not attenuate the bias of the survey estimate. However, drawing another sample in the context of the error of a survey can impact the value of that error across samples.

Graphically, this can be represented by a bull's-eye in which the center of the bull's-eye is the true value of the relevant population statistic and the shots at the target represent the sample estimates of that population statistic. Each shot at the target represents an estimate of the true population value from a sample using the same survey design. For any given sample, the difference between the sample estimate (a shot at the target) and the true value of the population (the bull's-eye) is the error of the sample estimate.

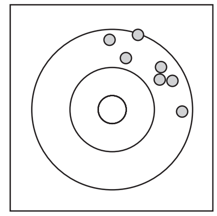

Figure 1 Example of a biased sample statistic

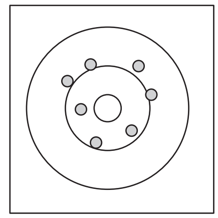

Figure 2 Example of an unbiased sample statistic

Multiple shots at the target are derived from repeated samplings using the same survey design. In each sample, if the estimator of the population statistic generates estimates (or hits on the bull's-eye) that are consistently off center of the target in a systematic way, then the sample statistic is biased.

Figure 1 illustrates estimates of the true value of the population statistic (the center of the bull's-eye), all of which are systematically to the upper right of the true value. The difference between any one of these estimates and the true value of the population statistic (the center of the bull's-eye) is the error of the estimate. The difference between the average value of these estimates and the center of the target (the true value of the population statistic) is the bias of the sample statistic.

Contrasting Figure 1 to a figure that illustrates an unbiased sample statistic, Figure 2 shows hits to the target that center around the true value, even though no sample estimate actually hits the true value.

Unlike Figure 1, however, the sample estimates in Figure 2 are not systematically off center. Put another way, the average, or expected value, of the sample estimates is equal to the true value of the population statistic indicating an unbiased estimator of the population statistic. This is an unbiased estimator even though all of the estimates from repeated samplings never hit the center of the bull's-eye. In other words, there is error associated with every sample estimate, but not bias.

Bias can be classified into two broad categories: (1) the bias related to the sampling process, and (2) the bias related to the data collection process. In the former case, if the survey design requires a sample to be taken from the target population, shortcomings in the sample design can lead to different forms of bias. Biases related to the sampling design are (a) estimation (or sampling) bias, (b) coverage bias, and (c) nonresponse bias. All of these are related to external validity.

Bias related to the data collection process is measurement bias and is related to construct validity. Measurement bias can be due to (a) data collection shortcomings dealing with the respondent, (b) the questionnaire, (c) the interviewer, (d) the mode of data collection, or (e) a combination of any of these.

To gauge the size of the bias, survey researchers sometimes refer to the *relative bias* of an estimator. The relative bias for an estimator is the bias as a proportion of the total population estimate.

Estimation Bias

Estimation bias, or sampling bias, is the difference between the expected value, or mean of the sampling distribution, of an estimator and the true value of the population statistic. More specifically, if θ is the population statistic of interest and $\hat{\theta}$ is the estimator of that statistic that is used to derive the sample estimate of the population statistic, the bias of $\hat{\theta}$ is defined as:

$$Bias[\hat{\theta}] = E[\hat{\theta}] - \theta.$$

The estimation bias of the estimator is the difference between the expected value of that statistic and the true value. If the expected value of the estimator, $\hat{\theta}$, is equal to the true value, then the estimator is unbiased.

Estimation bias is different from estimation, or sampling, error in that sampling error is the difference between a sample estimate and the true value of the population statistic based on one sampling of the sample frame. If a different sample were taken, using the same sample design, the sampling error would likely be different for a given sample statistic. However, the estimation bias of the sample statistic would still be the same, even in repeated samples.

Often, a desirable property of an estimator is that it is unbiased, but this must be weighed against other desirable properties that a survey researcher may want an estimator to have. For example, another desirable property of an estimator can be that it is the most efficient estimator from a class of estimators. In that case, even if the estimator is biased to some degree, the corresponding gain in efficiency can still lead to a smaller mean squared error when compared with unbiased estimators.

Coverage Bias

Coverage bias is the bias associated with the failure of the sampling frame to cover the target population. If the sampling frame does not allow the selection of some subset of the target population, then a survey can be susceptible to undercoverage. If a sampling frame enumerates multiple listings for a given member of the target population, then a survey can suffer from overcoverage.

In the case of undercoverage, a necessary condition for the existence of coverage bias is that there are members of the target population that are not part of the sampling frame. However, this is not a sufficient condition for coverage bias to exist. In addition, the members of the target population not covered by the sampling frame must differ across the population statistic of interest in some nonignorable way from the members of the target population covered by the sampling frame. To the extent that there is not a statistically significant nonignorable difference between the members of the target population covered by the sampling frame and the members of the target population not covered by the sampling frame, the coverage bias is likely to be small, even in instances when there is significant noncoverage of the population by the sampling frame.

If one defines the following:

$\bar{\theta}_C \equiv$ The population mean for the relevant variable for all members of the population covered by the sampling frame

$\bar{\theta}_{NC} \equiv$ The population mean for the relevant variable for all members of the population *not* covered by the sampling frame

$p_C \equiv$ The proportion of the target population covered by the sampling frame

coverage bias, due to undercoverage, is defined as:

$$Bias_{Coverage} \equiv (1 - p_C) * (\bar{\theta}_C - \bar{\theta}_{NC}).$$

Coverage bias is composed of two terms. The first term is the proportion of the target population not covered by the sampling frame. The second term is the difference in the relevant variable between the population mean for those members covered by the sampling frame and the population mean for those members not covered by the sampling frame. From this equation, it is clear that, as the coverage of the population by the sampling frame goes to 1, the amount of coverage bias goes to 0, even for large differences between the covered and noncovered population cohorts. Consequently, a sampling frame that covers the target population entirely cannot suffer from coverage bias due to undercoverage.

In those instances where there is not perfect overlap, however, between the target population and the sampling frame, methods have been developed to ameliorate possible coverage bias. Dual- and other multi-frame designs can be used to augment a single-frame design, thereby reducing the amount of noncoverage, which reduces the potential coverage bias. Another approach that can be used in conjunction with a dual-frame design is a mixed-mode survey, whereby different modes of data collection can be employed to address population members that would only be reached by one mode. Both of these approaches require implementation prior to data collection. However, post-survey weighting adjustments can be used, as the name implies, after data collection has taken place.

Nonresponse Bias

Nonresponse is the bias associated with the failure of members of the chosen sample to complete one or more questions from the questionnaire or the entire questionnaire itself. *Item nonresponse* involves sampled members of the target population who fail to respond to one or more survey questions. *Unit nonresponse* is the failure of sample members to respond to the entire survey. This can be due to respondents' refusals or inability to complete the survey or the failure of the researchers to contact the appropriate respondents to complete the survey.

Like coverage bias, to the extent that there is not a statistically significant nonignorable difference between the sample members who respond to the survey and the sample members who do not respond to the survey, the nonresponse bias is likely to be small (negligible), even in instances when there is significant item or unit nonresponse.

If one defines the following:

$\overline{\theta}_R \equiv$ The population mean for the relevant variable for all members of the sample who respond to the survey

$\overline{\theta}_{NR} \equiv$ The population mean for the relevant variable for all members of the sample who do *not* respond to the survey

$p_R \equiv$ The proportion of the sample that responds to the survey

nonresponse bias is defined as:

$$Bias_{Nonresponse} \equiv (1 - p_R) * (\overline{\theta}_R - \overline{\theta}_{NR}).$$

Nonresponse bias is composed of two terms. The first term is the proportion of the sample that did not respond to the survey (or to a question from the questionnaire in the case of item nonresponse). The second term is the difference in the relevant variable between the sample members who responded and the population mean for those sample members who did not respond. From this equation, it is clear that, as the response rate goes to 1, the amount of nonresponse bias goes to 0, even for large differences between the respondents and the nonrespondents. Consequently, a survey (or a question) that has a 100% response rate cannot suffer from nonresponse bias.

In those instances where there is not a 100% response rate, however, methods have been developed to lessen possible nonresponse bias. One method is to invest survey resources into maximizing the response rate to the survey. With this approach, regardless of how different respondents and nonrespondents might be, as the response rate goes to 1, the possibility of nonresponse bias may become more remote. However, often the survey resources required to achieve response rates that approach 100% are sizable. For example, in a telephone survey, conducting a large number of callbacks and undertaking refusal conversions can lead to higher response rates. But, by investing a large amount of the survey resources into higher response rates, the likelihood of diminished returns to this investment becomes more likely.

Survey researchers recognize that, in the context of nonresponse bias, the response rate is only part of the story. Therefore, some other methods that survey researchers use to combat nonresponse bias are (a) designing questionnaires that attempt to minimize the respondents' burden of completing the survey;

(b) identifying interviewers who are skilled in overcoming refusals and training these interviewers to hone these skills further; and (c) developing a motivational incentive system to coax reluctant respondents into participation.

Another approach that adjusts survey data to attempt to account for possible nonresponse bias is the use of post-stratified weighting methods, including the use of raking adjustments. With these methods, auxiliary information is used about the target population to bring the sample, along selected metrics, in line with that population. Imputation methods can also be used to insert specific responses to survey questions suffering from item nonresponse.

Measurement Bias

Measurement bias is the bias associated with the failure to measure accurately the intended variable or construct. The bias results from the difference between the true value for what the question or questionnaire intends to measure and what the question or questionnaire actually does measure. The source of the bias can be the interviewer, the questionnaire, the respondent, the mode of data collection, or a combination of all of these.

Measurement bias can be particularly difficult to detect. The problem with detection stems from the possibility that the bias can originate from so many possible sources. Respondents can contribute to measurement bias due to limitations in cognitive ability, including recall ability, and due to motivational shortcomings in the effort required to answer the survey questions properly. To combat measurement bias from respondents, surveys can be designed with subtle redundancy in the questions asked for variables and constructs where the survey researcher suspects some problem. This redundancy allows the researcher to examine the survey results for each respondent to determine whether internal inconsistencies exist that would undermine the data integrity for a given respondent.

The questionnaire can contribute to measurement bias by having questions that inadequately address or measure the concepts, constructs, and opinions that make up the subject matter of the study. The questionnaire can also contribute to measurement bias if the question wording and order of questions impact the quality of respondents' answers. Typically, the amount of measurement bias introduced due to the questionnaire will be difficult to gauge without controlled experiments to measure the difference in respondents' answers from the original questionnaire when compared to the questionnaire that was reworded and that reordered questions and possible response options.

Interviewers can contribute to measurement error by failing to read survey questions correctly, by using intonations and mannerisms that can influence respondents' answers, and by incorrectly recording responses. To address possible measurement bias from interviewers, the researcher can invest additional survey resources into the training of interviewers to eliminate habits and flawed data collection approaches that could introduce measurement bias. Moreover, the researcher can focus efforts to monitor interviewers as data collection is taking place to determine whether measurement bias is likely being introduced into the survey by interviewers.

The mode of data collection can also contribute to measurement bias. To the extent that respondents' answers are different across different modes of data collection, even when other factors are held constant, measurement bias could result due to different data collection modes.

Bilingual Interviewing

Bilingual interviewing refers to in-person and telephone surveys that employ interviewers who have the ability to speak more than one language. Typically in the United States, this means they are fluent in English and in Spanish. These interviewers use their language abilities to gain cooperation from sampled respondents and/or to gather data from these respondents.

It has become increasingly common for survey research organizations and their clients to gather the voices, viewpoints, and experiences of respondents who speak only in a native language other than English or prefer to speak in a language other than English. Representation from a sample that closely resembles the target population is important in reducing possible coverage and nonresponse biases. Even though the most common bilingual ethnic group in the United States is the Spanish-speaking or "Spanish Dominant" group, some survey researchers have been known to delve deep into ethnic communities, collecting survey data in more than 10 languages.

Knowing the Population

Bilingual interviewing presents a number of considerations for the survey researcher. First, survey researchers and clients need to determine which bilingual and non-English populations will be included in the survey. Before the questionnaire is translated into the foreign language(s), it is important to understand the bilingual population the survey will reach. Some bilingual populations have cultural perceptions about survey research that are different from non-bilingual populations. Foreign-born bilingual respondents often are not familiar with the field and practice of survey research, necessitating an easily understood explanation of the purpose of the survey provided by the interviewer at the time of recruitment, thereby increasing the level of trust between the interviewer and respondent.

Interviewer Support

Additionally, bilingual populations may show hesitation in answering particular questions that may not be problematic for non-bilingual populations. For example, many Spanish-speaking respondents tend to routinely hesitate when asked to provide their names and addresses. Each bilingual group may have its own set of questions that are considered "sensitive" when asked by an outsider (i.e., the survey interviewer). Thus the interviewer will need to find ways to minimize respondent hesitation and reluctance in order to continue successfully with the questionnaire. In order to anticipate sensitive questions, the researcher may want to hold focus groups with members of the bilingual population prior to the start of the study. Alterations to wording, improvements to transitions leading into question sequences, clarifying statements, and the addition of proactive persuaders can be useful in minimizing the negative effects of asking sensitive survey questions in languages other than English. The training bilingual interviewers receive thus needs to include attention to all these matters.

The survey researcher also will want to find out how the target population might respond to the survey mode. Some bilingual populations prefer to be interviewed in person, where they can see the facial expressions of the interviewer and pick up on body language. Other bilingual populations are more private and may prefer to be interviewed over the phone. Even though each bilingual population might have its own preference, the client and researchers may choose to use only one mode of data collection across different or mixed ethnic groups. Survey researchers can train bilingual interviewers on techniques to make the bilingual respondent feel comfortable in any type of survey mode.

Translation Process

The quality of the bilingual questionnaire translation will depend on the time and resources the survey researcher can devote to the task. It is in the best interest of the survey researcher to provide the group that is doing the translation with information on the background of the study, information about the questionnaire topics, country-of-origin statistics of the target population, acculturation level of the target population, effective words or phrases that may have been used in prior studies, and the format in which the survey will be conducted (i.e., phone, mail, in person, etc.). All of this information provides the translators with the tools to tailor the questionnaire translation to the bilingual target population(s). The preferred method of translation is to allow at least two translators to independently develop their own translated versions of the survey questionnaire. Next, the two translators use their independent versions to develop a single version and review the new version with the project lead to make sure the concepts have been conveyed correctly and effectively. The team then finalizes the version for use in bilingual interviewing pilot testing. Even though this translation process takes additional time and resources, it is preferred as a way to avoid problems common in most survey translations that are associated with (a) the overreliance of word-for-word literal translations, (b) oral surveys that are translated into written style (vs. spoken style), (c) translations in which the educational level is too high for the average respondent, (d) terms that do not effectively convey the correct meaning in the non-English language, (e) terms that are misunderstood, and (f) terms that are inappropriate to use in a professional survey. These problems become evident when the survey researcher has not provided enough information to the translation group.

The survey researcher will want to conduct the final check of translated document for words that may not be appropriate to use with the targeted bilingual population(s). Word meaning can vary by country, culture, and regional dialect, and inappropriate meanings may not be evident to the translation company. It is helpful to have a staff member who is knowledgeable in both bilingual translations and cultural considerations conduct the final questionnaire review. A fine-tuned script is essential to building trust and rapport with the bilingual respondent and to avoid any fear or hesitation invoked by an outside party collecting personal information.

Interviewing

In order to interview bilingual populations, the survey research organization must employ bilingual interviewers and bilingual support staff that are fluent in all the languages in which respondents will be recruited and interviewed. Interviewers and support staff should be able to show mastery of the relevant languages, and their abilities (including their ability to speak English or the dominant language in which the survey will be administered) should be evaluated through use of a language skills test to measure spoken fluency, reading ability, and comprehension in the other language(s). During data collection, it is important for interviewers and support staff to be able to communicate with the researchers and project supervisors to work together to address any culturally specific problem that may arise.

Depending on the level of funding available to the survey organization, there are a few areas of additional training that are useful in improving bilingual staff interviewing skills: listening techniques, language and cultural information about bilingual respondents, and accent reduction techniques.

The researcher may want to have bilingual interviewers trained to listen for important cues from the respondent, that is, the respondents' dominant language, level of acculturation, culture or country of origin, immigration status, gender, age, education level, socioeconomic status, individual personality, and situation or mood. The bilingual interviewer can use these cues proactively to tailor the survey introduction and address any respondent concerns, leading to a smooth and complete interview.

Survey researchers can provide interviewers with information on language patterns, cultural concepts, and cultural tendencies of bilingual respondents. Understanding communication behavior and attitudes can also be helpful in tailoring the introduction and addressing respondent concerns. Survey researchers need to train bilingual interviewers to use a "standard" conversational form of the foreign language, remain neutral, and communicate in a professional public-speaking voice. The use of a professional voice helps reduce the tendency of both the interviewer and respondent to judge social characteristics of speech, especially when the interviewer has the same regional language style as the respondent.

For those bilingual interviewers who will also be conducting interviews in English but have trouble with English consonant and vowel pronunciation, a training module that teaches *accent reduction* will help the interviewer produce clearer speech so that English-language respondents do not have to strain to understand.

Bipolar Scale

Survey researchers frequently employ rating scales to assess attitudes, behaviors, and other phenomena having a dimensional quality. A rating scale is a response format in which the respondent registers his or her position along a continuum of values. The *bipolar scale* is a particular type of rating scale characterized by a continuum between two opposite end points. A central property of the bipolar scale is that it measures both the direction (side of the scale) and intensity (distance from the center) of the respondent's position on the concept of interest.

The construction of bipolar scales involves numerous design decisions, each of which may influence how respondents interpret the question and identify their placement along the continuum. Scales typically feature equally spaced gradients between labeled end points. Data quality tends to be higher when all of the gradients are assigned verbal labels than when some or all gradients have only numeric labels or are unlabeled. Studies that scale adverbial expressions of intensity, amount, and likelihood may inform the researcher's choice of verbal labels that define relatively equidistant categories.

Both numeric and verbal labels convey information to the respondent about the meaning of the scale points. As shown in Figure 1, negative-to-positive numbering (e.g., –3 to + 3) may indicate a bipolar conceptualization with the middle value (0) as a balance point. By contrast, low-to-high positive numbering (e.g., 0 to + 7) may indicate a unipolar conceptualization, whereby the low end represents the absence of the concept of interest and the high end represents a great deal. The choice of gradient labels may either reinforce or dilute the implications of the end point labels.

Extremely dissatisfied	–3	–2	–1	0	+1	+2	+3	Extremely satisfied

Figure 1 Example of bipolar scale

While negative-to-positive numbering may seem the natural choice for a bipolar scale, this format has a potential drawback. In general, respondents are less likely to select negative values on a scale with negative-to-positive labeling than they are to select the formally equivalent values on a scale with low-to-high positive labeling. Similarly, bipolar verbal labels result in more use of the midpoint and less use of the negative values than when unipolar verbal labels are used. Systematic reluctance to select negative values shifts the distribution of the responses to the positive end of the scale, yielding a relatively high mean score. In addition, the spread of the responses attenuates, yielding a reduction in variance.

The number of gradients represents a compromise between the researcher's desire to obtain more detailed information and the limited capacity of respondents to reliably make distinctions between numerous scale values. Research suggests that 7-point scales tend to be optimal in terms of reliability (test–retest) and the percentage of undecided respondents. Thus, 7-point scales plus or minus 2 points are the most widely used in practice.

Scales featuring a large number of labeled gradients may be difficult to administer aurally, as in a telephone interview. A common solution is to decompose the scale into two parts through a process called "branching" or "unfolding." The respondent is first asked about direction (e.g., *Overall, are you satisfied or dissatisfied?*) and then about degree (e.g., *Are you extremely (dis)satisfied, very (dis)satisfied, somewhat (dis)satisfied, or only a little (dis)satisfied?*). In certain multi-mode studies, branching may also be used to increase the comparability of responses across different modes of administration. In self-administered modes and face-to-face interviewing, respondents are often provided with a pictorial rendering of the scale, but respondents in telephone interviews usually cannot be provided with such visual aids. Administering a common branching question in each mode reduces the effect of mode on respondents' answers.

The midpoint of a bipolar scale may be interpreted in different ways. It can be conceived of as signaling indifference (e.g., neither satisfied nor dissatisfied) or ambivalence (e.g., satisfied in some ways but dissatisfied in others). When a middle position is explicitly offered, more respondents will select it than will volunteer it if it is not explicitly offered. In general, including a midpoint reduces the amount of random measurement error without affecting validity. If, however, the researcher has a substantive interest in dichotomizing respondents between the two poles, excluding a middle position may simplify the analysis.

Bogus Question

A bogus question (also called a *fictitious question*) is one that asks about something that does not exist. It is included in a survey questionnaire to help the researcher estimate the extent to which respondents are providing ostensibly substantive answers to questions they cannot know anything about, because it does not exist. Bogus questions are a valuable way for researchers to gather information to help understand the nature and size of respondent-related measurement error.

Examples of how a researcher can use a bogus question abound, but they are especially relevant to surveys that measure recognition of, or past experience with, people, places, or things. For example, in pre-election polls at the time of the primaries, candidate name recognition is critical for understanding the intentions of voters. Thus, the name of a fictitious candidate could be added to the list of real candidates the survey is asking about to learn how many respondents answer that they know the fictitious (bogus) candidate. Similarly, when people (e.g., surveys of teenagers) are asked about the use of illegal substances they may have used in the past, it is advisable to add one or more bogus substances to the list of those asked about to be able to estimate the proportion of respondents who may well be answering erroneously to the real survey questions.

Past experience has shown that in some cases as many as 20% of respondents answer affirmatively when asked if they ever have "heard about X before today," where X is something that does not exist. That is, these respondents do not merely answer that they are "uncertain"—they actually report, "Yes," they have heard of the entity being asked about. Past research has suggested that respondents with lower educational attainment are most likely to answer affirmatively to bogus questions.

The data from bogus questions, especially if several bogus questions are included in the questionnaire, can be used by researchers to (a) filter out respondents who appear to have answered wholly unreliably, and/or (b) create a scaled variable based on the answers given to the bogus questions and then use this variable as a covariate in other analyses. Researchers need to explicitly determine whether or not the needs of the survey justify the costs of adding bogus questions to a questionnaire. When a new topic is being studied—that is, one that people are not likely to know much about—it is especially prudent to consider the use of bogus questions.

BOOTSTRAPPING

Bootstrapping is a computer-intensive, nonparametric approach to statistical inference. Rather than making assumptions about the sampling distribution of a statistic, bootstrapping uses the variability within a sample to estimate that sampling distribution empirically. This is done by randomly resampling with replacement from the sample many times in a way that mimics the original sampling scheme. There are various approaches to constructing confidence intervals with this estimated sampling distribution that can be then used to make statistical inferences.

Goal

The goal of statistical inference is to make probability statements about a population parameter, θ, from a statistic, $\hat{\theta}$, calculated from sample data drawn randomly from a population. At the heart of such analysis is the statistic's sampling distribution, which is the range of values it could take on in a random sample of a given size from a given population and the probabilities associated with those values. In the standard parametric inferential statistics that social scientists learn in graduate school (with the ubiquitous *t*-tests and *p*-values), a statistic's sampling distribution is derived using basic assumptions and mathematical analysis. For example, the central limit theorem gives one good reason to believe that the sampling distribution of a sample mean is normal in shape, with an expected value of the population mean and a standard deviation of approximately the standard deviation of the variable in the population divided by the square root of the sample size. However, there are situations in which either no such parametric statistical theory exists for a statistic or the assumptions needed to apply it do not hold. In analyzing survey data, even using well-known statistics, the latter problem may arise. In these cases, one may be able to use bootstrapping to make a probability-based inference to the population parameter.

Procedure

Bootstrapping is a general approach to statistical inference that can be applied to virtually any statistic. The basic procedure has two steps: (1) estimating the statistic's sampling distribution through resampling, and (2) using this estimated sampling distribution to construct confidence intervals to make inferences to population parameters.

Resampling

First, a statistic's sampling distribution is estimated by treating the sample as the population and conducting a form of Monte Carlo simulation on it. This is done by randomly resampling with *replacement* a large number of samples of size *n* from the original sample of size *n*. Replacement sampling causes the resamples to be similar to, but slightly different from, the original sample, because an individual case in the original sample may appear once, more than once, or not at all in any given resample.

For the resulting estimate of the statistic's sampling distribution to be unbiased, resampling needs to be conducted to mimic the sampling process that generated the original sample. Any stratification, weighting, clustering, stages, and so forth used to draw the original sample need to be used to draw each resample. In this way, the random variation that was introduced into the original sample will be introduced into the resamples in a similar fashion. The ability to make inferences from complex random samples is one of the important advantages of bootstrapping over parametric inference. In addition to mimicking the original sampling procedure, resampling ought to be conducted only on the random component of a statistical model. For example, an analyst would resample the error term of a regression model to make inferences about regression parameters, as needed, unless the data are all drawn from the same source, as in the case of using data from a single survey as both the dependent and independent variables in a model. In such a case, since the independent variables have the same source of randomness—an error as the dependent variable—the proper approach is to resample whole cases of data.

For each resample, one calculates the sample statistic to be used in the inference, $\hat{\theta}^*$. Because each resample is slightly and randomly different from each other resample, these $\hat{\theta}^*$s will also be slightly and randomly different from one another. The central assertion of bootstrapping is that a relative frequency distribution of these $\hat{\theta}^*$s is an unbiased estimate of the sampling distribution of $\hat{\theta}$, given the sampling procedure used to derive the original sample being mimicked in the resampling procedure.

To illustrate the effect of resampling, consider the simple example in Table 1. The original sample was drawn as a simple random sample from a standard normal distribution. The estimated mean and standard deviation vary somewhat from the population parameters (0 and 1, respectively) because this is a random sample. Note several things about the three resamples. First, there are no values in these resamples that do not appear in the original sample, because these resamples were generated from the original sample. Second, due to resampling with replacement, not every value in the original sample is found in each resample, and some of the original sample values are found in a given resample more than once. Third, the sample statistics estimated from the resamples (in this case, the means and standard deviations) are close to, but slightly different from, those of the original sample. The relative frequency distribution of these means (or standard deviations or any other statistic calculated from these resamples) is the bootstrap estimate of the sampling distribution of the population parameter.

How many of these resamples and $\hat{\theta}^*$s are needed for an analyst to conduct valid bootstrap inference? This bootstrap estimate of the sampling distribution of $\hat{\theta}$ is asymptotically unbiased, but how many resamples yield a sampling distribution estimate with a variance small enough to yield inferences precise enough to be practical? There are two components to this answer. First, the asymptotics of the unbiasedness proof for the bootstrap estimate of the sampling distribution require an original sample of data so that the statistical estimate has about 30–50 degrees of freedom. That is, bootstrapping needs samples of only about 30–50 cases more than the number of parameters being estimated. Second, the number of resamples needed to flesh out the estimated sampling distribution needs to be at least about 1,000. But with high-powered personal computers, such resampling and calculation requires a trivial amount of time and effort, given the ability to write an appropriate looping algorithm.

Confidence Intervals

After one estimates the sampling distribution of $\hat{\theta}$ with this resampling technique, the next step in bootstrap statistical inference is to use this estimate to construct confidence intervals. There are several ways to do this, and there has been some controversy as

Table 1 Original data and three resamples

Case Number	*Original Sample (N(0,1))*	*Resample #1*	*Resample #2*	*Resample #3*
1	0.697	−0.27	−1.768	−0.27
2	−1.395	0.697	−0.152	−0.152

15	−0.152	1.099	−1.395	−0.27
16	−1.768	−0.727	−1.415	−0.914
17	−0.016	−1.121	−0.097	−0.860
18	0.587	−0.097	−0.101	−0.914
19	−0.27	2.204	−1.779	−0.457
20	−0.101	0.875	−1.121	0.697
21	−1.415	−0.016	−0.101	0.179
22	−0.860	−0.727	−0.914	−0.366
23	−1.234	1.408	−2.039	0.875
24	−0.457	2.204	−0.366	−1.395
25	−0.133	−1.779	2.204	−1.234
26	−1.583	−1.415	−0.016	−1.121
27	−0.914	−0.860	−0.457	1.408
28	−1.121	−0.860	2.204	0.261
29	0.739	−1.121	−0.133	−1.583
30	0.714	−0.101	0.697	−2.039

Table 1 (continued)

Case Number	Original Sample (N(0,1))	Resample #1	Resample #2	Resample #3
Mean	−0.282	−0.121	−0.361	−0.349
StDev	1.039	1.120	1.062	1.147

Note: Column 2 holds the original sample of 30 cases drawn randomly from a standard normal distribution. Columns 3–5 hold bootstrap re-samples from the original sample.

to which confidence interval approach is the most practical and statistically correct. Indeed, much of the discussion of the bootstrap in the statistical literature since its development in the 1980s has been devoted to developing and testing these confidence interval approaches, which are too complicated to discuss here. (*See* Further Readings for details and instructions on these confidence interval approaches.)

Useful Situations

There are two situations in which bootstrapping is most likely to be useful to social scientists. First, the bootstrap may be useful when making inferences using a statistic that has no strong parametric theory associated with it, such as the indirect effects of path models, eigenvalues, the switch point in a switching regression, or the difference between two medians. Second, the bootstrap may be useful for a statistic that may have strong parametric theory under certain conditions, but those conditions do not hold. Thus, the bootstrap may be useful as a check on the robustness of parametric statistical tests in the face of assumption violations.

BOUNDING

Bounding is a technique used in panel surveys to reduce the effect of telescoping on behavioral frequency reports. Telescoping is a memory error in the temporal placement of events; that is, an event is remembered, but the remembered date of the event is inaccurate. This uncertainty about the dates of events leads respondents to report events mistakenly as occurring earlier or later than they actually occurred. Bounding reduces telescoping errors in two ways. First, bounding takes advantage of the information collected earlier to eliminate the possibility that respondents report events that occurred outside a given reference period. Second, bounding provides a temporal reference point in respondents' memory, which helps them correctly place an event in relation to that reference point.

A number of specific bounding procedures have been discussed in the survey literature. The bounding interview procedure was first developed by John Neter and Joseph Waksberg in the 1960s in a study of recall of consumer expenditures (they call it "bounded recall"). The general methodology involves completing an initial *unbounded* interview in which respondents are asked to report events that occurred since a given date. In the subsequent *bounded* interviews, the interviewer tells the respondents the events that had been reported during the previous interview and then asks for additional events occurring since then. In other words, the information collected from each bounded interview is compared with information collected during previous interviews to ensure that the earlier reported events are not double counted.

For example, suppose panel respondents are interviewed first in June and then in July. The June interview is unbounded, where respondents are asked to report events that occurred in the previous month. The July interview is bounded. Interviewers would first inform respondents of the data they had provided in June and would then inquire about events that happened since then. Often the data from the initial unbounded interview are not used for estimation but are solely used as a means for reminding respondents in subsequent interviews about the behaviors that have already been reported.

Neter and Waksberg demonstrated in their study that bounding effectively reduced 40% of telescoping on expenditures and 15% on the number of home improvement jobs. This finding encourages panel or longitudinal surveys to employ the bounding technique to reduce the effect of telescoping. The National Crime and Victimization Study (NCVS) is one example. In its redesign, NCVS uses the first of its seven interviews to "bound" the later interviews. There is some evidence suggesting that this bounding technique reduces the likelihood of respondents reporting duplicate victimizations.

The bounding procedure proposed by Neter and Waksberg requires multiple interviews; thus, it is viable only for longitudinal or panel surveys. For one-time surveys, researchers have proposed bounding respondent memory by first asking about an earlier period and then about the more current period. For instance, within a single health interview, respondents are first asked about their health behavior in the previous calendar month and then asked about the same events in the current calendar month. One study shows that bounding within a single interview with two questions reduces reports by between 7% and 20% for health-related behaviors. It reduces telescoping by about 30% to 50% for trivial events, such as purchasing snacks.

Bounding also reduces telescoping error by providing a cognitive reference point in respondents' memory. The initial unbounded interview in Neter and Waksberg's procedure serves a cognitive function for the respondents who recall the last interview and then use that to ascertain whether an event occurred since then. Similarly, the single-interview bounding technique uses the first question to create temporal reference points that assist the respondent in correctly placing an event. A related technique to create a reference point is to use significant dates or landmark events. Landmark events such as New Year's Day, political events, and personally meaningful events (such as a graduation, a wedding, or a local flood) have been used to bound respondents' memory. Research shows that bounding with these landmark events or personally meaningful events significantly reduced incidence of telescoping.

However, bounding with landmark events has its own problems. First, the landmark events might be telescoped forward in one's memory. Second, the landmark events that survey researchers use in a questionnaire might not be equally salient for all respondents interviewed. Thus, subgroup differences might exist in the extent of telescoping error with landmark events, which further distorts comparisons among subpopulations.

Bounding has been shown to be effective in reducing forward telescoping errors and external telescoping errors, but it is less effective in reducing errors resulting from backward telescoping or internal telescoping. In addition, it does not address the effect of forgetting and other types of errors related to retrieving temporal information from long-term memory. Additional research is needed to further investigate the mechanism and the effectiveness of bounding on reducing telescoping error.

Branching

Branching is a questionnaire design technique used in survey research that utilizes skip patterns to ensure that respondents are asked only those questions that apply to them. This technique allows the questionnaire to be tailored to each individual respondent so that respondents with different characteristics, experiences, knowledge, and opinions are routed to applicable questions (e.g., questions about a treatment for diabetes are only asked to respondents who have been diagnosed with diabetes).

Branching also is used to ask respondents to choose among a large number of response options without requiring them to keep all the response options in working memory (e.g., respondents can be asked whether they identify with the Republican or Democratic party and then asked how strongly they identify with the relevant party in follow-up questions).

Branching can be conditional, compound conditional, or unconditional. In conditional branching, a single condition is met where routing occurs based on the answer to a single question (i.e., if the answer to question #1 is "No," then skip to question #3). In compound conditional branching, more than one condition must be met. The branching in this case is dependent on multiple answers, and routing occurs based on a combination of answers (i.e., if the answer to question #1 is "Yes" *or* the answer to question #2 is "Yes," skip to question #5). Unconditional branching is a direct statement with no conditions, often used to bring the respondent back to a specific point in the main survey after following a branching sequence. The approaches to branching differ depending on survey administration.

As a general rule, computer-assisted data collection (i.e., Internet surveys or computer-assisted self, telephone, or personal interviews) allows for more complex branching than paper-and-pencil data collection. Branching can be accomplished in computer-assisted survey instruments using programmed Boolean logic statements (i.e., if (question #) (state condition, such as $=$, $<$, $>$) (value), then (skip to question #)). Branching in paper-and-pencil survey instruments cannot make use of these technological complexities. Rather, it requires the appropriate placement of visual cues to guide respondents or interviewers through the branching instructions. Some common visual layouts include using arrows, placing the branching instructions within approximately nine characters of text (within foveal view), using enlarged, bold, and/or italicized font, and changing the background color. Two additional techniques that can be employed to guide the respondent or interviewers through paper-and-pencil branching instructions are the *prevention technique* and the *detection technique*. In the prevention technique, respondents are educated before reaching the branching instruction by including statements to remind them to look for instructions. In the detection technique, respondents are able to detect any branching errors they may have made through the use of feedback, such as inserting an additional branching instruction before the question that is supposed to be skipped, allowing them to correct the error and follow the instruction as intended.

There are two types of errors associated with branching. *Errors of omission* occur when respondents skip questions that were intended for their completion and result in item nonresponse for those items that were inadvertently skipped. Conversely, *errors of commission* occur when respondents provide answers to questions that were not intended for their completion. Accurate computer-assisted survey programming and proper paper-and-pencil survey visual layout of branching instructions can significantly reduce or even eliminate these errors.

Bureau of Labor Statistics (BLS)

The Bureau of Labor Statistics (BLS) is an agency within the U.S. Department of Labor (DOL) that is charged with collecting, processing, analyzing, and disseminating essential statistical data about business, finance, employment, and the economy. Other government agencies and many organizations in the private and public sectors heavily rely upon BLS to provide reliable data that is both sweeping in its scope and timely. Its parent organization, the DOL, counts on the BLS to serve as its statistical resource, as does the rest of the federal executive branch, Congress, academic researchers, subnational governmental bodies, private business, labor interests, and ultimately the American public.

BLS has adopted as part of its mission the continual effort to remain relevant to contemporary social and economic issues. It strives for impartiality and data integrity in its statistical reporting. Specifically, BLS follows the Office of Management and Budget's Statistical Policy Directive. Historically, the BLS was established in the late 19th century's period of national expansion and growing economic complexity. The American economy was, and still remains, a rich phenomenon that is accompanied by a large amount of raw data output that can shed light on various aspects of the whole.

In an effort to synthesize the expanse of data into digestible form, BLS conducts survey programs, either themselves or through contracts with the U.S. Bureau of the Census or a cooperating state agency. BLS will then release the gathered data in monthly, quarterly, and annual publications or in periodically published topical reports. Both the chronologically issued reports and the special publications are available in a variety of media including disks and microfiche; however, the most widely used forum for their dissemination is the BLS Web site. Furthermore, the data are available on the Internet at the federal government's multi-agency statistical depository Web site. In addition to these national level reports, the six BLS regional offices (Atlanta, Boston, Chicago, Dallas, Philadelphia, and San Francisco) make available unique data as well. While other government agencies work in the economic data area, notably including the Department of Commerce's Bureau of Economic Analysis and the Federal Reserve Board, it is BLS that offers the most diverse data on the economy. BLS leadership has divided its survey programs into six categories: (1) employment and unemployment, (2) prices and living conditions, (3) compensation and working conditions, (4) productivity and technology, (5) employment projections, and (6) international programs.

Mass media outlets frequently report the work of the BLS on topics that interest a great number of citizens. However, in the process of editing and summarizing the data for the sake of brevity, the media rarely explain the methods by which the information is acquired. The primary survey instrument used by the BLS to gather both employment and unemployment data and compensation and working conditions data is their Current Population Survey (CPS). The CPS is notable because of its sample size and its steady ongoing form, which allows for time series analysis of its results. The survey's 60,000-person sample is drawn from the civilian noninstitutionalized population of the United States that is at least 16 years of age. The basic labor force data are gathered monthly, and special topics are covered on a periodic basis. Because of BLS's compliance with federal privacy guidelines, microdata from individual respondents are not made available. Rather, the data are reported in summary table and aggregate analyses. Information is available for researchers on the population's employment status, broken down by the categories of age, sex, race, Hispanic identity, marital status, family relationship, and Vietnam-era veteran status. The individuals' occupations, industry, class of worker, hours of work, full-time or part-time status, and reasons for working part-time are also included. There are questions posed that are unique to multiple jobholders and discouraged workers as well. The special topic surveys are myriad; they include subjects such as the labor force status of working women with children, and disabled veterans; and also information on work experience, occupational mobility, job tenure, educational attainment, and school enrollment of workers. The results of this survey can be found in BLS-produced sources including the following: *The Employment Situation*, *Employment and Earnings*, *Usual Weekly Earnings of Wage and Salary Workers*, and the *Monthly Labor Review*. Indeed, uses for the data are as diverse, including measuring the potential of the labor supply, determining factors affecting changes in labor force participation of different population groups, and the evaluation of wage rates and earnings trends.

Other than the unemployment rate, perhaps the most widely recognizable output from BLS surveying is that used to calculate the Inflation Rate. The inflation rate is the percentage change in the Consumer Price Index from the preceding year. The BLS collects and processes data on the prices of thousands of goods and services every month, data that in turn produces the cost of a "basket of goods" for a consumer. Additionally, the cost of a "basket of goods" for a firm rather than a consumer is used to calculate the analogous Producer Price Index. Survey work on consumer spending habits, as well as imports and exports, rounds out the BLS's efforts to track prices and living conditions. Notable other statistical output from BLS includes the *Quarterly Labor Productivity Report*, which uses data from the Current Employment Survey, the National Compensation Survey, and the Hours at Work Survey; as well as the *Occupational Outlook Handbook*. The handbook is administered by the Office of Occupational Statistics and Employment Projections and contains information summarizing the working conditions and career prospects of established occupations.

Busies

Busies are a survey disposition that is specific to telephone surveys. They occur when the interviewer or a predictive dialer dials a number in the sampling pool and encounters a busy signal. Busies can be considered a positive outcome because they often indicate (a) that the telephone number is in service, and (b) that a person likely can eventually be reached at the number.

Busies can usually be considered a temporary disposition code because the presence of a busy signal is not sufficient to establish whether the respondent or household is eligible for the survey (i.e., busies are cases of unknown eligibility). As a result, it is important to have the interviewer redial the number. One common sample management strategy is to have the number redialed immediately, thus ensuring that the number was dialed correctly and making it possible to reach the person using the phone if he or she was in the process of finishing the call. However, depending on the sample management rules used by the survey organization, busies often also are redialed later in the same interviewing session and on a variety of other days and times in order to maximize the chances of reaching a person. Busies normally are considered a final survey disposition only if a busy signal is the outcome of all call attempts (i.e., the number is always busy) or the only other call outcome is "ring–no answer."

A potential problem in coding busy signals is that they can be confused with *fast busy* signals. These fast busy signals are sometimes used by a number of telephone companies to identify nonworking telephone numbers and can also occur when heavy call volumes fill all of the local telephone circuits. Fast busy case dispositions often are considered final dispositions and ineligible numbers, and thus they usually have a survey disposition code that is different from the code used for normal busies. Telephone interviewers need to understand the difference between busies and fast busy signals, along with the different dispositions of cases that reach busies and fast busy signals. This knowledge will ensure that interviewers code the ineligible, fast busy cases appropriately and will prevent interviewers from making unnecessary additional call attempts on these cases.

C

CALLBACKS

Callbacks are a survey disposition that is specific to telephone surveys. They are a common temporary survey disposition because fewer than half of all completed interviews occur on the first dialing of a case. Callbacks happen for a number of reasons. For example, an interviewer might dial a telephone number in the sampling pool and be told that the designated respondent is not available to complete the interview at the time of the call. In other cases, the interviewer might reach the designated respondent but learn that he or she would prefer to complete the interview at another time. A callback might also occur if an interviewer dials a telephone number and reaches an answering machine or a voicemail service. Callbacks are considered a positive outcome because they usually indicate that the household or designated respondent is eligible and that an interview is likely to be completed with the respondent if the interviewer is able to reach him or her at a good time. Cases coded with the callback disposition usually are considered eligible cases in calculating survey response rates because the interviewer has been able to determine that the household or designated respondent meets the qualifications set by the survey researcher for completing the interview.

Callbacks can occur for multiple reasons, and as a result the callback disposition often is further categorized into a *general* callback disposition and a *specific* callback disposition. In a general callback, the interviewer learns that the designated respondent is not available at the time of the call but does not learn anything that would help him or her determine the best time to reach the designated respondent. In other cases coded with a general callback disposition, the interviewer may obtain some information about when to next make a call attempt on the case (such as "evenings only" or "before 2:30 p.m.") but is not able to make an appointment to contact the designated respondent at a definite day or time. In a specific callback, however, the interviewer learns enough to set a definite day and time for the next call attempt (such as, "appointment set for 2:30 p.m. tomorrow"). Aside from learning the day and time for subsequent call attempts, interviewers also should attempt to obtain other information that might increase the chances of converting the callback into a completed interview. This information might include the name and/or gender of the designated respondent, or any other information that might help the interviewer reach the designated respondent on subsequent call attempts.

Because cases coded with the callback disposition are eligible and continue to be processed in the sampling pool, information learned during previous call attempts about when to contact the designated respondent can be used to better target subsequent call attempts by the interviewer. For a specific callback, additional call attempts should occur at the appointment time set by the respondent; additional call attempts on a general callback in which little is known might be made at a variety of other days and times in order to increase the chances of reaching the designated respondent and/or to learn more about how to target additional call attempts.

Caller ID

Caller ID is a telephone service in the United States that transmits the caller's name and/or telephone number to the called party's telephone. Today most telephones come with caller ID capabilities, and telephone companies regularly offer the service for little or no cost as part of their monthly service packages. Caller ID consists of two elements: the calling number and the subscriber name. This information appears on a person's telephone or display unit. Caller ID service lets you identify yourself to the person you are calling and lets you see who is calling before you answer the phone. It is estimated that more than half of all households in the United States have caller ID. Because this technology allows people to see who is calling, it is frequently used to screen unwanted calls, including those from survey research organizations. More and more people are using caller ID technology and caller ID–based services to screen incoming calls. A variety of call screening services or devices allow households to selectively or arbitrarily reject anonymous callers or any phone number that is not preidentified to ring through.

The Federal Communications Commission (FCC) has developed national caller ID rules. These rules allow subscribers to block or prevent their names and numbers from being displayed permanently or on a call-by-call basis. Conversely, the FCC rules require telemarketers to transmit caller ID information and prohibit them from blocking such information. Calls to emergency lines, such as 911, are exempt from federal caller ID rules and are governed by state rules and policies.

Caller ID technology and related call-blocking services will certainly continue to grow in popularity. Therefore researchers must continue to analyze the impact of this technology on response rates and to experiment with using caller ID technology to improve response rates. Although research firms are not required to send caller ID information, there is some experimental evidence that response rates may be improved by sending the survey firm name or an 800-number as their caller ID tag.

Call Forwarding

Call forwarding is a feature on most U.S. and international telephone networks that allows an incoming call to be redirected to one or more other telephone numbers as directed by the subscriber. This feature is popular with individuals who want or need to be reached when they are not at home or want to avoid the delays inherent with answering machines and voicemail. The use of call forwarding features can cause problems for telephone survey researchers. When an incoming call has been forwarded to another location, the called party may be less willing to participate in a survey at that location. When a call is forwarded to a cell phone in the United States, the called party will incur a cost in terms of dollars or minutes and may be in a location or other circumstance that is incompatible with survey participation.

Standard call forwarding transfers all calls from phone number A to phone number B. Special types of call forwarding are also available. Call forwarding can automatically route calls that are not answered within a designated number of rings or when the line is busy to another telephone number. Finally, call forwarding can transfer only those calls coming from a select set of telephone numbers. Remote access to call forwarding allows customers to activate or deactivate call forwarding from any telephone equipped with touch tone. In the North American Numbering Plan, vertical service codes, such as * 72 for activation, are used to control call forwarding. Usually, the forwarded line rings once, to remind anyone there that calls are being redirected.

The fee structures associated with placing a call to a called party who has his or her number forwarded can be subtle. For example, in the United States, Person A in Pittsburgh calls Person B in Chicago, who has forwarded his calls to Person C in Los Angeles. Person A will be charged for a long-distance call from Pittsburgh to Chicago, and Person B will be charged for a long-distance call from Chicago to Los Angeles. Call forwarding from a landline number to a cell phone will result in additional costs to respondents and problems associated with location of the respondent at the time of contact. These charges and unexpected circumstances may make respondents less likely to cooperate in a survey when reached at a telephone number or location other than their residences. Since sample suppliers routinely remove numbers assigned to wireless services from their databases, most of the cell phones encountered in telephone surveys are likely the result of call forwarding. Researchers should attempt to identify these cell phones early in the interview process and offer alternative means for completing the interview.

Finally, call forwarding may mean that an interview is completed in a location other than that associated with the telephone number dialed. For example, in the case of the areas affected by the hurricanes of 2005, call forwarding was included in the list of waived services that customers of BellSouth could consider using during their displacement. Also, a telephone company sometimes briefly uses call forwarding to reroute calls from an old number to a new number after a customer moves or ports his or her number to a new provider.

A problem caused by call forwarding that researchers doing surveys of the general population must address occurs when the original number dialed is a business number and it is forwarded to a residential number. In these cases, the household that actually is reached is not considered eligible because it was reached by sampling a nonresidential number. To determine when this happens, interviewers need to verify with the respondent that she or he has been reached at the number that was dialed.

CALLING RULES

Telephone survey researchers often utilize a set of guidelines (or *calling rules*) that dictate how and when a sample unit should be contacted during the survey's field period. These rules are created to manage the sample with the goal of introducing the appropriate sample elements at a time when an interviewer is most likely to contact a sample member and successfully complete an interview. In telephone surveys, calling rules are typically customized to the particular survey organization and to the particular survey and should be crafted and deployed with the survey budget in mind.

Calling rules are a primary mechanism that researchers can use to affect a survey's response rate. All else equal, making more dialing attempts will lower noncontact-related nonresponse, thereby yielding a higher response rate. In general, the more call attempts placed to a telephone number, the more likely someone will eventually answer the phone, thereby giving the survey organization's interviewers the opportunity to try to complete an interview. However, the trade-off to making more and more phone calls is the additional costs incurred with each call, both in terms of interviewers' labor and the toll charges related to the calls.

Since all surveys have finite budgets and resources that must be allocated for dialing attempts, resources allocated for these purposes cannot be used for other important purposes, such as additional questionnaire testing or development or gathering data from larger sample sizes. This competition for survey resources, along with the tension between achieving higher response rates with more calls made and the added expenditure of these additional call attempts illustrates the importance of a well-thought-out approach to the development and implementation of calling rules to manage a telephone survey sample.

When examining calling rules, an important distinction is often made between first call attempts to a sample member, or *cold calls*, versus subsequent calls to sample members, or *callbacks*. The importance of this distinction lies in the different information that is available to the survey researcher to establish calling rules.

In the case of first call attempts, little information exists about the sample member, including no information about the effectiveness of calls previously placed to that sample member. For subsequent call attempts, however, the call history for the sample numbers can be utilized to refine the placement of calls to these sample members. Consequently, calling rules for subsequent calls often differ from the calling rules used to place initial calls.

These calling rules, regardless of whether they apply to first call attempts or subsequent call attempts, can be classified into two different types: *ranked category type* calling rules and *priority scoring type* calling rules. Each type denotes an inherent property of calling rules, which is to create some calling order for survey administrators to follow with active samples.

Ranked Category

In the case of ranked category calling rules, the sample is categorized into independent (nonoverlapping) cohorts, based on sample member characteristics and/or previous call outcomes, and then ranked in order of the most likely categories to lead to a contacted sample member. For example, a simple ranked category calling rules system might suggest that previously reached sample members, answering machines, and ring–no answers are categorized as such and then should be called in that order. More complicated ranked category systems would classify the sample into more specialized categories and, therefore, have more elaborate calling rules to process the sample. As an example, for sample members who have yet to be contacted, categories could be created that take into account the time and day that previous calls had been made. Calling rules could then dictate that future calls should be made at times and days on which previous calls had not been attempted. Once a call attempt is made under a ranked category calling rules system, assuming that the sample member remains part of the active sample, the information gained from the last call is incorporated into the information set for that sample member. This additional information collected from the last call is used to recategorize the sample member, possibly into a different sample category.

Ranked category calling rules can be implemented using computer-assisted telephone interviewing (CATI), but they can also be implemented without the use of computers, making them an effective means by which to control and process the sample. However, a drawback to the use of ranked category calling rules is the multitude of different categories that may be necessitated and then the elaborate system of calling rules that would be developed to rank these categories.

Priority Scoring

Priority scoring calling rules differ from ranked category calling rules in that, with priority scoring, it is not necessary to categorize the sample into discrete, nonoverlapping categories. Instead, the information collected for each sample member is used in a multivariate model, typically a logistic regression model, to estimate the probability of the next call attempt leading to a contact and/or completion, conditioned on relevant information. Using the estimated coefficients from this multivariate model, the probability of contact or completion can be calculated for any possible permutation of the conditioning information set. These probabilities are then used to order the sample, from the highest probability calls to the lowest, with the highest probability calls being made first.

For example, a sample member who has been called three times previously, once in the afternoon and twice in the evening, with the outcomes of one ring–no answer, one busy signal, and one callback may have a contact probability of 0.55 if the next call attempt is placed in the evening. Another sample member who has been called five times previously, once in the morning, twice in the afternoon, and twice in the evening, with the outcomes of three ring–no answers, one busy signal, and one callback may have a contact probability of 0.43 if the next call attempt is placed in the evening. Although both contact probabilities indicate a fairly high likelihood of reaching these sample members in the evening, the contact probability for the first sample member is higher, so that priority scoring calling rules would rank that sample member higher in the calling queue.

Once the call attempt is made, assuming that the sample member continues to be part of the active sample, the information gained from this call attempt updates the sample member's information set. This updated information is used to calculate an updated contact probability, which is then used to rank order the sample member in the existing active sample.

Priority scoring calling rules are a model-based approach that, once implemented, can effectively manage samples, continually updating contact probabilities to deliver the most likely sample members to be contacted. Moreover, not only can the conditioning information be used to determine jointly the effects of that information on contact probabilities, but also, to the extent there are interaction effects with the conditioning information, these effects can be explicitly modeled with a priority scoring system of calling rules. However, a drawback to the use of priority scoring is the requirement of CATI, both because the multivariate model that serves as the basis for the priority scoring calling rules typically is a function with numerous covariates and also because the calculation and updating of contact probabilities does not lend itself to manual calculation.

Conditioning Information

In order to develop ranked category calling rules or priority scoring calling rules, some prior understanding of the likelihood of contacting sample members, given the condition information, must be available. Typical conditioning information that is used can be classified into external information about sample members—for example, demographics, telephone number or exchange information—and call history information about sample members. Call history information that has been used for initial calls includes the time of day and the day of the week the first call is made. Call history information that has been used for subsequent calls includes not only the information used for first calls but also the number of previous calls that have been made, the length of time between the last call and the next call, the disposition of the previous call, the entire history of call dispositions, and the time and days that previous calls were made.

Typically, previous survey experience governs not only the use of conditioning information either to categorize or to score the sample, but also how this conditioning information impacts the contact probabilities. To the extent that the population for a survey has been studied before, the use of the conditioning information from that prior survey can be used to develop calling rules for subsequent surveys of that same population. However, to the extent the survey researcher is studying a population for the first time, the only avenue open for the development of calling rules may be to base them on a survey of a population that is similar, albeit unrelated.

CALL-IN POLLS

A call-in poll is an unscientific attempt to measure public preferences by having radio or television audience members or newspaper readers call a telephone number and register their opinions. Usually a single question is posed, and people are asked to call one phone number in support of a viewpoint and another number in opposition. Call-in polls are used by some media organizations as a way to measure public opinion and get the audience involved. But they are very problematic from a data quality standpoint and should not be referred to as "polls."

A major problem with call-in polls is that the participants are entirely self-selected. Only those people who tuned in to that particular broadcast at that time, or read that newspaper, can be included. Further, those who make the effort to participate are often very different from those who do not. That is because participants are usually more interested in the topic or feel very strongly about it. For these reasons, survey researcher Norman Bradburn of the University of Chicago coined the term *SLOP*, which stands for "self-selected listener opinion poll," to refer to call-in polls.

Another big problem is that call-in polls are open to manipulation by any individual or group with a vested interest in the topic. With no limit on the number of calls that can be placed, people can call multiple times and groups can set up more elaborate operations to flood the phone lines with calls in support of their point of view. As a result, call-in polls often produce biased results, and their "findings" should be ignored. Legitimate survey researchers avoid the types of bias inherent in call-in polls by selecting respondents using probability sampling techniques.

There are many examples of call-in polls producing distorted results. In one famous example, *USA Today* conducted a call-in poll in 1990 asking its readers whether Donald Trump symbolizes what is wrong with the United States or symbolizes what makes the United States great. *USA Today* reported overwhelming support for Trump, with 81% of calls saying he symbolizes what makes the United States great. Later, *USA Today* investigated the results and found that 72% of the 7,802 calls came from a company owned by a Trump admirer.

Another example comes from a 1992 CBS television program called *America on the Line*, where viewers were asked to call in and register their opinions after President George H. W. Bush's State of the Union address. The views of the approximately 317,000 calls that were tallied were much more pessimistic about the economy than what was measured in a traditional scientific poll conducted by CBS News at the same time. For example, 53% of those who called in to the program said their personal financial situation was worse than 4 years ago, compared with 32% in the scientific poll. The views of those who called in were quite different than those of the general public on a number of measures.

Although those with survey research training know that call-in polls should not be taken seriously, many members of the public do not make a distinction between these pseudo-polls and the real thing. In fact pseudo-polls may be incorrectly seen as even more credible than real polls because they often have much larger sample sizes.

Call Screening

Call screening is a practice in which many people engage whereby they listen to an incoming message on their answering machine or look on their caller ID to see who is calling before deciding whether or not to answer the call. This behavior is thought to negatively affect survey response rates. Over time, respondents have become increasingly unwilling to participate in surveys or even answer unsolicited telephone calls. This desire for privacy has resulted in legislation such as do-not-call lists and the use of a variety of technological barriers such as answering machines, caller ID, and call blocking to screen incoming calls. These screening devices allow individuals to determine which calls they will answer, making it more difficult for researchers to contact them. Further, individuals who always screen may also be more likely to refuse to participate if and when they are contacted.

More than two thirds of U.S. households have answering machines, and about 18% report always using their answering machine to screen calls. Telephone companies improved on the answering machine as a screening device with the development of caller ID technology. This service displays the caller's name and/or telephone number on a person's phone or caller ID device. It is estimated that more than half of all U.S. households now have caller ID and that nearly 30% always use it to screen calls. Call-blocking services that allow subscribers simply to reject certain numbers or classes of numbers are also growing in popularity.

Owners of these devices and those who regularly use them to screen calls have been shown to be demographically different from the general population. It is not always easy to identify a screening household, particularly if the dialing always results in a noncontact.

A number of approaches are being used by researchers in an attempt to improve contact with screening households. The most common approaches include mailing advance letters (when a phone number can be matched to an address), leaving a message on the answering machine, or transmitting the name of the research firm along with an 800 call-in number. However, when it comes to actually improving contact with these households, the results remain mixed.

Call Sheet

A call sheet is a record-keeping form that is used by telephone survey interviewers to keep track of information related to the calls they make to reach survey respondents. As paper-and-pencil interviewing (PAPI) was replaced by computer-assisted telephone interviewing (CATI), these call sheets moved from being printed on paper to being displayed on the interviewer's computer monitor. The fact that they are named "call sheets" refers to the days when thousands of such call sheets (each one was a piece of paper) were used to control sampling for a single telephone survey.

The information that is recorded on a call sheet—also called "paradata"—captures the history of the various call attempts that are made to a sampled telephone number. Typically these forms are laid out in matrix format, with the rows being the call attempts and the columns being the information recorded about each call. For each call attempt, the information includes (a) the date; (b) the time of day; (c) the outcome of the call (disposition), for example, ring–no answer, busy, disconnected, completed interview, and so on; and (d) any notes the interviewer may write about the call attempt that would help a subsequent interviewer and/or a supervisor who is controlling the sample, for example, "The respondent is named Virginia and she is only home during daytime hours." Since most telephone interviews are not completed on the first calling attempt, the information that interviewers record about what occurred on previous call attempts is invaluable to help process the sample further and effectively.

It is through the use of the call outcome information recorded on the call sheet—and described in detail in the American Association for Public Opinion Research's *Standard Definitions*—that the sample is managed. In the days when PAPI surveys were routinely conducted and the call sheets were printed on paper, supervisory personnel had to sort the call sheets manually in real time while interviewing was ongoing. When a questionnaire was completed, the interviewer manually stapled the call sheet to the top of the questionnaire and then the supervisor removed that case from further data collection attempts. For call sheets that did not lead to completed interviews but also did not reach another final disposition (e.g., disconnected or place of business), the supervisor followed a priori "calling rules" to decide when next to recycle a call sheet for an interviewer to try dialing it again. With the shift to CATI and computer control of the sampling pool (i.e., the set of numbers being dialed) all this processing of the information recorded on call sheets has been computerized. The CATI software serves up the call sheet on the interviewer's monitor at the end of the call for pertinent information to be entered. That information drives other logic in the CATI software that determines whether, and when, to serve up the telephone number next to an interviewer. The information captured on the call sheet is used for many other purposes after the survey ends, including helping to create interviewer performance metrics and calculating survey response rates.

Capture–Recapture Sampling

Capture–recapture sampling (also referred to as "capture–mark–recapture sampling" or "mark–release–recapture sampling") is a method used to estimate the unknown size of a population. In practice, it is often not feasible to manually count every individual element in a population because of time, budget, or other constraints. And, in many situations, capture–recapture sampling can produce a statistically valid estimate of a population size in a more efficient and timely manner than a census.

The most basic application of capture–recapture sampling consists of two stages. The first stage involves drawing (or capturing) a random sample of elements from a population of unknown size, for example, fish in a pond. The sampled elements are then marked, or tagged, and released back into the population. The second stage consists of drawing another random sample of elements from the same population. The second-stage sample must be obtained without dependence on the first-stage sample. Information from both stages is used to obtain an estimate of the population total.

The capture–recapture technique assumes that the ratio of the total number of population elements to the total number of marked elements is equal, in expectation, to the ratio of the number of second-stage sample elements to the number of marked elements in the sample. This relationship can be expressed as follows:

$$N/C = n/R, \quad (1)$$

where N is the unknown population total of interest, n is the number of elements in the second-stage sample (both marked and unmarked), C is the total number of marked elements from the first-stage sample (i.e., the captures), and R is the number of marked elements found in the second-stage sample (i.e., the recaptures). By solving for N, it is then possible to obtain an estimate of the population total:

$$N = nC/R. \quad (2)$$

Example

A classic example comes from the field of ecology. Suppose the goal is to estimate the size of a fish population in a pond. A first-stage sample of 20 fish is drawn, tagged, and released back into the pond. A second-stage sample of 30 fish is subsequently drawn. Tags are found on 12 of the 30 sampled fish, indicating that 12 fish captured in the first sample were recaptured in the second sample. This information can be used to assign actual quantities to the variables of interest in Equation 1, where $n = 30$, $C = 20$, and $R = 12$. Solving for N using Equation 2 yields the following estimate of the population total:

$$N = nC/R = ((30)(20))/12 = 50.$$

Therefore, the estimated size of the pond's fish population is 50. A more stable estimate of the population total, subject to less sampling variability, can be obtained if multiple second-stage samples are drawn, and estimated totals, computed from each sample, are averaged together.

Assumptions

In order for the capture–recapture sampling technique to produce a valid estimate of a population size, three assumptions must hold:

1. Every population element has an equal probability of being selected (or captured) into both samples.
2. The ratio between marked and unmarked population elements remains unchanged during the time interval between samples.
3. Marked elements can be successfully matched from first-stage sample to second-stage sample.

Assumption 1 holds if simple random sampling is used to capture elements into both samples. A possible violation of this assumption occurs if those who were captured in the first-stage sample have a higher probability of being captured in the second-stage sample, which would lead to overestimation of the population total. Assumption 2 follows from the relationship described in Equation 1. In general, this assumption holds if there is no change in the population, or if the population is closed during the study. However, births or deaths and immigration or emigration are permitted as long as the ratio is preserved.

frame for those people or households in the overlap; instead, they make use of inclusion probabilities that are frame specific (i.e., either CPN frame or LLN frame). Adjustments to the weights for multiple cell phones are made for subscribers in the cell phone sample; similarly, weight adjustments are applied for multiple landlines for households selected from the landline frame. Using the frame-specific adjusted weights, estimates for the variables of interest are derived from the CPO and C&L and the LLO and C&L pieces from the cell phone and landline samples, respectively. The two estimates of the overlap (C&L) are combined via a composite estimator, with the weights chosen to minimize the variance of the statistic of interest.

A simpler but related alternative that avoids having to weight the sample for inclusion in both frames and seems to be used frequently in current practice involves conducting a random-digit dial (or other common sampling technique, such as list-assisted, etc.) of landline numbers. This sample is then augmented by a sample of cell phone numbers that has been screened for cell phone only households. The phone ownership distribution of the combined sample is then weighted using some type of post-stratification weighting technique (such as raking, etc.) to the distribution obtained via a personal interview survey such as the National Health Interview Survey or the Current Population Survey. However, these data are only available at the U.S. national level.

The adjustments and estimators discussed thus far assume complete response, which is not likely in practice. Additional adjustments for nonresponse will be needed in the weights. Of course, it always helps to attempt to reduce nonresponse. Some details of the cell phone numbering systems and plan attributes may be helpful for designing more efficient data collection measures for units included in cell phone samples.

Cell Phone Numbering Systems

Numbering systems or agencies such as the North American Numbering Plan Administration (NANPA) assign banks of numbers to cell phone providers. One main difference in the CPNs between countries is the level of geographic specificity that can be inferred. In some countries (e.g., United Kingdom, Italy), CPNs are organized in two parts: the prefix indicates the cell phone provider and the suffix is the number assigned by that provider to the final user. In the United States, CPNs are organized into three parts: area code, prefix, and suffix. The area code is three digits and indicates specific geographic regions that usually do not cross state boundaries. Generally, there is a strong concordance between place of residence and area code, but because cell phones are portable and national networks exist for many providers, it is possible that the degree of specificity could be limited to the location in which the cell phone contract was initiated. The three-digit prefix generally indicates the cell phone provider and, to a lesser degree, a geographic area within the region of the area code. The four-digit suffix is assigned by the cell phone provider. The assignment rules for these numbers are more ambiguous when compared to that of landlines. In fact, an informal survey of major U.S. providers in 2005 did not reveal any trends or clustering patterns by which CPNs are assigned to new subscribers. However, in many cases company representatives indicated that number assignments are highly proprietary, especially in an era when NANPA is imposing new regulations on number bank allocations based on usage capacity quotas: some prefixes now include suffixes that are either LLNs or CPNs assigned by the same provider (i.e., mixed-use bank) or LPNs or CPNs assigned by different providers (i.e., mixed-provider bank). This ambiguity in number assignment makes methods like the Mitofsky-Waksberg method of limited utility for cell phone samples. Also, unlike LLNs, CPNs are not usually publicly available in phone directories, so list-assisted approaches are also limited for cell phone samples. There are exchange-type codes available within the telephone industry and from vendors who supply samples of cell and landline numbers that can be used by researchers to help determine which of the 1,000-banks contain both cell and landline numbers. There are companies in the United States that now provide samples of cell phone numbers from a frame of 10,000-banks that have already been screened for mixed use.

Cell Phone Services

Cell phone services are generally organized differently, tend to vary more, and change more rapidly than landline phone services. Subscribers access cell phone service through a wide array of contracts and service plans. These contracts can be classified into two broad categories: pre-paid and post-paid. For the pre-paid contracts, limits vary by provider for the amount of time the associated phone number can be retained for accounts that have become dormant (i.e., have not been

Assumption 3 holds if there is no loss of tags and no erroneous matching.

Typically, these assumptions cannot be tested using a two-stage sampling approach. More advanced capture–recapture methods exist that allow these assumptions to be tested, and in some cases, permit certain assumptions to be relaxed. For example, methods have been proposed that consider situations where elements have different probabilities of being captured—a violation of Assumption 1.

1990 Post-Enumeration Survey

One of the most notable applications of capture–recapture sampling occurred during the 1990 Post-Enumeration Survey (PES). The goal of the PES was to evaluate the accuracy of the 1990 Census enumeration. A capture–recapture approach was used to estimate the total number of individuals who were omitted from the census enumeration. The first-stage sample consisted of all individuals who were enumerated in the 1990 Census. Census Bureau records were used to help identify those who were included in the enumeration. In the second stage, an area probability sample of household blocks was drawn. Individuals within sampled households were interviewed, and census records were checked to determine whether or not they had been included in the census. By counting the number of individuals in the second-stage sample who were left out of the census enumeration, an estimate of the total census undercount was obtained.

Other applications of capture–recapture sampling have been applied to estimating birth and death rates, estimating the number of HIV-infected drug users, estimating the incidence of stroke, and estimating salmon spawning escapement.

CASE

The term *case* refers to one specific element in the population of interest that has been sampled for a survey. A "completed" case contains the responses that were provided by that respondent for the questionnaire used in that survey. A case may be an individual, a household, or an organization. Being able to identify each individual respondent can be critical for the conduct of the survey. Assignment of a unique *case number* identifier associated with each individual sampled element should be done in every survey. Although most computer-assisted surveys assign a *respondent number*, it should not be confused with assignment of a case number. As a general rule, case numbers are assigned before a questionnaire is distributed, while respondent numbers are assigned when a respondent is contacted and an attempt is made to complete the survey.

Prior to data collection, a simple case number may be assigned sequentially to each questionnaire before being distributed for completion. The case number can also be used to identify any number of background characteristics of the individual or household to which the survey was distributed—such as census block, zip code, or apartment or single-family home. Assignment of a case number should not be used to compromise the confidentiality of either those who complete the survey or the information they provide. During data processing, the case number can be used to assist in coding open-ended responses and conducting edit checks on the data set, such as verifying information that is outside the normal response range or that is inconsistent with other data in the case record. In those designs for which respondents may be contacted at a future date, the unique case number can be used to ensure that responses to future surveys are linked to the correct respondent.

Case-Control Study

Case-control studies measure the association between the exposure to particular risk factors and the occurrence of a specific disease. These types of studies are common in public health and medical research. The basic premise of such studies is the comparison of two groups: "cases," individuals who have a particular disease of interest to the researcher, and "controls," who do not have the disease.

In case-control studies, individuals in the case group are selected and matched to persons in the control group on a common set of characteristics that are not considered to be risk factors for the disease being studied. These characteristics are frequently demographic variables such as age, gender, education, income, and area of residence. Comparisons across the case-control pairs are made, examining hypothesized risk factors for a particular disease. For example a case-control study of heart disease among women may compare cases and controls on their level of exposure to factors thought to influence the risk of heart disease such as family history of heart disease, smoking, cholesterol, high blood pressure, diet, and exercise. These differences are usually assessed using statistical tests.

Data for case-control studies is typically collected by interviewing or surveying the cases and the controls. Individuals in both groups are asked the same series of questions regarding their medical history and exposure to factors that are considered to increase the risk of developing the disease in question. Data may also be collected from medical records.

The advantages of case-control studies include the following:

- Data collection does not typically require medical tests or other intrusive methods.
- The studies are typically inexpensive to conduct in comparison to other methods of data collection.
- They are good for examining rare diseases because the investigator must identify cases at the start of the research rather than waiting for the disease to develop.
- Case-control studies allow for the examination of several risk factors for a particular disease at the same time.

As with all research studies, there are some significant disadvantages as well, including the following:

- Data on exposure and past history is subject to the individual's memory of events.
- It can be difficult to confirm and/or measure the amount of exposure to a particular risk factor of interest.
- Defining an appropriate control group can be difficult, especially if the risk factors for a particular disease are not well defined.
- Case-control studies are not good for diseases that result from very rare risk factors (rare exposures) unless there is a high correlation between the disease and the exposure.

Cell Phone Only Household

The widespread availability of cell phone service and the relatively low cost of such service means that some people are now indifferent as to whether they make a call on a landline or a mobile telephone. In fact, many people have substituted one or more wireless cell phones for their traditional household wired telephones (also called "residential landline telephones"). These cell phone only households pose a problem for most major survey research organizations in the United States because cell phone numbers are not typically included when conducting random-digit dial (RDD) telephone surveys in the United States.

The Telephone Consumer Protection Act of 1991 prohibits the use of autodialers in the United States when calling cell phones; therefore, the inclusion of such telephone numbers would be very expensive for most survey call centers because of the requirement to have interviewers dial the cell phone numbers manually. In addition, nonresponse rates may be high because most cell phone owners do not expect to receive survey calls on their cell phones, and some cell phone owners must pay to receive calls.

The inability to reach cell phone only households has potential implications for coverage bias in random-digit dialed telephone surveys. Coverage bias may exist if cell phone only households are not included in survey sampling frames and if persons living in cell phone only households differ on the survey variables of interest from persons living in households with landline telephones.

The National Health Interview Survey (NHIS) provides the most up-to-date estimates regularly available from the U.S. federal government concerning the prevalence and characteristics of cell phone only households. This cross-sectional, in-person, household survey of the U.S. civilian noninstitutionalized population, conducted annually by the National Center for Health Statistics of the Centers for Disease Control and Prevention, is designed to collect information on health status, health-related behaviors, and health care utilization. However, the survey also includes information about household telephones and whether anyone in the household has a working cell phone. Approximately 40,000 household interviews are completed each year.

NHIS data permit an analysis of trends in the prevalence of cell phone only households in the United States since 2003. The percentage of cell phone only households doubled from 2003 to 2005, and as of 2006, approximately 11% of U.S. households were cell phone only. The rate of growth in the size of this population has not slowed, increasing at a compound growth rate of more than 20% every 6 months. Cell phone only households now compose the vast majority of non-landline households. More than 80% of non-landline households have cell phone service in the household, and this proportion also continues to increase; the proportion was 62% during the first 6 months of 2003. This largely reflects the fact that the percentage of households without any telephone service has remained unchanged, whereas the percentage of cell phone only households has increased.

Since the NHIS began collecting data on cell phone only households and the persons who live in such households, the prevalence of cell phone only adults has been greatest for adults 18–24 years of age, adults renting their homes, and adults going to school. Men are more likely than women to be living in cell phone only households. Hispanic adults are slightly more likely to be living in cell phone only households than are non-Hispanic white adults or non-Hispanic black adults. Adults living in the Midwest, South, or West are more likely to be living in cell phone only households than are adults living in the Northeast. Adults living in urban households are more likely than adults living in rural households to be in cell phone only households.

Adults working at a job or business in the week prior to the interview are also more likely to live in cell phone only households than adults who are keeping house or are unemployed or doing something else. Yet, adults living in poverty are more likely than higher income adults to be living in cell phone only households.

Adults living with unrelated roommates are more likely to live in cell phone only households than adults with other living arrangements. Looking at other family structure subgroups, adults living alone are more likely to be cell phone only than are adults living with other related adults or adults living with children.

Despite the differences in demographic characteristics between persons living in households with landline telephones and persons living in cell phone only households, the potential for coverage bias in population-based surveys of adults has been found to be small so far. Estimates from health surveys and from political polls that did not include data from the cell phone only population have not been substantially biased when proper survey weighting and estimation strategies have been employed. However, as the size of the cell phone only population grows in this rapidly changing technological environment, the potential for coverage bias may also increase.

If this occurs, survey researchers will need to determine how best to add cell phone only households to their sampling frames. This may occur by calling cell phones directly or by conducting multi-mode surveys that reach cell phone only households by mail, Internet, and/or in person. Methodologies are being developed currently for conducting surveys on cell phones and for combining sampling frames that use multiple modes.

Cell Phone Sampling

The rise of personal cell phone ownership in many industrialized countries and, more important, the increase in the number of people who can be contacted only via cell phone poses some challenges to traditional telephone surveys. Some of the sampling techniques used for selecting traditional landline (wired) telephone samples still apply when selecting cell phone samples. There are, however, specific characteristics of the cell phone that impact frame construction and sample selection that should be incorporated into designs to maximize yield from cell phone samples. The sampling issues will vary by country as a function of differing cell phone penetration rates, numbering taxonomies, and local market conditions, including technology and plan attributes. Designs for cell phone sampling and weighting, along with a general consensus for their use in practice, are currently continuing to emerge within the survey research community. Based on a query of cell phone systems worldwide, it does appear that the cell phone situation in the United States has a tendency for more complexities. The solutions for other countries may be much simpler versions of these designs.

The New Phone Subscriber Population

The cell phone subscriber population is expanding worldwide and is rapidly changing telephone systems and how people communicate within them. In some countries, the ratio of cell phone subscribers to total residents is quickly reaching a 1:1 ratio. Only 15 years ago, these ratios were in the range of 1:20 to 1:10. Table 1 summarizes the penetration rate of cell phones in selected countries (unadjusted for multiple cell phone ownership) collected by the International Telecommunication Union in 2005. Comparisons between countries should be made carefully due to variations in age distributions within different countries, since age is associated with cell phone ownership. The table gives an idea

of potential undercoverage biases that may result in samples of landline phones that exclude cell phones.

The percentage of cell phone numbers (CPNs) to total inhabitants generally overestimates the number of unique users as reflected by the reality that multiple numbers may be used by a single subscriber. Thus a sampling frame of CPNs may have a problem of multiple listings for some individuals, thereby increasing the probability of selection for those subscribers with multiple CPNs. Another phenomenon that has direct impact on telephone surveys in general is masked in Table 1: In many countries the number of people dismissing a landline or not having one in the first place is also rising. Currently, it is not unrealistic to predict that, in the near future, in some countries everyone could potentially be reached more easily via a cell phone than by a landline phone.

Diversification of Telephone Sampling Frames

As a result of the new presence of cell phone subscribers, the telephone subscriber universe as we know it is changing and can be best described in four parts: (1) cell phone only (CPO), (2) landline only (LLO), (3) cell and landline (C&L), and (4) no phone service of any kind (NPS), as depicted in Figure 1.

In Table 2, the distribution of the population within each of these four subsets is provided for several countries. These data were obtained via nationwide probability samples using face-to-face interviews. A common theme among industrialized countries is the continued rise in the number of inhabitants who fall into the "cell phone only" category; this increase poses threats to undercoverage bias for traditional telephone surveys that typically sample households via random-digit dial samples from frames consisting of only landline numbers (LLNs).

In response to the diversification of the telephone universe, the researcher wishing to conduct telephone sampling is now faced with two key questions:

1. Is the amount of undercoverage in a probability sample selected from a frame of only LLNs acceptable? A related question that is usually asked in making the decision regarding the impact of the undercoverage of CPO households is, "How different are CPO households with respect to survey variables?"
2. Is the amount of undercoverage in a probability sample selected from a frame containing only CPNs acceptable? In this case, a related question is, "How different are LLO households for the survey variables of interest?"

In the case where neither single-frame approach (i.e., using a frame of only LLNs or a frame of only CPNs) will produce acceptable estimates (i.e., minimal undercoverage bias, etc.), does the researcher need to employ a dual-frame sampling design consisting of independent samples selected from available landline as well as cell phone number banks (i.e., collections of phone numbers that are grouped according to a combination of area code [United States], prefix, and suffix; a "10,000-bank," for example, represents numbers that have the same area code and prefix [e.g., 999-888-XXXX])?

Cell Phone Sampling Designs

In response to these two scenarios, at least two types of sampling designs can be used to select a cell phone sample, including those involving the selection of only CPNs and those designs that select a cell phone sample in conjunction with a landline sample. For the first case, a sample of cell phones can be selected from a frame constructed using CPNs that have been identified via area code and prefix combination (United States) or simply via prefix (Europe). Selection strategies such as systematic or stratified random sampling (stratified by provider, area code, etc.) can be used with the cell phone number frame.

For the second case, the researcher can employ a dual-frame sample in which a sample of cell phone numbers is selected from the cell phone frame and a second sample of landline numbers is selected from the landline frame. The sampling plans within these two frames can be similar or different. For example, list-assisted sampling plans are generally more efficient for landline phones but may not be a useful design strategy for cell phones, as many countries do not have published lists of working CPNs. More auxiliary information may be available for landline numbers (i.e., corresponding addresses), so stratified random sampling designs may be more feasible for landlines. However, stratifying the cell phone frame by provider or sorting the selected sample by provider may be a very efficient way to incorporate provider variations or add to the efficiency of calling designs once the sample of CPNs is selected.

Regardless of the sampling design used for selecting a cell phone sample, selection of multiple members from a single household is possible for those individuals who live in households with multiple cell phone subscribers. Depending on the survey outcome of interest, the clustering of people by household within the sample may slightly inflate the design effect (*deff*), with the degree of the inflation being a function of the sampling design, the overall penetration rate, and the sample size. In contrast, samples of landline numbers typically use techniques such as the "latest birthday" to randomly select one and only one member from the household for inclusion in the sample. However, a similar clustering effect could happen in landline samples if multiple numbers (and adults) were selected for a single household.

Regardless of the single- or dual-frame sampling designs used to select the sample of CPNs (and LPNs), standard weighting techniques consistent with the chosen design can be used to derive estimates appropriate for inference to each frame. Because the initial sampling units for cell phones are usually people—whereas for landlines it is households—it is important to adjust the weights of these estimators so inference can be made about a common unit. For inference about households, it will be necessary to adjust the initial sampling weights for the number of cell phones or landline phones per household; for person-level inference, additional adjustments incorporating the number of users per cell or landline will be necessary. For dual-frame estimators, these adjustments are typically done separately for each sample drawn from each respective frame.

Traditional dual-frame estimators are derived using separate unbiased estimates for CPO and LLO based on the sample of CPNs and LLNs, respectively, along with a composite estimate that optimally combines the two estimates of the C&L overlap. Treating the dual-frame sample data as though it were from one larger sample, researchers can derive "single-frame estimators" that do not have a separate and explicit component for the overlap.

The single-frame estimator does not make use of frame sizes (which in the case of telephone sampling should be known—that is, banks from which samples are drawn have a fixed size, usually either 10,000 or 1,000), nor does it take advantage of the relative efficiency of the sampling designs used for selecting samples in the two frames. The single-frame estimator can incorporate the known frame sizes via raking ratio estimation or regression. While the form of the estimator does not have a component that comes directly from the "overlap" of people or households from the cell and landline frames, it does require knowledge of the inclusion probabilities in each of the respective frames. For example, for each person or household in the cell phone sample who has at least one landline number, it is necessary to determine the probability for being included in the landline sample, and vice versa. In practice, this amounts to computing the number of both landlines and cell phones that could be used to contact the person or household for all those households or people who fall into the C&L domain. Device grids are a novel tool that can be used in practice as a basis for collecting data from sampled numbers on the number and type of phone devices attached to the household as well as the number of people in the household who use each device. These data then form the basis of person-level weights to be used for person-level inference from single-frame estimators.

The dual-frame estimators avoid the need to compute sample inclusion probabilities for the second "recharged" during the course of ownership). Pre-paid plans sometimes imply multiple cell phone devices per person in the population of interest. For example, in Italy, where a bulk of the plans would be considered pre-paid, the penetration rate for cell phone subscribers was 124% (or 1.24:1) as seen from Table 1. A study conducted in 2002 estimated that upward of one fourth of Italian subscribers owned more than one cell phone number. While the multiplicity of devices per person certainly increases the overall hit rate for samples of cell phone subscribers, it does have implications for the effective sample size of unique subscribers for any given randomly selected sample of CPNs from a CPN frame. As people move from using one cell phone to the other, temporary usage or transitional usage patterns may also impact the number of cell phones with unknown eligibility (i.e., ring–no answer), or a continuous string of only voicemails). In general, pre-paid plans have either no long-term commitments or have generally shorter contract periods than post-paid plans. In the United States, typical post-paid plans have contract periods between 1 and 3 years. These plans tend to make the sampling frame of CPNs more stable over a given study period, but it is possible for CPNs to remain active while the subscribers attached to those numbers change, resulting in potentially ambiguous call outcomes over longer study periods. Experience suggests that shorter field periods for making dialing attempts to reach the user(s) of the CPN, as compared to longer periods for typical landline phone surveys, may be more cost-effective for cell phone sample surveys.

Within contract types there are various plan attributes that may vary within and among providers. For example, in countries such as Canada, the United States, and Hong Kong, cell phone subscribers pay for incoming calls; in many European countries, Japan, and Australia, subscribers receive incoming calls for free. Usually, cell phones worldwide have some type of caller identification that shows the number or programmed name of the caller. This feature, along with the trend of having the called party pay, has a potential impact on the cell phone user's propensity to answer a survey call and also on the general response rate of sample surveys using CPNs.

Cell Phone Sampling in Practice

While limited information is available from just a cell phone number, in the United States the area code or prefix of a cell phone number conveys some level of geographic specificity, and this portion of the phone number can be linked to a larger exchange database to acquire the name of the provider, which can then be used by the researcher as additional stratification variables, namely provider. Also, some providers offer more localized services with free incoming calls or more pre-paid plans that may be associated with a specific demographic target of interest (e.g., younger, college-age subscribers). Of course, stratifying the sample frame by provider allows researchers flexibility in having different sampling plans with the potential to maximize coverage across geographic areas (served sometimes exclusively by some providers, especially in rural areas) and age groups.

At this point in practice there is little evidence to suggest that stratifying cell phone samples by provider increases the accuracy of resulting estimators. In general, however, if questions relating to the usage of technology-related options of cell phone plans, such as Internet, text messaging, or photo exchange, are of interest, then variations in provider offerings may be at a level that provider stratification may improve the overall efficiency of the estimates. Perhaps more useful at this point in the evolution of cell phone practice would be a design that includes a post-stratification of the sample by provider prior to subscriber contact. Much like responsive call designs, provider information can be used to screen numbers for nonworking status using text messaging interfaces available from provider Web sites as well as to design optimal calling schedules based on the off-peak hours generally offered by the providers. In general, calling rule strategies that can take advantage of cell phone provider plan attributes, such as peak and off-peak call time differences or uniform text messaging options or other technologies that are offered to a majority of subscribers from a particular provider, may be more efficient in terms of overall survey yield. As another example, the time intervals associated with peak and off-peak usage vary more across than within provider. For a given plan, subscribers are generally allocated fewer peak time minutes than off-peak time minutes. However, common times for survey researchers to contact sampled cell phone subscribers generally coincide with peak time intervals. In contrast to calls made during peak times, those made during off-peak times do not generally pose a threat of additional or higher costs for the subscriber. Thus "time called" may be a predictor for response in some cases where the called party pays—in these cases, it may be important to vary the day and time called to include peak and off-peak time intervals and weekdays and weekends. On the other hand, some cell phone providers either offer plans for free incoming calls or simply do not charge for incoming calls; such cell phone numbers could be called first in a provider-assisted call design, for example.

Regardless of the design or calling strategy, there are some instances in which disposition codes for cell phones may need to be modified to better describe the different landscape. For example, the proliferation of family plans in the United States is creating multiple cell phones per household. Many of the cell phones within a household will be registered to adults but used primarily or exclusively by children under 18. The disposition "ineligible-underage" is not commonly encountered in landline (household) samples and may need to be added to cell phone sample call disposition codes to more precisely describe the larger "ineligible" category. Rather than imply that there is no adult 18 years or older in the household, this disposition when used with cell phones would imply that the primary user is under 18 years of age and is thus ineligible for surveys of the adult population. While family plans are becoming more popular, there is also some current evidence to support a small degree of sharing of cell phones within households in the United States. In particular, some studies have suggested that cell phone sharing may occur more frequently between adult and child; with many surveys excluding children, the number would either be ineligible or the adult would be selected if an age-appropriate screener were included in the protocol. At this point there is no overwhelming evidence to suggest that within-household selection techniques are required for cell phone samples. However, as the penetration of cell phones increases and as the number of households having multiple cell phones per household increases, these types of selection techniques may become necessary.

The practice of telephone survey research is transitioning in response to the proliferation of cell phone use worldwide. While many of the survey research methods described are currently being used in conjunction with sample surveys of CPNs, it should be noted that general consensus for "best practices" for sampling designs, calling strategies, and weighting algorithms are at best in the experimental phases. As the cell phone landscape continues to evolve within the United States and worldwide, additional information will become available to confirm and possibly reform the current methods.

Cell Suppression

Under certain circumstances, it is considered necessary to withhold or suppress data in certain cells in a published statistical table. This is often done when particular estimates are statistically unreliable or when the information contained could result in public disclosure of confidential identifiable information. Suppression for reasons of statistical reliability involves consideration of sampling error as well as the number of cases upon which the cell estimate is based. Suppression to avoid the disclosure of confidential information in tabular presentations involves many additional considerations.

Cell suppression may involve *primary* suppression, in which the contents of a sensitive cell are withheld; or if the value for that cell can be derived from other cells in the same or other tables, *secondary* or *complementary* suppression. In the latter instance, the contents of nonsensitive cells as well those of the sensitive cells are suppressed. Sensitive cells are identified as those containing some minimum number of cases. In an establishment survey, for example, a cell size of 2 would be regarded as sensitive because it could reveal to one sample establishment (included in the tabulation and knowing its contribution to an estimate reported in the table) the value of a variable reported by another establishment known to have participated in the survey. Often, the minimum cell size for suppression is considerably higher than 2, depending upon such factors as total sample size, sampling ratio, and potential harm to survey participants resulting from disclosure.

Once sensitive cells have been identified, there are some options to protect them from disclosure: (a) restructure the table by collapsing rows or columns until no sensitive cells remain, (b) use cell suppression, (c) apply some other disclosure limitation method, or (d) suppress the entire planned table.

When primary and complementary suppressions are used in any table, the pattern of suppression should be audited to check whether the algorithms that select the suppression pattern permit estimation of the suppressed cell values within "too close" of a range. The cell suppression pattern should also minimize the amount of data lost as measured by an appropriate criterion, such as minimum number of suppressed cells or minimum total value suppressed. If the information loss from cell suppression is too high, it undermines the utility of the data and the ability to make correct inferences from the data. Cell suppression does create missing data in tables in a nonrandom fashion, and this harms the utility of the data.

In general, for small tables, it is possible to select manually cells for complementary suppression and to apply audit procedures to guarantee that the selected cells adequately protect the sensitive cells. However, for large-scale survey publications having many interrelated, higher-dimensional tables, the selection of a set of complementary suppression cells that are optimal is an extremely complex problem. *Optimality* in cell suppression is achieved by selecting the smallest number of cells to suppress (to decrease information loss) while ensuring that confidential information is protected from disclosure.

Census

A census is an attempt to list all elements in a group and to measure one or more characteristics of those elements. The group is often an actual national population, but it can also be all houses, businesses, farms, books in a library, cars from an assembly line, and so on. A census can provide detailed information on all or most elements in the population, thereby enabling totals for rare population groups or small geographic areas. A census and a sample survey have many features in common, such as the use of a questionnaire to collect information, the need to process and edit the data, and the susceptibility to various sources of error. Unlike a sample survey, in which only a subset of the elements is selected for inclusion and enumeration, a census generally does not suffer from sampling error. However, other types of errors may remain. The decision to take a census versus a sample survey—if not mandated by statute—is often based on an assessment of the coverage, cost, errors in the data, and other qualitative factors.

Aspects of a census include the types and historical purposes for taking a census, its statistical properties, the differences between a census and a sample survey, and errors that can occur in a census.

General Background

Perhaps the most well-known type of census is one that enumerates the population or housing characteristics of a specified country or other politically defined region. Others measure the output in a specified sector of the economy, such as agriculture, transportation, manufacturing, or retail sales. These censuses are typically authorized and funded by the central government of the region covered.

Censuses were first conducted hundreds (Canada, Sweden) and even thousands (China) of years ago in some parts of the world. In many countries, a census is repeated in a fixed cycle, often every 5th (the United Kingdom, Canada, Australia, New Zealand) or 10th (Portugal, Spain, Italy, Poland, Turkey) year. In the United States, the census of population and housing has been conducted every 10th year, beginning in 1790. The U.S. economic census is taken every 5th year.

Historically, the purpose of the census has varied. At first, governing bodies wanted to know the number of people for assessing taxes or determining the number of men eligible for the military. Currently, governments use census data to apportion their legislative bodies, set boundaries for political districts, distribute government funds for social programs, track the nation's economy, measure crops to predict food supplies, and monitor people's commute to work to determine where to improve the region's infrastructure. As a by-product, census lists of households, businesses, or farms are often used as frames for surveys or follow-up studies. Further, the detailed information collected in the census allows for more efficient sample designs and improved estimation in the surveys.

Content and Mode of Collection

The content of a census form can range from a few basic questions to many detailed questions. Indeed, the same census may combine the two approaches. In recent decades, in the U.S. Census of population and housing most households received a "short form" limited to the names, ages, and a few other characteristics of the people living in the household. At the same time, a sample of about 1 in 6 U.S. households received a "long form" that solicited the basic information as well as more detailed data on the residents' demographic and educational background, the housing unit's physical size and structure, and other characteristics. Plans for the U.S. Census in 2010 call for only a short form. The detailed data formerly solicited in the long-form census are now collected in the American Community Survey, a large survey conducted by the U.S. Census Bureau designed to produce estimates at the county level every year. In an economic census, dozens of different forms may be used to tailor the questions to specific types of business.

Traditionally, census takers went door to door asking questions, an approach still used in many countries, especially in the developing world. In the developed world, one or several modes of enumeration may be used. People or businesses are often contacted by mail or in person, perhaps by telephone if a current number is available. When no response is received from a mailing, a census representative may be sent to a housing unit or establishment to follow up. Where feasible, especially when canvassing businesses, an electronic questionnaire might be provided on a disk. In some censuses, respondents may be encouraged to reply via the Internet.

Alternative or combination approaches can be used to solicit or collect data. As an example, in the U.S. Census of Retail Trade in 2002, all of the larger establishments and a sample of the smaller ones were mailed a complete questionnaire. For the smaller firms not selected into the sample, the basic economic information was collected through available tax records. Such an approach can lessen the reporting burden of the respondents and, in some cases, provide valuable auxiliary data. However, combining alternative methods of data collection usually requires an examination of several key aspects: the coverage of the population, differences in the definitions of data items, the consistency of information collected via different modes, and the accuracy of the data.

To Take a Census or a Sample Survey?

A census generally attempts to collect information on all eligible elements in a defined population, while a sample survey pre-selects a subset of elements for inclusion. But it is doubtful whether any census has ever successfully captured all elements, for reasons involving frame deficiencies, census procedures, the cooperation of respondents, or other issues. While a census may produce almost complete coverage, there are also advantages to taking a sample survey. To start, taking a census requires extensive planning and complex operations. In making contact with only a fraction of the population, a sample survey usually imposes a burden on many fewer respondents and costs much less to complete.

Some costs—questionnaire materials, mailing charges, interviewer salaries—tend to be proportional to the size of the canvassed population. Other costs can escalate with the size. For example, when planning for a large-scale census, one might have to hire and train two or three times as many interviewers as will be needed during the census, because many will drop out or be discharged before the census is completed. With a sample survey, because of the smaller scale of the operation, one can better control the hiring and training of interviewers and thus lower costs. For repeated surveys or when several surveys are run out of the same field office, interviewers who work on one survey may be used on other surveys when their schedules permit, taking advantage of experience and reducing training costs.

The decision to take a census or a sample survey is at times a trade-off between the breadth of detail and the currency of the information. Often, only a census can produce useful information for rare populations or small geographic areas. For example, the U.S. Census produces data for the population classified by age, race, and Hispanic identity for each block in the country. No survey could possibly produce such information. Yet, in a census, data are generally collected at one point in time and can take months or years to process and disseminate. When it is released, that information may have to suffice until the next census is completed and processed. On the other hand, a survey can be taken at much more frequent intervals—perhaps on a monthly, quarterly, or annual basis—but might collect only a subset of the information captured in the census.

Errors in a Census

While the results from a census typically do not suffer from sampling error—those errors introduced by canvassing only a sample of the entire population—censuses are susceptible to the nonsampling errors found in sample surveys. A common problem is missing data, such as unit nonresponse (when no usable data are obtained for a population element) or item nonresponse (when only a portion of a response is usable), due to failure to reach the respondent or the respondent's unwillingness or inability to provide information.

Nonsampling errors can arise in various ways. Respondents can misinterpret questions on the census form, especially if the questions are vague or too complex. Errors may be introduced when respondents must estimate the quantity requested on the questionnaire. When conducting a personal interview, the behavior of a census field representative can influence the responses. Other sources of nonsampling errors include coverage problems (undercoverage or overcoverage of the target universe), processing errors, and mistakes recording or keying data. For example, census data describing industry or place of work must be coded to be useful. But coding can introduce both random and systematic errors into the census results.

To address nonsampling errors, statistical procedures are sometimes applied. For example, to treat unit or item nonresponse, a missing item might be replaced by the item's value from a respondent whose characteristics are similar to those of the nonrespondent. Inserting values for missing items on a questionnaire is called "imputation."

In a sample survey, sampling error generally decreases as the size of the sample increases. But any systematic biases introduced in a census process or operation generally are not eliminated—even though the entire population is canvassed or targeted. Estimating the size of nonsampling errors requires follow-up studies or data from independent sources. As a result, the level of nonsampling error in a census is generally not known or published.

Because conducting a sample survey is a much smaller operation than taking a complete census, nonsampling errors can sometimes be contained better in surveys. A greater proportion of the allotted time and budget can be spent obtaining responses, eliminating sources of error, and improving the quality of the data. Consequently, at times survey results can be more accurate than census results. Still, by attempting to cover the entire population, a census retains advantages over a sample survey. As mentioned previously, a census provides direct summary statistics for the characteristics of small areas or domains. With a sample survey, indirect methods or models are often required to produce small-area estimates when the size of the sample falling in the area or domain is too small. Such procedures are susceptible to errors when the models are specified incorrectly.

Statistical procedures—including probability sampling—are often used while a census is being taken and after its completion. For example, quality control measures can be applied in a sample of regions to monitor operations and determine whether procedures are being followed as specified. After the enumeration, to measure the coverage or accuracy of the census, a sample of areas or domains may be selected and examined in greater detail. Data obtained from re-interviews or administrative records can be used to produce estimates of the total number of census omissions or erroneous enumerations in the entire population or in subgroups.

Certificate of Confidentiality

In order to collect sensitive information, researchers need to be able to ensure for themselves that identifiable research data will remain confidential and assure respondents that this is the case. However, neither legislatures nor courts have granted researchers an absolute privilege to protect the confidentiality of their research data. Despite this, there are several federal statutory mechanisms that can be helpful. In some cases researchers can obtain legal protection for the confidentiality of research data through a federally issued Certificate of Confidentiality as authorized by the Public Health Service Act § 301 (d), 42 U.S.C § 241(d):

> The Secretary may authorize persons engaged in biomedical, behavioral, clinical, or other research (including research on mental health, including research on the use and effect of alcohol and other psychoactive drugs) to protect the privacy of individuals who are the subject of such research by withholding from all persons not connected with the conduct of such research the names or other identifying characteristics of such individuals. Persons so authorized to protect the privacy of such individuals may not be compelled in any Federal, State, or local civil, criminal, administrative, legislative, or other proceedings to identify such individuals.

Certificates of Confidentiality allow the investigator and others who have access to research records to refuse to disclose identifying information on research participants in any civil, criminal, administrative, legislative, or other proceeding, whether at the federal, state, or local level. Certificates of Confidentiality may be granted for studies collecting information that, if disclosed, could have adverse consequences for subjects or damage their financial standing, employability, insurability, or reputation (such as drug use, sexual behavior, HIV status, mental illness).

Research need not be federally supported to be eligible for this privacy protection. Certificates of Confidentiality are issued by various Public Health Service component agencies, the Food and Drug Administration, the Health Resources and Services Administration, and the National Institutes of Health. Researchers are expected to inform subjects in the consent form about the Certificate of Confidentiality protections and the circumstances in which disclosures would be made to protect the subject and others from harm (such as suicidal intention, child abuse, elder abuse, intention to harm others) and certain types of federal audits.

There is very little legal precedent considering the scope of the protections afforded by Certificates of Confidentiality. However, in at least one case from 1973 (*People v. Newman*), a New York state court of appeals found that a certificate provided a substance abuse program with a proper basis for refusing to turn over the names of program participants.

There are other types of legal protection available for some federally funded research. The privacy of research subjects in Department of Justice–funded research is protected by statute—42 U.S.C. Section 3789g. Similarly, the privacy of research subjects in Agency for Health Care Quality and Research–funded research is protected by a statute 42 U.S.C. Section 299a-1(c) titled "limitation on use of certain information." For these studies, Confidentiality Certificates are not appropriate. All researchers collecting sensitive data as part of projects under the jurisdiction of an institutional review board will need to work closely with their board and also may require legal counsel.

CHECK ALL THAT APPLY

The check-all-that-apply question format presents respondents with multiple response options to a single question, as shown in Figure 1.

What race or races are you? (Please check all that apply)

___ Asian
___ Black
___ Native American
___ Pacific Islander
___ White
___ Other (Please specify:_________________)

Figure 1 Check all that apply

In response to the question, the respondents are instructed to select as many of the response options as are perceived to apply to them. Although the check-all-that-apply question format is commonly used in survey questionnaires, research has shown that it can result in a less than optimal response strategy by respondents and may be especially sensitive to primacy effects when the question is asking about past experiences, behaviors, or attitudes.

When evaluating a list of response options to a check-all-that-apply question, respondents may strive for satisficing and burden avoidance. For example, respondents may select only the first of several reasonably acceptable response options and fail to adequately consider the remaining response options before proceeding to the next question. Because of this, some researchers believe it is important to deploy several versions of a check-all-that-apply question, with the response options listed in different orders that are randomly assigned to different respondents, so as to scramble the order of the list of response options across the entire sample.

The check-all-that-apply question format is distinct from the forced choice format (e.g., a list of Yes/No response options). In the forced choice format, respondents are asked to evaluate each forced choice response option individually before moving on to the next. The literature suggests that this difference may result in respondents following divergent cognitive approaches in responding to the forced choice format versus the check-all-that-apply format. In particular, respondents may show more careful consideration and greater cognitive processing of each response option in the forced choice format, while selecting only the first few of several response options that apply in the check-all-that-apply format. Research has shown that in addition to a primacy effect associated with the check-all-that-apply format, the difference between the two formats may result in a higher average number of response options selected per respondent in a forced choice question than in a comparable check-all-that-apply question.

While the addition of the "No" category in the forced choice format should provide greater discrimination when compared to the check-all-that-apply format (which lacks an explicit "No" category), research also has shown that, without adequate instruction, respondents may treat a forced choice format in self-administered questionnaires as Check All That

Apply. This occurs when respondents correctly select the "Yes" category for positive responses but fail to select the "No" category for negative responses. As a result, the data can be difficult to interpret. Blank responses may either be intended as a negative response, a not applicable response, or simply an undecided, don't know, or a missing response.

The check-all-that-apply question format is commonly used in self-administered paper-based and Internet surveys. It is less well suited to telephone surveys and consequently is rarely used in that mode. In interviewer-administered in-person surveys, use of the check-all-that-apply format should be paired with the use of a show card displaying the choices to the respondent. In multi-mode surveys, there has been a tendency to pair a check-all-that-apply question in a self-administered questionnaire with a forced choice version in a telephone interview. However, considering the findings in the literature that show that respondents do not treat the two question formats similarly, converting a check-all-that-apply question from a self-administered questionnaire to a forced choice format for use in a telephone interview may not be an optimal approach.

CHI-SQUARE

The chi-square (χ^2) is a test of significance for categorical variables. Significance tests let the researcher know what the probability is that a given sample estimate actually mirrors the entire population. The chi-square can be used as a goodness-of-fit test, in univariate analysis, or as a test of independence, in bivariate analysis. The latter is the most generally used. In this case, the test measures the significance of the relationship between two categorical variables, representing the first step toward bivariate analysis. For example, if a survey researcher wanted to learn whether gender is associated with an attitude (negative or positive) toward the U.S. involvement in Iraq, chi-square is the simplest significance test to consider to investigate whether or not there are reliable gender-related differences in these attitudes (see Table 1).

The logic behind the chi-square is to calculate the distance between the observed frequencies within the contingency table and the condition of statistical independence (i.e., the hypothesis of no association or "null hypothesis"). The frequencies that Table 1 would contain in case of no association (the so-called expected frequencies) are calculated by dividing the product of the marginal frequencies (row and column) of each cell by the sample size. The greater the distance between the observed frequencies and the expected frequencies, the higher is the chi-square. This is the formula:

$$\chi^2 = \Sigma \frac{(f_o - f_e)^2}{f_e},$$

where f_o represents the observed frequencies and f_e are the expected frequencies. If the value of the chi-square is 0, there is no association between the variables. Unfortunately, the chi-square has no maximum, and this makes its interpretation not intuitive.

In order to interpret the value obtained, the researcher must first calculate the degrees of freedom (*df*) of the contingency table, multiplying the number of the rows minus 1 by the number of the columns minus 1. Second, given the values of chi-square and *df*, he or she has to search for the corresponding value of *p*-level. This value can be located on the chi-square

Table 1 Example of contingency table for chi-square analysis (frequency counts)

Support/Oppose U.S. Involvement in Iraq	*Female*	*Male*	*Total*
Support	**170**	**200**	370
Oppose	**250**	**150**	400
Total	420	350	770

distribution table, usually reported in most handbooks of statistics, or calculated through statistical software such as Statistical Package for the Social Sciences (SPSS) or SAS.

The *p*-level is the crucial figure to consider when evaluating the test. This is the actual value that indicates the significance of the association. It says, in short, how probable it is that the relationship observed in the survey data is due to mere sampling error. The chi-square test must be used cautiously. First, the researcher should have a probability sample whose size is ≥ 100. Second, since the chi-square statistic is sensitive to the sample size, the researcher cannot compare the chi-square values coming from different samples. Third, researchers should be careful that the expected values in the contingency table are not too small (≤ 5), because the chi-square value will be heavily biased. Finally, sometimes it makes no sense to calculate the chi-square: for example, when the number of categories of both variables is too high.

In all these cases, the chi-square test should not be separated from the detailed inspection of the contingency table and/or the use of more sophisticated measures. Since the chi-square value is not easily interpretable, other measures have been derived from it, like phi-square, Pearson's C, and Cramér's V. They are not influenced by the sample size and, above all, tend to range from 0 to 1 (this maximum, however, is actually achievable only by Cramér's V), measuring the strength of the association, even when this latter is nonlinear.

CLOSED-ENDED QUESTION

A closed-ended survey question is one that provides respondents with a fixed number of responses from which to choose an answer. It is made up of a question stem and a set of answer choices (the response alternatives). When administered by a survey interviewer, a closed-ended question is expected to be read exactly as written to the respondent, along with the full set of response alternatives. The set of answer choices must fulfill two properties: they must be (1) mutually exclusive and (2) exhaustive. In being mutually exclusive, no two answers can overlap in conceptual meaning. In being exhaustive, the answer choices must cover all logically possible answers for the question.

The following example of a closed-ended question has answers that are neither mutually exclusive nor are they exhaustive:

> *How many times in the past 30 days have you entered a grocery store?*
> *(a) 1–5 (b) 6–10 (c) 11–15 (d) 15 or more*

In the example, a respondent who entered a grocery store 15 times in the past 30 days would not know if she or he should choose response (c) or (d), because the two are not mutually exclusive, as both contain the number 15. A respondent who never entered a grocery store in the past 30 days should answer "0," but the response choices do not include that answer and thus they are not exhaustive of all logically possible answers.

With interviewer-administered questionnaires, such as those used in face-to-face and telephone surveys, closed-ended questions typically are constructed so that the interviewer can code a "Don't know/Uncertain" (DK) response when that is appropriate for a given respondent. They also typically include a "Refused" (RF) response choice for the interviewers to code when a given respondent refuses to provide an answer to that question. DK and RF response choices are not provided to the respondent by the interviewer. In self-administered questionnaires, closed-ended questions do not often contain these additional response choices, as their inclusion likely would "open the door" for respondents to avoid providing substantive answers to questions.

Clustering

In broad terms, *clustering*, or *cluster analysis*, refers to the process of organizing objects into groups whose members are similar with respect to a similarity or distance criterion. As such, a cluster is a collection of similar objects that are distant from the objects of other clusters. Unlike most classification techniques that aim to assign new observations to one of the many existing groups, clustering is an exploratory procedure that attempts to group objects based on their similarities or distances without relying on any assumptions regarding the number of groups.

Applications of clustering are many; consequently, different techniques have been developed to address the varying analytical objectives. There are applications (such as market research) in which clustering can be used to group objects (customers) based on their behaviors (purchasing patterns). In other applications (such as biology), clustering can be used to classify objects (plants) based on their characteristics (features).

Depending on the application and the nature of data at hand, three general types of data are typically used in clustering. First, data can be displayed in the form of an $O \times C$ matrix, where C characteristics are observed on O objects. Second, data can be in the form of an $N \times N$ similarity or distance matrix, where each entry represents a measure of similarity or distance between the two corresponding objects. Third, data might represent presumed group membership of objects where different observers may place an object in the same or different groups. Regardless of data type, the aim of clustering is to partition the objects into G groups where the structure and number of the resulting natural clusters will be determined empirically. Oftentimes, the input data are converted into a similarity matrix before objects are portioned into groups according to one of the many clustering algorithms.

It is usually impossible to construct and evaluate all clustering possibilities of a given set of objects, since there are many different ways of measuring similarity or dissimilarly among a set of objects. Moreover, similarity and dissimilarly measures can be univariate or multivariate in nature, depending on whether one or more characteristics of the objects in question are included in calculations. As such, it is impractical to talk about an optimal clustering technique; however, there are two classes of techniques (hierarchical and nonhierarchical) that are often used in practice for clustering.

Hierarchical techniques proceed in a sequential fashion, producing an increasing or decreasing number of nested arrangements of objects. Such techniques can be agglomerative, whereby individual objects start as single clusters and thereafter similar clusters are merged to form progressively fewer larger clusters. As the number of clusters decreases, so do their similarities, eventually leading to the single most dissimilar cluster that includes all objects. In contrast, hierarchical techniques can be divisive, whereby a single cluster of all objects is first partitioned into two clusters of similar objects and thereafter the resulting clusters are further portioned into two new similar clusters. As the number of clusters increases, so do their similarities, eventually leading to the set of most similar clusters that consists of one object per cluster. With hierarchical techniques, the criterion for merging or partitioning interim clusters can be based on the distance (linkage) between their nearest objects, furthest objects, average distance among all objects, or more sophisticated distance measures such as those based on Ward's or Centroid methods. The results of both agglomerative and divisive clustering techniques are often displayed via a two-dimensional graph (tree) called a "dendogram."

Nonhierarchical techniques aim to partition objects into a number of clusters by starting with an a priori set of clusters. Alternatively, such techniques can start the partitioning process based on a set of initial seed points that serve as the nuclei of the emerging clusters. Under either approach, the starting points (initial clusters or seed values) can be chosen in a random fashion to reduce systematic bias. It should be noted that the number of possible clusters of size K that can be formed from O objects can be fairly large (of order $KO/K!$) to allow an exhaustive search for the initial selection.

While there are several nonhierarchical methods of clustering, the method of K-means is the most commonly used technique in practice. This partitioning technique relies on the Euclidean distance between group centroid to measure proximity. Upon formation of the initial K clusters, using either a set of a priori clusters or seed points, the algorithm proceeds by successively assigning each object to the cluster with the nearest centroid. After each reassignment, the centroid points for the donating and receiving clusters are recalculated to identify the structure of the resulting clusters.

Aside from the algorithm chosen for clustering, several guidelines have been developed over the years regarding the number of clusters. While a few of these guidelines rely on visual clues such as those based on sizable change in dendograms, others incorporate formal statistical tests to justify further bisecting of clusters. It has been suggested that visual guidelines can be somewhat ad hoc and result in questionable conclusions. Test-based approaches, on the other hand, might require more distributional conformity than the data can afford.

Cluster Sample

Unlike stratified sampling, where the available information about all units in the target population allows researchers to partition sampling units into groups (strata) that are relevant to a given study, there are situations in which the population (in particular, the sampling frame) can only identify pre-determined groups or clusters of sampling units. Conducive to such situations, a *cluster sample* can be defined as a simple random sample in which the primary sampling units consist of clusters. As such, effective clusters are those that are heterogeneous within and homogenous across, which is a situation that reverses when developing effective strata.

In area probability sampling, particularly when face-to-face data collection is considered, cluster samples are often used to reduce the amount of geographic dispersion of the sample units that can otherwise result from applications of unrestricted sampling methods, such as simple or systematic random sampling. This is how cluster samples provide more information per unit cost as compared to other sample types. Consequently, cluster sampling is typically a method of choice used when it is impractical to obtain a complete list of all sampling units across the population of interest, or when for cost reasons the selected units are to be confined to a limited sample of clusters. That is, feasibility and economy are the two main reasons why cluster samples are used in complex surveys of individuals, institutions, or items.

Operationally, clusters can be defined as collection of units that are geographic, temporal, or spatial in nature. For instance, counties or census blocks often serve as geographic clusters for households sampling; calendar years or months are used for temporal clustering; while boxes of components or plots of land are examples of spatial clusters of objects. Depending on the nature of a study and the extent of heterogeneity among units within each cluster, different numbers of clusters might be needed to secure reliable estimates from a cluster sample. When units within all clusters display the same variability with respect to the measure of interest as the target population as a whole, reasonable estimates can be generated from a small number of clusters. In contrast, when variability is small within but large across clusters, a larger number of clusters of smaller size might be needed to ensure stability.

In spite of feasibility and economical advantages of cluster samples, for a given sample size cluster sampling generally provides estimates that are less precise compared to what can be obtained via simple or stratified random samples. The main reason for this loss in precision is the inherent homogeneity of sampling units within selected clusters, since units in a given cluster are often physically close and tend to have similar characteristics. That is, selection of more than one unit within the same cluster can produce redundant information—an inefficiency leading to higher standard errors for survey estimates.

Kish provided a model for estimating the inflation in standard errors due to clustering. Accordingly, this multiplicative clustering design effect, *deff*, can be estimated by

$$deff = 1 + \rho(\overline{m} - 1).$$

In the preceding formulation, $\overline{m}$ represents the average cluster size and ρ (rho) denotes the so-called intraclass correlation, which is an estimate of relative homogeneity within clusters measured with respect to key analytical objectives of the survey. Obviously, the above effect approaches unity (or no effect) when the average cluster size approaches 1—that is, when the design approaches simple random sampling with no clustering. When ρ becomes exceedingly large due to high correlation between sampling units within clusters, it becomes exceedingly less efficient to select more than one unit from each cluster. Stated differently, even a relatively moderate measure of intraclass correlation can have a sizable inflationary effect on the standard errors when the average cluster size is large.

It should be noted that single-stage cluster sampling is rarely used for selection of the final sampling units. Instead, this methodology is often combined with other sampling techniques to improve the efficiency of the resulting sample. In multi-stage designs, commonly, the first stage consists of stratification of units into similar subsets or those for which reporting is required. It is at the second stage that usually cluster samples are selected within each stratum. Given that sampling with probability proportional to size (PPS) often reduces the standard errors of estimates, cluster sampling provides an ideal framework for this type of sample selection since the number of units in a cluster forms a natural measure of size for the given cluster. In particular, sampling with probabilities proportional to the size of clusters pays big dividends with respect to reducing the error of estimation when the cluster total is highly correlated with the number of units in the cluster.

Cochran, W. G. (1909–1980)

William Gemmell Cochran was an early specialist in the fields of applied statistics, sample surveys, experimental design, observational studies, and analytic techniques. He was born in Rutherglen, Scotland, to Thomas and Jeannie Cochran on July 15, 1909, and he died on Cape Cod, Massachusetts, on March 29, 1980, at the age of 70. In 1927, Cochran participated in the Glasgow University Bursary competition and took first place, winning enough funds to finance his education. After taking a variety of classes, he was awarded an M.A. in mathematics and physics at the University of Glasgow in 1931. He then received a scholarship for a Cambridge University doctoral program, where he studied mathematics, applied mathematics, and statistics. He began his professional career at the Rothamsted Experimental Station in England after being persuaded by Frank Yates to leave Cambridge prior to the completion of his doctorate. Cochran remained at Rothamsted until 1939, working on experimental designs and sample survey techniques, including a census of woodlands with colleague and mentor Yates. During his years at Rothamsted, Cochran remained in touch with R. A. Fisher and was heavily influenced by Fisherian statistics. In his 5 years at Rothamsted (1934–1939), he published 23 papers. Also during his time at Rothamsted, Cochran met and married Betty I. M. Mitchell.

In 1939 Cochran accepted a post in statistics at Iowa State University, where he taught from 1939 to 1946. His task at Iowa was to develop their graduate program in statistics. During his years at Iowa he both served on and chaired the advisory panel to the U.S. Census and published a number of papers on experimental design. Cochran joined Samuel Wilks and the Statistical Research Group at Princeton University in 1943, examining probabilities of hits in naval warfare and the efficacy of bombing raid strategies. Shortly after World War II, he joined Gertrude Cox at the North Carolina Institute of Statistics, where he assisted in developing graduate programs in statistics. Cochran chaired the Department of Biostatistics at Johns Hopkins University from 1949 until 1957. During this time he authored two books, *Sampling Techniques* and (in collaboration with Gertrude Cox) *Experimental Designs*. In 1957 Harvard University established a Department of Statistics and appointed Cochran to head the department. Cochran remained at Harvard until his retirement in 1976.

During his career, Cochran was lauded with many honors. He was the president of the Institute of Mathematical Statistics in 1946, the 48th president of the American Statistical Association in 1953–1954, president of International Biometric Society 1954–1955, and the president of the International Statistical Institute from 1976 to 1981. Cochran was elected honorary fellow of the Royal Statistical Society in 1959, held a Guggenheim Fellowship in 1964, and won the S. S. Wilks medal of the American Statistical Association in 1967. He received honorary doctorate degrees from Johns Hopkins University and the University of Glasgow. From 1974 until his death in 1980, he worked with the National Academy of Sciences' National Research Council panel on incomplete data in sample surveys.

Cochran developed methods for including or excluding an independent variable in multiple linear regression. He also developed the Cochran *Q*-test, used to evaluate two variables measured on a nominal scale. Cochran was the statistical representative for the U.S. Public Health Service research on the effects of smoking on lung cancer. His work as part of the advisory committee provided the surgeon general with proof that lung cancer was directly related to smoking. He also worked on the Kinsey Report on human sexual behavior, on polio research, and on the effects of radiation on Hiroshima victims. He is well remembered for his many agricultural studies such as the yield of cereals, field counts of diseased plants, and the influence of rainfall.

Cochran developed his knowledge of statistics by both studying and working at some of the most prestigious universities. During his lifetime he was involved in diverse research projects and made many important contributions to the field of statistics, not the least of which was establishing statistics departments at several universities. As a teacher, he is remembered for his high expectations for his students, his individuality, and his clarity.

CODEBOOK

Codebooks are used by survey researchers to serve two main purposes: to provide a guide for coding responses and to serve as documentation of the layout and code definitions of a data file. Data files usually contain one line for each observation, such as a record or person (also called a "respondent"). Each column generally represents a single variable; however, one variable may span several columns. At the most basic level, a codebook describes the layout of the data in the data file and describes what the data codes mean. Codebooks are used to document the values associated with the answer options for a given survey question. Each answer category is given a unique numeric value, and these unique numeric values are then used by researchers in their analysis of the data.

As a guide for coding responses, a codebook details the question-and-answer wording and specifies how each individual answer should be coded. For example, a codebook entry for a question about the respondent's gender might specify that if "female" is chosen, it should be coded as "1," whereas "male" should be coded as "2." Directions may also be given for how to code open-ended answers into broad categories. These values are then used to enter the data the values represent into the data file, either via computer-assisted data entry software or in a spreadsheet.

There are many ways to create a codebook. Simple codebooks are often created from a word processing version of the survey instrument. More complex codebooks are created through statistical analysis software, such as SAS or Statistical Package for the Social Sciences (SPSS). Codebooks generated through statistical analysis software will often provide a variable label for each question, describing the content of the question, word and numeric labels for all answer categories, and basic frequencies for each question.

Codebooks can range from a very simple document to a very complex document. A simple codebook will detail each question-and-answer set along with the numeric value assigned to each answer choice, whereas a more complex codebook will also provide information on all associated skip patterns as well as any variables that have been "created" from answers to multiple other questions.

There are seven types of information that a codebook should contain. First, a short description of the study design, including the purpose of the study, the sponsor of the study, the name of the data collection organization, and the specific methodology used including mode of data collection, method of participant recruitment, and the length of the field period. Second, a codebook needs to clearly document all of the sampling information, including a description of the population, methods used to draw the sample, and any special conditions associated with the sample, such as groups that were oversampled. Third, the codebook needs to present information on the data file, including the number of cases and the record length of each case. Fourth, the data structure needs to be clearly delineated, including information on whether the data are presented in a hierarchical manner or some other manner. Fifth, specific details about the data need to be documented, including, at the very least, the variable names, the column location of each variable, whether the variable is numeric or character (string), and the format of numeric variables. Sixth, the question text and answer categories should be clearly documented along with frequencies of each response option. Finally, if the data have been weighted, a thorough description of the weighting processes should be included.

Major survey research projects conducted for the federal and state government often create electronic versions of codebooks that are accessible through the agencies' Web sites. There are also numerous centers and libraries at universities that provide archives of survey data from research projects along with Web access to electronic codebooks.

Coder Variance

Coder variance refers to nonsampling error that arises from inconsistencies in the ways established classification schemes are applied to the coding of research observations. In survey research, coder variance is associated with the process of translating the raw or verbatim data obtained from open-ended survey items into a quantitative format that can be analyzed by computers.

To appreciate how coder variance can occur, it is useful to review the process of preparing open-ended survey item data for analysis. Once all or a representative sample of the data have been collected, verbatim answers are examined for the purpose of defining a list of response categories (i.e., "code labels") that may be used for shorthand representations of the item data collected from each respondent. This list is known as the "coding frame" for the open-ended survey item. Depending on the coding protocol established, exactly one element or multiple elements of the coding frame may be associated with the item data.

Members of the research team designated as "coders" are entrusted with the responsibility of examining each verbatim response given to an open-ended item and assigning one or more of the elements of the coding frame to represent that data. Coders attempt to perform their task in such a manner that another coder would choose the identical set of elements from the coding frame. However, since judgment in interpreting both the raw verbatim data and the coding frame elements themselves is involved, inconsistency in the use of the coding frame elements (or code labels) is inevitable.

Any differences or inconsistencies in the combination of coding frame elements assigned to represent the actual verbatim data across interviewers constitute coder variance. These inconsistencies can arise as the consequence of four types of error:

1. Encoding error is introduced when the coding frame fails to feature code labels that are sufficiently exhaustive to clearly capture and discriminate the information in the verbatim data. Thus, when coders encounter data not well reflected in the coding frame, they must choose among imperfect alternatives. This promotes inconsistencies in the assigned code labels chosen across coders.
2. Interpretation error occurs when different coders haphazardly draw different meanings or nuances from the data. When this happens, different coders may apply different code labels from the coding frame to represent the data.
3. Coding error is a consequence of incorrect or inconsistent application of the code labels to the verbatim data. Because coding frame labels are highly condensed shorthand for highly varied, often detailed, and nuanced information, coders may interpret the meanings of these condensed labels in varied ways that, in turn, result in inconsistencies in their applications across coders.
4. Systematic coder bias arises from the tendencies of coders—human beings who possess personal

biases, either innate or learned—toward avoidance or overuse of specific elements in the coding frame.

Researchers examining the phenomenon of coder variance typically have found it to be a substantial problem for some survey items and a relatively inconsequential concern for others. When truly a problem, coder variance can account for as much as half of all nonsampling error in the statistical estimates produced for an item. Likewise, even when components of coder variance are small, the loss of precision in statistical estimates can be substantial. Indeed, coder variance can reduce the statistical reliability of survey estimates to a level achievable with half the sample size in the absence of coder variance.

While it is impossible to anticipate the extent of error that coder variance is likely to introduce into an item's results, studies have shown that the lion's share of the unreliability associated with coder variance results from the use of code labels that are general in nature or included as "catch-all" codes. Thus, researchers who choose to include open-ended survey questions should recognize the inherent unreliability and limited value of such items unless they (a) take pains to develop coding frames featuring only highly nuanced and specific code labels and (b) engage their coders in detailed training regarding the meaning and assignment of code labels.

CODING

Coding is the procedural function of assigning concise and specific values (either alpha or numeric) to data elements collected through surveys or other forms of research so that these data may be quickly and easily counted or otherwise processed and subjected to statistical analyses, most often using a computer. These values may be alphanumeric in format, although it is common practice to use entirely numeric characters or entirely alphabetical characters when assigning labels. Numeric character values generally are almost universally referred to as "numeric codes" while alphabetical character values (and sometimes alphanumeric labels) are commonly referred to in several fashions, including "strings," "string codes," and "alpha codes," among others.

Inasmuch as data processing and analysis is typically accomplished through the use of specialized computer application software programs (e.g., Statistical Package for the Social Sciences [SPSS] or SAS), the assignment of designated values permits data to be transferred from the data collection instrument (which itself may be an electronic system, such as a computer-assisted telephone interviewing network) into a compact, computer-readable, database form.

The process of value development and specification may occur at any of several points in time during the conduct of the research project.

Precoding refers to code development and specification that occurs prior to the commencement of data collection activities. Precoding is appropriate for those data elements of the study where observations (e.g., respondent responses to survey questions) can be anticipated and exhaustively (or nearly exhaustively) specified before the research data are collected. As such, in survey research, precoding is routinely employed for all closed-ended items, all partly closed-ended items, and certain open-ended questions with which the investigator can anticipate the exhaustive range or set of possible responses. In addition, precoding occurs naturally and virtually automatically for open-ended items where clear constraints pertaining to the respondent's answer are implied by the question itself—for example, *How many times, if any, in the past year did you visit a dentist for any type of dental care?*—and, for this reason, such questions are said to be "self-coding."

In contrast, *postcoding* refers to code development and assignment that occur after data collection activities have begun. Most often, *postcoding* refers to code development and specification procedures implemented after the completion of data collection. However, to reduce the length of time between the data collection and subsequent data analysis activities of a study, postcoding might be initiated during data collection whenever a reliable subset of the full data set has been collected or when there is prior experience with similar questions.

Precoded labels are typically assigned in a manner that coincides with the measurement level implied by the item. For example, code labels assigned to response possibilities that correspond to interval or ratio level measures typically are numerical, with number values chosen to reflect the ordered and evenly spaced characteristics assumed by these measurement levels. (If a ratio level of measurement is involved, the code "0" is assigned to represent the measure's zero value.) Similarly, when ordinal level measurement items are involved, numerals (rather than alphabetical characters) are typically used for the codes, and the number values chosen appear in a logical sequence that is directionally consistent with the ordinal character of the measure's response categories; for example, 1 = None of the time, 2 = Some of the time, 3 = Most of the time, and 4 = All of the time. In contrast, code labels for items featuring nominal levels of measurement may be assigned in an arbitrary manner, as they bear no meaning or relationship to the response categories themselves; for example, 1 = No, 2 = Yes, or N = No, Y = Yes. Therefore, while sequenced numerals may be used for the code labels, these are typically assigned in an order corresponding to the sequence in which the response choices are documented in the research instrumentation. In other cases with nominal variables, simple alpha codes might be used, the convention often being using the first letter of the response choice.

Postcoding operations in survey research are bound to the categorization and structuring of responses culled from open-ended items, questions where the respondent's answers are self-composed and subject to unpredictable variation. To convert such data to computer-readable form, responses need to be associated with uniform categories and designated codes (typically numerals rather than letters) for these categories need to be assigned.

There are two approaches to accomplishing these postcoding tasks. One possibility is to develop a coding scheme prior to data collection activities. This approach requires that there is some theoretical basis for anticipating the possible responses and/or that the investigator has knowledge of and/or experience with a similar question or questions in one or more previous studies. The other possibility requires waiting until data collection activities have been completed or, alternately, until a representative subset (e.g., 20%) of the data have been collected. The available data are then examined for the purpose of establishing categories that capture the breadth and depth of the information collected and then assigning code labels to correspond to these categories. Then, once categories and corresponding labels have been established, item data for each interview are reviewed and one or more of these code labels are assigned to represent the information that was collected.

Standard research practice is to document the coded label values for each planned research observation (i.e., survey interview item) in a codebook. This document is more than just a listing of coded values, however; it is a blueprint for the layout of all information collected in a study. As such, the codebook not only identifies the value assigned to each research datum (i.e., survey answer, observation, or measurement) and the name of that value (i.e., the value label), but it also documents each label's meaning, specifies the name used to identify each item (i.e., "variable name"), includes a description of each item ("variable label"), and defines the data structure and reveals the specific location within that structure in which coded label values are stored.

Cognitive Aspects of Survey Methodology (CASM)

The cognitive aspects of survey methodology (CASM) is the interdisciplinary science involving the intersection of cognitive psychology and survey methods. CASM research endeavors to determine how mental information processing by respondents influences the survey response process and ultimately the quality of data obtained through self-report (or by proxy). CASM is mainly concerned with the study of response tendencies involving questionnaire data collection, but it can be more broadly defined as involving any aspect of survey-related mental processing, including respondent perceptions of survey interviewers and the survey introductions they use, the effects of administration mode (paper, telephone, computer), or responses to private or otherwise sensitive topics.

Background and History

Following the cognitive revolution of the 1970s, in which cognition was applied to a wide range of behavioral domains, the CASM field developed as an approach to questionnaire design that emphasizes the vital importance of cognition in the survey response process. Although the origins of this interdisciplinary science are rooted in earlier work, CASM as an identifiable movement was initiated by two key events: (1) the 1983 Advanced Research Seminar on Cognitive Aspects of Survey Methodology in the United States, now referred to as CASM I, and (2) the 1984 Conference on Social Information Processing and Survey Methodology held at ZUMA in Germany.

One influential outcome of the CASM I conference was the introduction of the four-stage cognitive model by Roger Tourangeau. To a great extent, the CASM approach is predicated on the key assertion that in order for a respondent to provide an accurate answer to a survey question, that individual must successfully negotiate a series of mental processing steps:

1. Comprehension of the survey question in the manner intended by the designer
2. Recall or retrieval from memory of information necessary to answer the question correctly
3. Decision and estimation processes that are influenced by factors such as item sensitivity, social desirability, or the respondent's assessment of the likelihood that the retrieved information is correct
4. The response process, in which the respondent produces an answer to the question in the form desired by the data collector

Some authors have elaborated this basic cognitive model by introducing other processes or mental states, such as motivational level. Others have envisioned a more flexible processing chain, in which the order of cognitive processes, and whether each is operative in a given case, varies depending on the survey question, the particular respondent, and the environment in which data collection occurs (e.g., the physical and social context).

Applied and Basic CASM Research

The CASM orientation has generated a wide range of research, which Monroe Sirken and colleagues have categorized as falling within two fundamental areas: applied CASM research and basic CASM research. Applied CASM research is focused on a specific questionnaire and attempts to improve that instrument through the use of cognitive interviewing methods to identify defects in survey questions having a cognitive origin. Basic CASM research is more general in scope. Rather than focusing on a particular instrument, basic CASM studies are devoted to the use of experimental methods to identify consistent cognitive tendencies that impact survey responding. Basic cognitive research is therefore intended to be applicable across a range of surveys and to serve as a guide to initial question design, rather than as a tailored pretesting method. That is, as opposed to focusing on quality control concerning a particular instrument, basic CASM research strives to elucidate rules of questionnaire design that incorporate a cognitive focus and that are developed through the use of empirical experimentation.

Examples of Basic CASM Research Studies

Some of this experimentation has concerned issues of response order effects, or how the respondent's tendency to select a particular response category (e.g., choice of a vague quantifier such as *excellent, very good, good, fair, poor*, or *very poor*) may depend on the order in which these options appear. Experiments by Jon Krosnick and colleagues have determined that response order effects depend on factors such as survey administration mode, for reasons having a cognitive basis. When response categories appear visually, as on a self-administered instrument, a *primacy effect* is often observed, where respondents are more likely to select items early in the list, presumably due to motivational factors such as satisficing that lead to fuller processing of earlier items than later ones. On the other hand, when the same response categories are read aloud under interviewer administration, a *recency effect* is obtained, in which later items in the list are more likely to be selected. From a cognitive point of view, recency effects are hypothesized to occur due to short-term memory limitations, where the items read most recently (those later in the list) are better represented in the respondent's memory and are therefore favored.

As a further example of experimentally oriented basic CASM research, Norbert Schwarz and colleagues cited in Tourangeau et al. have considered the effects of open-ended versus closed response categories for questions that ask about the frequency and duration of common, mundane behaviors. Their results suggest that respondents make use of information that is implicitly conveyed through such design decisions. In one experiment, subjects were asked to estimate the number of hours per day that they watched television, but one group was given closed-ended response categories ranging between "Up to ½ hour" through "More than 2½ hours" (low range), and the other was presented ranges from "Up to 2½ hours" through "More than 4½ hours" (high range). Individuals in the low-range condition tended to select a relatively lower duration of television watching than did those presented the higher ranges. The investigators concluded that respondents in both situations considered the middle category to represent normative or expected behavior and therefore relied on this central value as an anchor point when selecting their own answer from the presented list. Given the potentially contaminating effect of such response category ranges, the investigators suggested that designers instead choose an open-ended format for questions asking about behaviors like television watching, as this will obtain the desired information without subtly promoting any particular response category.

Similarly, CASM theorizing and research have concerned the effects of a number of other questionnaire design variables, such as (a) question ordering and its relationship to context effects, due to comprehension, memory, and decision-related processes; (b) variation in item sensitivity or degree of threat to personal privacy, which may influence respondents' decision making concerning the likelihood of providing a truthful response; (c) question length and complexity, which may affect overall cognitive processing burden; and (d) the effects of varying reference periods for recall of information, especially as this produces forward and backward telescoping effects.

Practical Use of Basic CASM Research Results

Basic CASM studies have been compiled and summarized in books by Roger Tourangeau, Lance J. Rips, and Kenneth Rasinski and by Seymour Sudman, Norman Bradburn, and Norbert Schwarz. Questionnaire designers can rely on this body of evidence to determine the cognitive factors that are likely to influence responses to their questions and to consider design alterations expected to improve overall response quality (e.g., the use of an administration mode that removes the presence of a human interviewer when sensitive questions are asked). This body of evidence is certainly useful in providing guidance, as it considers vital design issues and is dependent on the results of controlled experimentation. An important limitation, however, is that such experimental results are often insufficient, in themselves, for purposes of directing design decisions in specific cases, because the "rules" that emanate from such results tend to be somewhat generic in nature and subject to exception. For example, the knowledge that longer questions generally tend to reduce comprehension, relative to shorter ones, will not reveal the optimal length for a particular combination of respondent population and survey topic. For this reason, the basic CASM research approach is supplemented by empirical pretesting techniques, such as cognitive interviewing and behavior coding, which represent the applied CASM orientation.

Extension to the General Study of Cognition

CASM research is intended by its proponents to ultimately forge a path toward a two-way street in which research findings benefit not only survey researchers, but as well inform the science of cognitive psychology. This outcome may be facilitated in part because the study of cognition within the survey context provides an environment that widens the scope of inquiry to naturalistic circumstances beyond those investigated within the typical psychological laboratory situations (e.g., memory for real-world autobiographical events). Further, CASM studies often involve a broad range of the population, in terms of demographic characteristics such as age and educational level, rather than focusing on college students as study subjects. Despite these potential benefits, however, the impact of CASM on the general field of cognitive psychology has to date been somewhat limited. Expanding this direction remains an endeavor that is ripe for further development.

Cognitive Interviewing

Cognitive interviewing is a psychologically oriented method for empirically studying the ways in which individuals mentally process and respond to survey questionnaires. Cognitive interviews can be conducted for the general purpose of enhancing the understanding of how respondents carry out the task of answering survey questions. However, the technique is more commonly conducted in an applied sense, for the purpose of pretesting questions and determining how they should be modified, prior to survey fielding, to make them more understandable or otherwise easier to answer.

The notion that survey questions require thought on the part of respondents is not new and has long been a central premise of questionnaire design. However, cognitive interviewing formalizes this process, as it approaches the survey response task from the vantage point of cognition and survey methodology (CASM), an interdisciplinary association of cognitive psychologists and survey methodologists. The cognitive interview is generally designed to elucidate four key cognitive processes or stages: (1) comprehension of the survey question; (2) retrieval from memory of information necessary to answer the question; (3) decision or estimation processes, especially relating to the adequacy of the answer or the potential threat it may pose due to sensitive content or demands of social desirability; and (4) the response process, in which the respondent produces an answer that satisfies the task requirements (e.g., matching an internally generated response to one of a number of qualitative response categories on the questionnaire).

For example, answering the survey question *In the past week, on how many days did you do any work for pay?* requires that the respondent comprehends the key elements "week" and "work for pay," as well as the overall intent of the item. He or she must retrieve relevant memories concerning working and then make a judgment concerning that response (for instance, the individual may have been home sick all week, but in keeping with the desire to express the notion that he or she is normally employed, reports usual work status). Finally, in producing a response, the respondent will provide an answer that may or may not satisfy the requirements of the data collector (e.g., "Four"; "Every day"; "Yes, I worked last week"). The cognitive model proposes that survey questions may exhibit features that preclude successful cognitive processing and that may result in survey response error (in effect, answers that are incorrect). In the preceding example, the question may contain vague elements ("week"; "work for pay") that create divergent interpretations across respondents; or it may induce biased responding (e.g., the socially desirable impulse to provide a nonzero response).

Cognitive Interviewing Procedures

The major objective of cognitive interviewing is to identify sources of response error across a wide range of survey questions, whether autobiographical (involving behavior and events), attitudinal (involving opinions and attitudes), or knowledge based. To this end, a specially trained cognitive interviewer administers the questions individually to persons (often referred to as "laboratory subjects") who are specifically recruited for purposes of questionnaire evaluation or pretesting. In departure from the usual question-and-answer sequence within a survey interview, the cognitive interview involves procedures designed to delve into the cognitive processes that underlie the production of the answers to evaluated questions, by inducing the subject to produce verbal reports.

Two related procedures are used to elicit verbal reports: *think aloud* and *verbal probing*. The think-aloud procedure was adapted from psychological laboratory experiments and requires subjects to verbalize their thoughts as they answer survey questions. The interviewer prompts the subject as necessary by providing feedback such as "Tell me what you are thinking" or "Keep talking." The researchers then analyze the resulting verbatim verbal stream to identify problems in answering the evaluated questions that have a cognitive origin. For example, the subject's verbal protocol relating to the preceding question on work status might include a segment stating, "Besides my regular job, last Saturday I, uh, did help a friend of a friend move into a new apartment—he gave me pizza and beer—and a gift card that was lying around with a little money on it still, so I guess you could call that working for pay, but I'm not sure if that's supposed to count." Given this accounting, the investigators might surmise that the meaning of "work for pay" is unclear, in this case concerning irregular work activities that result in noncash remuneration. Especially if this finding were replicated across multiple cognitive interviews, the questionnaire designer could consider revising the question to more clearly specify the types of activities to be included or excluded.

However, practitioners have observed that some subjects are unable to think aloud effectively, and that the pure think-aloud approach can be inefficient for purposes of testing survey questions. Therefore, an alternative procedure, labeled "verbal probing," has increasingly come into prominence and either supplements or supplants think aloud. Probing puts relatively more impetus on the interviewer to shape the verbal report and involves the use of targeted probe questions that investigate specific aspects of subjects' processing of the evaluated questions. As one common approach, immediately after the subject answers the tested question, the interviewer asks probes such as "Tell me more about that"; and "What does the term 'work for pay' make you think of?" Probe questions are sometimes designed to tap a specific cognitive process (e.g., comprehension probes assess understanding of the question and its key terms; retrieval probes assess memory processes). However, probes also lead the subject to provide further elaboration and clarify whether the answer provided to the evaluated question is consistent with and supported by a picture gleaned through a more thorough examination of the subject's situation.

Verbal probing can be used to search for problems, proactively, when probes are designed prior to the interview, based on the anticipation of particular problems. Or, probes may be reactive, when they are unplanned and are elicited based on some indication by the subject that he or she has some problem answering it as intended (e.g., a delay in answering or a response that seems to contradict a previous answer). The proactive variety of probing allows the cognitive interviewer to search for covert problems that otherwise do not surface as a result of the normal interchange between interviewer and subject. Conversely, reactive probes enable follow-up of unanticipated overt problems that emerge.

Further, the type of probing that is conducted depends fundamentally on variables such as survey administration mode. For interviewer-administered questions (telephone or in person), probes are often administered concurrently, or during the conduct of the interview, immediately after the subject has answered each tested question. For self-administered questionnaires in particular, researchers sometimes make use of retrospective probes, or those administered in a debriefing step after the main questionnaire has been completed, and that direct the subject to reflect on the questions asked earlier. Concurrent probing provides the advantage of eliciting a verbal report very close to the time the subject answers the tested questions, when relevant information is likely to remain in memory. The retrospective approach risks the loss of such memories due to the delay between answering the question and the follow-up probes. On the other hand, it more closely mirrors the nature of the presentation of the targeted questions during a field interview (i.e., uninterrupted by probes) and prompts the subject to reflect over the entire questionnaire. Cognitive interviewing approaches are flexible, and researchers often rely both on concurrent and retrospective probing, depending on the nature of the evaluated questionnaire.

Analysis of Interview Results

Concerning analysis of obtained data, the focus of cognitive interviewing is not primarily the answers to tested questions, or quantitative data, but rather qualitative data relevant to the evaluation of tested questions. Cognitive interviews normally produce data in the form of written notes taken by the interviewer during the course of the interview, of notes taken by observers, or of analysis of (audio or video) recordings. Such analyses sometimes depend on a coding scheme that applies a particular category of outcome to subjects' behaviors or to interviewer comments (e.g., identification of a "vague term"). More often, however, data derived from cognitive interviews consist of written summaries that describe the problems observed on a question-by-question basis, across a set of interviews, and that also propose modifications intended to address these problems. On the basis of these results and suggestions, the investigators may revise the questions and then conduct further sets, or *rounds*, of cognitive testing. Such iterative testing rounds are useful for determining if the proposed solutions have solved identified problems without introducing additional difficulties.

Logistics of Cognitive Interviewing

Because the major emphasis of the cognitive interview is not survey data collection but rather the efficient and timely development and evaluation of survey questions in an applied setting, sample sizes for a round of cognitive interviews are generally small; typically between 8 and 12 subjects. In departure from the random selection procedures of the field survey, cognitive interviewing most often depends on volunteers who are recruited explicitly to represent as wide as possible a range of the population to be surveyed, primarily through the use of newspaper advertisements and posted flyers, or visits by researchers to locations where eligible individuals can be located (e.g., a clinic, service agency, school, or elderly center). Cognitive interviews are often conducted within permanent questionnaire design laboratories staffed by trained and experienced professionals and recruitment specialists, but they can also be accomplished informally by a questionnaire designer for the purpose of evaluating a single questionnaire. Within a laboratory environment, cognitive interviewing is conducted as one component of a more comprehensive pretesting process that includes additional pretesting procedures such as review by subject matter experts and focus groups (which normally precede cognitive interviews), or behavior coding (which is generally conducted after cognitive interviewing rounds, as part of a survey field pretest).

Variation in Practice

Although cognitive interviewing is a common and well-established pretesting and evaluation method, the precise activities that are implemented by its practitioners vary in key respects. Cognitive testing of questionnaires used in surveys of businesses and other establishments places significant emphasis on information storage and retrieval, especially because relevant information is often retained in administrative records rather than respondent memories and is distributed among multiple sources. For any type of survey, questions that focus on sensitive information (e.g., drug use, sexual behavior, or income) tend to focus on decision processes that influence the truthfulness of responses.

Practitioners also vary widely with respect to how they conduct the interviews, concerning reliance on think aloud versus verbal probing, and whether the cognitive interviews are conducted by researchers who will also serve as analysts or by an interviewing team that will present the testing results to the investigators for further consideration. At this time it is not clear which of these approaches are most reliable or valid, although researchers have recently begun rigorously to evaluate the effectiveness of cognitive interviews in various guises.

Researchers have recently focused increasingly on cultural as well as cognitive aspects of survey questions. One promising new direction, therefore, is the use of the cognitive interview to assess the cross-cultural comparability of questions, especially when they are translated from a source language into one or more target languages. As such, cognitive interviewing procedures are extended to diverse population subgroups to determine whether these questions function appropriately across group or language. Further, although cognitive interviewing has mainly been applied to survey questionnaires, practitioners have also begun to use this method to assess a wide range of other survey-relevant materials, such as advance letters to survey respondents, survey introductions used by interviewers to gain respondent cooperation, research consent forms, statistical maps and graphs, and computer Web sites (in a manner very similar to usability testing). The cognitive interview is in principle applicable in any case in which researchers wish to investigate the ways in which individuals understand and react to orally or visually presented materials that demand mental processing activity.

Cold Call

A cold call refers to the circumstance that takes place in many surveys when a respondent is first called or contacted in person by a survey interviewer without any advance knowledge that he or she has been sampled to participate in the survey, and thus does not know that the call or contact is coming. This circumstance contrasts to other instances in which some form of advance contact has been made with the sampled respondent to alert him or her—that is, to "warm up" him or her—that he or she has been sampled and that an interviewer soon will be in contact. Survey response rates consistently have been found to be lower for those sampled respondents that receive cold calls than for those that receive advance contact.

For many people who are sampled in telephone surveys, there is no way that researchers can use an advance mail contact technique because all that is known about the sampled household is the telephone number. This occurs even after the researchers have run matches of sampled telephone numbers against address databases and no address match is identified. Granted, an advance telephone contact attempt could be made in which a recorded message is left alerting the respondent that he or she has been sampled for a survey and that an interviewer will call him or her within a few days. However, there is no reliable evidence that this approach ever has been found to be effective. Instead the concern is that such a telephonic advance contact will lower response propensity at the given telephone number when the human interviewer eventually makes contact.

Despite this concern, the argument can be made that advance telephone contacts that merely leave a recorded message that a household has been chosen for a survey are not dissimilar to instances in which interviewers reach an answering machine the first time they call a household and leave a message saying that they will be calling back to conduct a survey. Past research has found that these types of answering machine messages tend to raise response rates. As such, even with households that cannot be mailed an advance contact, the proportion that receives cold calls for telephone surveys can be greatly reduced.

With face-to-face interviewing in address-based sampling or area probability sampling, all sampled households can be mailed an advance contact because, by definition, the researchers know their addresses. Thus, in such surveys there are no structural barriers that make it impossible to avoid any household receiving a cold contact from the in-person interviewer when he or she arrives the first time to recruit the household and/or gather data.

Common Rule

The Common Rule refers to a set of legal and ethical guidelines designed for protection of human subjects in research either funded by federal agencies or taking place in entities that receive federal research funding. The term *Common Rule* technically refers to all the regulations contained in Subpart A of Title 45 of the Code of Federal Regulations Part 46 (45 CFR 46). As applied to survey research, the most important elements of the

Common Rule are those relating to oversight by an institutional review board and the requirements of informed consent and voluntary participation.

Background

In the early 1970s, a number of high-profile cases of clearly unethical research made headlines and resulted in calls for congressional hearings. A few of the most striking examples include the following:

- *The Tuskegee Syphilis Study (1932–1972)*. Begun in 1932 to test syphilis treatments, the federal Public Health Service enrolled hundreds of African American men to participate. Deception was a key feature of the research from the start, but it was taken to new levels in the 1940s, after penicillin was proven an effective cure for syphilis. The researchers prevented their subjects from obtaining beneficial medical treatment and maintained their deception until 1972, when details of the study first came out in the press. The study directly caused 28 deaths, 100 cases of disability, and 19 cases of congenital syphilis and was in direct violation of several elements of the Nuremberg Code (1945), developed after World War II in response to Dr. Joseph Mengele's infamous experiments on Nazi concentration camp victims.
- *Milgram's Experiments on Obedience to Authority*. In attempting to determine the extent to which typical Americans might be willing to harm others simply because an authority figure told them to, psychologist Stanley Milgram designed an experiment in the early 1960s in which the subjects believed that they were delivering ever-stronger electrical shocks to a "learner" who was actually part of the research team. A large majority of subjects continued to comply even after they believed they were causing severe pain, unconsciousness, and even, potentially, death. Very early on, subjects showed clear signs of severe psychological stress, but Milgram continued his experiments to the end, even adding an especially cruel treatment condition in which the subject had to physically hold the "victim's" hand in place. (The ethics of Milgram's work has been debated for years, but many believe that it served a very positive role in showing the power and danger of authoritarianism and also served as an important warning to the scientific community for the need to make more formal and stringent ethical procedures for all social research.)
- *Zimbardo's Prison Experiment*. As part of a research study, and after randomly assigning student volunteers to be either "prisoners" or "guards" in the early 1970s, psychologist Philip Zimbardo found that members of both groups were taking to their roles to a much greater extent than he had anticipated. Despite clear indications within 36 hours that some of the students were deeply stressed by participating in the study, the experiment was continued for 6 full days.

The Milgram and Zimbardo experiments, in particular, served as wake-up calls to social science researchers who, until that point, had generally considered research ethics a topic of interest to medical research but not to the social sciences. In both cases the unethical behavior occurred not so much with regard to the research designs but rather with regard to the choices the researchers made after their studies went in unanticipated harmful directions. The principal investigators decided to continue their experiments long after they were aware of the harm they were causing their research subjects, a fact that made comparisons to the Tuskegee Experiment both inevitable and appropriate. Indeed, by failing to balance the anticipated benefits of the research with the risks to their subjects, they were in violation of a key provision of the Nuremberg Code.

Congressional and Regulatory Action

As a result of press reports and resultant public outcries about these cases, Congress held hearings in 1973 titled "Quality of Health Care—Human Experimentation." The hearings led to the passage of the National Research Act of 1974, which established the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research and required the creation of institutional review boards (IRBs) at all institutions receiving funding from the Department of Health, Education, and Welfare (HEW).

The commission was charged "to identify the basic ethical principles that should underlie the conduct of biomedical and behavioral research involving human subjects and to develop guidelines . . . to assure that such research is conducted in accordance with those principles." The first regulations were issued as 45 CFR 46, "Regulations for the Protection of Human Subjects of Biomedical and Behavioral Research," in 1974 by HEW (now Health and Human Services, or HHS); these were revised and expanded on after the release of the commission's report in April 1979. The Belmont Report first laid out three "Basic Ethical Principles": (1) respect for persons, (2) beneficence, and (3) justice. Then it detailed specific ways in which those principles should be applied in practice and focused especially on the importance of informed consent, assessment of risk and benefits, and the selection of subjects. These provisions of the Belmont Report are now encoded in 45 CFR 46 section 111, leading some researchers to use the terms *Belmont Report* and *Common Rule* interchangeably.

After revisions to the regulations in 1991, 16 other federal agencies adopted them, leading to their current informal name, the Common Rule. Thus, the provision requiring all institutions that receive federal research funds to establish IRBs now includes federal funds from virtually any federal agency. As a result, virtually all colleges and universities now have IRBs.

Applicability to Survey Research

According to subsection 101 of the regulations, survey research is not subject to IRB review unless "human subjects can be identified, directly or through identifiers linked to the subjects; and (ii) any disclosure of the human subjects' responses outside the research could reasonably place the subjects at risk of criminal or civil liability or be damaging to the subjects' financial standing, employability, or reputation." Nonetheless, most university IRBs still require at least expedited review of survey research conducted under their auspices to ensure that the basic principles outlined in the Belmont Report and encoded in the Common Rule are observed.

Although survey research only rarely poses the sorts of ethical dilemmas or risks to human subjects found in medical research, or even psychological experimentation, many survey researchers consider it a matter of best practices to abide by most elements of the Common Rule. For example, although even survey research projects conducted under the supervision of university IRBs generally are not required to undergo the full process of informed consent, they generally are required to assure respondents of the confidentiality and/or anonymity of their responses and the voluntary nature of their participation. In fact, this norm is so strong that most non-academic survey researchers include some form of these assurances even though they are not covered by an IRB or by legal regulations.

IRBs provide especially strong oversight over surveys that focus on sensitive topics that might place respondents under stress. These areas would include drug and alcohol use, criminal behavior, sexual behavior, and experiences of victimization or discrimination. In addition, surveys of vulnerable populations—minors, mentally or developmentally disabled adults, and prison inmates—are also generally subject to a higher level of oversight.

But even when conducting research that is not covered by IRB oversight or that does not meet any legal definitions that would seem to require special attention to the rights of human subjects, survey researchers would do well to keep in mind the principles of the Common Rule. Survey response rates have already declined a great deal due to growing public resistance to survey research among the general public, fed by a variety of deceptive tactics such as push polls and FRUGing (fund-raising under the guise of survey research). In this environment, attention by legitimate survey researchers to the basic ethical principles of respect for persons, beneficence, and justice will be crucial to ensuring the viability of survey research in the future.

COMPLETED INTERVIEW

The completed interview survey disposition is used in all types of surveys, regardless of mode. In a telephone or in-person interview, a completed interview results when the respondent has provided answers for all of the questions on the survey questionnaire that were asked by the interviewer. In a mail survey, a completed interview results when the respondent receives a paper-and-pencil survey questionnaire, answers all questions on the questionnaire, and returns the completed questionnaire to the researcher. In an Internet survey, a completed interview occurs when the respondent logs into the survey, enters answers for all of the questions in the questionnaire, and submits the questionnaire electronically to the researcher. Completed interviews are eligible cases and are considered a final survey disposition.

It is worthwhile to note that a completed interview usually indicates that the respondent has provided data (answers) for all applicable items on a questionnaire. However, at times respondents may answer most of the questions on a questionnaire but may accidentally skip or refuse to answer some questions on the survey instrument (called "item nonresponse"). Depending on how much data are missing, these interviews may be considered partial completions due to this item nonresponse but may also be considered breakoffs (or refusals) if the respondent began the interview or questionnaire but answered only a few of the applicable questions.

In practice, the level of item nonresponse may be very small, and it may be difficult to differentiate a completed interview from a partial interview. For this reason, most survey organizations have developed rules that explicitly define the differences among breakoffs, partial interviews, and completed interviews. Common rules used by survey organizations to determine whether an interview with item nonresponse can be considered a completed interview include (a) the proportion of all applicable questions answered; and (b) the proportion of critically important or essential questions administered. For example, cases in which a respondent has answered fewer than 50% of the applicable questions might be defined as breakoffs; cases in which the respondent has answered between 50% and 94% of the applicable questions might be defined as partial completions; and cases in which the respondent has answered more than 94% of applicable questions might be considered completed interviews.

Completion Rate

The term *completion rate* has been used often in the survey research literature to describe the extent of cooperation with and participation in a survey. However, it is an ambiguous term because it is not used consistently. Therefore readers of the literature should interpret the term with caution.

Completion rate is often used to describe the portion of a questionnaire that has been completed. In self-administered surveys, it is used widely to differentiate between the number of eligible individuals who do not complete a questionnaire and those who do. In this context, the completion rate is the number of questionnaires completed divided by all eligible and initially cooperating sample members. Researchers using completion rate in this sense should state so explicitly. This rate is an important indicator of item nonresponse in self-administered surveys. It has implications for the visual layout of a self-administered instrument, since the layout may affect how willing sample members are to complete the questionnaire. In addition, it also has implications for the content and the placement of critical questions in the questionnaire.

Completion rate is also an umbrella term used to describe the extent of sample participation in a survey—including the response rate, the contact rate, and the cooperation rate. Since these outcome rates are often used as criteria for evaluating the quality of survey data, analysts and other data users should know which rate is being referred to by the term completion rate. The *response rate* indicates the proportion of the total eligible sample that participates in the survey, the *contact rate* indicates the proportion of those contacted out of all eligible sample members, and the *cooperation rate* indicates the proportion of the contacted sample that participates in (or consents to participate in) the survey. The American Association for Public Opinion Research (AAPOR) recommends that researchers define how they are using the terms *response rate, contact* *rate*, and *cooperation rate* and offers standard definitions for these terms and how they should be calculated. AAPOR recommends that researchers explain in detail how they calculated the rates and how they categorized the disposition codes. Of note, AAPOR does not define the calculation of the term *completion rate*.

In addition to responding to a survey, people may participate in studies in other ways as well, and instruments other than questionnaires are often used to collect data. For instance, a screener interview may be used to determine an individual's eligibility for a study before he or she is asked to participate in the full survey. In addition to self-reported information collected during an interview, other data may be collected from participants, such as biomeasure data (height and weight measures, hair samples, or saliva samples). In epidemiological or randomized controlled studies, sample members may be asked to participate in a health regimen, in special education programs, or in an employment development program. The term *completion rate* may therefore be used to indicate the extent to which any or all of these activities have been completed. This more or less "universal" nature of the term underscores the importance of defining how it is being used in any given context. For example, in reporting findings based on biomeasure data, researchers should be clear about whether *completion* means completing the questionnaire only or if they are referring to completing the additional data collection.

Because it is impossible to assign a term to every possible permutation of a survey, it is critical for researchers to fully explain the sense in which they are using terms such as completion rate. It is equally important to use the terminology defined by the standard-setting organization(s) in a given discipline so as to promote a common understanding and use of terms.

Complex Sample Surveys

Complex sample surveys involve the identification and data collection of a sample of population units via multiple stages or phases of identification and selection. In contrast, a simple sample survey design involves a simple random sample, where there is a list of the elements of the population and a certain number of these elements is selected by drawing one at a time. The classic textbook example is when each element of the frame is numbered from 1 to N (i.e., population size) and then n (i.e., sample size) elements are drawn using a table of random numbers. By contrast, complex sample surveys may rely on stratification, clustering, multi-stage or multi-phase designs, unequal probability sampling, or multi-frame sampling. These techniques often reduce the cost of data collection and may be more efficient, but they also require special methods of variance estimation and in many cases yield larger variances than a simple random sample of the same size. Ultimately the objective of a complex sample design is to minimize variance and costs for all the desired estimates while preserving the ability to obtain valid point and variance estimates for population parameters of interest.

Stratification

One aspect of a complex sampling design may involve *stratification*, defined as a partition of the population into mutually exclusive and collectively exhaustive subsets called "strata." One primary reason for using stratification is usually associated with the recognition that members of the same stratum are likely to be more similar to each other than members of different strata. Other reasons for using stratification include the desire to have every part of the population represented, or the desire to reduce sampling variance by using a larger sampling fraction in strata when the unit variance is larger than in more homogeneous strata, or it may reflect a strategy based on differential data collection costs from stratum to stratum. Stratification could also be used if stratum-specific domain estimates are desired. As previously alluded to, the sampling fractions used within the different strata may or may not be the same across all the strata. Strata may be explicit, and the number of units to be selected from each strata may be determined beforehand. Or stratification may be implicit, when systematic sampling is used and the units are arranged with all the units in each stratum appearing together when the population is ordered. In the case where strata are explicit, algorithms such as Neyman allocations for single estimands or the Chromy allocation algorithm for multiple estimands may be used to decide how many units to select from each stratum. A minimum of 2 units per stratum is usually recommended, as this facilitates variance estimation.

Cluster Designs

While stratification attempts to partition the population into sets that are as similar to each other as possible, *clustering* tries to partition the population into sets that are as heterogeneous as possible, but where data collection is less expensive by selecting a number of clusters that contain population units. One example is in a survey of students in which a given number of schools are selected, and then students are sampled within each of those chosen schools or clusters. In this case, the schools are called the "primary sampling units" (PSUs), while the students within the schools are referred to as the "secondary sampling units" (SSUs). It is possible to take either a sample or census of the secondary sampling units contained within each of the selected clusters. This would be the case when sampling additional units is extremely inexpensive, such as sampling entire classrooms from selected schools. More common, however, is to select clusters as a first sampling stage and then to select a subset of units within the clusters as a second stage. Sometimes there are more than two stages within a design, such as when school districts are selected first, then schools within the districts, and then intact classrooms within the schools.

Another variant of cluster design is the multi-phase design. In this instance the clusters are selected as in a multi-stage design, but instead of selecting units within each cluster, units are selected from the union of all units within the selected clusters. Of course, depending on the assigned probabilities and selection method, some multi-phase designs are strictly equivalent to multi-stage designs.

Unequal Probability Designs

Whether a sampling design is stratified, clustered, or selected without any partitions of the population, one may select units with the same probability or with unequal probabilities. Or one may select PSUs with unequal probabilities in order to have each element of the population have the same probability of selection. Often the probability of selection is chosen to be proportional to some measure of size (i.e., sampling with probabilities proportional to size or PPS), particularly when sampling PSUs in a multi-stage or multi-phase sample. In order to achieve equal probabilities for each unit of the population, in a multi-stage design it is desirable to designate a probability of selection for every cluster that is proportional to the number of population units in the cluster and then to sample an equal number of units at the second stage. As with simple random sampling, the selection of clusters can be with or without replacement. A third option is to *sample with minimum replacement*, a term introduced by Chromy in 1979. According to such a design, the large PSUs (those that are to be sampled with certainty) may be sampled more than once. A decision to include PSUs multiple times in the final sample will usually depend on the intraclass correlation (rho)—a measure of how homogeneous are the clusters (PSUs).

Unequal probabilities may actually be used directly for the elements of the population and not just for the PSUs. One example is in an establishment survey by which one wants to determine the price of a particular product. If in an establishment survey the volume of sales of the product is listed for every element in the frame and one samples with PPS, when the volume of sales is the measure of size, a simple average of the prices charged by the establishments in the sample would yield an (unbiased) estimate of the average price of the units sold.

On the other hand, sometimes unequal probabilities may be used because there is a desire to oversample certain subpopulations. And sometimes a probability is calculated based on the need to obtain multiple estimates. For example, in an establishment survey in which the prices of different items need to be estimated and the volumes vary by the items, Chromy's allocation algorithm may be used to obtain a probability of selection for every establishment in the frame, but this probability of selection will not be proportional to any particular measure of size.

Weighting

The purpose of sampling in a survey is to obtain an estimate of a parameter in the population from which the sample was drawn. In order to do this, one must know how to weight the sampled units. The most common approach to weighting is to calculate a probability of selection and then take its multiplicative inverse. This yields the Horvitz-Thompson estimator, and though it seems straightforward, there are many designs for which this estimator is difficult or impossible to obtain. Dual-frame estimators represent a case in which the straightforward Horvitz-Thompson estimators have to be modified to incorporate the probability of being included into the sample via multiple frames. It is often the case that the initial weights (i.e., inverse of selection probability) are not the final versions used to produce the final estimates. Rather, the weights are often adjusted further to account for population sizes and/or nonresponse using a variety of techniques, including post-stratification, trimming of the weights, and the use of ratio or regression estimators.

Variance Estimation

Survey weights as well as the design upon which the weights are computed play an important role in both the parameter estimates and variance computations. Whereas estimating the variance of simple survey estimates is rather straightforward, variance estimation in complex sample surveys is much more complicated. Some sampling approaches have variance formulas that may be applied, but a multi-stage approach in which clusters are sampled with PPS and weight adjustments are made can be far more complex. There are two basic sets of methods that may be used: (1) Taylor series linearization and (2) replicate methods. In each of these methods it is important, although not always obvious, that the design be properly specified. One important consideration is that if a PSU is sampled with certainty, it must be treated as a stratum, and the units at the next level of sampling should be treated as PSUs.

Taylor series linearization has the advantage of using a straightforward approach that is available in many standard statistical packages. Replicate methods, such as the jackknife and balanced half sample pseudo-replications, allow one to reproduce aspects of the design, taking imputation into account. These methods are also available in many packages, but it is also easy to fail to specify the design properly. A more complex method is the bootstrap, which needs to be programmed specific to each design but allows for a closer reproduction of the initial sample.

Composite Estimation

Composite estimation is a statistical estimation procedure that combines data from several sources, for example, from different surveys or databases or from different periods of time in the same longitudinal survey. It is difficult to describe the method in general, as there is no limit to the ways one might combine data when various useful sources are available. Composite estimation can be used when a survey is conducted using a rotating panel design with the goal of producing population estimates for each point or many points in time. If the design incorporates rotating groups, composite estimation can often reduce the variance estimates of level variables (e.g., totals, means, proportions). In addition, composite estimation can reduce the variance estimates of variables dealing with changes over time, depending on the structure of the sample design, the strength of the correlations between group estimates over time, and other factors.

How a Composite Estimator Works

In a typical rotation design, the sampled groups are phased in and out of the sample in a regular, defined pattern over time. To estimate the level of a characteristic in the time period designated by t, a simple compositing strategy is to take a convex combination of the Horvitz-Thompson estimate of level for period t, Y_t^{HT1}, with a second estimate for period t, Y_t^{HT2}. The latter estimate might start with the composite estimate for period $t-1$, Y_{t-1}^{CE}, brought forward by a measure of change from period $t-1$ to period t:

$$Y_t^{HT2} = Y_{t-1}^{CE} + \Delta_{t-1,t}.$$

This measure of change, $\Delta_{t-1,t}$, can be a difference (ratio) estimated using data only from the overlapping rotation groups, which is then added to (multiplied by) the composite estimate for period $t-1$. The composite estimate then becomes a recursively defined function of data collected in prior time periods:

$$Y_t^{CE} = (1-k)Y_t^{HT1} + kY_t^{HT2},$$

where $0 < k < 1$.

Composite estimators can often be expressed as a linear combination of simple estimates—one formed from each rotation group at each period. A few constraints are usually imposed. First, when estimating levels of a variable at time t, one usually requires that (a) the weighting coefficients of the group estimates at time t add to 1, and (b) for each period before t, the coefficients sum to 0. These restrictions ensure that no bias is introduced through the compositing. Second, to maintain the consistency of estimates, it is customary, at least for statistical agencies, to require that (a) the estimate of changes in a variable equal the difference (or ratio, for multiplicative composite estimators) of the appropriate estimates of levels for that variable, and (b) the estimates of components sum to the estimate of the corresponding total.

Composite estimation tries to take advantage of correlations over time. For example, suppose $x_{t-1,g}$ and $x_{t,g}$ are estimates from the same rotation group, g, for periods $t-1$ and t. If, due to sampling variability, $x_{t-1,g}$ is below its expected value, then $x_{t,g}$ tends to be as well. By assigning coefficients with opposite signs to the two estimates, one can temper the sampling variations while still balancing coefficients to ensure an unbiased estimate overall.

Variances and biases for composite estimators are computed according to the rotating panel design and depend on the variances and correlations of the rotation group estimates, which are often assumed to be nearly stationary over time. Thus, determining an optimal design becomes a problem of choosing the estimator's coefficients to minimize the expected error function. However, the problem becomes more complex when one considers the effect of the design on the different variables of interest, and on the several types of estimates to be disseminated: levels at specific points in time, changes across time, or averages over time. Changing the design or the estimators' coefficients to lower the expected error for a composite estimator of the level for a variable may induce a corresponding increase in the estimator for the change in a variable, and vice versa.

When the survey's most important estimate is a measure of the change in a variable over consecutive periods, a complete sample overlap is often the most efficient, as it makes the greatest use of the correlations over time. With a complete overlap, composite estimation with information from prior periods is generally not a consideration. However, for estimating the level at each time period, a partial sample overlap is often the most productive. Due to the constraint of consistency (see earlier discussion), when estimates of level and changes are both required, a compromise design may be used whereby a large fraction of the sample, but not all of the sample, is carried over from one period to the next.

Specific Examples of Composite Estimators

A specific example of a composite estimator is the one used in the Current Population Survey, jointly sponsored by the U.S. Bureau of Labor Statistics and the Census Bureau, to measure the U.S. labor force. In each month, separate estimates of characteristic totals are obtained from the eight rotation groups. Six of these groups contain households that were interviewed the prior month. The composite estimator implemented in 1998 combines the estimates from current and prior months to estimate the number of unemployed using one set of compositing coefficients, and the number of employed using a different set that reflects the higher correlations over time among estimates of employed:

$$Y_t^{CE} = (1-K)Y_t^{AVG} + K(Y_{t-1}^{CE} + \Delta_{t-1,t}) + Ab_t,$$

where Y_t^{AVG} is the average of the estimates of total from the eight rotation groups; $\Delta_{t-1,t}$ is an estimate of change based only on the six rotation groups canvassed at both times $t-1$ and t; b_t is an adjustment term inserted to reduce the variance of Y_t^{CE} and the bias arising from panel conditioning; and $(K, A) = (0.4, 0.3)$ when estimating unemployed, and (0.7, 0.4) when estimating employed. For researchers, a problem with composite estimates is producing them from public use microdata files, because computing the composite estimate for any period generally requires one to composite recursively over a number of past periods. This problem has been addressed for the Current Population Survey, which now produces and releases a set of "composite weights" with each month's public use file. First, for any month, composite estimates are determined for the labor force categories broken down into a number of race and ethnicity subgroups. Then, using these composite estimates as controls, the survey weights are raked to guarantee that the corresponding weighted estimates agree with the composite controls. The resulting composite weights can then be used to produce composite estimates simply by summing over the weights of records with the appropriate characteristics.

In the U.S. monthly surveys of retail and wholesale trade conducted before 1998 by the U.S. Census Bureau, a different rotating panel design led to an interesting set of composite estimators. In each of three consecutive months, one of three rotation groups was canvassed. In month $t+1$, businesses in rotation group A provided sales data for the months t and $t-1$, yielding estimates x_t^A and x_{t-1}^A, respectively. A preliminary composite estimate for month t,

$$P_t = (1-\beta)x_t^A + \beta P_{t-1}\Delta_{t-1,t},$$

was released, where $\Delta_{t-1,t} = x_t^A / x_{t-1}^A$, and $\beta = 0.75$ for the retail survey and 0.65 for the wholesale survey. One month later, firms in rotation group B supplied data for months $t+1$ and t, providing estimates x_{t+1}^B and x_t^B, respectively. This led to a final composite estimate for month t,

$$F_t = (1-\alpha)x_t^B + \alpha P_t,$$

where $\alpha = 0.80$ for the retail survey and 0.70 for the wholesale survey and an analogous preliminary estimate for month $t+1$. The third group was similarly canvassed a month later, and then the sequence was repeated. The difference between the final and preliminary composite estimates for month t, $F_t - P_t$, was called the revision in the estimate. In 1997 this rotating panel design was replaced by a complete sample overlap, due to problems of panel imbalance and differential response bias (early reporting bias) that led to undesirably large revisions in some months.

Different forms of composite estimators can be used to combine information from a survey and outside sources. In Statistics Canada's Labour Force Survey, the households in all six rotation groups are interviewed each month, with a new group entering and an old one dropping out each month. In any month, an estimate of total is obtained from each of the six groups. A composite regression estimator uses information from the six group estimates, Y_t^{AVG}; current population controls, X_t^{POP}; and composite regression estimates of the labor force from the prior month, Z_{t-1}^{CR}:

$$Y_t^{CR} = Y_t^{AVG} + [(X_t^{POP}, Z_{t-1}^{CR}) - (X_t^{AVG}, Z_t^{AVG})]b_t^{CR},$$

where the superscript AVG denotes an estimate based on data from the current survey period, and b_t^{CR} is the estimated composite regression parameter for month t. The estimation procedure guarantees accordance with the population controls, while taking advantage of recent labor force data. Using a different approach, Statistics Netherlands combines responses from demographic surveys and administrative data from social registers through regression estimation and a method called "repeated weighting" in order to reduce the variances of the estimators and to maintain numerically consistent tables across all official publications.

Comprehension

Survey researchers, in developing questions, must bear in mind the respondent's ability to correctly grasp the question and any response categories associated with the question. Comprehension, which is defined in this context as a respondent's ability to accurately understand a question and associated response categories, is crucial to reliable measurement of attitudes and behaviors.

Scholars have identified a number of elements in question wording that can interfere with comprehension: ambiguous language, vague wording, complex sentence structures, and presuppositions about the experiences of the respondent. The consequences of comprehension problems can be severe. If respondents' understanding of the question varies significantly from one respondent to another, the responses could provide a highly distorted picture of an attitude or behavior at the aggregate level.

Researchers have identified a number of techniques and guidelines to reduce the potential effects of question wording on comprehension:

1. Use clear, simple language in questions.
2. Use simple question structures, minimizing the number of clauses in a question.
3. Include a screening question if the survey is measuring attitudes or behaviors that might be unique to a specific group, and thereby skip all other respondents past the measures targeted to that group.
4. Provide definitions or examples in questions that may have terms that are ambiguous or vague.
5. Offer a frame of reference for terms that define a period of time (e.g., "in the past 7 days" as opposed to "recently").
6. Train interviewers to recognize problems with comprehension, and provide the interviewers with a uniform set of definitions and probes to address the problems.
7. Pretest survey questions not only with survey interviews, but in qualitative settings such as focus groups or in-depth cognitive interviews if resources permit.

Computer-Assisted Personal Interviewing (CAPI)

Computer-assisted personal interviewing (CAPI) refers to survey data collection by an in-person interviewer (i.e., face-to-face interviewing) who uses a computer to administer the questionnaire to the respondent and captures the answers onto the computer. This interviewing technique is a relatively new development in survey research that was made possible by the personal computer revolution of the 1980s.

Background

To understand the evolution of CAPI it is necessary to understand the history that led to its development and widespread implementation. In the late 1980s, many surveys used early versions of computer-assisted telephone interviewing (CATI). The early CATI systems ran as terminal applications on a mainframe or minicomputer. Computer applications typically used compilers; the central computer had to handle many simultaneous processes to service a CATI research facility. The cost of mainframes and more capable minicomputer systems was so high that the economic case that CATI should replace paper-and-pencil interviewing (PAPI) was tenuous. In addition, CATI facilities tended to use interviewers quite intensively and with close supervision, so interviewers tended to make fewer errors of the sort that computerized systems suppress, at least relative to face-to-face interviewers. With computing costs high, CATI was not a strong value proposition.

As personal computers (PCs) started to penetrate the market, they offered only modest processing power—but CATI interviews did not require much power. An intensively used PC could be cost-effective, and its capabilities matched the CATI task better than a mainframe or minicomputer did. There was no strong need to have a networked solution for PC computing, since CATI facilities could use low-tech case management and scheduling systems and still get the work done.

The PC software solutions for computer-assisted interviewing were adaptations of software first used on minicomputers or mainframes. A boundary constraint was that the compiler needed to have a variant that ran on DOS—the disk operating system for PCs that soon outstripped the use of Apple computers' proprietary operating system. This limited the software options.

By the late 1980s all major survey organizations doing face-to-face interviewing looked to establish a CAPI capability. With limited computing power for laptop computers and the limitations of DOS (which limited executable size because of its address space), these organizations faced a daunting systems challenge. Designers had two major strategic software alternatives. One choice was to follow the existing strand of software development with CATI and program the instrument to run on a laptop, accepting the reductions in memory and processing speed imposed by the technology of the times. The second strategic strand was to represent the instrument not as program code to execute but as a series of data records to be processed one by one. Internal machine instructions became records to be processed in exactly the same way, except that there was no output to the screen. The first application of this second strategy was done by Willem Saris of the Netherlands for smaller, less complex market research and public opinion surveys. In 1989, the Center for Human Resource Research at Ohio State University used a CAPI system based on representing the instrument as data to administer Round 11 of the National Longitudinal Survey of Youth 1979 (NLSY79), a large, complex event history interview that collected socioeconomic data in a one-hour face-to-face interview.

Weakness and Benefits

While case management is important in face-to-face interviews, there is no compelling reason other than marketing strategy by vendors to integrate the data capture engine for CAPI with case management. The two processes are logically separable. Indeed, in the early days of CAPI, the case management systems were rudimentary, and the survey process went ahead with no problems, as it had for decades before.

The weakness of the current standard CAPI strategy is that it is based on a computing paradigm that is 2 decades old. The current standard for computing emphasizes two things: (1) the use of modern relational databases, and (2) the use of the Web, especially coupled with relational database technology. CAPI systems based on relational databases and Web technology have several advantages. First, they integrate with parts of the survey process for which integration is compelling. Second, they can exploit systems tools that service a variety of data processing applications instead of requiring survey organizations to write de novo auxiliary utilities for their CAPI systems. Third, they provide a simple path toward implementing multi-modal and multi-platform surveys. Fourth, question records can be reused and reshuffled, thus speeding the design and modification of an instrument.

CAPI changes the survey process in many ways, but perhaps the most important way is that it forces a great deal of preparation to come early in the process. With PAPI, one only had to type up a printed questionnaire that interviewers could follow. While the data were being collected, the central office could put together a plan for processing and preparing the data. With CAPI, one must specify every action to be taken under every interview contingency. This fully contingent interview form must guide the interviewer through every step of the interview, and it must be ready in time for complete testing and the preparation of training materials. This front-loads the work process to such a degree that once the survey is in the field, most of the processing work is done.

The programming versus database paradigm has implications for survey preparation. When the database approach is used, the preparatory work can be handled by a survey specialist rather than a programmer. With the instrument driven by data tables, the authoring process is primarily a matter of filling in the blanks on a form. With the programming approach, the survey specialist has to communicate with the programming staff, increasing the chances for confusion, error, and miscommunication.

Usage

When it comes to the field effort, it is important to remember that, more and more, survey efforts are multi-modal. Face-to-face surveys frequently work many of their cases over the phone, self-administered on the Web, by mail, or even self-administered on a personal digital assistant (PDA) or some other device. Unless the technical approach handles multi-modal surveys efficiently, the survey preparation phase will require a separate programming effort for each mode. Apart from the multi-modal aspects, whatever system is on the computer must be used by interviewers, many of whom do not have a technical background. Sometimes programmers forget this. The key to a successful CAPI effort is simplicity. For example, when interviewers were trained in 1989 when the NLS became the first longitudinal survey to conduct a CAPI interview, the keystone of the training sessions was three words: "Read the screen." By breaking a complex interview into a few simple question types that one used over and over, it was relatively easy to train the interviewers.

Nearly 20 years later, the Web has penetrated the market with near ubiquity. By adopting a standard Web interface for CAPI systems, chances are improved that the interviewers who are recruited will be familiar with the look and feel of the application. As wireless connections over the cellular network spread and become more capable, survey research organizations have begun to interview with laptops connected to the central office over the cellular network. This integrates the field effort around the central office, bringing the field full circle to where CAPI began with a central facility serving the interviewer who is working on what is, essentially, a terminal.

Once the interviewer completes a case, the system must transmit the files to the central office. With the programming approach, one must generate specifications for this process. Done incorrectly, some data simply come up missing. With the database approach, each question record processed generates an answer record, and that answer record gets loaded into the master database used to design the survey, integrating the data and the documentation in a single resource. Regardless of the method, this integration needs to be achieved before researchers can use the data.

Surveys are all about creating databases, and for all but the most simply structured surveys (every respondent gets asked every question), the data set will have a variety of relationships that hold among the survey responses. Researchers collect data to analyze, and having a system built around a relational database to represent all parts of the questionnaire makes it easy to move the data into SAS, Statistical Package for the Social Sciences (SPSS), STATA, or some other statistical package. In the 1989 fielding of the NLSY79, the Ohio State system automatically produced SAS and SPSS control statements that read the data from the field—a capability that was years ahead of other systems. In recent years, much has been made of the Data Documentation Initiative (DDI) to provide a systematic method of documenting survey data sets that is reasonably similar across surveys. This would be done via Extensible Markup Language (XML)-formatted data for the survey questions. Ironically, the database approach to CAPI enabled this approach to documentation more than 15 years ago and, because the relational database tables needed to execute a survey are so comprehensive, even the questionnaire tables will contain documentation attributes at the question level that are far superior to DDI. With a database-designed system, one can load the data from a survey into a DDI-like system with minimal effort.

When it comes to disseminating the data, having the data already loaded into a relational database makes it relatively easy to produce a Web interface that allows users to search the database, peruse the codebook, and extract the desired data. Other techniques make this a case-by-case implementation of the necessary steps. Increasingly, major surveys are storing their data in relational databases for storage and manipulation, so the question becomes whether to take that step from the beginning or at the end of the process. Wireless methods will re-center CAPI around the Web and high-speed and highly secure central servers, greatly simplifying the technical support of field interviewers.

Computer-Assisted Self-Interviewing (CASI)

Computer assisted self-interviewing (CASI) is a technique for survey data collection in which the respondent uses a computer to complete the survey questionnaire without an interviewer administering it to the respondent. This assumes the respondent can read well (enough) or that the respondent can hear the questions well in cases in which the questions are prerecorded and the audio is played back for the respondent one question at a time (audio computer assisted self-interviewing—ACASI).

A primary rationale for CASI is that some questions are so sensitive that if researchers hope to obtain an accurate answer, respondents must use a highly confidential method of responding. For a successful CASI effort, the survey effort must consider three factors: (1) the design of the questions, (2) the limitations of the respondent, and (3) the appropriate computing platform.

Unless one has a remarkable set of respondents, the sort of instrument needed for CASI (or any self-administered interview) will be different from what one uses when a trained interviewer is administering the questionnaire. Having a seasoned interviewer handling the questioning offers a margin of error when designing questions. When the researcher is insufficiently clear, she or he essentially counts on the interviewers to save the day. Their help comes in a variety of forms. The interviewer can explain a question the respondent asks about. Good interviewing technique requires the interviewer to avoid leading the respondent or suggesting what the expected or "correct" response is. The interviewer can also help salvage bad questions when the respondent's answer reveals that, although the respondent showed no overt confusion about the question, it is clear that the respondent either did not understand the question or took the question to be something other than what was asked. The interviewer can also help out the questionnaire designer when, during a complex interview, it becomes clear to the interviewer that something has gone wrong with the programming and the item occurs in a branch of the questionnaire where it should not be. The interviewer can then try to put things right or at least supply a comment that will help the central office sort out the problem.

In all of these cases, the interviewer plays a crucial role in improving data quality. With a self-administered survey, regardless of mode, the safety net of a trained interviewer is not available. The circumstances of a self-administered interview put a real premium on clarity, computer assisted or not. The need for clarity is all the higher because there are no learning-curve effects for CASI—interviewers may do hundreds of cases, but with CASI essentially each respondent does just one. Thus, the question wording itself needs to be clear and self-contained so the respondent does not need to ask clarifying questions. Many surveys provide "help" screens to interviewers that have supporting information about a question, but that is not a good idea with CASI—using help screens violates the "Keep it simple" rule. Anything the respondent needs to see or read should be on the display screen the respondent sees, with no additional scrolling, clicking, or pressing of function keys. One should also be wary of question fills or elaborate skip patterns, since a simple error by the respondent can produce myriad problems that ripple through the rest of the instrument.

Because each respondent will see a question only once, designers must pay special attention to the layout of the screen. The first step the designer can take to reduce respondent confusion is to make sure similar questions have the same appearance. When the respondent is to pick the single best answer from a list, the screen should work in exactly the same way for each such question. If the respondent is to enter a date, he or she should either have to pick a day from a calendar or fill the date into the same sequence of data entry boxes, or if month and year is desired, use the same month/year format each time. If one introduces too many question styles and types, the opportunities for confusion escalate. The better choice is to rely on the minimum number of question types presented and structure the questionnaire so the respondent only has to deal with a very few question types utilized over and over.

With self-administered questionnaires, respondent satisficing behavior may arise. One can keep the attention of the respondent by using appropriate graphics if they help illustrate the concept. In some cases the problem is not keeping the respondent's attention but dealing with a limited attention span or even a limited ability to read. To handle these problems, audio computer-assisted self-interviewing helps both engage the respondent and minimize literacy problems. Research Triangle Institute (RTI) is the acknowledged pioneer in this area, having deployed ACASI in 1995 for the National Survey of Family Growth with feasibility tests prior to that. Today, ACASI is common with audio text fills and alternate language versions to adapt to respondents whose first language is not English. As equipment becomes smaller and more capable, survey researchers are beginning to set up ACASI interviews on Palm Pilots or other handheld devices. Ohio State University recently deployed an ACASI interview on Palm Pilots using an interview that took about an hour to complete—an interview full of very sensitive questions. The process went very smoothly; the respondent wore headphones to hear the question and tapped on the answer with a stylus on the Palm's screen. Respondents whose reading skills are strong can choose to turn off the audio. Because no one can tell whether the respondent is using audio, there is no stigma to continuing to use it.

Most interviews, however, do not consist only of sensitive questions. By putting the sensitive questions in one section, one can often switch between modes, using a CASI or ACASI method only where it is necessary. In fact, interviewers have been utilizing CASI since they first walked into a household with a computer, just as interviewers have turned a paper-and-pencil interviewing (PAPI) document into a self-administered questionnaire when they thought circumstances required it. For example, when a questionnaire asked about former spouses and the current spouse was in the house, savvy interviewers would simply point to the question in the booklet and say something like "And how would you answer this one?" With a laptop, the interviewer would simply twist the machine around and have the respondent enter an answer.

There are differences when using CASI within a telephone interview. One can conceal the line of sensitive questioning from another person in the room by structuring the questionnaire to require simple "Yes" or "No" responses, simple numbers, and the like. While this affords some confidentiality from eavesdropping, it does nothing to conceal the respondent's answers from the interviewer. To work on this problem there has been some limited experimentation at Ohio State using Voice over Internet Protocol (VoIP) methods. With some sophisticated methods, one can transfer the respondent to a system that speaks the questions by stringing together voice recordings and then interprets the respondent's answers and branches to the appropriate question. When done with the sensitive questions, the "robot" reconnects the interviewer and the interview continues. This approach works quite well and allows telephone interviews to achieve a measure of the security attained with other "closed" methods, although there has yet to be a controlled experiment that has compared VoIP effectiveness with results achieved by traditional CASI or ACASI techniques.

Computer-Assisted Telephone Interviewing (CATI)

Computer-assisted telephone interviewing (CATI) in its simplest form has a computer replacing the paper questionnaire on a telephone interviewer's desk.

Advantages of Computer-Assisted Telephone Interviewing

CATI provides the following advantages:

- More efficient data collection, because the interviewer enters answers directly into the computer rather than sending a paper questionnaire for a separate data capture step.
- More efficient and more accurate questionnaire administration, because the computer delivers the questions to the interviewer in the correct programmed sequence, including any required rotations, randomizations, or insertions of information from a separate data file or from earlier in the interview.

- More accurate data collection, because the computer can apply various range and logic edits as the answers are entered. These edits can range from hard edits (in which the system will not accept an answer outside certain parameters—for example, age at first marriage being less than 14 years of age) to "query edits" that require the interviewer to confirm that, while unusual, the answer is indeed that intended by the respondent (e.g., to confirm that age at first marriage was indeed only 14 years of age).

While this has been the basic model for CATI systems since they were first introduced in the 1970s, and some CATI systems still have only this questionnaire administration component, technological developments during the past 30 years have provided many more ways in which the computer can assist the telephone interviewing process.

Quality Assurance Monitoring

For quality assurance, most telephone surveys have a sample of interviews monitored by a supervisor, so the researcher can be confident that the questions have been administered by the interviewer as instructed (correct wording, probing) and the answers given by the respondent faithfully recorded or correctly categorized. Computers allow this to be done in an unobtrusive and effective manner, usually by the supervisor listening in on the interview on a separate audio channel while watching an image of the interviewer's screen.

Further assistance by the computer for this process occurs with the automatic recording of the interviewer the supervisor is monitoring and for what time period. A data entry tool for the supervisor then records the results of the monitoring session and a database in which these results are stored. The use of better allocation of monitoring resources, typically by an algorithm, queries the database, so that more experienced interviewers who rarely have errors are monitored less than those who are newer or who have been identified as needing more assistance.

Sample Management and Call Scheduling

Most CATI programs now have at least two modules, one being the questionnaire administration tool already described, the other providing sample management and call scheduling functions, such as the following:

- Holding the list of all the telephone numbers to be called, along with any other relevant frame information, for example, geographic region if the sample is to be stratified by region
- Recording information about the call history, that is, each call made to each number, such as time and date the call was placed, the interviewer who placed the call, and the call outcome (completed interview, refusal, busy signal, etc.)
- Executing calling rules that determine when the next call (if any) should be placed to a number, which could include delays from the previous call, or certain times of day or parts of week
- Prioritizing among numbers competing for delivery at the same time, for example, by queuing numbers that have appointments first, calls to households where previous contact has occurred next, and fresh sample last
- Delivering phone numbers to the next available interviewer appropriate for that number (e.g., previous refusals to refusal converter interviewers)
- Producing sample progress information, such as number of interviews so far completed by strata, number of interviews refused, and amount of sample yet to be worked

The sample management module often has a separate supervisor interface, which enables the supervisor to execute additional sample management functions, such as stopping particular numbers from being delivered to increasing for a limited period of time the priority of numbers in strata where the survey is lagging.

Automated Dialing and Other Call-Handling Assistance

Telephone technology, typically with a separate computer residing in the PBX (private branch exchange) or dialer, can also be considered part of a CATI system. While the main drivers of telephone technology have been telemarketing and other call centers, they still provide assistance to the telephone survey process by the following features:

- Autodialing, in which the actual act of dialing is performed on some trigger (such as a keystroke instruction from an interviewer, the interviewer logging in to the system or hanging up from the previous caller, or in the case of predictive dialers, when the probabilities of both an interviewer becoming free and a call resulting in a connect exceed some threshold)

- Auto-dispositioning, where the outcome of certain types of calls (e.g., busy, fax, disconnected) can be detected from the signal tones and coded by the dialer rather than by the interviewer
- Interactive Voice Response, or IVR, where a prerecorded voice replaces the interviewer and data is collected either by the respondent's key strokes or machine-recognizable words and phrases
- Automatic Call Distribution, or ACD, which organizes incoming calls into queues and delivers them to interviewers according to rules relating to call type and interviewer attribute
- Message push-out, in which the dialer can call numbers without any interviewer involvement and deliver pre-recorded messages to any person, voicemail, or answering machine that answers the call
- Recording of interviews for more accurate verbatim data capture or for more effective coaching of interviewers
- Playing of sound clips to the respondent (although these can also be stored in the questionnaire administration tool)

While some dialers have some sample management and basic questionnaire administration capabilities, at the time of writing there are few systems that manage the sophistication in questionnaire administration or sample management that is typically needed in survey work.

Network and Internet Issues

Most CATI systems use networked computers so that all interviewers working on the same survey share a single pool of telephone numbers, access the same version of the questionnaire, and all data is stored in a central database. There are many advantages of a network system over separate laptops or other personal computers. One advantage is centralized control over the survey instrument, so that mid-survey changes to the questionnaire can be instantaneously implemented to all terminals. Centralized control of the sample and data is also advantageous in that the risks of exceeding targets or not identifying problem areas quickly enough are minimized, and ensuring appropriate data backups are made. Network systems also facilitate supervision and monitoring functions.

The Internet provides additional assistance by allowing the use of Voice Over Internet Protocol to carry the audio channel rather than needing multiple phones connected into a limited number of PBX exchanges. This simplifies wiring needs in centralized CATI centers and enables distributed virtual call centers, through which interviewers can work from their homes as long as they have a sufficiently fast Internet connection.

The Future of Computer-Assisted Telephone Interviewing

Benefits

When compared with the three other main modes of survey data collection (Web, personal interviewing, mail), CATI still retains two advantages. First, it enables interviewer administration of questionnaires rather than self-completion, as required by Web and mail surveys. While there are situations in which self-completion can be methodologically preferable (for example, when collecting data on very sensitive topics), interviewer-administered surveys typically carry the advantages of higher response rates, higher item completion rates, and the opportunity to probe the respondent to get more complete answers. The second advantage is that when compared with the other interviewer-administered mode—face-to-face interviewing—CATI is typically more cost-effective and provides for faster delivery of data.

Challenges

There are, however, challenges to CATI surveys that require resolution if CATI surveys are to retain more advantages relative to their disadvantages. One such challenge is the proliferation of cell phones (in many cases replacing landlines completely in households) combined with societal and sometimes legal restrictions on the extent to which cell phones can be used in surveys. Legislative restrictions also influence telephone surveys; some states include telephone surveys in the scope of "do-not-call" restrictions, and others restrict the use of some features on the more advanced automated dialers. Although such legislation is aimed more at reducing invasion of privacy by telemarketers, and in some cases specifically excludes legitimate survey research from the restrictions, the distinction between telemarketing and survey research often is not recognized at the household level. Another challenge is the increasing reluctance of the public to participate in telephone surveys, although the presence of "do-not-call" lists and other privacy-protecting measures may in fact work to the advantage of CATI surveys to the extent they will reduce telemarketing and other nuisance calls that have led to the current resentment of telephone intrusion in households. The apparently significantly lower cost of Internet surveys compared with CATI surveys also creates a challenge, although, as noted earlier, there are methodological issues that still work in favor of CATI surveys.

Computerized-Response Audience Polling (CRAP)

A number of survey designs deviate from the parameters of a scientific probability design, with significant consequences for how the results can be characterized. Computerized-response audience polling (CRAP) is an example of such a design. In this kind of poll, a sample of telephone numbers is typically purchased and loaded into a computer for automatic dialing. The questionnaire is produced through computer software that employs the digitized voice of someone assumed to be known to many of those who are sampled, such as the voice of a newscaster from a client television station. After an introduction, the computerized voice goes through the questionnaire one item at a time, and the respondent uses the key pad on a touchtone phone to enter responses to each question asked, as in an interactive voice response (IVR) system.

A major problem with CRAP polls is that the methodology does not allow for specific respondent selection, meaning that the basic premise of probability sampling, namely that each respondent has a known, nonzero probability of selection, is violated. Interviews are conducted with whoever answers the phone, and there is no guarantee that the person answering is eligible by age or other personal characteristics. Although information can be gathered about the household composition, there is no random selection of a designated respondent from the household. The computer can dial a large set of telephone numbers in a short period of time, working through a purchased sample quickly but producing a low contact or cooperation rate as a result. There also is no attempt to recontact a household to obtain an interview with a designated respondent who is not at home at the time of the first call. Because of these considerations, it is inappropriate to calculate a margin of error around any estimates produced from such a poll.

This method shares many characteristics with self-selected listener opinion polls (SLOP) and other designs that employ volunteer samples. A true response rate cannot be calculated, although a version of a cooperation rate can. The data can be collected rapidly and at low cost. Although post-stratification weighting can be applied to the resulting set of respondents, it is difficult to interpret its meaning when information about respondent selection is missing.

Computerized Self-Administered Questionnaires (CSAQ)

Computerized self-administered questionnaires (CSAQ) are a method of collecting survey data that takes advantage of computer technology to create an instrument (the questionnaire) that allows respondents to complete the survey with little or no other human assistance. Applications range from completely self-administered questionnaires to the use of data collectors who provide introductory information and technical assistance if needed. CSAQ applications include Web surveys in which respondents go to a designated Web site and complete the survey online; research in public access areas in which a respondent may answer questions presented at a kiosk or on a computer provided by a vendor at a conference or convention; touchtone data entry such as telephone surveys in which the respondents use the telephone keypad to enter their responses; and surveys in which the use of CSAQ is one portion of the overall interview process. Surveys of this type are also called "computer-assisted self-administered personal interviewing," "computer-assisted self-administered interviewing (CASI)," or "audio computer-assisted interviewing (ACASI)."

The use of CSAQ has several advantages over traditional self-administered paper-and-pencil (PAPI) surveys. It allows the use of complex skip patterns, directing respondents to the next appropriate question based on an answer or answers to previous questions. It also allows questions to be "personalized" based on demographic variables such as age, race, or sex; or use answers provided earlier in the questionnaire as part of wording of questions coming later. For example, knowing the sex of a child would allow a subsequent question wording to ask about the respondent's "son" or "daughter" rather than his or her "child." The use of CSAQ can be helpful in surveys that ask sensitive questions about sexual activity or drug use for which respondents might be hesitant to provide such information to an interviewer either face to face or over the telephone.

CSAQ designs that use devices with a video monitor and speakers (such as a laptop, monitor, or kiosk) can include graphics such as pictures and illustrations. Using speakers or headphones, audio clips can also be added. Video clips can be used to illustrate a product or to screen an advertisement or public service announcement. Audio clips can be used to "read" the questionnaire in those designs in which the target population may be illiterate or have limited reading ability.

Other advantages of CSAQ designs include reducing the cost of a survey (because interviewers may not be needed) and minimizing data entry errors (because the responses are entered directly into a database at the time the survey is completed). This can reduce the amount of time needed to verify the data and complete the analysis.

The major disadvantages of using CSAQ involve the design of the survey instrument. It must be designed in such a way that the questionnaire flows smoothly. Respondents, especially those who are less comfortable with the use of computers, may become easily frustrated with a questionnaire that is not self-explanatory or in which the questions are not easily understood. The visual layout will influence not only the response rate but the quality of data as well. Special attention must be paid to issues such as font size, color combinations, page layout, and the method used for the respondents to record their answers (radio button, number, open-ended). Web-based CSAQ must be designed in such a way that they are compatible with the variety of screen resolutions and Web browsers that are in use.

As with any survey, sample bias is a consideration. This is especially true for CSAQ designs that make no attempt to identify, screen, or select respondents on some random basis. While results from such a survey may be useful for some purposes, explicit reference must be made of the limitations of drawing any conclusions from the results.

Computerized self-administered questionnaires can be a powerful tool to improve the quality and reduce the cost of survey data collection. However, as with any survey research method, the researcher must consider the limitations of the method used and attempt to reduce or eliminate the effects of those limitations.

CONFIDENCE INTERVAL

A probability sample can provide a point estimate of an unknown population parameter and the standard error of that point estimate. This information can be used to construct a confidence interval to give an estimated range of values around the point estimate that is likely to include the unknown population parameter.

For example, assume that a soda can–filling plant fills soda cans at an average rate of 1,000 to 1,500 cans per minute. Several filling nozzles are simultaneously used to fill the cans. Electronic sensors are used to ensure that the filled amount is within specified limits. Due to inherent variability in the filling process, it is impossible to fill an exact amount (355 milliliters [ml]) of soda in each can. As a final quality control measure, a quality assurance inspector wants to estimate the mean amount of soda filled in one particular batch of 120,000 cans. To do so, one extreme option would be to open all the cans and measure the contents. Clearly, this approach is not cost-effective because doing so will destroy all the cans and contaminate the soda. A reasonable approach would be to take a random sample of, say, 20 cans, measure their contents, and calculate the average amount of soda in each can. In survey sampling terminology, this average is known as the "sample mean." The average amount of soda in each of the 120,000 cans is called the "population mean."

It is a common practice to use the sample mean as a point estimate of the population mean. Suppose the sample mean is calculated to be 352 ml. Does it make sense to infer that the population mean also is 352 ml? If "Yes," then what is the margin of error in drawing such an inference? If another random sample of 100 cans yields a sample mean of 355.8 ml, then the inspector will have more confidence in making an inference about the population mean as compared with an inference based on a random sample of 20 cans because she or he will be using more information in the inference. If the inspector had additional information that the filled amount of soda does not vary much from can to can (i.e., information that the population standard deviation of the filled amount of soda is quite small), then a random sample of 20 cans may be sufficient to draw a conclusion about the population mean with reasonable confidence. On the other hand, if the filled amount of soda varies a lot from can to can (i.e., the population standard deviation of the filled amount is very large), then even a random sample of 100 cans may not be sufficient to draw any conclusion about the population mean with desired confidence.

This example shows that point estimates alone are not sufficient for drawing conclusions about a population characteristic unless accompanied by some additional information regarding the level of confidence and margin of error involved in the estimation process. It would be more informative if the inspector could make a statement, such as "I am 95% confident that, on average, between 354.5 ml to 355.3 ml of soda is present in the 120,000 cans." Such statements are facilitated by adopting the method of confidence intervals for estimation or statistical inference purposes.

Detailed Definition of a Confidence Interval

In statistical terms, a confidence interval (two-sided) is defined as a random interval $[L, U]$ enclosing the unknown population parameter value (θ) (such as a population mean, variance, or proportion) with a given probability $(1-\alpha)$. That is, Probability $(L \leq \theta \leq U) = 1 - \alpha$, where $0 \leq \alpha \leq 1$ and it generally takes small values, such as 0.01, 0.05, or 0.1. The interval $[L, U]$ is known as the $100(1-\alpha)\%$ confidence interval for θ, and the probability $(1-\alpha)$ is known as the confidence level or the coverage probability of the interval $[L, U]$. In certain applications, only a lower or upper bound may be of interest, and such confidence intervals are known as "one-sided" confidence intervals.

If a sampling process is repeated a large number of times, and for each selected sample a confidence interval is obtained using the same confidence level and statistical technique, and if the population parameter was known, then approximately $100(1-\alpha)\%$ of the confidence intervals will enclose the population parameter. In reality, θ is unknown, and owing to budget and time constraints, only one sample is selected; hence, it is not possible to know with certainty if the calculated $100(1-\alpha)\%$ confidence interval encloses the true value of θ or not. It is hoped with the chances at $100(1-\alpha)\%$ that it does enclose the true value of θ. The lower and upper end points of the confidence interval depend upon the observed sample values, selected confidence level, statistical technique, the sample design, and population distributional characteristics, as illustrated by the following examples. The confidence interval definition given earlier comes from the *frequentist* school of thought. The alternative, Bayesian inference, is not yet commonly used in survey data analysis and hence is not covered here.

Construction of a Confidence Interval

Let $\hat{\theta}$ denote an estimator of θ and $v(\hat{\theta})$ denote its variance, then a $100(1-\alpha)\%$ confidence interval is given by $\hat{\theta} \pm c\sqrt{v(\hat{\theta})}$, where c is a constant such that

$$\text{Probability}\left(-c \leq \frac{(\hat{\theta}-\theta)}{\sqrt{v(\hat{\theta})}} \leq c\right) = 1-\alpha,$$

where the probability is calculated using the sampling distribution of $\hat{\theta}$. In most cases, the sampling distribution of $\hat{\theta}$ is not known and is assumed to be either a normal (Gaussian) or Student's t-distribution depending upon the sample size and distributional characteristics of the population. If $v(\hat{\theta})$ is also not known, then its estimated value, $\hat{v}(\hat{\theta})$, is used in the calculation. Due to these reasons, the confidence interval obtained will not be exact (i.e., the coverage probability will be close to $1-\alpha$).

In nonsurvey data analyses, confidence intervals are calculated based on the assumption that simple random sampling with replacement was used, or equivalently, that the random sample was selected from an infinite population. However, in most surveys the target population is finite, and a more complex sampling scheme is used to sample the finite population. Hence, the usual central limit theorem cannot be applied to the finite population sampling cases. Instead, a central limit theorem proposed by Jaroslav Hájek is used for approximating the sampling distribution of $\hat{\theta}$ by a normal distribution for sufficiently large sample sizes.

For the following examples, suppose U denotes the finite population consisting of N units $\{y_1, y_2, \ldots, y_N\}$ and Σ denotes a random sample of n units $\{y_1, y_2, \ldots, y_n\}$ selected from U. Let

$$Y = \left(\sum_{i=1}^{N} y_i\right), \bar{Y} = N^{-1}Y, \text{ and}$$
$$S^2 = (N-1)^{-1}\left(\sum_{i=1}^{N} y_i - \bar{Y}\right)^2$$

be the unknown population total, mean, and variance of the N units of the population U, respectively. Similarly, let

$$y = \left(\sum_{I=1}^{n} y_i\right), \bar{y} = n^{-1}y, \text{ and}$$
$$s^2 = (n-1)^{-1}\left(\sum_{i=1}^{n} y_i - \bar{y}\right)^2$$

be the sample total, mean, and variance of n units of sample S, respectively.

Simple Random Sampling Without Replacement

It is well known that the sample mean $\bar{y}$ is an unbiased estimator of the population mean $\bar{Y}$ and the variance of $\bar{y}$ is $v(\bar{y}) = n^{-1}(1-\frac{n}{N})S^2$. Then, an approximate $100(1-\alpha)\%$ confidence interval for $\bar{Y}$ is given by $\hat{\theta} \pm c\sqrt{v(\hat{\theta})} = \bar{y} \pm c\sqrt{v(\bar{y})}$. If the sample size n is large enough to satisfy the assumptions of Hájek's central limit theorem, then the sampling distribution of $\frac{(\hat{\theta}-\theta)}{\sqrt{v(\hat{\theta})}} = \frac{(\bar{y}-\bar{Y})}{\sqrt{v(\bar{y})}}$ can be approximated by a standard normal probability distribution function with $mean = 0$ and $variance = 1$. The value of c can be obtained by solving the equation Probability $\left(-c \leq \frac{(\bar{y}-\bar{Y})}{\sqrt{v(\bar{y})}} \leq c\right) = 1-\alpha$. By applying elementary statistics results, $c = z_{\alpha/2}$, where $z_{\alpha/2}$ is the 100 $(1-\alpha/2)th$ percentile of the standard normal distribution. Hence, an approximate large sample $100(1-\alpha)\%$ confidence interval for $\bar{Y}$ is given by $\bar{y} \pm z_{\alpha/2}\sqrt{v(\bar{y})}$. Note that $v(\bar{y})$ involves the unknown population variance S^2, which is estimated by the sample variance s^2. If the sample size is not large enough to ensure asymptotic normality, and it is reasonable to assume that the population units follow a normal distribution, and if S^2 is unknown, then the sampling distribution of $\frac{(\bar{y}-\bar{Y})}{\sqrt{v(\bar{y})}}$ can be approximated by a Student's t-distribution with $(n-1)$ degrees of freedom. In that case, $c = t_{n-1,\alpha/2}$, where $t_{n-1,\alpha/2}$ is the $100(1-\alpha/2)th$ percentile of the Student's t-distribution function with $(n-1)$ degrees of freedom.

In the original example regarding soda cans, suppose a sample of 20 soda cans is selected using the simple random sampling without replacement (SRSWOR) methodology. Let y_i be the amount of soda in the I–th can, where $i = 1, 2, \ldots, 20$. Using the amount of soda in each of the 20 cans, $\bar{y}$ and s^2 can be calculated. Let us assume that $\bar{y} = 351$ ml and $s^2 = 25$ ml^2, then $v(\bar{y}) = n^{-1}(1-\frac{n}{N})S^2 \simeq n^{-1}s^2 = 25/20 = 1.25$ because the sampling fraction $n/N = 20/120{,}000$ is negligible in this case. In this example, it is reasonable to assume that the amount of soda in each of the 120,000 cans follows a normal probability distribution. Hence, an approximate 95% confidence interval for the mean amount of soda in the 120,000 cans is given by $351 \pm t_{n-1,\alpha/2}\sqrt{1.25}$. For a 95% confidence interval, $\alpha = .05$ and from the Student's t-probability distribution tables $t_{n-1,\alpha/2} = t_{19,.025} = 2.093$; hence, the 95% confidence interval is $351 \pm t_{n-1,\alpha/2}\sqrt{1.25} = 351 \pm 2.093\sqrt{1.25} = [348.66, 353.34]$.

Stratified Sampling

Suppose that $N = 120{,}000$ cans were produced in three batches of 40,000 cans each. In order to account for batch-to-batch variability in the estimation process, it would make sense to select a random sample from each of the three batches. This is known as "stratified sampling." To find a confidence interval for the average amount of soda in the 120,000 cans ($\bar{Y}$), suppose the inspector took a SRSWOR sample of 40 cans from each of the three batches. In stratified sampling notation (from William Gemmell Cochran), the three batches are known as "strata," with $N_1 = N_2 = N_3 = 40{,}000$ denoting the stratum sizes and $n_1 = n_2 = n_3 = 40$ denoting the stratum sample sizes. From Cochran, an unbiased estimator of $\bar{Y}$ is $\bar{y}_{st} = \sum_{h=1}^{L} \frac{N_h}{n_h}\bar{y}_h$, where $\bar{y}_h$ denotes the sample mean for the $h - th$ stratum and L denotes the number of strata in the population. The variance of $\bar{y}_{st}, v(\bar{y}_{st}) = \sum_{h=1}^{L} \left(\frac{N_h}{N}\right)^2 \left(1 - \frac{n_h}{N_h}\right) n_h^{-1} S_h^2$ involves unknown stratum variances S_h^2, which are estimated by the corresponding sample variances, $s_h^2 = (n_h - 1)^{-1}(\sum_{i=1}^{n_h} y_{hi} - \bar{y}_h)^2$, where y_{hi} denotes the value of the $i - th$ unit in the $h - th$ stratum.

In the preceding example, a sample of 40 cans from each stratum may be sufficiently large to assume a normal probability distribution function for $\bar{y}_{st}$. Hence, an approximate $100(1-\alpha)\%$ confidence interval for $\bar{Y}$ is given by $\bar{y}_{st} \pm z_{\alpha/2}\sqrt{\hat{v}(\bar{y}_{st})}$, where $\hat{v}(\bar{y}_{st}) = \sum_{h=1}^{L} \left(\frac{N_h}{N}\right)^2 \left(1 - \frac{n_h}{N_h}\right) n_h^{-1} s_h^2$. If stratum sample sizes are not large enough, then a Student's t-distribution with n^* degrees of freedom is used to approximate the sampling distribution of $\bar{y}_{st}$. The calculation of n^* is not straightforward and should be done under the guidance of an experienced survey statistician.

Cluster Sampling

Now suppose that the $N = 120{,}000$ cans were packed in 12-can packs and shipped to a retailer. The retailer is interested in knowing the average amount of soda in the 120,000 cans ($\bar{Y}$). A stratified sampling would not be feasible unless all of the 12-can packs ($M = 10,000$) are opened. Similarly, for SRSWOR, it would require one to list all the 120,000 cans, which in turn may require opening all the packs. Because each pack can be regarded as a cluster of 12 cans, a cluster sample design is most suitable here. To obtain an approximate $100(1-\alpha)\%$ confidence interval for $\bar{Y}$, the retailer decided to select a SRSWOR sample of $m = 20$ packs from the population of $M = 10,000$ packs and measure the amount of soda in each of the cans. This is known as a single-stage (or one-stage) cluster sample, in which all the clusters (packs) have the same number (12 cans in each pack) of elements (soda cans). An unbiased estimator of $\bar{Y}$ is $\bar{y}_{cluster} = \frac{1}{N}\left(\frac{M}{m}\right)\sum_{i=1}^{m}\sum_{j=1}^{r} y_{ij}$, where r is the common number of elements in each cluster and y_{ij} denotes the value of the $j - th$ element in the $i - th$ selected cluster. Let $t_i = \sum_{j=1}^{r} y_{ij}$, $s_t^2 = (m-1)^{-1}(\sum_{i=1}^{m} t_i - \bar{t})^2$, and $\bar{t} = m^{-1}(\sum_{i=1}^{m} t_i)$, then the variance of $\bar{y}_{cluster}$ is estimated by $\hat{v}(\bar{y}_{cluster}) = v(\frac{M}{N}\frac{1}{m}\sum_{i=1}^{m}\sum_{j=1}^{r} y_{ij}) = \left(\frac{M}{N}\right)^2 v(\frac{1}{m}\sum_{i=1}^{m} t_i) = \left(\frac{M}{N}\right)^2 \frac{1}{m}(1 - \frac{m}{M})s_t^2$. If the number of clusters in the sample is large, then an approximate $100(1-\alpha)\%$ confidence interval for $\bar{Y}$ is given by $\bar{y}_{cluster} \pm z_{\alpha/2}\sqrt{\hat{v}(\bar{y}_{cluster})}$.

In the preceding example, $r = 12$ (because all 12 cans in a pack are examined) and t_i represents the total amount of soda in the $i - th$ selected pack. Because a SRSWOR sample of $m = 20$ packs is not large enough to assume a normal probability distribution, a Student's $t-$distribution with $t_{m-1,\alpha/2} = t_{19,.025} = 2.093$ could be used by the retailer to obtain a 95% confidence interval for $\bar{Y}$ (i.e., $\bar{y}_{cluster} \pm t_{19,.025}\sqrt{\hat{v}(\bar{y}_{cluster})}$).

It is a common mistake to analyze the data obtained from a cluster sample as if it were obtained by SRSWOR. In the preceding cluster sampling example, if clustering is ignored at the analysis phase and a 95% confidence interval is constructed by assuming that the 240 (20 packs × 12) soda cans were selected using the SRSWOR method, then the actual coverage probability may be less than 95%, depending upon the size of the intracluster (or intraclass) correlation coefficient. Generally, the point estimate of a population parameter will be the same whether the data are analyzed with or without incorporating the survey design information in the estimation process. However, the standard errors may be quite different if the survey design information is ignored in the estimation process, which in turn will result in erroneous confidence intervals.

The examples given deal with constructing a confidence interval for the population mean for some of the basic survey designs. In practice, survey designs are generally more complex, and a confidence interval for other population parameters—such as population proportions and quantiles; linear, log-linear, and nonlinear regression model parameters; survival function at a given time (Cox's proportional hazard model or Kaplan-Meier estimator)—may be needed.

Confidence Level

In statistical inference, it is common practice to report the point estimate of a population parameter along with its standard error (square root of the variance). Often, the point estimator and its standard error are combined by adding and subtracting from the point estimate a multiple of the standard error to obtain an interval estimator. Suppose $\hat{\theta}$ denotes an estimator of θ and $v(\hat{\theta})$ denotes its variance, then $\hat{\theta} \pm c\sqrt{v(\hat{\theta})}$ is an interval estimator of the parameter θ. The constant c is chosen in such a way that if the sampling process is repeated for a large number of times and for each sample an interval estimator is obtained, then approximately a pre-defined percentage of the intervals will enclose θ. This pre-defined percentage is known as the "confidence level" (or "coverage probability") of the interval estimator. Hence, interval estimators are also commonly known as "confidence intervals." In most cases, for a two-sided confidence interval, the value c is obtained by solving the equation

$$\text{Probability}\left(-c \le \frac{(\hat{\theta}-\theta)}{\sqrt{v(\hat{\theta})}} \le c\right) = 1-\alpha,$$

where $100(1-\alpha)\%$ is the chosen confidence level of the desired confidence interval and the probability is calculated using the sampling distribution of $\hat{\theta}$. Generally, the sampling distribution of $\hat{\theta}$ is not known and is assumed to be either a normal (Gaussian) or Student's t-distribution depending upon the sample size and distributional characteristics of the population. If $v(\hat{\theta})$ is also not known, then its estimated value, $\hat{v}(\hat{\theta})$, is used in the calculation.

If $\hat{\theta}$ is biased or $\hat{v}(\hat{\theta})$ is not calculated according to the sampling design or an incorrect sampling distribution of $\hat{\theta}$ is assumed, then the actual confidence level of the $100(1-\alpha)\%$ confidence interval will be different from the nominal confidence level $100(1-\alpha)\%$. For example, Carl-Erik Särndal, Benqt Swensson, and Jan Wretman examined the effect of bias on confidence level. Cherie Alf and Sharon Lohr showed that the true confidence level for a 95% confidence interval for the population mean may be less than 95% depending upon the intracluster correlation coefficient (i.e., if the sample design characteristics are ignored in the variance calculations, then the resulting confidence interval will not have the correct confidence level).

CONFIDENTIALITY

The confidentiality of survey data is expected by both survey researchers and survey participants. Survey researchers have multiple meanings for *confidentiality* that are not quite the same as the common definition. Dictionary definitions use terms such as *private, intimate*, and *trusted*, and some refer to national security concerns.

However, in survey research, the definition is more complex and can be used differently by different researchers and survey organizations. For the most part, confidentiality in survey research refers to the methods for protecting the data that are collected. It refers both to the promises made to survey participants that they will not be identified in any way to those outside the organization without their specific permission and to the techniques that organizations use to ensure that publicly available survey data do not contain information that might identify survey respondents.

For respondents, the promise of confidentiality is the agreement on the methods to prevent others from accessing any data that might identify them. Confidentiality of data is important for the success of survey research because survey participants would be much less willing to participate if they thought the survey organization would disclose who participated in the research and/or their identified responses to questions. The confidentiality protections provided to participants are not as strong as for anonymously collected data, but both anonymity and confidentiality are used for the same reasons.

The confidentiality of survey responses is important for the success of surveys under certain conditions. When the survey poses some risks for participants, promises of confidentiality may improve cooperation. Promises of confidentiality are also important to allow respondents to feel comfortable providing answers, especially to sensitive questions. When a survey asks especially sensitive questions, respondents may be more willing to share their thoughts if they know their responses are protected. Some participants would be reluctant to discuss attitudes and opinions on such topics as race, politics, and religion unless they believed their responses could not be identified to them.

Survey research organizations have policies and practices that support confidentiality and use a number of methods to protect confidentiality of survey data. Most organizations require staff members to sign forms stating they will keep the survey data confidential and not reveal any identifiable information outside the survey organization. Survey organizations have elaborate procedures and policies to protect data stored on their computers, particularly data stored on computers that are connected to public computer networks such as the Internet. In some surveys with especially large samples—for example, those conducted by the U.S. Census Bureau—the geographical identifiers could possibly identify respondents. To prevent disclosure of confidential information in these surveys, organizations use a variety of sophisticated data suppression techniques. Because of the multiple data protection methods, survey researchers have a strong record of protecting data integrity and confidentiality.

However, survey data have no clearly defined legal protections that would protect from court subpoenas and possibly other attempts to acquire confidential survey data through the legal system. Fortunately, acquiring identified survey data through legal processes requires substantial effort and is not often successful.

A few exceptions are available to protect survey data legally, but these do not cover most survey research. The U.S. Census Bureau can protect survey data when it collects data under Title 13. This legal protection is especially important for the decennial census, but other surveys are covered by it. Recently, a new confidentiality law—the Confidential Information Protection and Statistical Efficiency Act (CIPSEA)—was enacted to protect data collected by the three federal statistical agencies. The law provides strong confidentiality protections for data collected under it and permits the sharing of the data across the agencies.

Researchers who collect sensitive survey data can apply for Certificates of Confidentiality provided by the National Institutes of Health. The certificate protects the privacy of research subjects such that the investigators and institutions collecting data cannot be compelled to release information that could be used to identify subjects with a research project. The Certification of Confidentiality states that researchers may not be compelled in any federal, state, or local civil, criminal, administrative, legislative, or other proceedings to identify them by name or other identifying characteristic. However, some skepticism exists about whether this protection would survive a serious legal challenge.

The rules on privacy and confidentiality appear to be changing with the widespread use of computer networks and the analysis large scale databases. Yet, survey researchers and survey participants still expect that survey data will remain confidential and protected. The long-term success of the survey industry in protecting its data is important to the profession's overall success.

CONSENT FORM

In survey research, consent forms typically are used to gain the permission of a parent or guardian who has the legal authorization to give permission for someone in her or his charge to participate in a survey. However, in some studies an adult will be asked to sign a consent form about her or his own agreement to participate in a survey.

Consent forms are most commonly used in surveys of youth populations, regardless of survey mode. Federal regulations protecting human subjects (45 CFR 46), accompanying state or local regulations, and many institutional review boards (IRBs) hold that a youth cannot legally agree to complete a survey (provide consent for herself or himself) until he or she is 18 years of age. As a result, signed or written permission from a parent or legal guardian usually is required prior to the youth or child participating in a survey. This permission is obtained by providing a written permission form, called a "consent form," to parents and having a parent or guardian return it with his or her signature giving the child permission to participate in the survey. Consent forms document that youth have permission to participate in the survey and help ensure that parents or guardians have enough information about the survey to make a decision about whether the youth can participate.

Consent forms also can be required for surveys of adult populations; a key difference with adult populations is that the adult respondent is asked to sign the consent form documenting that she or he has enough information about the survey to make an informed decision to participate.

Under federal human subjects protection regulations (45 CFR 46.116(a)), consent forms usually must include the following elements (individual institutional review boards may require additional elements):

1. An explanation of the purposes of the survey, the expected length of the survey, and a description of the procedures to be followed
2. A description of any reasonably foreseeable risks or potential harm that could occur if the respondent participates in the survey
3. A description of any benefits to the respondent or to others that may be expected from the survey or that may be provided directly by the researchers
4. A statement describing the extent to which confidentiality of any answers or data identifying the respondent will be maintained by researchers
5. Details about whom to contact for answers to questions about the survey and about respondents' rights, and information about whom to contact if participation in the survey results in any harm to the respondent, and
6. A statement that participation is voluntary, refusal to participate will involve no penalty or loss of benefits to which the respondent is otherwise entitled, and a statement that the respondent may terminate participation at any time without any penalty

Although consent forms usually are required for surveys of youth populations, federal regulations and IRBs often provide some flexibility for surveys of adult populations. For adult populations, participation in surveys rarely puts respondents at more than the minimal risks of everyday life. Moreover, depending on the mode of a survey, documentation of consent may not be feasible and may harm surveys by significantly reducing response rates. Finally, some surveys of sensitive behavior rely on anonymity to increase the likelihood that respondents answer questions honestly; for these surveys, a signed consent form actually serves as the only link between a respondent and his or her answers, thus making anonymity impossible and providing a possible threat to confidentiality. As a result, IRBs often waive requirements of a consent form and a signature for surveys with adult populations and allow the informed consent process to occur informally as part of the survey itself. However, key elements of consent can be provided to respondents in a concise way at the beginning of a survey—in the introductory script in a telephone interview, in a cover letter for a self-administered survey, or on the introductory screen in a Web survey.

CONSTANT

The term *constant* simply refers to something that is not variable. In statistics, and survey research in particular, responses are typically described as random variables, roughly meaning that the responses cannot be predicted with certainty. For example, when people are asked whether they approve or disapprove of a particular political leader, typically there is uncertainty about what the response will be. As another example, in a survey regarding whether individuals approve or disapprove of the death penalty, responses are not constant simply because some individuals will approve and others will not.

Although at some level, the difference between a constant and a random variable is clear, the distinction between the two often becomes blurred. Consider, for example, the population mean, μ. That is, μ is the average of all individuals of interest in a particular survey if they could be measured. The so-called frequentist approach to statistical problems views μ as a constant. It is some fixed but unknown value. However, an alternative view, reflected by a Bayesian approach to statistics, does not view μ as a constant, but rather as a quantity that has some distribution. The distribution might reflect prior beliefs about the likelihood that μ has some particular value.

As another example, p might represent the probability that an individual responds "Yes" when asked if he or she is happily married. In some sense this is a constant: at a particular moment in time one could view p as fixed among all married couples. Simultaneously, p could be viewed as a random variable, either in the sense of prior beliefs held by the investigator or perhaps as varying over time.

Another general context in which the notion of constant plays a fundamental role has to do with assumptions made when analyzing data. Often it is assumed that certain features of the data are constant in order to simplify technical issues. Perhaps the best-known example is *homoscedasticity*. This refers to the frequently made assumption that the variance among groups of individuals is constant. In regression, constant variance means that when trying to predict Y based on some variable X, the (conditional) variance of Y, given X, does not vary. So, for example, if X is amount of solar radiation associated with a particular geographic region, and Y indicates breast cancer rates, constant variance means that the variance of Y does not differ among the geographic regions that are of interest.

CONSTRUCT

In the context of survey research, a construct is the abstract idea, underlying theme, or subject matter that one wishes to measure using survey questions. Some constructs are relatively simple (like political party affiliation) and can be measured using only one or a few questions, while other constructs are more complex (such as employee satisfaction) and may require a whole battery of questions to fully operationalize the construct to suit the end user's needs. Complex constructs contain multiple dimensions or facets that are bound together by some commonality that, as a whole, compose the construct. Without clearly conceptualizing the construct's dimensions and the common theme binding the dimensions together, the survey developer runs the risk of either creating a set of questions that does not measure all of what is intended or creating a set of questions that measures dimensions of an unintended construct.

Before question writing or compilation begins, the construct should be carefully considered and its relevant dimensions defined. As a cohesive set, the dimensions of a construct define the construct. Some constructs are relatively simple and do not have many dimensions. For example, the construct of political party identification is relatively simple and may require only a question or two in order to adequately encompass its dimensions. For years, the General Social Survey has asked the question *Generally speaking, do you usually think of yourself as a Republican, Democrat, Independent, or what?* with response options ranging from "Strong Democrat" to "Strong Republican." That one question adequately covers political party affiliation and strength of party identification, which are two relevant dimensions of the construct.

However, the broader a construct, the more dimensions it generally contains. For example, the construct "employee satisfaction" is a broad construct with many dimensions. Simply asking employees the question *How satisfied are you with your job?* is far from adequate. The construct of employee satisfaction has many dimensions that may include the company's culture and values, organizational leadership style, pay structure, working conditions, opportunities for advancement, long-term plans, and training. Each of these dimensions might be further broken down into smaller subdimensions that are more easily operationalized into separate questions.

If a construct is the abstract subject matter to be measured, operationalization is the concrete and measurable expression of the dimensions of that idea in the form of a question or questions. "Working conditions" is a dimension within the construct of employee satisfaction. This dimension of employee satisfaction could be examined using multiple questions dealing with topics ranging from the comfort of the desk chairs to the number of hours employees are expected to work in a normal week. It is the responsibility of those creating the questionnaire to determine the construct dimensions that are most important and operationalize accordingly. Various statistical methods such as factor analysis can help determine the centrality of operationalized questions to the construct.

Construct Validity

In survey research, construct validity addresses the issue of how well whatever is purported to be measured actually has been measured. That is, merely because a researcher claims that a survey has measured presidential approval, fear of crime, belief in extraterrestrial life, or any of a host of other social constructs does not mean that the measures have yielded reliable or valid data. Thus, it does not mean the constructs claimed to be measured by the researcher actually are the ones that have been measured.

In most cases, for survey measures to have high construct validity they also should have good "face validity." Face validity is a commonsensical notion that something should at least appear on the surface (or "at face value") to be measuring what it purports to measure. For example, a survey item that is supposed to be measuring presidential approval that asks, *How well is the country being run by the current administration*? has only some face validity and not much construct validity. Its face validity and thus its construct validity would be enhanced by adding the name of the president into the question. Otherwise it is a stretch to claim that the original wording is measuring the president's approval. One reason for this is that there could be many other members of "the current administration" other than the president who are affecting the answers being given by respondents.

The single best way to think about the likely construct validity of a survey variable is to see the full wording, formatting, and the location within the questionnaire of the question or questions that were used to gather data on the construct. In this way one can exercise informed judgment on whether or not the question is likely to have high construct validity. In exercising this judgment, one should also consider how the question was administered to the respondents and if there is anything about the respondents themselves that would make it unlikely for them to answer accurately. Unfortunately, too few consumers of survey results have access to this detailed type of information or take the time to think critically about this. This applies to too many journalists who disseminate survey information without giving adequate thought to whether or not it is likely to have solid construct validity.

For researchers and others who have a greater need to judge the construct validity of variables on the basis of empirical evidence, there are a number of statistical analyses that can (and should) be performed. The simpler of these analyses is to investigate whether answers given by various demographic groups are within reasonable expectations. For example, if it is reasonable to expect gender differences, are those gender differences actually observed in the data? Additional, correlational analyses should be conducted to determine if the variables of interest correlate with other variables they should relate to. For example, if a Democrat is president, do respondents who are strong Republicans give considerably lower approval ratings than respondents who are strong Democrats? A final consideration: variables that are created from multiple survey items, such as scaled variables, should be tested to learn if they have strong internal consistency using procedures such as factor analyses and calculating Cronbach's alpha. If they do not, then one should suspect their construct validity.

CONSUMER SENTIMENT INDEX

The Consumer Sentiment Index is a measure of consumer confidence in the United States that has been measured and reported by the University of Michigan every month, starting in the early 1950s.

Consumer sentiment, which often is called "consumer confidence," is cited by government officials, business executives, the media, and by ordinary citizens to describe national economic conditions. It has become so much a part of the national economic dialogue that many people think that consumer confidence has a specific and widely agreed-upon definition. Nonetheless, the definition of consumer confidence has remained elusive, since the confidence of consumers can never be directly observed; it is only the behavior of consumers that can be observed. Interest in consumer confidence is thus defined by an interest in the economic behavior of consumers. It is the consumer who determines whether the economy moves toward expansion and growth or toward contraction and recession. Indeed, consumer spending and residential investment account for three quarters of all spending in the U.S. domestic economy, and consumers invest more in homes, vehicles, and other durable goods than business firms invest in new structures and equipment.

The usefulness of measures of consumer sentiment as leading economic indicators has garnered worldwide recognition and is now measured by countries in all six inhabited continents. The countries include Argentina, Austria, Australia, Belgium, Bulgaria, Brazil, Canada, China, Cyprus, the Czech Republic, Denmark, Estonia, Finland, France, Germany, Greece, Hong Kong, Hungary, Indonesia, Ireland, Italy, Jamaica, Japan, Korea, Lithuania, Luxembourg, Latvia, Malaysia, the Netherlands, Mexico, Norway, New Zealand, Poland, Portugal, Romania, Russia, Spain, the Slovak Republic, Slovenia, South Africa, Sweden, Switzerland, Taiwan, Thailand, Turkey, the United Kingdom, and the United States. In addition, there are a large number of other Central and South American countries that have measured consumer confidence sporadically without the establishment of a consistent time series.

Early Development

An economic behavior research program at the University of Michigan began as part of the post–World War II planning process. Its agenda was focused on understanding the role of the consumer in the transition from a wartime economy to what all hoped would be a new era of peace and prosperity. The primary purpose of the first survey in 1946 was to collect in-person data on household assets and debts. The sponsor of the survey, the Federal Reserve Board, initially had little interest in the attitudes and expectations of consumers. Their goal was a financial balance sheet, the hard currency of economic life, not the soft data of consumer sentiment. George Katona, the founder of the survey program, convinced the sponsor that few respondents would be willing to cooperate if the first question asked was, *We are interested in knowing the amount of your income and assets. First, how much do you have in your savings account?* Instead, sound survey methodology required that other, more general, and less threatening questions were first needed to build respondent rapport and to establish a sense of trust and confidence with the respondents.

Katona devised a conversational interview that introduced each new area of interest with questions that first elicited general opinions before asking the detailed questions on dollar amounts. Although the sponsor was convinced that such attitudinal questions were needed for methodological reasons, Katona was told that he did not need to report any of these results since the Federal Reserve had no interest in the attitudinal findings. Ultimately, the Federal Reserve Board, as well as many others, became as interested in the findings on consumers' expectations as on consumers' balance sheets. Although the first measures of consumer expectations may seem serendipitous, it was in reality no happenstance. Katona had clear and unmistakable intentions and seized this opportunity to give life to an innovative research agenda. Katona had long been interested in the interaction of economic and psychological factors, what he termed "the human factor" in economic affairs. When Katona advocated his theory of behavioral economics, few economists listened; 50 years later behavioral economics is at the center of new theoretical developments.

When the sentiment measure was first developed in the late 1940s, it was intended to be a means to directly incorporate empirical measures of income expectations into models of spending and saving behavior. Katona summarized his views by saying that consumer spending depends on both consumers' ability and willingness to buy. By *spending*, he meant discretionary purchases; *by ability*, he meant the current income of consumers; and by *willingness*, he meant consumers' assessments of their future income prospects. Katona hypothesized that spending would increase when people became optimistic, and precautionary saving would rise when they became pessimistic.

Consumer confidence was originally conceptualized as a broad measure of expected changes in income. It was not simply the expected size of a consumer's future income, but the certainty or uncertainty that was attached to those expectations. Thus, an important component of the definition of consumer confidence was that it encompassed both the expected level as well as the expected variance of income. To recognize this dual criterion, Katona defined the *dimension* of consumer confidence as ranging from optimism and confidence to pessimism and uncertainty.

Moreover, Katona argued that consumer confidence has affective as well as cognitive dimensions. Indeed, it was this recognition that led Katona to change the name of the index from "Consumer Confidence" to "Consumer Sentiment." Katona recognized that few consumers thought of inflation or unemployment, for example, without making evaluative judgments. The affective components of economic attitudes and expectations are what serve to integrate diverse pieces of economic information. Moreover, it is the affective component that enables waves of optimism or pessimism to sweep across the population with great speed.

The University of Michigan's Index of Consumer Sentiment was formed at the start of the 1950s when sufficient time-series data had been collected. The index is based on the responses to five questions—two questions on personal finances, two on the outlook for the economy, and one question on buying conditions for durables:

1. *We are interested in how people are getting along financially these days. Would you say that you (and your family) are better off or worse off financially than you were a year ago?*
2. *Now looking ahead—do you think that a year from now you (and your family) will be better off financially, or worse off, or just about the same as now?*

3. *Now turning to business conditions in the country as a whole—do you think that during the next twelve months we'll have good times financially, or bad times, or what?*
4. *Looking ahead, which would you say is more likely—that in the country as a whole we'll have continuous good times during the next five years or so, or that we will have periods of widespread unemployment or depression, or what?*
5. *About the big things people buy for their homes—such as furniture, a refrigerator, stove, television, and things like that. Generally speaking, do you think now is a good or a bad time for people to buy major household items?*

While Katona would have preferred to report on the detailed findings from the surveys, he recognized that a summary index was needed for both the ease of dissemination as well as empirical testing. It is inherently difficult to summarize the diverse implications for all forms of consumer spending in a single index, and there was never an attempt to do so. Indeed, the Michigan surveys include a large range of additional questions. The questions range from income, unemployment, interest rates, and inflation expectations to what respondents think are the most important recent changes in economic conditions, measures about buying conditions for a variety of products, attitudes toward savings and debt, holdings of various assets, and many other topics.

Adaptation to Change

In the late 1940s, most consumers viewed all aspects of the economy through the single dimension of how it affected their jobs and income prospects. In the 21st century, while job and income prospects are still important, there are many other aspects of the economy that are just as important to consumers. For example, consumer expectations for interest rates, inflation, stock prices, home values, taxes, pension and health care entitlements as well as jobs and incomes have moved independently, and often in opposite directions. Furthermore, consumers are now more likely to make distinctions between the near- and longer-term prospects for inflation and stock prices as well as between near- and longer-term job and income prospects. Moreover, consumers have also recognized the importance of the global economy in determining wage and job prospects as well as determining the prices of products sold on Main Street and financial assets sold on Wall Street.

Demographic shifts also influence the measurement of confidence. The retirement of the baby boom generation will reduce their concerns about adverse developments in domestic labor markets in comparison to their heightened dependence on inflation-adjusted returns on their retirement savings. The impact of globalization on financial markets is far greater and nearly instantaneous compared with its influence on labor markets. In addition, older consumers have different spending priorities, and it can be expected that the importance of low import prices for durable goods will fade in comparison to the provisions for health care and other services to the elderly. More generally, the trend toward the increase in purchases of services compared with the purchase of durable goods requires a new conceptualization of consumer confidence.

As a result, the measurement of consumer confidence will likely become even more challenging as it continues to expand into a broader and more complex assessment of economic prospects. Indeed, the economic environment may have become too diverse, and consumers too sophisticated, for any single index to accurately and unambiguously describe consumers as either optimistic or pessimistic. It may be true that no single index can be devised to accurately predict all types of expenditures for all types of consumers at all times. The most accurate models of consumer behavior will relate specific spending and saving behaviors to specific expectations. Nonetheless, there is still a need for an overall index of consumer sentiment that broadly summarizes trends, just as there is a need for aggregate statistics such as the gross domestic product (GDP).

Along with the growing sophistication among consumers, there is a growing demand for more precise measures of expectations. As expectations have become more central components of economic models, the theoretical specifications of the desired measures have become more exacting. Economists generally favor probability measures, while psychologists generally favor verbal likelihood questions. Numeric probability scales are assumed to allow the comparability of responses among different people, across situations, and over time. The simple formulations of verbal likelihood scales, in contrast, are presumed to be answerable by nearly everyone, even by those with limited information or computational skills. The Michigan surveys now incorporate both types of measures.

The strength of household surveys is that they are based on the premise that the description and prediction of consumer behavior represent the best means to foster advances in theory. While there is nothing more useful than good theory, there is nothing more productive in generating theoretical advances than good data. To this end, the Michigan surveys have always stressed the substance of the research rather than the format of the questions or the components of the sentiment index. The more rapid changes that may accompany an aging population and the globalization of the economy are seen as an opportunity for scientific advancement. Consumer confidence will still be part of popular culture, still be thought to have a specific and widely agreed-upon definition, and still be an unobserved variable that is defined by the evolving economic behavior of consumers.

Sample Design

The monthly survey is based on a representative sample of all adult men and women living in households in the coterminous United States (48 states plus the District of Columbia). A one-stage list-assisted random-digit design is used to select a probability sample of all telephone households; within each household, probability methods are used to select one adult as the designated respondent. The probability design permits the computation of sampling errors for statistics estimated from the survey data.

The sample is designed to maximize the study of change by incorporating a rotating panel in the sample design. An independent cross-section sample of households is drawn each month. The respondents chosen in this drawing are then reinterviewed six months later. A rotating panel design results, with the total of 500 monthly interviews made up of 60% new respondents and 40% being interviewed for the second time. The rotating panel design has several distinct advantages. This design provides for the regular assessment of change in expectations and behavior both at the aggregate and at the individual level. The rotating panel design also permits a wide range of research strategies made possible by repeated measurements. In addition, pooling the independent cross-section samples permits the accumulation of as large a case count as needed to achieve acceptable standard errors for critical analysis variables.

CONTACTABILITY

The ease or difficulty with which a sampled respondent can be contacted by a survey organization is referred to as her or his “contactability.” It can be expressed as a quantity (or “contact propensity”) and ranges from 0.0 to 1.0, with 0.0 meaning it is impossible to contact the respondent and 1.0 meaning it is certain that the respondent will be contacted.

Contactability will vary by the mode that is used to attempt to contact a respondent in order to recruit her or his cooperation and/or gather data. Contactability also will vary according to the effort a survey organization expends to reach the respondent and what days and times these contact attempts are tried.

For example, take the case of young adult males, ages 18 to 24 years, who are among the hardest of demographic groups for survey organizations to make contact with. The mode of contact that is used will affect the contactability of this cohort, as they are far less likely to be contacted via a traditional random-digit dialed (RDD) landline survey. If the telephone mode is used, then researchers trying to contact this cohort also need to sample cell phone numbers, as nearly one third of these adults in the United States were “cell phone only” in 2007 and their proportion is growing each year. If the mode of contact is the postal service (mail), this young adult male cohort also will have relatively lower contactability, as they are likely to move from address to address more than other demographic groups.

The number of days, which days of the week, and what times of day a survey organization uses its interviewers (telephone or in-person) to make contact with respondents also will affect the contactability of respondents. In the case of the young adult cohort, fielding the survey for only a few days (e.g., a weekend poll, Friday through Sunday) will greatly lower the contactability of this cohort, especially if no late evening hours are included.

In a telephone survey, contactability also will vary by whether or not the survey organization sends out some form of name identifier to be shown on caller ID or on the privacy manager devices that many households use to decide whether or not to answer their incoming calls. (Yet, even if the survey organization's name is displayed on such a device it will not help raise contactability unless the respondents know the name and think positively toward it.) Leaving a message on an answering machine when it is first encountered at a household is thought to aid contactability, assuming the message is a persuasive one, given that many household use these machines to screen their incoming calls.

Low levels of contactability within a sample will lead to higher nonresponse due to noncontact. Thus, it behooves researchers to think explicitly about cost-effective ways to increase the contactability of their sampled respondents.

Paul J. Lavrakas

CONTACT RATE

Contact rate measures the proportion of eligible cases in the sampling pool in which a member of a sampled household was contacted—that is, reached by an interviewer (in telephone and in-person surveys) or received the survey request (in the case of mail and Internet surveys). Contact rates can be computed for all surveys, regardless of the mode in which the data are gathered. The contact rate is a survey outcome rate that can be cited in survey reports and in research literature. Although no single rate or number can reflect the total quality of a survey, contact rates (along with survey response rates, survey cooperation rates, and survey refusal rates) are one of the most common outcome tools that researchers use to evaluate survey quality.

Both household-level and respondent-level contact rates can be computed for a survey by using the final sample dispositions. In the former case, the household-level contact rate reflects the proportion of cases in which any sort of contact was made with a person at a household, including cases in which contact was made with eligible respondents. The respondent-level contact rate is similar, with the exception that it reflects only the proportion of contacts with known survey respondents. Researchers typically compute 1 of 3 standard contact rates.

Contact Rate 1

The numerator of this rate is comprised of all of the kinds of contacts (e.g. completion, refusals, language barrier, and so on) a survey or interviewer (depending on the mode) might make with a person in a sampled household or unit (or with the respondent, if a respondent-level contact rate is being computed). The denominator includes all known eligible cases and all cases of indeterminate eligibility. As such, this rate is the most conservative contact rate.

Contact Rate 2

As before, the numerator of this rate is comprised of all of the kinds of contacts a survey or interviewer (depending on the mode) might make with a person in a sampled household or unit (or with the respondent, if a respondent-level contact rate is being computed). However, the denominator of this rate includes all known eligible cases and a proportion of the cases of indeterminate eligibility that is based on the researcher's best estimate of how many of the cases of indeterminate eligibility actually are eligible.

Contact Rate 3

As with Contact Rates 1 and 2, the numerator of this rate is comprised of all of the kinds of contacts a survey or interviewer (depending on the mode) might make with a person in a sampled household or unit (or with the respondent, if a respondent-level contact rate is being computed). The denominator of this rate includes only the known eligible cases. As a result, Contact Rate 3 is the most liberal contact rate.

CONTACTS

Contacts are a broad set of survey dispositions that are used with all surveys (telephone, in-person, Internet, and mail), regardless of mode. The set of contact dispositions includes all the kinds of contacts a survey or interviewer (depending on the mode) might make with a person or sampled household or unit.

Many of the most common types of contacts occur in all surveys, regardless of the mode in which they are conducted. These include completed interviews, partial interviews, refusals, and breakoffs. Other, less common types of contacts include cases in which contact is made with a respondent or sampled unit or household but an interview is never started because the sampled respondent is physically or mentally unable to participate, or an interviewer is told the respondent is unavailable to complete the questionnaire during the entire field period. Contacts also include cases involving language barriers (with a telephone or in-person survey) and literacy issues relating to respondents not being able to read and understand the questionnaire, in the case of mail and Internet surveys. A final type of contact occurs when it is determined that the person or household is ineligible for the survey. Of note, in many cases in mail and Internet surveys, the researcher has no idea whether or not contact ever was made with anyone at the sampling unit.

Contacts are used for computing contact rates for surveys. A contact rate measures the proportion of all cases in the sampling pool in which a member of a sampled household was reached by an interviewer (in telephone and in-person surveys) or received the survey request (in the case of mail and Internet surveys).

CONTENT ANALYSIS

As it relates to survey research, content analysis is a research method that is applied to the verbatim responses given to open-ended questions in order to code those answers into a meaningful set of categories that lend themselves to further quantitative statistical analysis. In the words of Bernard Berelson, one of the early scholars explaining this method, "Content analysis is a research technique for the objective, systematic, and quantitative description of the manifest content of communication." By coding these verbatim responses into a relatively small set of meaningful categories, survey researchers can create new variables in their survey data sets to use in their analyses.

Example of Content Analysis in Survey Research

Imagine a questionnaire that asks respondents, *What is the biggest problem facing the nation today?* Some of the answers that respondents have given to this open-ended question are shown in Figure 1 (along with the spelling and grammar mistakes made by telephone interviewers).

For a survey researcher to be able to analyze the "biggest problem" question, these verbatim answers must be coded into a relatively small and meaningful set of categories. Using the verbatims in Figure 1, a plausible set of categories could be as follows:

President Bush; His administration and its policies

The Republican Congress

ILLWILLED AND MALICE DRIVEN BY IGNORANCE
LOSS OF CIVIL LIBERTIES
THE PRICES OF HOUSES ARE TOO HIGH
TRUST
MORAL DECLINE
WELFAIR
THE PRESIDENT
REPUBLICAN ADMISTRATION
THE BUDGET DIFFCIET
NATIONAL SECURITY
ILLIGAL IMMIGRATION
A PRESIDENT WHO DOESNT UNDERSTAND INTERNATIONAL POLITICS
NATIONS DEBT
THE LACK OF PUTTING GOD FIRST IN OUR LIVES
KILLING
GAS PRICES
UNEMPLOYMENT
ILLEGAL ALIENS
MORAL DECLINE
ECONOMY AND WAR IN IRAQ
BAD GOVERNMENT
APATHEY NOBODY CARING ABOUT ANYTHING
NEIGHBORHOOD SECURITY
TAKING GOD EVERYTHING
GEORGE BUSH
PRSEDENT THAT A LEIR
GEORGE BUSH
TO MANY PEOPLE TO MANY COMEING INTO THE US
PRESENT ADMINISTRATION
OUR ADMINISTRATION OR OUR GOVERNMENT OUR CURRENT POLICIES
A DISHONEST GOVERNMENT
CORRUPTION IN OUR GOGERNMENT
GOVERNMENT POLICY REGARDING IRAQ AND TERROR ACTIVITY AROUNFD THE WORLD
GREED
REPUPLICANS CONTROLLING LEGISLATIVE AND EXECUTIVE BRANCHES AT THE NATIONAL LEVEL
AFFORDABLE HOUSING

Figure 1 Examples of answers given to open-ended question, "What is the biggest problem facing the nation today?"

Honesty in government

Immigration; Illegal aliens

Moral decline

Housing

War in Iraq

National security; Terrorism

Misc. Other

Coders need to be carefully trained and regularly monitored to apply these categories reliably to each verbatim answer and thereby assign a numerical value to that answer. In this example, a new coded variable would be created that ranges in value from 1 to 9. This variable then could be analyzed via cross-tabulation or other statistical procedures to learn, for example, whether certain demographic characteristics of the respondents (e.g., age, gender, and race) are related to the answers given to the open-ended question.

Content analysis can also be performed by computer software programs. Again, the researchers need to devise a reliable coding scheme in order for the end product to be reliable. For many researchers, the limitations of what software can accomplish are offset by the lower costs of doing the content coding with software compared to the much higher cost of doing it with human coders. However, many content coding solutions will be beyond the capacity of current computer software to apply reliably, and in those instances human coders will need to be utilized.

Analytic Considerations

A general rule of thumb that many survey researchers have found in doing content analyses of open-ended answers is to code as many as three new variables for each open-ended question. For example, if the open-ended question is Q21 in the questionnaire, then the three new variables might be named Q21CAT1, Q21CAT2, and Q21CAT3. This follows from experience that indicates that nearly all respondents will give at least one answer to an open-ended question (since most of these open-ended questions do not ask for only one answer). Many respondents will give two answers, and enough will give three answers to justify coding up to three answers from each respondent. When this approach is used, the researcher also may want to create other new dichotomous (dummy) variables coded "0" or "1" to indicate whether each respondent did or did not mention a certain answer category. Thus, for the earlier example using the "biggest problem" question, new dichotomous variables could be created for each category (BUSH, CONGRESS, HONESTY, IMMIGRATION, etc.). For each of these new variables, the respondent would be assigned the value of "0" if she or he did not mention this category in the open-ended verbatim response and "1" if this category was mentioned.

Context Effect

The term *context effect* refers to a process in which prior questions affect responses to later questions in surveys. Any survey that contains multiple questions is susceptible to context effects. Context effects have the potential to bias the thinking and answers of survey respondents, which reduces the accuracy of answers and increases the error in survey measurement. Psychologists refer to context effects as the general effect of *priming*. Priming occurs when the previous activation of one type of information in active memory affects the processing of subsequent related information. For example, the prior presentation of the word *doctor* reduces the time it takes to subsequently recognize the word *nurse* in comparison to an unrelated word. This priming effect is thought to occur because the activation of one concept spreads and activates related concepts in the brain. Similarly, for example, attempting to remember a list of words that all relate to "bed" (i.e., *sleep, pillow*, etc.) increases the likelihood that a person will falsely remember that the related word was present in the list during recall. In both cases, the previous context consistently primes, or biases, thinking in a certain direction by increasing the saliency of that information.

Context effects are most noticeable in attitude surveys. These contexts effects may occur (a) within a question, and (b) between questions (also referred to as "question order effects"). An example of a within-question context effect is how the label *anti-abortion* instead of *pro-choice* affects attitudes toward abortion. The wording choice leads the respondent to frame a question in a certain way or increases the saliency and importance of some information over other information within a question. A between-question context effect occurs, for example, when previous questions regarding attitudes toward an ongoing war influence a subsequent question regarding presidential performance. Question order effects are evident in the fact that answers to questions on related themes are more similar and consistent when the questions are asked in a group than when these questions are separated and scattered throughout a questionnaire. Effects of question order are also evident when questions regarding a negative life event lead to more negative attitudes for subsequent questions regarding present feelings.

It is possible to control for context effects by counterbalancing question order across several versions of a survey. However, due to cost concerns, this option is rarely feasible to implement properly. It is unavoidable that the wording of survey questions frames and defines issues for survey respondents in ways that affect responses. Questions will be interpreted by respondents within the context of the entire questionnaire, previous questions, and the wording of the present question. Given that these processes are unavoidable and cannot be eliminated, survey designers must at least be aware of the possible effects of context and thereby try to design questionnaires in order to minimize their effect. Question construction must balance the positive impact of greater question detail on retrieval performance with the negative effects leading respondents toward certain responses because of greater detail.

It should be noted that although awareness of possible context effects is advisable, there is actually little evidence that context effects have a great impact on most overall survey results. The percentage of questions in any survey affected by context effects in any significant way tends to be around only 5%. Thus, even though a few particular items may be affected by prior information, context effects rarely appear to alter survey answers away from a respondent's "true" answers to any great extent across whole surveys.

Contingency Question

Questions that are limited to a subset of respondents for whom they are relevant are called "contingency questions." Relevancy is sometimes based on a respondent characteristic such as gender or age. For example, it is typical to ask only women of childbearing age if they are currently pregnant; conversely, only men are asked if they have ever have had a prostate cancer screening examination. Other times, questions are asked only of those that engage in a certain activity or hold a certain opinion about an issue.

A question that determines if a contingency question is asked is called a "filter," "skip," or "branching" question. In the research literature, the terms *filter question* and *contingency question* are sometimes used synonymously. However, in practice, the latter is dependent, or contingent, on the response to the former. Filter questions help route respondents through the questionnaire by skipping them over questions that are not relevant. Questionnaire "pathing" can be simple, as when one filter question determines receipt of one contingency question. Complexity is increased when responses to a series of filter questions are used to determine if a respondent gets one or more contingency questions.

Filter and contingency questions can be deployed in any data collection mode. In certain modes (Web, computer-assisted telephone interview [CATI], computer-assisted personal interviewing [CAPI], or computer-assisted self-interviewing [CASI]), the determination of who receives a contingency question can be programmed electronically. Once respondent characteristics are pre-loaded, survey programs will automatically skip contingency questions that would otherwise have required asking one or more filter questions. For example, respondents who are known to be male would automatically skip questions contingent on being female without first being asked a filter question about gender.

Contingency questions are not required on survey instruments; however, their use, in conjunction with filter questions, can reduce overall burden by asking respondents only those questions that are relevant. In the absence of filter questions, "Not Applicable" should be added as a response category for items relevant to only a subset of respondents. In the absence of an explicit Not Applicable option, respondents for whom inapplicable questions are asked may respond with a "Don't Know" or "Refuse." This could be interpreted erroneously as missing data.

Survey researchers should be cognizant of the fact that some respondents may purposely answer filter questions in a way that will result in skipping contingency questions. This may occur when respondents lose interest in the survey, whether it is due to fatigue, boredom, or lack of topic saliency, and when they can too easily anticipate how a particular answer to a filter question will skip them out of another question or series of questions. This can lower data quality, as the result would be undetected missing data on items for which a respondent was actually eligible.

Contingency Table

A contingency table (or *cross-tabulation*) is an effective way to show the joined distribution of two variables, that is to say, the distribution of one variable within the different categories of another. Data in the table are organized in rows and columns. Each row corresponds to one category of the first variable (usually considered as the dependent variable), while each column represents one category of the second variable (usually considered as an independent variable). The intersection of a row and a column is called a "cell." Each cell contains the cases that have a certain combination of attributes corresponding to that row and column (see Table 1). Inside each cell a variety of information can be displayed, including (a) the total count of cases in that cell, (b) the row percentage represented by the cell, (c) the column percentage represented by the cell, and (d) the proportion of the total sample of cases represented by that cell.

Generally, a contingency table also contains the sums of the values of each row and column. These sums are called the "marginals" of the table. The sum of column or row marginals corresponds to the sample size or grand total (in the lower right-hand cell of the table).

The product of the number of the rows by the number of the columns is called the "order" of the table (Table 1, for example, is a 2×2 table), while the number of the variables shown in the table represents its dimension.

Table 1 An example of contingency table: Gender by education

		Gender		
		M	*F*	*Total*
Education	*Low*	32	87	119
		26.9%	73.1%	100%
		17.0%	37.5%	28.3%
		7.6%	20.7%	
	High	156	145	301
		51.8%	48.2%	100%
		83.0%	62.5%	71.7%
		37.1%	34.5%	
	Total	188	232	420
		44.8%	55.2%	100%
		100%	100%	

A bivariate contingency table represents the first device the researcher can use in the exploration of the relationship between two variables (including ones that are nominal or ordinal). In order to establish whether the variables are associated or not, however, the researcher has to abandon the raw frequencies in favor of the percentages, because only these allow a proper comparison. One can calculate three types of percentages: (1) row, (2) column, and (3) total percentages. However, not all these percentages are generally reported in the contingency table, as that would be more information than needed in most instances; although they are shown in each cell in Table 1 below the cell count. Which percentages the researcher takes into account depends on the specific research question. However, if the researcher aims at exploring the influence of the variable shown in the columns (considered as independent) on the variable shown in the rows (considered as dependent), she or he should report the column percentages. Therefore, keeping fixed the first category of the dependent variable (in the rows), the researcher will analyze how the values change along the categories of the independent variable (in the columns). If one considers the column percentages in the Table 1 (i.e., the 2nd percentage below the count in each cell) for example, keeping fixed the category "low educated," one can see that females in this sample are significantly more likely to be "less educated" than are males. Of note, if the percentages in a cell are based on too small a number of cases, the results will not be reliable.

Contingency tables with the same number of rows and columns are generally easier to analyze. For example, with such tables, if the larger frequencies of the table gather along the diagonal cells, this clearly indicates an association between the variables. Sometimes, however, the figures within a contingency table are quite difficult to interpret. This can happen for two main reasons: (1) the categories of one or both the variables are too numerous and/or uneven; (2) the frequencies and/or the percentages have no discernible pattern, because, for instance, the relationship between the variables is not linear. In the first case, it could be useful to aggregate or dichotomize the categories (this often happens in the case of Likert scale variables). In most cases, this solution leads to more readily interpretable results, though some information is lost in the process. In general, it is quite helpful to calculate the chi-square test or other measures of significance and/or association that summarize in a single figure the relationship between the variables.

CONTINGENT INCENTIVES

Past research has shown that contingent incentives can be used in survey research as a way of increasing survey response rates. The concept of contingent versus noncontingent incentives is that a noncontingent incentive is given to the respondent regardless of whether the survey task is completed, whereas giving a contingent incentive is dependent on the respondent's completion of the survey task, such as completing and returning the questionnaire in a mail survey. Contingent incentives are most commonly used with phone and Internet surveys, although they can be used with any mode of survey data collection. Usually the researcher will use the promise of the incentive as an inducement to coax the respondent into completing the survey, because the respondent does not receive the contingent incentive unless the survey task is completed.

The most common type of contingent incentive in survey research is the monetary incentive, most often paid either in the form of cash or in the form of a check. The recent introduction of cash cards and gift cards have made this form of monetary incentive another viable option for use in surveys. Some examples of nonmonetary contingent incentives include sweepstakes entries, charitable donations, videos, gas cards, coupons, online credits, small household appliances, books, electronic devices, small gadgets or knickknacks, and so on. However, research indicates that monetary contingent incentives are more effective than nonmonetary incentives of the same value.

Contingent incentives have generally been found to be less effective than noncontingent incentives for completing a survey. This often is the case even when the contingent (promised) incentive is several times larger in value than the noncontingent incentive given to a respondent before she or he completes the survey task. However, in some situations, it is impractical to offer a noncontingent incentive. Normally a noncontingent incentive would be offered in a situation in which there is an easy way to deliver it at the same time as the survey instrument, such as in a mailed survey. In contrast, the contingent incentive is, by definition, given after the survey task is completed. How soon after this is promised to take place will also affect the power of the contingent incentive to raise the response rate. The sooner the contingent incentive is given to the respondent after she or he completes the survey task, the greater its power to raise response rates. With telephone and in-person interviews, a contingent incentive can be a strong persuader for the interviewer to use to gain cooperation. However, in the case of a telephone survey, gratification in receiving the contingent incentive is delayed, unlike an in-person interview in which the incentive can be given immediately after the survey task is completed. Similarly, a monetary contingent incentive paid in cash provides more immediate gratification than one paid via check or cash card. Thus, contingent incentives paid in cash immediately upon completion of the survey task are likely to have the greatest positive impact on raising responses rates compared to contingent incentives of the same value that are given after some lag in time and/or are not given as cash.

The decision to use a contingent incentive is somewhat independent from the decision to use a noncontingent incentive. If the survey budget can afford both, researchers will still be somewhat at a loss as to how to distribute the total value that will be used across the noncontingent and contingent incentives. That is, there is no definite guidance provided by the research literature indicating what is the most optimal balance between the value of a contingent incentive and a noncontingent incentive when both are used in the same survey.

When considering which type of contingent incentive, if any, to use in a particular survey, the researcher should consider the type of survey instrument (mailed, phone, Internet, in-person), the relative importance of the response rate, the level of effort required to complete the survey, the probable motivation of the sample to comply without any incentive, and the need possibly to differentially incent certain hard-to-reach demographic cohorts. For simple, short mailed surveys, short phone interviews, and short Internet surveys, an incentive may not be needed. As the length and complexity of the survey increases or respondent engagement (e.g., level of interest) decreases, the need to consider the use of a noncontingent incentive is likely to increase.

The amount of contingent incentive offered to the respondent should not be out of proportion to the effort required to complete the survey. When a promised contingent incentive amount is the sole motivating factor in the decision of a respondent to cooperate, the respondent may put in a less than adequate effort in accurately and completely answering the questions in the survey. Researchers should be aware of this "buying cooperation" phenomenon. Some research organizations offer points for completing surveys that can later be redeemed for prizes. Some firms form panels of households that will complete numerous surveys and can accumulate points over time and redeem them for larger prizes.

Another use for contingent incentives is to persuade the participants to return all materials and do so in a timely manner. The participant may be motivated to make a deadline for returns if they are aware that the amount of the contingent incentive is at least partially dependent on returning the materials by the cutoff date.

A concern to some researchers who are considering use of a contingent versus noncontingent incentive with a mail or Internet survey (ones not administered by an interviewer) is the possibility of confusion about whether the survey task (e.g., questionnaire) was fully completed and returned in a timely manner.

Respondents may think that they did everything required to qualify for the incentive, while the researcher's records indicate otherwise. This confusion could cause both a public relations problem and a logistical nightmare for the survey organization if not properly handled. Thus researchers must ensure that clear and complete procedures and guidelines as well as contingency plans are established when using a contingent incentive. Any contingent incentive offer should be structured in such a way that the respondent is aware of what needs to be done to qualify for the incentive and that the researcher has a means of delivering that incentive in a reliable and straightforward way.

Control Group

In experimental designs, a control group is the "untreated" group with which an experimental group (or treatment group) is contrasted. It consists of units of study that did not receive the treatment whose effect is under investigation. For many quasi-experimental studies, treatments are not administered to participants, as in true experimental studies. Rather, treatments are broadly construed to be the presence of certain characteristics of participants, such as female gender, adolescence, and low socioeconomic status (SES), or features of their settings, such as private schools or participation in a program of interest. Thus, the control group in quasi-experimental studies is defined to be those lacking these characteristics (e.g., males, respondents who are older or younger than adolescence, those of high and medium SES) or absent from selected settings (e.g., those in public schools, nonparticipants in a program of interest). Control groups may alternatively be called "baseline groups."

In a true experiment, control groups are formed through random assignment of respondents, as in between-subject designs, or from the respondents themselves, as in within-subject designs. Random assignment supports the assumption that the control group and the experimental group are similar enough (i.e., equivalent) in relevant ways so as to be genuinely comparable. In true experimental studies and between-subject designs, respondents are first randomly selected from the sampling frame; then they are randomly assigned into either a control group or an experimental group or groups. At the conclusion of the study, outcome measures (such as responses on one or more dependent variables, or distributions on survey items) are compared between those in the control group and those in the experimental group(s). The effect of a treatment (e.g., a different incentive level administered to each group) is assessed on the basis of the difference (or differences) observed between the control group and one or more experimental group.

Similarly, in within-subject designs, respondents are randomly selected from the sampling frame. However, in such cases, they are not randomly assigned into control versus experimental groups. Instead, baseline data are gathered from the respondents themselves. These data are treated as "control data" to be compared with outcome measures that are hypothesized to be the result of a treatment after the respondents are exposed to the experimental treatment. Thus, the respondents act as their own control group in within-subject designs.

Control groups are often used in evaluation studies that use surveys, and they are also relevant to methodological research on surveys. Research that examines the effects of questionnaire design, item wording, or of other aspects of data collection often uses a classical "split-ballot" design or some variant. In these studies, respondents are assigned at random to receive one of two versions of a questionnaire, each version varying on a single point of question order, wording, or presentation. In practice, these studies often depart from the conception of presence versus absence that typically marks the contrast between treatment and control groups. Researchers may present a variation of an item to both groups, for example, as opposed to administering the item to one group and not to the other. Nevertheless, these lines of survey research rely on the control group—either literally or by extension—as a necessary support for claims about the causal effects of the items, procedures, or programs being studied.

Controlled Access

Any sampled housing unit to which access by a data collector is physically blocked or impeded is considered to be a situation of controlled access. Impediments may include people (e.g., a "gatekeeper"), structures, and/or animals. Controlled access situations are encountered only in studies using the in-person field data collection methodology. Dealing effectively with these impediments is necessary to further the objectives of a field data collection operation.

Controlled access situations can take many forms and may involve one impediment or multiple impediments occurring simultaneously. For example, a single-family home may be surrounded by a locked fence or may have a growling dog loose in the yard, or both. A secured apartment building may have a locked entrance, a security guard, or both. An entire residential neighborhood may have keycard access–only gated entrances.

It is important to consider that controlled access situations may involve not just one but multiple sampled housing units. For example, in the case of an area probability sample, a locked apartment building may encompass a number of sampled units.

Security features that impede access to housing units are not limited to particular socioeconomic areas. High-crime, lower–socioeconomic status areas may have more gated yards with guard dogs, bars on windows and doors, and locked apartment buildings. More affluent areas may have gates on the street and/or driveway entrances, security guards, and locked apartment buildings.

Another example of controlled access situations affecting multiple sample units is group quarters. University dormitories, military barracks, and other institutionalized living units are primary examples. Similarly, in the United States, Native American Indian reservations often present controlled access challenges.

Addressing controlled access situations will generally fall into one of two approaches: *overt* or *covert*. Covert methods often are more efficient and effective provided they do not put the data collector in legal or physical jeopardy. One example would be following a resident into a locked apartment building when he or she open the door. Another would be, once a selected unit resident grants entrance to the building over the intercom, using that access to go to all other selected units in the building. Overt methods, however, may be the only practical means of dealing with some situations. This may involve sending letters and/or making presentations to the controllers (gatekeepers) of the physical barrier (e.g., building manager, homeowners' or tenants' association).

Regardless of the type of intervention, success will depend first on gathering sufficient, detailed information about the situation. After analyzing the information, appropriate options and strategies must be devised and implemented. Although it is sometimes better to "beg forgiveness later than ask permission first," it may be advisable to require field data collectors to consult with their supervisors before using a covert method of gaining entry to a controlled access environment.

Researchers should include in their procedural manuals and training programs material on how to deal effectively with various controlled access situations. Strategies and tools for dealing with locked facilities, complexes, and neighborhoods should be developed, utilized, and continually enhanced in an effort to negotiate past these impediments. This is particularly important so that data collectors do not find themselves taking unnecessary risks. They must be prepared to exercise good judgment to avoid legal issues such as trespassing or being injured attempting to surmount a physical barrier or outrun an aggressive animal.

As our society becomes increasingly security- and privacy-minded, the presence of controlled access situations and facilities will similarly increase. It is important for researchers to recognize this trend and the potential negative effect on survey nonresponse that controlled access situations represent.

CONTROL SHEET

A control sheet, also called a "case control form," is used by interviewers in in-person (face-to-face) surveys to record information about the contact attempts they make with households or persons who have been sampled.

Similar in purpose to the call sheet used by telephone interviewers, the control sheet captures key paradata about each contact attempt an interviewer makes with the household or person. This includes (a) the date of the contact attempt, (b) the time of day of the contact attempt, (c) the outcome (disposition) of the contact attempt, and (d) any additional information that is pertinent about the effort to make contact (e.g., the name of the designated respondent if she or he is not home at the time the attempt is made and the best time to recontact her or him).

The information recorded on control sheets serves several important purposes. First, it allows the interviewers and supervisory field staff to better control the processing of the sample according to the a priori contact rules that have been established by the researchers. For example, these rules set guidelines about how many times a person or household can be contacted within a week's period; how many of these contacts should be during the day on weekdays, in the evening hours of weekdays, or on weekends; and how many days must elapse between a first refusal and an attempt to convert the refusal. The control sheet is the mechanism that brings order to the systematic processing of the sample. Second, the information on the control sheet about previous contact attempts allows an interviewer to be better prepared to gain a completed interview the next time she or he tries to contact the household. Third, the information on the control sheet can be used by supervisory staff in their ongoing and annual evaluations of the performance of individual interviewers, teams of interviewers, and/or the interviewing staff as a whole. Fourth, the information on the control sheet can be analyzed by the researchers to investigate ways to improve the cost-effectiveness of future interviewing (e.g., studying the optimal time lapse between a first refusal and a successful conversion attempt).

CONVENIENCE SAMPLING

Convenience sampling is a type of nonprobability sampling in which people are sampled simply because they are "convenient" sources of data for researchers. In probability sampling, each element in the population has a known nonzero chance of being selected through the use of a random selection procedure. Nonprobability sampling does not involve known nonzero probabilities of selection. Rather, subjective methods are used to decide which elements should be included in the sample. In nonprobability sampling, the population may not be well defined. Nonprobability sampling is often divided into three categories: purposive sampling, convenience sampling, and quota sampling.

Convenience sampling differs from purposive sampling in that expert judgment is not used to select a representative sample of elements. Rather, the primary selection criterion relates to the ease of obtaining a sample. Ease of obtaining the sample relates to the cost of locating elements of the population, the geographic distribution of the sample, and obtaining the interview data from the selected elements. Examples of convenience samples include mall intercept interviewing, unsystematically recruiting individuals to participate in the study (e.g., what is done for many psychology studies that use readily available undergraduates), visiting a sample of business establishments that are close to the data collection organization, seeking the participation of individuals visiting a Web site to participate in a survey, and including a brief questionnaire in a coupon mailing. In convenience sampling the representativeness of the sample is generally less of a concern than in purposive sampling.

For example, in the case of a mall intercept survey using a convenience sample, a researcher may want data collected quickly using a low-cost method that does not involve scientific sampling. The researcher sends out several data collection staff members to interview people at a busy mall, possibly on a single day or even across a weekend. The interviewers may, for example, carry a clipboard with a questionnaire that they may administer to people they stop in the mall or give to people to have them fill out. This variation in convenience sampling does not allow the researcher (or the client) to have any sense of what target population is represented by the sample. Although convenience samples are not scientific samples, they do on occasion have value to researchers and clients who recognize their severe limitation; for example, they may allow some quick exploration of a hypothesis that the researcher may eventually plan to test using some form of probability sampling.

Convention Bounce

Support for presidential candidates usually spikes during their nominating conventions—a phenomenon so reliable its measurement has become a staple of pre-election polling and commentary. Some of these *convention bounces* have been very short-lived, the race quickly reverting to its pre-convention level between the candidates. Others have been more profound—a coalescing of voter preferences that has charted the course for the remaining campaign.

While convention bounces have been apparent since 1968 (previous election polling was too infrequent for reliable identification of such bounces), focus on the convention bounce owes much to Bill Clinton, who soared from a dead heat against Republican presidential incumbent George H. W. Bush before the 1992 Democratic convention to nearly a 30-point lead after it. While the race later tightened, Clinton never again trailed in pre-election polls.

No bounce has matched Clinton's, but others are impressive in their own right. Jimmy Carter rode a 16-point bounce to a 33-point lead after the 1976 Democratic convention, lending authority to his challenge and underscoring incumbent Gerald Ford's weakness. Ford in turn mustered just a 7-point bump following the 1976 Republican convention; while the race tightened at the close, Carter's higher bounce foretold his ultimate victory.

If a solid and durable bounce suggests a candidate's strength, its absence can indicate the opposite. Neither Hubert Humphrey nor George McGovern took significant bounces out of their nominating conventions in 1968 and 1972, both en route to their losses to Richard Nixon.

Assessment

Standards for assessing the bounce differ. While it sometimes is reported among "likely voters," it is more meaningfully assessed among all registered voters, which is a more stable and more uniformly defined population. And the fullest picture can be drawn not by looking only at change in support for the new nominee, but—offense sometimes being the best defense in politics—at the change in the margin between the candidates, to include any drop in support for the opposing candidate. For example, the 1968 Republican convention did more to reduce Humphrey's support than to bolster Nixon's.

Timing can matter as well; surveys conducted closer to the beginning and end of each convention better isolate the effect. In 2004, Gallup polls figured John Kerry's bounce from a starting point measured 5 days before his convention began and assigned him a net loss of 5 points—its first negative bounce since McGovern's 32 years earlier. Using different timing, ABC News and *The Washington Post* started with a pre-convention measurement done 4 days later than Gallup's, and found an 8-point bounce in Kerry's favor, much nearer the norm.

Using the change in the margin, among registered voters, the average bounce has been 10 points in Gallup polls from 1968 through 2004 (and, for comparison, a similarly sized bounce of 13 points in ABC News polls from 1992 to 2004). While individual bounces vary, on average they have been consistent across a range of parameters: in Gallup data, 11 points for Democratic candidates (9 points leaving aside Clinton's 1992 bounce), 9 points for Republicans, 8 points for incumbents, 11 points for challengers, 10 points for better-known candidates (incumbent presidents and incumbent or former vice presidents), 10 points for less-known candidates, 12 points after each cycle's first convention, and 9 points after the second convention.

While the average size of the bounces by the candidate's political party are similar, more of the drama has been among Democratic candidates—a standard deviation of 10 in their bounces (8 without Clinton's in 1992) compared with 4 in the Republicans'. The average Democratic bounce correlates significantly with the average bounce overall, while the average Republican bounce does not.

Causes

The basis for the bounce seems clear: a specific candidate dominates political center stage for a week, laying out his or her vision, burnishing his or her credentials and—directly or through surrogates—criticizing his or her opponent. It takes a problematic candidate, an off-key convention, or an unusually immovable electorate not to turn the spotlight into support.

But exposure is not the sole cause; while airtime for network coverage of the conventions has declined sharply over the years, the bounces haven't. The two national conventions received a total of 73 hours of broadcast network coverage in 1968, declining sharply in ensuing years to a low of 6 hours in 2004 (as reported by Harold Stanley and Richard Niemi in *Vital Statistics on American Politics* 2003–2004). Audience ratings likewise dropped. Yet there is no significant relationship between hours of network coverage and size of convention bounces. Indeed, the largest bounce on record, Bill Clinton's in 1992, occurred in the modern era of less network news coverage—8 hours for his convention—while George McGovern's bounceless 1972 convention was one of the most heavily covered, at 37 hours.

A range of other factors may contribute to the bounce. Vice presidential running mates often are named during or shortly before conventions. Events outside the convention doors can play a role, such as the Chicago riots of 1968 or the on-again, off-again Ross Perot candidacy of 1992 (although data from that time indicate that Perot was more a casualty of Clinton's convention surge than its cause). Strength of support is another factor, informed by the level of political polarization or the extent of economic discontent heading into the convention season. And atop the heap stands the effectiveness of the individual candidates and their campaigns.

As to why there is more variability in Democratic bounces, causal influences may include the objective quality of individual candidates, a generally declining Democratic advantage in partisan self-identification across this period, and perhaps, more steadfast support among Republican self-identifiers for their party's nominees.

Whatever the other influences, presidential nominating conventions mark unique and highly fraught periods in the election cycle, when public attention focuses, candidates pass—or fail to clear—the basic bar of acceptability to a broader audience, and their support often undergoes its biggest swings of the contest.

The varying size of convention bounces suggests that they are founded on evaluative assessments, not simply the quantity of news coverage. The fact that some bounces fade rapidly while others endure similarly underscores the substance of what is occurring beneath the bright lights and balloons. A focusing of the public's attention may inspire the bounce, but a more deliberative judgment determines its size, staying power, and ultimate impact on Election Day.

Conversational Interviewing

Conversational interviewing is also known as "flexible" interviewing or "conversationally flexible" interviewing. These terms refer to an alternative style of survey interviewing that allows deviations from the norms of standardized interviewing. Under conversational interviewing procedures, interviewers are allowed to ask respondents if they did not understand a question and provide unscripted feedback to clarify the meaning of questions as necessary. Conversational interviewing represents an alternative set of techniques to standardized survey interviewing whereby interviewers are allowed to provide unscripted information to respondents in an effort to clarify question meaning.

Proponents of conversational interviewing techniques argue that standardized procedures may reduce the accuracy of survey responses because standardization precludes conversational interactions that may be required for respondents to understand some questions. A key distinction between standardized and conversational interviewing is that standardization requires the interpretation of questions to be accomplished entirely by respondents. A central tenet of standardized interviewing is that interviewers must always read questions, response options, and instructions to respondents exactly as they are scripted. Further definitions, clarifications, or probes can only be read in standardized interviews if these elements are included in the interview script. A second tenet of standardized interviewing is that any probes used by interviewers must be nondirective, so that the probes do not lead respondents to give particular answers. As a result, standardized interviewers can only provide clarification when respondents request it, and can then only provide standardized forms of assistance such as nondirective probes.

In conversational interviewing, interviewers can provide whatever information is needed to clarify question meaning for respondents, and they can provide these clarifying statements whenever they perceive respondents are having difficulty understanding a question. Proponents of conversational interviewing hypothesize that these more flexible techniques can produce more accurate survey responses by standardizing the *meaning* of questions, not the wording or exact procedures used to administer the questions. Because the same terms can have different meanings to different respondents, conversational interviewing may improve response accuracy by allowing unscripted exchanges between interviewers and respondents to clarify the meaning of specific terms. Based on this reasoning, conversational interviewing techniques are assumed to increase the accuracy of survey responses, particularly in those situations in which respondents cannot initially map the specific terms in a question to the relevant information they have to report.

Experimental studies have been conducted to assess whether more flexible conversational interviewing techniques could produce more accurate data than standardized procedures for some survey questions. In these experiments, respondent interviews were assigned either to a standardized condition in which interviewers were not allowed to deviate from the script or to a conversational condition in which interviewers were allowed to encourage respondents to ask questions if they did not understand and provide unscripted feedback to clarify the meaning of question terms.

Results of this research indicated that the two alternative interviewing procedures both produced nearly perfect accuracy when question concepts clearly mapped onto the situations respondents had to report. For example, respondents were asked about purchasing furniture, so those who had purchased items like tables and chairs could clearly map their situation onto the question concept and accurately answer this question with either interviewing procedure. In contrast, respondents who had purchased an item such as a lamp, for example, could not clearly answer the question about purchasing furniture. In interviews in which question concepts did not clearly match respondents' situations, conversational interviewing procedures increased response accuracy by nearly 60%. Additional research indicated that data from follow-up interviews using conversational techniques increased the accuracy of reports compared to an initial round of standardized interviews. In addition, respondents in this experiment were twice as likely to change their answers between a first standardized interview and a second conversational interview (22%) than between a first standardized interview and a second standardized interview (11%). The results of these experiments generally confirmed that conversational techniques led to greater response accuracy when ambiguity existed between the key concepts of the question and the information respondents had to report.

Successfully applying conversational interviewing techniques in social surveys remains limited by a few important considerations. First, research has not yet demonstrated whether large numbers of interviewers can be trained and supervised effectively to apply conversational techniques in a way that does not introduce other kinds of response bias. Research to date has involved only a small number of interviewers and a limited number of interviews in which interviewer training and procedures could be tightly controlled. A second limitation is that research has indicated conversational interviews improves response accuracy compared to standardized interviews only for questions in which considerable ambiguity exists. Most of the questions developed, tested, and implemented in various surveys are not subject to the same degree of ambiguity required to produce benefits from conversational techniques. Third, using conversational interviewing procedures increased the average interview length in experimental studies by 80% compared to administering the same set of questions with standardized techniques. Conversational interviewing may produce more accurate data than standardized interviewing for some survey items, but the more flexible interviewing conditions limit the number of survey items that can be asked in the same interview time.

COOPERATION

Cooperation is a term used by survey researchers that refers to the degree to which persons selected (sampled) to participate in research accept (agree to) their invitation and engage (cooperate) in the research process. The composition of the group under study is a fundamental (and vitally important) consideration in the design, execution, and interpretation of a survey. A researcher must both identify and collect information from an appropriate sample in order to successfully and validly answer the research question. Ideally, the rate of cooperation among those sampled will be very high.

Applied to a specific study, cooperation refers to the breadth of participation that researchers are able to elicit from those that they have chosen to study. To help objectively measure levels of cooperation within a study, the American Association for Public Opinion Research (AAPOR) developed a series of standard definitions that include how to define and compute cooperation rates. AAPOR's cooperation rates are mathematical formulae that reflect the proportion of respondents who actually participate in a survey divided by all of the sampled cases that are ever contacted, and are eligible, to participate in the survey.

Together with the response, refusal, and contact rates, the cooperation rate is included in a category of formulas collectively known as "outcome rates." These rates are calculated by survey researchers in order to better understand the performance of surveys. Methods sections of survey reports typically include at least some information regarding these rates.

Factors Affecting Cooperation

There is a wide body of literature regarding the theory, application, and relationship of the factors that affect cooperation. Examples of the major types of factors that can affect cooperation include the following:

- Level of effort used in recruiting respondents
- Respondents' interest in the topic of the survey
- Study's mode of data collection
- Skill of interviewers in interviewer-administered surveys
- Information given to respondent prior to his or her engaging in survey
- Length/burden of the survey

- Whether or not incentives are offered
- Characteristics of the population of interest

Cooperation in Random Samples

Statistical theory explains that data should be collected from all those selected for inclusion (sampled) in probabilistic samples. In practice, this is seldom achieved. Any individual who is selected but does not participate in a study is termed a "nonrespondent" and may (or may not) induce nonresponse bias. One possible scenario, for example, is that the data from a survey yielding poor cooperation levels may be heavily distorted if nonresponders differ systematically in nonnegligible ways from responders.

Although there is common agreement that general cooperation levels within the United States have been in a state of decline for years, many within the survey research community believe that poor cooperation levels have been overstated as a threat to validity in random samples. Nevertheless, cooperation continues to be viewed as one of the important indicators of the performance of a survey and is properly considered in the context of both the study's target population and variables of interest.

The term *cooperation* is strongly associated with probabilistic samples in quantitative surveys because of its connection to the validity of random samples. However, cooperation plays an important role in both quantitative and qualitative research.

Society and Cooperation

In its broadest sense, cooperation is often discussed in the context of the overall state, or health, of survey research. From this perspective, survey research professionals are concerned with how society perceives survey research as an activity or "enterprise." For example, an atmosphere of low cooperation in society may reflect dissatisfaction with research (or research techniques) among the public, which in turn, may result in legislation that restricts or inhibits survey and opinion research.

CMOR, the Council for Marketing and Opinion Research, operates to promote respondent cooperation and protect and promote government affairs on behalf of the survey research profession. CMOR stresses that a critical step in improving general respondent cooperation includes researchers universally adopting practices that foster a favorable relationship between research and the public. To this end, CMOR has published and encourages all researchers to adhere to the Respondent Bill of Rights. It also encourages members of the profession to use the same outcome rate calculations to ensure that there are consistent measures in the profession.

Cooperation Rate

The cooperation rate to a survey indicates the extent to which contacted individuals cooperate with a request to participate in a survey. It is often mistakenly reported or interpreted as the response rate. Generally, the cooperation rate is the ratio of all cases interviewed out of all eligible units ever contacted, whereas a response rate is the ratio of all cases interviewed out of all eligible sample units in the study, not just those contacted.

The American Association for Public Opinion Research (AAPOR), which has established a standard definition of the cooperation rate, offers at least four ways to calculate it. The numerator includes all completed interviews but may or may not include partial interviews. The denominator includes all eligible sample units that were contacted (including refusals and other non-interviews that may have been contacted), but may or may not include sample units that are incapable of cooperating (e.g., because of health or language barriers).

When reporting the cooperation rate, researchers should clearly define the rules for survey eligibility and explain how they decided to calculate the rate. The level at which the rate has been calculated (individual, household, school district, business, etc.) should be reported. Though cooperation rates are most often calculated using only contacts with known eligible respondents, if there is a screener, consumers of survey results might also want to know the percentage of people who cooperate with the screener in addition to the percentage of people who participated in the full survey.

One important variation in how the cooperation rate is calculated is whether contacted sample members with unknown eligibility are included in the denominator of the calculation. It is possible to include in the denominator an estimate of all eligible cases (or *e*, the proportion of cases with unknown eligibility assumed to be eligible), not just the cases confirmed as eligible.

A lower cooperation rate implies a lower response rate, raising concerns about the representativeness of the participating sample members. For example, Robert Groves and Mick Couper report that some research has shown that noncooperating sample members score lower on social engagement indices than do cooperating sample members. If measures of social engagement are important analytical variables, then a low cooperation rate may bias survey estimates.

The cooperation rate also has implications for survey costs, as it is an indicator of sample yield (i.e., the number of completed interviews achieved from a fixed number of sample units). The lower the cooperation rate, the more the effort needed to achieve a required number of completed interviews, whether that effort involves enlarging the sample, making additional contacts to sample members, training interviewers, or providing incentives to increase cooperation. For interviewer-administered surveys, the cooperation rate serves as one measure of the interviewer's success.

Survey organizations try to maximize the response rate by maximizing the cooperation rate (in addition to maximizing the contact rate, or the proportion of all sample members for which a person was reached). For instance, researchers may try to alter the sample members' predisposition toward survey participation by changing the nature of the initial contact to make the survey more appealing. Very often, cooperation is manipulated through advance mailings and through the interviewer. The issue of interviewer–respondent interaction and its influence on survey cooperation has received considerable attention in the recent literature on survey research, thus motivating survey organizations to focus on interviewer training. The training generally emphasizes avoiding refusals, tailoring the interview approach to sample members, and maintaining the interaction with sample members while on the telephone or at the doorstep. Evidence from studies of interviewer training and interviewer–respondent interactions suggests that tailoring and maintaining interaction are important to maximizing cooperation rates.

CORRELATION

Correlation is a statistical measure of the relationship, or association, between two or more variables. There are many different types of correlations, each of which measures particular statistical relationships among and between quantitative variables. Examples of different types of correlations include Pearson's correlation (sometimes called "product-moment correlation"), Spearman's correlation, Kendall's correlation, intraclass correlation, point-biserial correlation and others. The nature of the data (e.g., continuous versus dichotomous), the kind of information desired, and other factors can help determine the type of correlation measure that is most appropriate for a particular analysis.

The value of the correlation between any two variables is typically given by a correlation coefficient, which can take on any value between and including −1.00 (indicating a perfect negative relationship) up to and including +1.00 (indicating a perfect positive relationship). A positive correlation between two variables means that as the value of one variable increases, the value of the second variable tends to increase. A negative correlation means that as the value of one variable increases, the value of the second variable tends to decrease. A correlation that is equal to zero means that as one variable increases or decreases, the other does not exhibit a tendency to change at all.

One frequently used measure of correlation is Pearson's correlation; it measures the linearity of the relationship between two variables. The Pearson's correlation coefficient is calculated by dividing the covariance of two variables by the product of the standard deviation of each variable. That is, for n pairs of variables x and y, the value of the Pearson's correlation is

$$\frac{\sum_{i=1}^{n}[(x_i-\bar{x})\times(y_i-\bar{y})]}{n}\Bigg/\left(\sqrt{\frac{\sum_{i=1}^{n}(x_i-\bar{x})^2}{n}}\times\sqrt{\frac{\sum_{i=1}^{n}(y_i-\bar{y})^2}{n}}\right).$$

For instance, as part of a study on smokers' health and demographics, a survey researcher might collect data on smokers' annual household income and the average number of cigarettes smoked daily. The data for 10 smokers—sorted in ascending order of income—might look like Table 1.

In this case, simple inspection reveals that the correlation is negative. That is, as income increases, the average number of cigarettes smoked daily tends to decrease. The value of the Pearson's correlation between these variables equals –0.484, confirming that the relationship between the two variables is, in fact, negative and moderately linear. A scatter plot of these variables visually illustrates the nature of this relationship, as shown in Figure 1 (next page).

While correlation analysis describes one aspect of the quantitative relationship between variables, it certainly has its limitations. First, it cannot be used to infer the extent of a causal relationship. For example, the preceding example shows only that income and average number of cigarettes smoked daily for these 10 individuals are related in a negative, somewhat linear fashion.

Table 1 Cigarettes and income

Average Number of Cigarettes Smoked / Day	*Yearly Household Income (in $1,000s)*
10	28
30	31
5	45
25	46
22	48
12	55
4	57
13	62
4	62
8	77

It does not mean that increasing a smoker's income would cause a reduction in the number of cigarettes smoked or that smoking fewer cigarettes would cause an increase in an individual's income.

A second important limitation is that correlation analysis does not provide any information about the magnitude—or the size—of the relationship between variables. Two variables may be highly correlated, but the magnitude of the relationship might, in fact, be very small. For instance, the correlation of –0.484 between income and average number of cigarettes smoked daily in the example says only that the relationship is negative and that the relationship is somewhat linear. It does not provide any information regarding how many fewer cigarettes are related to an increase in income. That is, every extra dollar of income could be associated with a decrease in average number of cigarettes that is very large, very small, or anywhere in between.

COUNCIL FOR MARKETING AND OPINION RESEARCH (CMOR)

The Council for Marketing and Opinion Research (CMOR) is a national nonprofit organization founded to work on behalf of the marketing and opinion research industry in two key areas:

1. To improve respondent cooperation across all modes of survey data collection and focus groups
2. To promote positive state and federal legislation that affects marketing and opinion research, to monitor and prevent restrictive legislation that has the potential to impact research work, and to encourage self-regulation among the survey research profession

CMOR was founded in 1992 by four of the major marketing research trade associations: AMA (American Marketing Association), ARF (Advertising Research Foundation), CASRO (Council of American Survey and Research Organizations), and MRA (Marketing Research Association). These organizations believed that the two areas of focus—respondent cooperation and government affairs—were so critical to the research industry that a specialized industry group should be created to devote attention and solutions to these research issues.

CMOR is composed of more than 150 organizations that represent all facets of the research profession:

- Client companies (or end users of research)
- Full-service research companies
- Data collection companies
- Other associations in the profession
- Academic institutions
- Government entities
- Research-related services (such as sampling and software companies)

Organizational Structure

A volunteer board of directors and volunteer committee set CMOR's policy and vision and determine the direction of CMOR's initiatives. Members are drawn from all sectors of the research industry: full-service research firms, data collection companies, research analysts, and end users.

CMOR is structurally organized into two separate departments: Respondent Cooperation and Government

Affairs. Each department maintains a permanent volunteer committee in order to drive the organization's work. Additional committees are formed on an ad hoc basis. A professional staff person oversees both departments and acts as a liaison with counterparts in the other research organizations. Further, professional staffers are hired to head each department and support staff assist in implementing the initiatives.

Respondent Cooperation and Government Affairs are inextricably related due to government's influence, through legislation, over what methods for conducting research are deemed legal and how this may affect the validity of research and the ability of the researcher to achieve respondent cooperation. Conversely, Respondent Cooperation is partially a reflection of the public's perceptions and attitudes toward research, and it may play a very strong role in the types of legislation that are proposed and adopted as law.

Respondent Cooperation

With regard to respondent cooperation, CMOR's mission is to evaluate the public's perceptions of the research process, to measure the effects of alternative methods of improving respondent cooperation, and to provide a foundation upon which to build an improved set of industry guidelines. Since its formation, CMOR has worked to increase respondent cooperation and has advocated the importance and necessity of marketing and opinion research to the general public. Objectives related to respondent cooperation objectives include the following:

- Provide objective information about level of cooperation in surveys
- Monitor the ever-changing research environment
- Develop industry-accepted and -supported solutions to improve respondent relations
- Educate and develop training programs for our members and members of the research community about the issues affecting respondent cooperation and of CMOR's efforts to improve participation
- Educate the research community's external audiences, including the public, media, and businesses, about the value of research and their participation in legitimate research surveys and polls
- Promote the social utility and value of survey research
- Act quickly to provide guidance to our members and the research community about environmental issues that may affect cooperation

Government Affairs

In terms of government affairs, CMOR's mission is to monitor relevant legislative and regulatory activity, to ensure that the interests of the research community are protected, and to educate industry members regarding relevant legislative, statutory, and legislative issues. The following are among the objectives in this area:

- Monitor and respond to legislative and regulatory activities that affect the research industry
- Educate CMOR members and members of the research community about the legislative and regulatory measures that threaten research and of CMOR's efforts to protect the research industry
- Educate CMOR members and members of the research community about existing statutes and regulations that impact the research industry
- Educate lawmakers and policymakers about the value of research, the distinction between research and sales-related activities and the negative implications restrictive measures have on research
- Respond to abuses of the research process and work with lawmakers and government officials to regulate and prosecute such activities
- Act pro-actively on legislative and regulatory measures
- Build coalitions with other organizations to use as resources of information and to strengthen our ability to act on restrictive and proactive legislative and regulatory measures

Council of American Survey Research Organizations (CASRO)

The Council of American Survey Research Organizations (CASRO) is the national trade association for survey research businesses, whose 300-plus member companies (predominantly in the United States, but also in Canada, Mexico, and abroad) represent about 80% of the U.S. annual revenues in survey research businesses. Established in 1975, CASRO advances the business of research through standards, guidelines, professional development, and self-regulation in the process and performance of survey research. CASRO's mission is to provide the environment and leadership that will promote the profitable growth and best interests of those firms and other entities engaged in the survey research industry.

Standards and Guidelines

CASRO standards and guidelines provide mandatory and recommended processes and practices in survey research that ensure the quality and integrity of the survey research conducted by all CASRO members. CASRO's Code of Standards and Ethics for Survey Research, which is mandatory for all members, describes its members' responsibilities to respondents, to clients, and to the public. CASRO is the U.S. delegate (along with the American National Standards Institute) to the International Standards Organization's (ISO) planned development of a quality standard for market, opinion, and social research.

Professional Development

CASRO University is a professional development curriculum that provides certificates in Survey Research Practice, Business Management, Project Management, and Privacy Management. CASRO University includes an annual series of conferences, workshops, Webcasts, and other professional development and educational programs that contribute to the career development of survey researchers. CASRO and CASRO University work in cooperation with academic programs as well, including the graduate degree programs in survey research at the University of Georgia (Athens), University of Texas (Arlington), University of Wisconsin (Madison), Southern Illinois University (Edwardsville), and the Market Research Institute International (MRII). CASRO Financial Reports include annual Financial and Compensation Surveys, as well as an annual Data Collection Survey.

Self-Regulation

The CASRO Government and Public Affairs (GPA) program monitors, lobbies as appropriate, and provides guidance on compliance with legislation and regulations that impact survey research. In addition, the CASRO GPA proactively protects professional survey research from abuses and misuses such as "SUGing" (selling under the guise of research) and "FRUGing" (fundraising under the guise of research). The mission of CASRO GPA is to promote continued self-regulation, to encourage and support professional accountability, and to foster and ensure public trust.

COVARIANCE

Covariance is a measure of association between two random variables. It has several applications in the design and analysis of surveys.

The covariance of two random variables, X and Y, is equal to the expected product of the deviations between the random variables and their means:

$$Cov(X,Y) = E[(X-\mu_X)(Y-\mu_Y)].$$

Under a design-based perspective to surveys, the sample inclusion indicators are random variables, and covariance is present when the probabilities of inclusion are correlated.

For a simple random sample of n units from a population of size N, the covariance between the means $\bar{x}$ and $\bar{y}$ is estimated as:

$$cov(\bar{x},\bar{y}) = \left(1-\frac{n}{N}\right)\frac{1}{n}\frac{1}{n-1}\sum_{i=1}^{n}(x_i-\bar{x})(y_i-\bar{y}).$$

This is equivalent to the variance formula when x_i and y_i are the same for each unit in the sample. For complex sample surveys, standard variance estimation techniques, such as Taylor series linearization, balanced repeated replication, or jackknife replication, can be used to compute covariance.

Covariance can be written as a function of the correlation $\rho(x,y)$:

$$cov(x,y) = \rho(x,y)var(x)var(y),$$

where var(x) and var(y) are the variances of x and y, respectively. The covariance of x and y is equal to zero when x and y are uncorrelated, as is the case when they are derived from two independent samples or from independent strata within the same sample. However, in many situations in sample surveys, the covariance is present and should not be ignored.

For example, suppose a nonresponse bias analysis is conducted to determine the impact of a low response rate on survey estimates. The bias in an estimate is

$$bias(y_R) = y_R - y,$$

where y_R is the estimate based on only the respondents and y is the estimate from the entire sample. The variance of the bias is

$$var(bias(y_R)) = var(y_R) + var(y) - 2 * cov(y_R, y).$$

In general, the variance of a linear combination of random variables, X_1 through X_n, is

$$Var\left(\sum_{i=1}^{n} a_i X_i\right) = \sum_i \sum_j a_i a_j Cov(X_i, X_j).$$

The percentage of females in the population is estimated as 48% based on only respondents but as 50% from the full sample, for a bias of -2%. Using the appropriate variance estimation method, the variances are found to be 1.2 for the estimate from respondents and 1.0 for the full sample, with a covariance of 0.9. Taking into consideration the correlation between estimates from the full sample and estimates from respondents only, the variance of the bias is 0.4 $(= 1.2 + 1.0 - (2^*0.9))$. Using a t-test to test the null hypothesis that the bias is equal to zero, the p-value is found to be < 0.001, indicating significant bias in the estimate of females. However, if the covariance term is ignored, the variance of the bias is calculated as 2.2, and the bias is no longer determined to be statistically significant.

Ignoring the covariance term leads to an overestimation of the variance of the difference of the estimates, given the two estimates are positively correlated. This result is important in other survey contexts, such as comparing estimates between two time periods for a longitudinal survey or from different subdomains involving clustering. Covariance also has several other applications in surveys, including intraclass correlations, goodness-of-fit tests in a regression analysis, and interviewer effects.

Coverage

The term *coverage*, as used in survey research, indicates how well the sampling units included in a particular sampling frame account for a survey's defined target population. If a sampling frame does not contain all the units in the target population, then there is undercoverage of the population. If the frame contains duplicate units or other units beyond those contained in the population, then there is overcoverage. Undercoverage and overcoverage do not necessarily mean there will be coverage error associated with the frame.

Overcoverage occurs when members of the survey population are erroneously included in the survey sampling frame more than once or are included erroneously. Noncoverage (including undercoverage) occurs when members of the targeted population are erroneously excluded from the survey sampling frame. The meaning of the term *noncoverage* is not the same as the meaning of *unit nonresponse*, which is the failure to obtain complete survey data because of issues such as noncontacts, refusals, lost questionnaires, and so on.

Both overcoverage and noncoverage can occur at several junctures during the survey process. For example, in population surveys in which the sample is selected in two or more stages to obtain estimates of persons within households, coverage errors may occur at any or all stages when creating the sampling frame of primary sampling units, during field listing of housing units, or when creating a household roster of persons within a given family. Noncoverage that occurs during field listing can result if members of the survey sample are excessively expensive to locate or are part of multi-unit structures, or if maps do not accurately display the sampling area. Survey coverage is affected by the amount of time that has lapsed between obtaining the information for constructing the frame, creating the frame, drawing the sample, and finally collecting the data by methods such as personal visit, telephone, mail, Web, or by abstracting records. Several months or years may have passed during this time period, and many changes may have occurred to the units in the initial sampling frame that will not be reflected in the final sample.

Noncoverage

Noncoverage can occur when sampling units are omitted or missing from the sampling frame. For example, a sampling frame of business establishments may omit newly created businesses, or an administrative system may exclude units that failed to submit reports, or newly constructed buildings may be omitted from a housing survey. This will result in an incomplete frame from which the sample is drawn. Biases in the resulting survey estimates can occur when it is incorrectly assumed that the frame is complete or that the missing units are similar to those included in the frame, if units are actually known to be missing from the sampling frame.

A special case of noncoverage can be attributed to sampling units that are misclassified with respect to key variables of interest, such as a person's race-ethnicity or a household's vacancy status. When these key variables are missing, the sampling units cannot be properly classified in order to determine their eligibility status for the survey. In population household surveys, groups such as homeless persons or constant travelers are generally excluded from coverage. Special procedures may be necessary to account for these groups to prevent understating these populations in the survey estimates. Alternatively, if this is not feasible, it is important that published survey results document the limitations in coverage and possible errors in the survey estimates associated with imperfect coverage.

Overcoverage

Overcoverage can occur when the relationship between sampling units is not properly identified, resulting in duplicate or erroneous entries on the sampling frame. For instance, use of lists to develop the survey sampling frame might overlook events such as business mergers or changes in a facility's ownership. When the survey sampling frame is created by merging several lists, consistent identifiers for each sampling unit are essential in order to discard duplicate entries. (In practice this is very difficult to institute, and sometimes it even may require manual labor to purge all true duplicates from frames.) Potential overcoverage also occurs when sampling units cannot be identified as out of scope and are subsequently included in the survey sampling frames. Another example is in agricultural surveys, when using small grids for selecting samples of crops tends to introduce overcoverage, since many plants appear on the borderline area and field workers tend to include them; thus larger grids with smaller proportions of borderline areas are preferable for creating the survey sampling frame.

When there is overcoverage in the sampling frame due to the inclusion of out-of-scope cases, these cases may be in the sample and coded as missing during the weighting or imputation processes, if it is not possible to obtain information about them a priori so they can be excluded from the sample. This can occur in establishment surveys in which nonrespondents may be assumed to be eligible sampling units when, for instance, the establishment is no longer in operation.

Overcoverage occurs less frequently in most household surveys than noncoverage.

Solutions to Coverage Problems

It is important to routinely assess and measure survey coverage to evaluate survey quality and to improve sampling frames. For surveys in which the sample is selected in two or more stages, administering coverage rules that uniquely associate persons with households or businesses within multi-unit corporations are essential to counter both overcoverage and noncoverage. Proper training is important to verify that these rules are understood by field staff who perform tasks such as survey listing, interviewing, and providing oversight of data collection.

Typical methods to reduce or minimize coverage problems include the use of pilot tests to assess coverage; the use of multiple frames during frame construction, such as a list frame along with an area frame; the use of weighting adjustments to reduce the bias resulting from coverage errors; and truncation of the sampling frame. Pilot tests are useful for uncovering unexpected deficits in coverage and allow for survey plans to be modified in various ways.

The use of multiple frames can increase chances of selection for target population elements. To address the problem of identifying duplicate entries, one simple method is designating a principal frame for sample selection and supplementing by a frame that provides better coverage for elements that are unlikely or absent from the principal frame. This approach is taken by the U.S. Bureau of the Census, which supplements its area sampling frame (that was constructed from census information) with a list of permits for residential units built after the decennial census.

Weighting adjustments usually involve benchmarking to appropriate administrative data, so that sample estimates agree with nationally known estimates. Numerous household surveys, such as the National Survey of Family Growth in the United States, use census data in this manner.

Truncation of certain sampling units within the sampling frame is a typical compromise. The decision to truncate is made because specific sample cases, such as unregulated or smaller businesses in establishment surveys, are difficult to list. This action can help considerably to reduce both coverage problems and the cost of the survey, for example, when removal of the smaller businesses has a trivial impact on the final survey estimates. Estimates for the sampling units removed from the sampling frame may be obtained through synthetic estimation techniques, in which survey estimates are benchmarked to subgroups of the target population.

Coverage Error

Coverage error is a bias in a statistic that occurs when the target population does not coincide with the population actually sampled. The source of the coverage error may be an inadequate sampling frame or flaws in the implementation of the data collection. Coverage error results because of undercoverage and overcoverage. Undercoverage occurs when members of the target population are excluded. Overcoverage occurs when units are included erroneously. The net coverage error is the difference between the undercoverage and the overcoverage.

Bias in Descriptive and Analytical Statistics

Both undercoverage and overcoverage are biases and therefore may distort inferences based on descriptive or analytical statistics. Weaknesses in the sampling frame or the survey implementation create coverage error by compromising the random selection and thus how representative of the target population is the resulting sample. This is particularly the case if the cause of the coverage error is correlated with the characteristics being measured.

The amount of bias in descriptive statistics, such as means and totals, from undercoverage depends on the proportion of the population not covered and whether the characteristics of individuals not covered differ from those who are. If those not covered are merely a simple random sample of the population, then means will not be biased, although totals may be. For example, when estimating the mean, excluding individuals in the target population will not bias the mean if the mean of those covered equals the mean of those not covered. However, usually the exclusion of individuals is not random. More often, the excluded individuals are difficult to identify and to contact for interviews because of their characteristics. For example, a telephone survey measuring income would exclude individuals with low incomes who could not afford a telephone.

Coverage error also may affect analytical statistics, such as regression coefficients. The amount of bias in a regression coefficient from undercoverage depends on the ratio of the dependent variable's variance in the target population to that in the covered population and the quality of the fit of the regression model in the target population. If the variance of the dependent variable in the covered population is lower than the variance in the target population, the measured regression coefficient will be too small. In the telephone survey mentioned previously, the exclusion of low-income individuals would reduce the variance of income in the sampled population to be lower than in the target population. The effect on the regression coefficient is diminished when the fit of the regression model is very good in the target population.

Overcoverage also may create a bias in both descriptive and analytical statistics. The mechanism creating the bias when inappropriate or duplicate units are included mirrors the mechanism when appropriate units are excluded. The amount of bias in descriptive statistics from overcoverage depends on the proportion of the population sampled that is inappropriate and whether the characteristics of the inappropriate units differ from those in the target population. The amount of bias in a regression coefficient from overcoverage depends on the ratio of the dependent variable's variance in the target population to that in the population sampled and the quality of the fit of the regression model in the target population. Inappropriate units may cause the variance of the dependent variable to be larger or smaller than its variance in the target population.

Causes of Coverage Error

Coverage error may occur at the outset of a survey, in the sampling frame, or in the course of the survey, in the data collection. Ideally every member of the population is attached to one and only one listing record on the sampling frame. However, an exact one-to-one correspondence between population units and frame listings is often hard to find in practice. Either the frame fails to include some members of the target population, or it includes other units that are not eligible, or both.

One way to deal with a frame that is incomplete is to supplement it with a special frame or frames for the units that are not covered, resulting in what is known as a "multiple-frame" survey. For example, the researcher may have a list of all the large stores but not the small stores. Adding an area frame for sampling the small stores may be a solution to the undercoverage from the list frame.

Blanks or listings that are not members of the target population may be a problem with a sampling frame. More listings than members of the target population on a frame create overcoverage. The optimal solution for a frame with listings that are blank or not in the target population is to remove them before selecting the sample. When blanks and nonmembers can be identified during sample selection, one remedy to overcoverage is to reject such units when selected and draw another unit at random to attain the desired sample size.

Clustering of several population members into one unit on a frame may be a source of coverage error. One listing on the frame may be tied to more than one unit in the population. There are different ways that researchers still can work with the frame. One option is to take the whole cluster into the sample. The other option is to subsample within the cluster and make a weight adjustment in the estimation. For example, if the researcher wanted to interview adults but had a frame of households (e.g., in a random-digit dialing [RDD] telephone survey), the interviewer could list all the adult members of the household and then choose one member at random to interview instead of interviewing all the adults.

Multiple listings of the same individual may cause a coverage problem. When one individual in the population is attached to more than one unit on the frame, the researcher has two ways to address this problem. One is to remove the duplicate listings in the frame before selecting the sample. However, removing the duplicate listings prior to sample selection may not be practical. If the number of listings an individual has on the frame can be determined during the interview, there is another option. This option accounts for the individual's increased selection probability by weighting the unit in estimation by $1/k$ where k equals the number of times the population unit occurs on the list (such as when a person can be reached by more than one telephone number in an RDD survey).

Coverage error also may arise during the course of data collection. Interviewers need specific instructions about how to define the target population and sample unit. Otherwise, they may exclude members of the target population or include some who are not in the target population. Even experienced interviewers may have difficulties when faced with complicated situations. For example, whether a commercial structure at an address contains residential living quarters is not always clear. A business may have an apartment at the back or upstairs that is not obvious from the street. Also, an interviewer in a household survey may have to deal with ambiguities about the members of a household because a person may stay with the household only some of the time.

Longitudinal surveys that interview a sample periodically over a period of years have the potential for coverage error due to attrition, in addition to coverage concerns at the time of the initial sample selection. One approach is to estimate the attrition rate and then draw an initial sample large enough to produce a desired sample size at the end. Adjustments for the attrition may be made in the estimation.

Avoiding Coverage Error by Design

Minimizing coverage error is a major consideration when designing the survey. The measurement unit, the frame selection, and data collection and processing may contribute to coverage error if not designed properly. The researcher has to weigh many things when choosing a frame. First the list has to be available or feasible to use for sample selection. The units on the list have to be clearly defined. The extent of the coverage of the target population has to be assessed. The accuracy and completeness of the information on the list is important to assess whether the survey can be implemented without causing coverage error. Also, the amount and quality of auxiliary information on the list has to weigh on whether it will be helpful in the analysis of the data collected.

There may be more than one way to define the target population. The researcher has to assess the potential for coverage error for each way. For example, in medical expense audits, the researcher has to decide whether the units will be patients or visits to the doctor's office. In studies of income, the researcher has to decide whether the unit for measurement will be households or persons.

When selecting the units for measurement, the researcher has to be sure that those selected can answer the questions required to achieve the goals of the research. For example, using visits to doctors' offices instead of individual patients may not portray total medical expenses accurately. Also, using persons instead of households may skew the estimates of total disposable income.

Measurement of Coverage Error

Measuring coverage error is often difficult because an auxiliary data source for the target population is required. Estimates of coverage error generally cannot be made with the data collected for the survey. When a suitable auxiliary data source is available, statistics estimated with survey data may be compared to statistics estimated with the auxiliary data. Although the auxiliary data source may be available for only some of the characteristics the survey measures, such a comparison provides guidance regarding coverage error.

When using an auxiliary source for estimating coverage error, the researcher also has to be concerned about the coverage error in the auxiliary source. Even a census, which is often used to judge whether coverage error exists, may have coverage error itself. For the U.S. Population Census in 2000, two different methods estimated coverage error. Both found the net coverage error for the population overall to be very close to zero, but also found that the net coverage error rate was not uniform across the population. To illustrate the differential coverage error within groups, both methods estimated undercoverage for black males and overcoverage for nonblack females.

Compensating for Coverage Error

When auxiliary data are available for the target population, the researcher may use an adjustment to correct for coverage error. The method is a weight adjustment applied after the data are collected as opposed to corrections to the frame or methods applied during data collection to improve coverage.

A weight adjustment similar to post-stratification compensates for undercoverage, although it is sometimes used to compensate for unit nonresponse or to reduce sampling variance. After the data are collected, the sample is separated into groups for which known population totals are available and for which there may be differential coverage error. Within each group, one weighting component is applied to each member of the group. The weight for individuals in the sample equals its known group total divided by the group total estimated from the survey. The known group total may come from a census, administrative records, or other auxiliary source.

When two or more sets of marginal distributions are known, a procedure known as "raking" can be used to form the weighting adjustments in a similar way, so that estimated marginal distributions from the survey agree with each set of known marginal distributions.

Coverage Error in Surveys Using Area Frames

An area frame is constructed by dividing the geographic area of interest into mutually disjoint sections.

These sections are the units for sampling and may be areas such as counties, blocks, or districts defined for the purposes of the survey. In addition to selecting samples of housing units, area frames are often used to survey crops, wildlife, and business establishments. Area frames may be used for other topics such as a survey of school children when school districts are sample units. For example, in a multi-stage sample design, school districts could be the first-stage sample unit with the schools and students as the second- and third-stage sample units, respectively.

Area frames can have unique coverage problems when the boundaries for the sample units are ambiguous. An interviewer may have difficulty in determining whether a member of the target population is in the geographic unit selected for the sample. A tendency to include population members when the boundaries are unclear may lead to overcoverage, while the tendency to exclude members when the boundaries are uncertain may result in undercoverage.

Coverage Error in Household Surveys

The different types of household surveys have both shared concerns and unique concerns about coverage error from their frames and sampling within households for each type of survey.

In surveys of households, researchers have to be concerned not only about coverage of households but also about coverage within households (i.e., possible within-unit coverage error). Whether the survey collects data for all the household members or just some, coverage errors may occur through the interview. If the survey collects data for every member of the household, determining whom to include may be difficult because some people may have a tenuous attachment to the household.

If a survey targets only one member of the household, always interviewing the person who answers the telephone or the door may cause coverage error. Many households have one member who usually does these activities. If so, the other members of the household essentially have a zero probability of selection, which would lead to undercoverage at the person level. To achieve a random sample of respondents, the interviewers need a method for sampling within the household, which may be as simple as asking to speak to the household member with the next birthday.

Movers may be a source of coverage error, even though the frame is perfect and the sample selection and interviewing methods are perfectly designed to produce a random sample of the population. Movers may have a higher probability of selection because they may have the opportunity to be included twice, once at the old residence and once at the new residence. A survey with a long data collection period may be more vulnerable to problems with movers than one in which there is a short data collection period. Also, movers may practically have a zero probability of being selected if they are in transit while the survey is being conducted because they will be missed at both the old residence and the new residence.

People with multiple residences also may be a source of coverage error. Multiple residences are often hard to detect during interviews because some respondents tend not to report the second residence. Designing questions that allow interviewers to determine a respondent's primary residence accurately is challenging because the patterns of alternating between the residences are not uniform. Some people maintain two or more homes in different parts of the country and stay at each one several months at a time. Others commute weekly between cities, having a family home in one city and an apartment in the city where they work. These situations may cause some people to have an increased probability of selection because they would be interviewed if either of their homes were selected for the sample. Others may practically have a zero probability of selection because they would always be considered to live at the residence other than where an interviewer finds them. Interviewers need specific definitions for determining where a person lives to avoid introducing coverage errors.

Typical modes for conducting household surveys are mail, face-to-face, or telephone. Although the Internet is a fast mode of communication, no frame exists for email addresses that will provide a random sample of those who have email addresses. Of course, if such a frame existed, it would not cover those who do not have email addresses. Sometimes researchers use the Internet to gather data. In these cases, the respondents are recruited by another means that does provide a random sample and then merely convey their responses over the Internet.

Unique Coverage Error Concerns

Mail surveys use address lists as frames. A frame currently in use in the United States for mail surveys of households is the list of all the addresses where the

U.S. Postal Service delivers mail. Researchers may purchase the list from the U.S. Postal Service. No addresses are withheld if the purpose is research, although residents can request their address not be released for marketing purposes. However, such a list may have coverage problems because not every household receives mail at their houses. In addition, some people have multiple homes and thereby have a higher selection probability.

Face-to-face surveys use address lists or area frames composed of geographic areas such as blocks. When geographic areas are used for the frame, typically a list of the housing units is made in the selected areas before the interviewing begins. An interviewer starts at a particular point and proceeds around the block in the clockwise (or counterclockwise) direction, listing addresses until arriving back at the starting point. If some time has elapsed between the listing and the sample selection, new addresses may have appeared on the block. A method known as the "half-open interval" allows these new units to be linked to a unit already on the frame of addresses. When a new unit would have been listed after an address selected for the sample, the interviewer conducts an interview at the new unit in addition to the unit in the sample. The half-open interval method does not help with duplicate listings or addresses on the list for units that have been demolished or even moved, which may happen with mobile homes.

For telephone surveys of households, telephone books are not suitable for a frame because unlisted numbers, substantial in some states, are excluded. In addition, more and more people use only a cellular (mobile) telephone, and in the United States and some other countries those numbers are not included in telephone books. The method called "random-digit dialing" (RDD), which is used most often to obtain a random sample, starts with the 6-digit area code and prefix combinations that contain working residential numbers and generates telephone numbers randomly. Identifying the first 8 digits in telephone numbers with a pre-specified minimum number of telephone numbers that are listed creates the frame. In the United States, the creation of the sample starts by selecting the first 8 digits of the telephone number and then randomly generating the last 2 digits to create a 10-digit telephone number. Choosing the pre-specified minimum has to balance the trade-offs of avoiding the cost of dialing a large number of nonresidential numbers but including as many residential numbers as possible on the frame. The first 6 digits of working cellular (mobile) telephone numbers also are available in some countries.

In the United States, undercoverage from an RDD survey is possible because some telephone number banks defined by their first 8 digits will have fewer than the minimum number of listed numbers specified by the sampling design, thus giving any household in these banks a zero probability of selection. If cellular telephone numbers are excluded because of the expense, undercoverage of households that use only cellular telephones will occur. Overcoverage may also occur because many residences have more than one telephone line. To account for multiple lines, the interviewer needs to ask how many lines there are in the home. Since some lines are never answered because they are restricted to fax machines or modems, the interviewers also need to ask how many of the lines are answered. If there are k lines answered, the household's increased selection probability may be addressed by weighting the household in estimation by $1/k$, the correction for multiple listings on a frame.

One way researchers attempt to cope with the difficulty of avoiding coverage error is to recruit a group of people who agree to respond several times during a period of time, say, a year. This method usually attempts to match demographic and geographic distributions. If the recruiting is based on a random sample, then this method may be effective. However, if the recruiting is not based on random sampling, then there may be coverage error.

Coverage Error in Surveys of Events

Some surveys seek to inquire about events. There are no lists of some types of events, such as pregnancies, purchase or service of a particular product, or listening to a radio station. Some events, such as births, are recorded, but a list of such events may not be available to survey researchers for privacy reasons. The survey researcher has to rely on another type of frame to arrive at a sample of these events. Often household frames are used to sample for events. The respondents are asked if anyone in the household experienced the event during a given time period, such as within the past month. If the event is unusual, the cost of screening to find people who have experienced the event may be substantial.

Opportunities for coverage error are present because a respondent who has experienced the event may not remember exactly when it happened. The recall problem may lead to reports of events that happened prior (i.e., telescoping) to the time period or failing to report events within the time period. Undercoverage also may happen because the respondent for the screening questions may not know that the event happened to another member of the household.

Coverage Error in Establishment Surveys

Establishment surveys have their own unique sources of coverage error. Miscoding of industry, size, geographic location, or company structure may lead to frame errors that result in coverage error. The list frame may not be updated often enough to reflect the population corresponding to the survey reference period. Changes that make frames out of date include acquisitions, mergers, and growth in one line of business. In addition, the maintenance process for the list may not enter new businesses in the frame in a timely manner. Businesses that are no longer operating may remain on the list for some time after they close. There may be a delay in recording changes in a business that would cause its industry or size coding to change.

For the United States, Dun & Bradstreet has a list of businesses that is publicly available. These listings have addresses and telephone numbers. When a business has more than one location, researchers have to decide whether the target population is establishments or a more aggregated level within the company. The U.S. Census Bureau maintains its own list of businesses for its surveys, but the list is not available to the public.

Small businesses pose more difficult coverage error concerns because they are less stable than larger businesses. The process for forming the large lists is unable to keep up with the start-ups and failures in small businesses. Sometimes researchers use multiple-frame methodology that relies on a list frame and an area frame to reduce the potential for coverage error.

Cover Letter

A cover letter accompanies or transmits another document such as a survey questionnaire. Its purpose is to alert the respondent about the questionnaire it accompanies and to provide the details of requested actions on the part of the respondent. When used as a part of multiple communications or overall research strategy, such as an advanced contact or future reminder mailings, it can help increase response by conveying important information (e.g., research topic, survey sponsor, incentives) that is likely to influence a respondent's decision to cooperate and/or to comply fully and accurately with the survey task. As with all communications (including the questionnaire), the cover letter should be written in a way that maximizes the likelihood of participation and minimizes or eliminates any possible objectionable content.

Cover letters are an accepted and commonly used part of good survey design. There is a large amount of experimental research available on cover letter style, layout, elements, wording, and so on.

Style and Layout

Typically, a cover letter is brief (i.e., preferably one page), and it is best to print it on a formal letterhead.

Use of letterhead and stationery-quality paper speaks to the importance of the letter. Some cover letters are incorporated into a questionnaire's front cover or first page; but they usually are a separate (stand-alone) piece. When designing the cover letter text, the researcher should take into account the target population of the study and write to an educational level just below the average respondent's. For example, the language and vocabulary used in a cover letter to an organization or business or a survey of physicians or lawyers should differ from that of the general public. In writing the cover letter, one should make statements using an active voice.

The overall layout of the letter takes into consideration the chance that it will not be fully read by the respondent. One of the most important aspects is for the letter to be concise and to the point. Extensive and unneeded information will "crowd" the letter or give it a busy or daunting appearance. When composing the cover letter, one should evaluate whether information has been conveyed in other communications or on the questionnaire itself to eliminate overly redundant information, although some degree of redundancy is useful across various survey materials. The letter should incorporate the following stylistic features: (a) at least 1-inch margins on all sides, (b) indented paragraph–style, (c) either Times New Roman or Arial font, and (d) 11- or 12-point size font. There should be plenty of "white space" on the page so as to reduce respondent burden and increase the likelihood that the letter will be read.

The use of bold, underlined, or different color font can bring attention to critical pieces of information (e.g., "Once we receive your completed survey, we will send you **a $10.00 cash 'Thank You' gift**"), but should be used sparingly and for only the information most likely to increase cooperation. The style of all-capitalized font should not be used, or only minimally used, because some consider it to be "shouting" and it can be difficult to read.

Using sincere, polite wording also is highly recommended, such as the word *please* (e.g., "Please complete and return the questionnaire in the enclosed postage paid return envelope no later than May 31").

Elements

The elements listed following are used commonly in professional letters; they assume the use of common word processing and mail merge software. For specifics (i.e., number of lines between elements, left/center/right justification, etc.), see available letter or writing guides.

Date of Mailing

The date that the questionnaire is mailed is important to include. Giving no date or just month and year would be conspicuous and would fail to convey the timing of the request you are making to get the completed questionnaire returned.

Name of Addressee

Depending on the sample type and source, a name should be used to customize the letter whenever possible and appropriate. If the name of the addressee is from a third-party or matching service, it may be more beneficial not to use the name, because if the name is wrong (as it often is with matching services), the recipient may ignore the mailing even if the survey is of the residents of the mailed address, as opposed to a particular person at that address.

Address

Listing the address helps convey the personalization of the survey request. Be sure to include all relevant addressing elements to assist with accurate delivery; such as apartment number, lot, or unit number and the zip + 4 extension if available.

Salutation

The salutation greets the addressee by Dear [Mr. / Mrs. / Ms. surname]. Use of *Dear Sir* or *Dear Madam* is out of fashion. If the recipient's gender is unknown, use the full name, such as "Dear Chris Jones." If no name is available, and the survey is not one of named persons, then use a generic identifier, such as "Dear Health Survey Respondent" or even "Dear Resident."

Body of the Letter

The body of the cover letter, usually, is comprised of three to seven paragraphs and depends on the length or extent that each element is discussed. The elements of the body of the cover letter are as follows:

- *Survey Request.* The first paragraph of a cover letter serves as an introduction and conveys the key point or purpose of the mailing, that is, requesting that the respondent complete and return the enclosed questionnaire and identifying what organization is conducting the survey and why.

- *Importance of Participation.* This is a statement or even an appeal to the respondent of the importance of his or her cooperation in the research. This could include or separately state how the research results will benefit others.
- *Method of Selection.* A common concern for respondents is that they want to know how they were selected. The explanation should be worded appropriately, but succinctly, for the understanding by the target respondent (i.e., accurate but nontechnical). For example, for an RDD sample, "We used a computer to scientifically select your phone number and then compared it with publicly available records to match with this address."
- *Confidentiality.* Research has shown that including a statement of confidentiality can improve response rates. It is an ethical imperative that the researcher and sponsor organization adhere to this statement if it is pledged to a respondent.
- *Voluntary Participation.* Many research organizations or institutional review boards (IRBs) require that a statement be included to inform the respondent that their participation is voluntary.
- *Explanation of Incentive.* If an incentive is included or otherwise offered as a part of the survey, it should be mentioned in the cover letter. The researcher should consider carefully the type or amount of incentive and how it is referred to in the cover letter. A small cash incentive of a few dollars can be referred to as a "token of appreciation," consistent with social exchange theory; whereas a larger cash incentive may be referred to as a "payment for your participation" consistent with economic exchange theory.
- *Where to Get More Information.* Provide the respondent the ability to contact the researcher (i.e., mail, email, and/or toll-free telephone number).
- *Instructions for Return.* Provide any critical details about the questionnaire's return that the recipient needs or would like to know, for example, any specific instructions, return method (call-in, mail-in, and/or Internet), and the desired "return by" date.
- *Thank You.* Include a sincere sentence to thank the respondent or extend appreciation for their participation in advance of their giving it.

Complimentary Close

End the letter with a traditional close (first letter capitalized), such as, "Sincerely yours," "Yours sincerely," "Regards," "Best regards," and so on.

"Real" Signature

The complimentary close is followed by the signature, four lines down from the close, which states the writer's full name and below that her or his title. The use of an actual signature using ballpoint pen or blue ink digital signature has been found to raise response rates compared to no signature or a machine-imprinted signature. However, the use of an actual signature is judged to be impractical by most researchers when sample sizes are large. The actual (real) name of a person at the survey organization should be used, as it is unethical to use a fictitious name.

Postscript

Usually, a postscript ("P.S.") is read by the respondent. Careful consideration of what might or should be included in the postscript is important.

CRONBACH'S ALPHA

Cronbach's alpha is a statistic that measures the internal consistency among a set of survey items that (a) a researcher believes all measure the same construct, (b) are therefore correlated with each other, and (c) thus could be formed into some type of scale. It belongs to a wide range of reliability measures.

A reliability measure essentially tells the researcher whether a respondent would provide the same score on a variable if that variable were to be administered again (and again) to the same respondent. In survey research, the possibility of administering a certain scale twice to the same sample of respondents is quite small for many reasons: costs, timing of the research, reactivity of the cases, and so on. An alternative approach is to measure reliability in terms of internal consistency. Internal consistency would indicate that all of the items (variables) vary in the same direction and have a statistically meaningful level of correlation with each other. This can be done, for instance, using the so called split-half method. The most widespread approach, however, in the case of attitude and opinion scales, is to measure the coherence of the responses through the different items in order to discover which of the items are less correlated with the overall score: this is what item–total correlations do. A more sophisticated statistic that uses this same logic is Cronbach's alpha, which is calculated as follows:

$$\alpha = \frac{n\bar{r}}{1 + \bar{r}(n-1)},$$

where n represents the number of the items, and $\bar{r}$ is the average intercorrelation among them.

Cronbach's alpha ranges between 0 and 1. The greater the value of alpha, the more the scale is coherent and thus reliable (alpha is actually an approximation to the reliability coefficient). Some authors have proposed a critical value for alpha of 0.70, above which the researcher can be confident that the scale is reliable. The logic of this rule is that with an alpha of .70 or greater, essentially 50% (or more) of the variance is shared among the items being considered to be scaled together. Others have proposed the value of 0.75 or the stricter 0.80. If alpha is $\leq .70$, it is recommended that the scale be modified, for example, by deleting the least correlated item, until the critical value of 0.70 is finally reached or hopefully exceeded. The output of Statistical Package for the Social Sciences (SPSS) and other statistical packages used by survey researchers gives the researcher critical information on this issue, reporting the value of alpha if each of the items would be deleted. The researcher then deletes the item that, if removed, yields the highest alpha.

Since Cronbach's alpha tends to rise with the number of the items being considered for scaling, some researchers tend to solve the problem of its possible low value by building scales with numerous items. It has been noted that this praxis is often abused. In the end, a proliferation of items may yield a scale that annoys many respondents and can lead to dangerous respondent burden effects (e.g., yea-saying, false opinions, response set, satisficing).

A low value of alpha can have another explication, however. If the scale has a multi-dimensional structure (i.e., it contains more than one construct), in fact, alpha will usually be low. For this reason, alpha is not sufficient alone, because it is not a measure of unidimensionality, as some authors maintain. It would be helpful, then, before the calculation of alpha, to check for the unidimensionality of the scale through factor analysis. If two or more subsets (i.e., factors) of the scale are found, alpha should be calculated for each of the subsets separately. Therefore it is recommended that a factor analysis be conducted before calculating alpha even when alpha shows a high value, because the high value could be determined by a high correlation of the subsets, which could mask the multidimensionality of the scale. Note also that a scale can have a low value of alpha even when it is unidimensional: this can happen if there is a high random error across the data.

If alpha is negative—which is statistically possible but meaningless in interpretation—there is surely a problem in the orientation (direction) of the categories of at least some of the items being scaled. The researcher, then, has to be careful that the polarities of the items are set coherently with the concept or attitude to measure. If not, she or he needs to recode the items so that they all are scaled in the same direction.

A final matter to consider is the paradox of alpha as it approaches its maximum value (1.00). Were a scale to have an alpha of 1.00, that would mean that all items composing that scale are perfectly correlated with each other. It also would mean that any one of the items would measure the construct as well as any other of the items, and also that any one item would measure the construct as well as the entire multi-item scale. As such, if alpha values much exceed 0.90, a researcher should give consideration as to whether or not all of the items need to be measured (used) in subsequent surveys using the scale.

CROSSLEY, ARCHIBALD (1896–1985)

Archibald Maddock Crossley was born on December 7, 1896, in Fieldsboro, New Jersey. His love for the state of his birth carried him to Princeton University in 1917; he later worked for a small advertising firm based in Philadelphia. Crossley's research career began soon afterward, in 1918, when he was asked by an executive in his firm to create a research department, something he knew nothing about. Once the department was created, Crossley began work on "Crossley Rating," which many believe is the first ratings system. Using this rating, one could estimate the number of telephone subscribers tuned in to any radio show at any given time. Creating the ratings was no easy task, requiring various Crossley aides to thumb through telephone books covering more than 80 U.S. cities. From these telephone books, researchers were able to randomly call individuals and determine to what programs they were listening. For 16 years, people were asked one by one until May 1942, when Crossley's rating system was replaced with a simpler Hooper telephone poll. Even though Crossley's measure gave no indication about what people thought of a program, it was still used to get a sense of what programs people were listening to, which soon became synonymous with good and bad programming, similar to the Nielsen and Arbitron ratings systems of today.

Crossley's work in radio ratings served as a catalyst for other research endeavors, leading him to form Crossley, Inc., in 1926, a company that still operates today under the name Crossley Surveys, created in 1954 when Crossley, Inc., merged with another firm. During this time, Crossley collaborated with George Gallup and Elmo Roper and successfully predicted the 1936 presidential election, which was made infamous in public opinion circles after the *Literary Digest* incorrectly predicted Alfred Landon would defeat Franklin D. Roosevelt, an error that Crossley and others attributed to sample bias and the misanalysis of poll returns. This experience led Crossley to participate actively in the establishment of the Market Research Council, the National Council on Public Polls, and the American Association for Public Opinion Research, for which he served as president from 1952 to 1953.

During his academic career, Crossley concentrated on the psychology of questionnaires, focusing on how question wording could affect how the intensity of a given response is measured. This led him to crusade for ethics and professional polling standards at many different levels. This in turn led him to publicly admonish the Lyndon Johnson administration in 1967 for leaking a private Crossley poll to the press in an attempt to bolster Johnson's diminishing popularity. This emphasis on the importance of research and ethics some say is Crossley's most important contribution, since it frames the way social scientists think about their research and profession. Time and time again Crossley would remind his colleagues about the importance of using public opinion research to improve the human condition. Perhaps it is appropriate that Archibald Crossley passed away in his home in Princeton on May 1, 1985, since that is where he spent the majority of his professional life. However, even in memory Archibald Crossley serves as an important reminder to all social scientists about the potential of our research and the importance of our profession.

CROSS-SECTIONAL DATA

Cross-sectional data are data that are collected from participants at one point in time. Time is not considered one of the study variables in a cross-sectional research design. However, it is worth noting that in a cross-sectional study, all participants do not provide data at one exact moment. Even in one session, a participant will complete the questionnaire over some duration of time. Nonetheless, cross-sectional data are usually collected from respondents making up the sample within a relatively short time frame (field period). In a cross-sectional study, time is assumed to have random effect that produces only variance, not bias. In contrast, *time series data* or *longitudinal data* refers to data collected by following an individual respondent over a course of time.

The terms *cross-sectional design* and *cross-sectional survey* often are used interchangeably. Researchers typically use one-time cross-sectional survey studies to collect data that cannot be directly observed, but instead are self-reported, such as opinions, attitudes, values, and beliefs. The purpose often is to examine the characteristics of a population.

Cross-sectional data can be collected by self-administered questionnaires. Using these instruments, researchers may put a survey study together with one or more questionnaires measuring the target variable(s). A single-source cross-sectional design asks participants to provide all data about themselves with the questionnaire generally administered in a single session. A multi-source cross-sectional design gathers data from different sources, such as the sampled respondents, their supervisors, coworkers, and/or families, with different questionnaires administered to the different populations.

Cross-sectional data can also be collected by interviews. There are one-to-one interviews, panel interviews, and focus groups. In a one-to-one interview, a participant is questioned by one interviewer. In a panel interview, a participant is interviewed by a group of interviewers. In a focus group, a group of participants are simultaneously asked about their attitudes or opinions by a discussion leader or facilitator.

Cross-sectional data can be gathered from individuals, groups, organizations, countries, or other units of analysis. Because cross-sectional data are collected at one point in time, researchers typically use the data to determine the frequency distribution of certain behaviors, opinions, attitudes, or beliefs. Researchers generally use cross-sectional data to make comparisons between subgroups. Cross-sectional data can be highly efficient in testing the associations between two variables. These data are also useful in examining a research model that has been proposed on a theoretical basis. Advanced statistical tests, such as path analytic techniques, are required to test more complex associations among multiple variables. The biggest limitation of cross-section data is that they generally do not allow the testing of causal relationships, except when an experiment is embedded within a cross-sectional survey. Cross-sectional data are widely used in social science research. Some advantages in conducting cross-section studies include the following:

1. Research participants are usually more willing to cooperate in a one-time survey research study than a series of multiple surveys taken at different points in time.
2. Researchers do not need to worry about the attrition problems that often plague longitudinal studies, with some respondents not providing data at subsequent survey waves.
3. Researchers are able to collect cross-sectional data from multiple individuals, organizations, countries, or other entities.
4. Compared to longitudinal surveys, cross-sectional data are less expensive and less time consuming to gather.

However, there also are disadvantages with cross-sectional data. For example, cross-sectional data are not appropriate for examining changes over a period of time. Thus, to assess the stability of social or psychological constructs, longitudinal data are required.

Sociologists, in particular, made significant contributions to the early design and conduct of cross-sectional studies. One of the major contributors in cross-sectional design and the use of cross-sectional data was Paul Lazarsfeld. Leslie Kish made significant contributions about how to sample subjects from a target population for cross-sectional data.

Cross-Sectional Survey Design

A cross-sectional survey collects data to make inferences about a population of interest (universe) at one point in time. Cross-sectional surveys have been described as snapshots of the populations about which they gather data. Cross-sectional surveys may be repeated periodically; however, in a repeated cross-sectional survey, respondents to the survey at one point in time are not intentionally sampled again, although a respondent to one administration of the survey could be randomly selected for a subsequent one. Cross-sectional surveys can thus be contrasted with panel surveys, for which the individual respondents are followed over time. Panel surveys usually are conducted to measure change in the population being studied.

Types of Cross-Sectional Surveys

Cross-sectional surveys can be conducted using any mode of data collection, including telephone interviews in which landline telephones are called, telephone interviews in which cell phones are called, face-to-face interviews, mailed questionnaires, other self-administered questionnaires, electronic mail, Web data collection, or a mixture of data collection modes. A variety of sampling frames can also be used to select potential respondents for cross-sectional surveys: random-digit dialing frames, lists of addresses or (landline) telephone numbers, lists of cell phone numbers, lists of businesses or other establishments, and area probability frames. They may also use a multiple-frame approach to sampling.

Examples of cross-sectional surveys include the American Community Survey, the Decennial Census long form, and many political and opinion polls.

Design Considerations

The principles of cross-sectional survey design are those that one would normally think of for survey design in general. Designing a panel survey would be similar, except that provisions would need to be made in sampling, operations, and questionnaire design in light of the need to maintain contact with respondents and collect repeated measurements on variable of interest. Some of the considerations particular to panel surveys could apply to a cross-sectional survey that is to be repeated in the future.

The steps in designing a cross-sectional survey may be thought of as (a) conceptualization (or research design), (b) sample design, (c) questionnaire (or other data collection instrument) design, and (d) operations planning.

Conceptualization

Conceptualization includes the following:

1. Defining the study population
2. Formulating hypotheses, if any, to be tested
3. Defining the outcome (dependent) variables of interest and important classification or independent variables
4. Specifying levels of precision, such as standard errors, confidence intervals (“margins of error”), or statistical power
5. Deciding whether the survey will be repeated
6. Establishing cost limits
7. Specifying whether the nature of the data to be collected—cost or other considerations—requires a certain data collection mode

These components of the conceptualization process should define the parameters for decisions made later in the design phase, and of course can be interrelated. The researcher should also be aware that as the design progresses, some initial decisions may have to be revisited.

While the process of conceptualization occurs in designing a study, it may not always occur in a neat and orderly fashion. A researcher may be bidding in response to a request for a proposal (RFP) or have been approached by a client with a survey design in mind. In these cases, the decisions mentioned previously may have been made and not subject to much discussion, even if the researcher thinks the design could be improved considerably.

Sample Design

The sample design builds on the process of conceptualization. Steps in designing the sample include the following:

1. Selecting (or planning to construct) a sampling frame
2. Defining the strata, if any, to be employed
3. Deciding whether the sample is to be a single-stage, clustered, or multi-stage design, and
4. Determining the sample size

The sampling frame (or alternative frames) should provide adequate coverage of the study population. The nature of the frame may be determined by the study population itself, cost, or the nature of the data to be collected. In a clustered or multi-stage design, frames will be needed at each level of sample selection.

Stratification can be used to ensure proportionate representation or to allow oversampling. Multi-stage and clustered designs are usually used when the costs of data collection are high. The sample size required is a function of the parameters being estimated, the precision desired, and the expected effects on sampling error of stratification, oversampling, and clustering.

Questionnaire Design

The questionnaire design also flows from the conceptualization process. The questionnaire or other instrument translates the dependent and independent variables into specific measurements. Often, questions available from previous studies can be used or adapted; sometimes new items must be developed. Scales to measure attitudes or psychological constructs may be available from the survey research or psychological literature. New items will require cognitive testing and pretests. The form of the questions will depend in part on the mode of data collection: for example, show cards cannot be used in a telephone survey.

Other considerations in questionnaire design include the overall length of the instrument, skip patterns, and the possibility of question ordering effects.

Operations Planning

Operations planning will depend largely on the mode of data collection. Elements of the plan include staffing, scheduling, training, and monitoring.

Telephone and in-person surveys will require a staff of interviewers, supervisors, and perhaps others, such as coders, data entry personnel, and field listers. Programmers and perhaps other information systems (IS) personnel will also be needed. If the data collection is to be done by Web, or by computer-assisted telephone or in-person methods (CATI or CAPI), the IS team may play a larger role.

The schedule for the data collection can be driven by the immediacy of the needs for survey data. Relatively short data collection schedules are often called for. Cross-sectional data can be affected by seasonality and by events such as natural disasters, wars, terrorist attacks, or even something as mundane as an election or a sports event.

Training and quality control monitoring at all levels, especially of interviewers, can have a great impact on data quality.

Current Population Survey (CPS)

The Current Population Survey (CPS) is a nationally representative large-sample survey of households in the United States, conducted by the U.S. Census Bureau and cosponsored by the Bureau of Labor Statistics. The survey's chief purpose is to provide monthly labor force data, including estimates of employment and unemployment. The survey is also a rich source of data widely used by social scientists seeking descriptive population statistics about the United States. The CPS consists of a core monthly survey and special topic supplements. Each month's core survey includes demographic and employment questions. Periodic supplements cover a variety of additional topics including income, poverty, and health insurance (each March), school enrollment (each October), voting and voter registration (in November of even-numbered years), tobacco use, computer and Internet use, occupational mobility and job tenure, and other topics. Many survey methodologists and statisticians rely upon the CPS estimates as a benchmark to test the accuracy of other surveys and as a source of population statistics that form the basis for survey weights.

The CPS originated as the Sample Survey of Unemployment, administered by the Work Projects Administration in 1940. Responsibility for the survey was transferred to the Census Bureau in 1942, and revisions over the following years led the CPS to assume many of its current characteristics during the 1950s. A decades-long span of comparable measurements is available for many key operational measures. However, substantial changes were made to the CPS in 1994, including the introduction of computer-aided personal interviewing (CAPI) and computer-aided telephone interviewing (CATI) techniques.

The CPS sample consists of approximately 60,000 households each month. The survey respondent, or "reference person," provides information about each household member. Households remain in the sample for a period of 16 months and are surveyed during the first 4 months and the last 4 months of this period, with an 8-month intervening period during which they are not interviewed. One eighth of the sample is replaced with fresh sample each month, so during any given month's survey, one eighth of the sample is being interviewed for the first time, one eighth for the second time, and so on. This sample design is intended to promote continuity in month-to-month and year-to-year comparisons of estimates. In 2 consecutive months, six eighths of the sample is the same. In the same month in 2 consecutive years, half of the sample is the same. The first and last interviews are usually conducted by CAPI, and most intervening interviews are conducted by CATI.

Data collection takes place during the week containing the 19th day of the month, and questions refer to the week containing the 12th day of the month.

Response rates on the Current Population Survey have been very high. The unweighted response rate for the core monthly survey has been 90 to 93% in recent years. Response rates on the supplements are typically above 90% of those who completed the basic monthly survey, or 80 to 90% overall.

Like nearly all sample surveys of the general population, the CPS uses complex sampling procedures rather than simple random sampling. In the CPS sampling procedure, the United States is first divided geographically into approximately 2,000 primary sampling units (PSUs), which are grouped into approximately 800 strata. One PSU is chosen from within each stratum, with a probability proportional to the population of the PSU. This design dramatically reduces the cost of data collection, particularly by limiting the areas within which interviewers must travel. With this design, CPS sampling errors are somewhat larger than they would be under the impractical alternative of simple random sampling. This means that the classical approaches to hypothesis testing and the estimation of sampling error and confidence intervals (which assume simple random sampling) are not appropriate for CPS data, as these procedures would generally overstate the precision of the estimates and lead researchers to erroneously conclude that the difference between two estimates is statistically significant when it is not.

Perhaps the most widely reported estimate from the CPS is the unemployment rate. The unemployment rate measured by the CPS is the percentage of adults in the civilian labor force who are unemployed, able to work, and actively looking for work. This rate is an estimate based on a series of CPS questions about employment status and job-seeking activities. It is worth noting that the unemployment rate is not the percentage of adult Americans who are not working; that number would be lower than the unemployment rate, because the denominator in the rate is the subset of Americans who are in the labor force (i.e., those who are employed or unemployed, but excluding those who are retired or not working for other reasons). It is also notable that the sampling error in the CPS, though small, is still large enough that a month-to-month change of 0.2 percentage points or less in the unemployment rate (e.g., from 5.5% to 5.7%) is not statistically significant at the 95% confidence level. Also, like all surveys, CPS estimates are subject to nonsampling error, which should be a further reason for interpreting small differences cautiously even if they are statistically significant.

CUTOFF SAMPLING

Cutoff sampling is a sampling technique that is most often applied to highly skewed populations, such as business establishments that vary considerably in employee size, gross revenues, production volume, and so on. Data collected on establishment surveys (from businesses or other organizations, including farms) are often heavily skewed. For any variable of interest there would be a few large values, and more and more, smaller and smaller values. Therefore, most of the volume for a given data element (variable) would be covered by a small number of observations relative to the number of establishments in the universe of all such establishments. If a measure of size is used, say, number of employees or a measure of industrial capacity or some other appropriate measure, then the establishments can be ranked by that size measure. A cutoff sample would not depend upon randomization, but instead would generally select the largest establishments, those at or above a cutoff value for the chosen measure of size. This is the way cutoff sampling is generally defined, but the term has other interpretations. Four methods are discussed here.

Cutoff sampling is used in many surveys because of its cost-effectiveness. Accuracy concerns—for example, noncoverage bias from excluding part of the population—are different than in design-based sampling and are mentioned following. Note that cutoff sampling could be used for other than establishment surveys, but these are where it is generally most appropriate.

Of the following methods, the first two are probably more universally considered to be cutoff sampling:

> *Method 1.* Assign a probability of one for sample selection for any establishment with a measure of size at or above (or just above) a cutoff value, and a zero probability of selection for all establishments with a measure of size below (or at or below) that cutoff. No estimation is made for data not collected from establishments not in the sample.
>
> *Method 2.* In the second case, the same cutoff method is applied as in the first case, but estimation is made for the data not collected from establishments not in the sample.
>
> *Method 3.* A cutoff level is established, as in the first two cases, but some establishments below the cutoff are also included in the sample. This is often referred to as "take all" and "take some" stratification. An example would be a stratified random sample with a "certainty" stratum of which all members would be sampled.
>
> *Method 4.* Data may simply be collected starting with the largest establishment and through a size-ordered list of establishments until a certain point is reached by some measure or measures, possibly subjective.

Method 1 is simple and may minimize survey costs, and it may be of suitable accuracy under a couple of alternatives. First, if the main objective of a survey is to obtain information on unit prices, or some other ratio of totals, accuracy may not be a big problem. A unit price is actually the ratio of total cost to total volume of product. If each of these totals is underestimated by truncating part of the population, then the impact on the ratio of these two totals is not as adverse as it is to each of the two totals themselves. Another consideration, even for totals, may be that the data are so highly skewed that considering the smallest numbers to be zeroes may not cause an appreciable downward bias. Considering total survey error, if collecting data from more of the smallest establishments detracts from resources needed for better accuracy in collecting from the largest establishments, this may be undesirable. However, perhaps in most cases, the main impetus for Method 1 is cost-effectiveness.

Method 2 involves the use of secondary information in estimation. For example, data from administrative records may be substituted for the missing data for the excluded smaller establishments. Perhaps a better alternative would be regression model-based estimation, typically ratio estimation. This would allow for the estimation of standard errors for the totals or ratios of totals that are being estimated. To accomplish this, there must be regressor data available for every establishment, including those not in the sample. The measure of size may be one such regressor. Multiple regression may be desirable. A related method is the link relative estimator. That relates a given set of data collected between different time periods.

Method 3 is a stratified random sample design and may therefore make use of model-based, design-based, or model-assisted design-based methods, as appropriate. Estimation for Method 4 depends on the details of the application but is similar to Method 2.

For all four methods it is desirable that some thought be given to an indication of the total survey error. Cutoff sampling is often considered cost-effective, but it can also be more accurate than other alternatives if it helps to limit nonsampling error. It also generally reduces variance due to sampling error when using regression to "predict" for data not collected, but at the risk of an unknown bias. It may be argued that part of the population is not represented when a cutoff sample is applied. It is generally advisable that the likely volumes that will not be collected for key data elements should not be large compared to the inaccuracies that can be easily tolerated.

DATA MANAGEMENT

Longitudinal projects and other large surveys generate large, complex data files on thousands of persons that researchers must effectively manage. The preferred data management strategy for such large, complex survey research projects is an integrated database facility built around modern relational databases. If one is dealing with a relatively small, simple questionnaire, many carefully implemented methods for data collection and data management will work. What needs to be done for technologically complex surveys touches upon all the considerations that can be given to less complex survey data sets.

As the scale, scope, and complexity of a survey project grow, researchers need to plan carefully for the questionnaire, how the survey collects the data, the management of the data it produces, and making the resultant data readily available for analysis. For these steps to run smoothly and flow smoothly from one to the other, they need to be integrated. For these reasons, relational database management systems (RDBMS) are effective tools for achieving this integration. It is essential that the data file preserve the relationships among the various questions and among the questionnaire, respondent answers, the sampling structure, and respondent relationships. In birth cohort or household panel studies there are often complex relationships among persons from the same family structure or household. In longitudinal surveys there are also complex relationships among the answers in various waves that result from *pre-fills* (i.e., data carried forward) from previous surveys and bounded interviewing techniques that create event histories by integrating lines of inquiry over multiple rounds of interviewing. Failure to use an RDBMS strategy for a longitudinal survey can be considered a serious error that increases administrative costs, but not using RDBMS methods in large and complex cross-sectional surveys can be considered just as big an error.

Structure

Questionnaires often collect lists, or rosters, of people, employers, insurance plans, medical providers, and so on and then cycle through these lists asking sets of questions about each person, employer, insurance plan, or medical provider in the roster. These sets of related answers to survey questions constitute some of the tables of a larger relational database in which the connections among the tables are defined by the design of the questionnaire. One can think of each question in a survey as a row within a table, with a variety of attributes that are linked in a flexible manner with other tables. The attributes (or columns) within a question table would contain, at a minimum, the following:

- The question identifier and the title(s) associated with the variable representing the question's answer with the facility to connect the same question asked in

different sweeps or rounds of a longitudinal survey. This same facility is useful in repeated cross-sections.
- Descriptors that characterize or index the content of the question (alcohol use, income, etc.).
- The question text.
- A set of questions or check items that leads into the question (in practice this information is contained in the skip patterns of contingency questions).
- A set of allowable responses to the question and data specifications for these allowable responses (whether the answer is a date, time, integer, dollar value, textual response, or a numerical value assigned to a categorical response, such as 1 = Yes, 0 = No).
- For multi-lingual surveys, there would be separate tables for question text and pick-lists for each language. This greatly simplifies the preparation and management of different survey versions for different languages that share the same core structure.
- Routing instructions to the next question, including branching conditions driven by the response to the current question, or complex check items that are contingent on the response to the current question as well as previous responses.
- Real-time edit specifications imposed upon dates, currency amounts, and other numerical (i.e., non-pick-list) data, such as numerical values that require interviewer confirmation (soft range checks) or limits on permissible values (hard range checks).
- Pre-loaded values.
- Text fill specifications.
- Instructions to assist the interviewer and respondent in completing the question and/or show cards, audio files used for audio computer-assisted self-interviews.
- Date and time stamps for the question, indicators of multiple passes through the question, and time spent in the question (this preserves an audit trail for each step in the questionnaire).
- Archival comments about the accuracy or interpretation of the item or its source or "See also notes" referring the user to associated variables that are available to users in the data set.
- Notes to the support staff about complexities associated with the question to document the internal operation of the survey.
- Links to supporting documentation produced by the survey organization or, in the case of standard scales or psychometric items, a URL to more comprehensive documentation on the item.

These attributes of questions often are referred to as "metadata." With RDBMS methods these pieces of information that describe a question are automatically connected to the variables generated by that question. For example, metadata include which questions lead into a particular question and questions to which that question branches. These linkages define the flow of control or skip pattern in a questionnaire. With a sophisticated set of table definitions that describes virtually any questionnaire, one can "join" tables and rapidly create reports that are codebooks, questionnaires, and other traditional pieces of survey documentation. The questionnaire itself is not "programmed" but rather is formed by the successive display on the screen of the question's characteristics, with the next question determined either by direct branching or by the execution of internal check items that are themselves specified in the question records. Sequential queries to the instrument database display the questions using an executable that does not change across surveys but guides the interview process through successive question records.

By breaking down the survey into a sequence of discrete transactions (questions, check items, looping instructions, data storage commands, etc.) stored in a relational database, with each transaction being a row in a database table and the table having a set of attributes as defined in the relational database, one can efficiently manage survey content, survey data, data documentation, and even public user data extraction from a single integrated database structure.

Web Integration

When the tools that reference the master database are Web enabled, staff at any field organization in the world can access this resource and share it. Access control and security measures are necessary, of course. Some users can be given access to some parts of the data set with varying read/write permissions. One person might only be able to edit database fields related to documentation and so on.

When the data capture system is built for the Web, multi-modal surveys on the Web (including cell phone Internet connections), computer-assisted telephone interview (CATI), or computer-assisted personal interviewing (CAPI) become simple to execute. (CAPI is done either by putting a client and server on the laptop or tapping into the cellular network with a wireless modem and using the Web.) The organizations involved in survey data collection are increasingly keen on multi-modal surveys in order to accommodate difficult users who have very particular preferences about how they want to do the interview. This technology meets that need.

Software

Relational database software is a major software industry segment, with vendors such as Oracle, Sybase, IBM, and Microsoft offering competitive products. Many commercial applications use relational database systems (inventory control; accounting systems; Web-based retailing; administrative records systems in hospitals, welfare agencies, and so forth, to mention a few), so social scientists can piggyback on a mature software market. Seen in the context of relational databases, some of the suggested standards for codebooks and for documenting survey data, such as the data documentation initiative (DDI), are similar to relational database designs but fail to use these existing professional tool sets and their standard programming conventions. Superimposing a DDI structure for documentation also fails to make an organic connection among the management of the instrument, management of the data, and the dissemination of the data. Rather than including the questionnaire specification in an RDBMS at the outset, the DDI approach requires the instrument to be retrofitted into DDI form with additional labor time and its attendant costs and fails to exploit the economies of scope RDBMS methods provide.

Either one plans for survey complexity at the outset of the effort or one retrofits the data from the field into an RDBMS, which amounts to paying for the same work twice or three times because of all the steps taken to manage these projects. For example, the designers must write down the questionnaire specifications. This sounds simple, but it is virtually always the case that the document the design team produces does not cover every contingency that can occur and where the instrument must branch in that case. For example, one needs to specify not only what is to happen if the respondent refuses to answer each question or says, "I don't know"; one must also decide how to handle any internal check item that encounters an answer with an item nonresponse. This means the questionnaire programmer needs to go back and forth with the design team to ensure the instrument is faithful to their intentions. Once designed, the instrument must be tested, and one needs a testing protocol that can test out the many pathways through the instrument, especially the unintended pathways. After the data are collected, they come back to the central office, but in what form? How are these data documented? How are the data checked during the field period to intercept serious problems before they affect too many cases? And then how are the data relayed to the documentation system? Every time the data or instrument changes hands, misunderstandings and errors are likely to occur. The best protection against this sort of human error is to keep a single integrated archival system that every step of the process references and uses.

The primary data collector has several data management choices:

1. Design the entire data collection strategy around a relational database that integrates with the design and testing process and also integrates with the data dissemination and documentation process that generates exports to SAS, Statistical Package for the Social Sciences (SPSS), STATA, and so on.
2. Take questionnaire specifications and program the instrument into some system, iteratively test and correct, migrate the post-field data and instrument information into a relational database for archiving, and then release the data in ASCII with documentation materials developed and maintained separately. One would produce control commands that allow SAS, SPSS, STATA, or a similar package to read the ASCII data. Alternatively, the data could be released as SAS, SPSS, or STATA system files accepting the very limited documentation tools they provide.
3. Follow #2, but without a relational database as the archival tool and try to manage the linkages with some other system, possibly a statistical software package that strips out most of the metadata implicitly present in the data capture software.

SAS, SPSS, and STATA are effective statistical packages, and one can move data among them with a package like STATA's Stat/Transfer. Statistical packages are themselves starting to incorporate relational database features. For example, SAS supports standard query language (SQL) queries to relational databases, and it also connects to relational databases. This means that building the project architecture around an RDBMS is entirely consistent with the use of established statistical packages for a wide variety of analytic and survey support activities. The trend for many years has been toward relational databases to manage databases. These tools were originally focused on large enterprise-level data management problems, but their strengths have led to their diffusion to a wider array of applications. When setting up large survey research projects, social scientists may benefit from building their data management strategies and staff resources around relational database management systems.

Data Swapping

Data swapping, first introduced by Tore Dalenius and Steven Reiss in the late 1970s, is a perturbation method used for statistical disclosure control. The objective of data swapping is to reduce the risk that anyone can identify a respondent and his or her responses to questionnaire items by examining publicly released microdata or tables while preserving the amount of data and its usefulness.

In general, the data swapping approach is implemented by creating pairs of records with similar attributes and then interchanging identifying or sensitive data values among the pairs. For a simplistic example, suppose two survey respondents form a "swapping pair" by having the same age. Suppose income categories are highly identifiable and are swapped to reduce the chance of data disclosure. The first respondent makes between \$50,000 and \$60,000 annually, and the other makes between \$40,000 and \$50,000. After swapping, the first respondent is assigned the income category of \$40,000 to \$50,000, and the second respondent is assigned \$50,000 to \$60,000.

One benefit of data swapping is that it maintains the unweighted univariate distribution of each variable that is swapped. However, bias is introduced in univariate distributions if the sampling weights are different between the records of each swapping pair. One can imagine the impact on summaries of income categories if, in the example given, one survey respondent has a weight of 1, while the other has a weight of 1,000. A well-designed swapping approach incorporates the sampling weights into the swapping algorithm in order to limit the swapping impact on univariate and multivariate statistics.

There are several variations of data swapping, including (a) directed swapping, (b) random swapping, and (c) rank swapping.

Directed swapping is a nonrandom approach in which records are handpicked for swapping. For instance, a record can be identified as having a high risk of disclosure, perhaps as determined through a matching operation with an external file, and then chosen for swapping. *Random swapping* occurs when all data records are given a probability of selection and then a sample is selected using a random approach. The sampling can be done using any approach, including simple random sampling, probability proportionate to size sampling, stratified random sampling, and so on. Once the target records are selected, a swapping partner is found with similar attributes. The goal is to add uncertainty to all data records, not just those that can be identified as having a high risk of disclosure, since there is a chance that not all high-risk records identified for directed swapping cover all possible high-risk situations. Finally, *rank swapping* is a similar method that involves the creation of pairs that do not exactly match on the selected characteristics but are close in the ranking of the characteristics. This approach was developed for swapping continuous variables.

The complexities of sample surveys add to the challenge of maintaining the balance of reducing disclosure risk and maintaining data quality. Multi-stage sample designs with questionnaires at more than one level (i.e., prisons, inmates) give rise to hierarchical data releases that may require identity protection for each file. Longitudinal studies sometimes involve adding new samples and/or new data items over the course of several data collections. Data swapping may be incorporated in longitudinal studies to ensure that all newly collected data are protected. Also in survey sampling, data-swapping strategies incorporate sampling weights by forming swapping partners that minimize or reduce the amount of bias introduced through the swapping process.

Another aspect of data swapping to be emphasized is that careful attention is needed for maintaining data consistency. Surveys typically contain highly related variables, skip patterns, or multiple response items (i.e., "Check all that apply"). When any one data item is swapped, all items directly related to the swapped item must be swapped as well; otherwise data inconsistencies will be created.

The amount of swapping conducted, as determined by the swapping rate, is designed to protect the confidentiality of the data without affecting its usability. There is no established literature on determining swapping rates. In practice, the threat of a "data snooper" using other publicly available data impacts the swapping rate as well as whether some of the data are unique. When data swapping is conducted, the swapping approach can be tested and the impact evaluated. If it is determined that the integrity of the data is violated, then the swapping parameters can be modified and reprocessed. Last, in order to ensure that the confidentiality edits are not reversible, the swapping rate and the swapping variables are typically not revealed.

Debriefing

Debriefing in survey research has two separate meanings. It is used to refer to the process whereby qualitative feedback is sought from the interviewers and/or respondents about interviews conducted and surrounding survey processes. It also is used to refer to the process whereby "justified" deception has been used by the researchers, and, following ethical research practices, respondents are then debriefed after the study ends to explain the deception to them and try to undo any harm that may have been caused by the deception.

Debriefing to Gain Qualitative Feedback

Debriefings for the purpose of gaining qualitative feedback occur in three critical phases:

1. During survey development
2. Ongoing during survey administration
3. Upon survey completion

Debriefings during survey development are the most common and the most valuable. In such debriefings, information is sought on issues that prove difficult for either interviewer or respondent, with the aim of improving the survey instruments, survey protocols, and/or interviewer training materials. The relative emphasis will depend on what other survey development activities have been undertaken; for example, respondent interpretation of questions and requests for clarification will be given less weight in a debriefing if a full cognitive interviewing process preceded the pilot test.

It is less common for a debriefing to occur during the main phase of interviewing; however, such debriefings are valuable to allow for fine-tuning of processes, answer categories, or interpretation of data. Generally it is not desirable to change any questions, as that will preclude the standardization usually sought; however, it may be appropriate to add clarifying transitional phrases in the questionnaire or clarifying questions at the end of the questionnaire if mid-survey debriefings identify serious issues that were not detected during the development phase.

Debriefings following a survey usually focus on the interpretation and limitations of the data collected. Debriefings involving respondents may also include an element of benchmarking or comparison, with information fed back to the respondent on how his or her responses compared with others surveyed. This may be for either the survey sponsor's benefit (particularly with business surveys, increased cooperation can often be obtained by the promise of such data, as long as confidentiality pledges are honored), or for the respondent's benefit (as may be the case if the survey is part of an audit procedure).

Techniques Used for Qualitative Informational Debriefings

Focus group techniques are the most often employed for interviewer debriefings, with the interviewers gathered together so that observations by one can be validated (or not) by the group. As with all focus groups, a skilled moderator is needed to balance the contributions of the participants, to keep the discussion on track, and to correctly interpret the information gathered in the discussion, so that forceful opinions are not misinterpreted as fact, and conclusions are considered within the context of the motivations of the participants. Often interviewers will be asked to complete a debriefing questionnaire prior to the focus group, to help them prepare for the discussion and/or to provide additional data for later analysis.

One-on-one interviews are more commonly used for respondent debriefings, particularly where the debriefing is a variation on cognitive interviewing techniques aimed at uncovering the various interpretations of the questions and the perceived meanings of various answer categories.

As useful as debriefing material is, at the development stage it should always complement, not replace, analysis of data collected during the pilot test. Such analysis should include at a minimum:

- Operational costs (call records, travel records, pay claims)
- Distribution of responses to questions over answer categories, compared across respondent groups and across interviewers
- Examination of responses given to open-ended questions

Such analysis can identify areas to focus on during the debriefing process and afterward to test hypotheses formed during the debriefing.

Debriefings Associated With Deception in Research

There are times when survey researchers are justified in using deception as part of their research design; for example, the need to keep respondents blind to the "real" purpose of a study until after all data have been gathered for the study. Doing so could be justified if the respondents' answers would be influenced (biased) if they understood the real purpose before their data were gathered. In these instances, it is the ethical responsibility of the researchers to debrief all respondents about the deception. This could be done in person, via telephone, via mail, and/or via an email, depending on the appropriateness of the mode of debriefing in light of the nature and extent of the deception. Through the debriefing process the researchers would (a) inform the respondents of the deception, (b) explain why it was used, (c) provide some opportunities for respondents to express any concerns they had with the deception, and (d) try to undo any harm the deception may have caused any respondent. (Sometimes, undoing the harm that deception in research causes is a very complicated, long-term, and expensive proposition.) In some instances with deception, researchers may need to gather quantitative data on the possible harm the deception may have caused as part of the debriefing of respondents, above and beyond any informal qualitative opportunities provided to respondents to express their concerns about the deception in the debriefing.

DECEPTION

According to *Webster's Dictionary*, *deception* is the act of making a person believe what is not true; that is, misleading someone. The use of deception in survey research varies in degree. Typically, its use by researchers is mild and is thought to cause no harm to survey respondents and other research subjects. At times, however, the use of deception has been extremely harmful to research subjects. Thus the nature of deception involved in research must be carefully considered. Currently, contemporary researchers in the academic and government sectors submit research proposals to their institutional review board (IRB) primarily to ensure that research participants are protected from harm. In the commercial sector in the United States, this process may not be followed as closely.

It is not uncommon in survey research that some deception occurs, especially in the form of not telling respondents in advance of data collection what is the actual purpose of the study being conducted. The justification for this type of deception is the fact that telling respondents of the actual study purpose in advance of gathering data from them is likely to bias their responses.

For example, psychologists studying differences in thought patterns of depressed and nondepressed individuals may use mild deception in the form of omission of information to avoid sensitizing the subjects to the purpose of the study and thereby biasing the findings. For example, one study conducted by Carla Scanlan in 2000 did not disclose to subjects that the purpose of administering a particular screening questionnaire was to identify depressed and nondepressed subjects; the questionnaire was an untitled version of the Beck Depression Inventory—II (BDI-II), which asked subjects to read 21 sets of statements and choose the statement in each set that best described how she or he had been feeling for the past 2 weeks, including today. The consent form merely stated that the participant would fill out various questionnaires in order to determine for which experiments subjects qualified. Later, subjects were told that the purpose of this particular research project was to study the emotional state of students coming to college for the first time. After data collection and data analysis were completed, a written summary of the results was provided to those interested in the outcome. This debriefing process was complete and disclosed the purposes of the research. If the purpose of the research had been fully disclosed to participants beforehand, data collection would have been compromised.

In another example, in 2006, Scott Keeter conducted several studies in order to investigate whether cell phone only individuals differed from individuals who had landlines. That goal was not disclosed at the outset of the call; some of the questions were political in nature and others were demographic. The purpose of the call was given as a political survey, although the real intent was to investigate how cell only individuals differed from landline users. In this example, failing to disclose this purpose harmed no one and preserved the integrity of the survey responses, and it was deemed that no debriefing was necessary.

Although the uses of mild deception in survey research almost never causes harm to the respondent, there have been nonsurvey research situations utilizing deception that have caused grievous harm to the participant. For instance, the infamous Tuskegee Syphilis Study was conducted from 1932 to 1972 in Macon County, Alabama. The purpose of this study was to investigate the progression of untreated syphilis. The men (all blacks) were told that they were receiving treatment for their disease when actually it was actively withheld; the researchers secured the cooperation of all medical personnel in the county to withhold treatment from the men. Although penicillin became the standard treatment for syphilis in 1947, it continued to be withheld from the participants in the Tuskegee Syphilis Study until 1972. Some of the men had untreated syphilis infections for 40 years before they finally received treatment, but, shamefully, many of the men did not survive the disease. By 1947, if not earlier, their suffering and deaths could have been easily prevented by a penicillin injection. No one ever told them. In this case, research deception caused irreparable harm and death.

During recent presidential election years, a form of "survey" has been carried out that pretends to be gathering opinions from potential voters but in fact is an attempt to sway large numbers of voters' opinions in a particular direction as a primary approaches. This practice is known to survey professionals as a *push poll* and is actually a form of political telemarketing. For example, members of an organization that support Candidate X hire personnel to stage a telephone "survey" in which initially it may appear that a legitimate survey is being conducted. However, after the apparent legitimate start of the "interview," the person administering the "survey" begins to convey unfavorable and often false information about Candidate Y in the guise of survey questions. This is done to persuade the person being "interviewed" to vote against

Candidate Y. No debriefing takes place in these push polls, and the deceptive practice is highly unethical.

In contrast, if this approach were being done as part of a legitimate survey that involved deception, at the conclusion of the interview an ethical researcher would have interviewers debrief the respondents about the deception that took place. For example, the debriefing would honestly disclose why the false information was conveyed about Candidate Y and a sincere attempt would be made to undo any harm that the deception may have caused, including informing the respondent that the information about Candidate Y in the questions was not accurate.

Deliberative Poll

A deliberative poll is a methodology for measuring public preferences that combines small group discussions and traditional scientific polling. It was created by James Fishkin, political science and communications professor, with the goal of improving the quality of public opinion expression and measurement.

Fishkin argues that traditional polls often do not provide good measures of public opinion because members of the public are not knowledgeable enough about the important issues of the day and do not have the motivation or opportunity to engage in deliberation on the issues. He first proposed the idea of deliberative polling in 1988 as a corrective. Fishkin, who has since trademarked the term *Deliberative Poll*, currently conducts deliberative polls through the Center for Deliberative Democracy at Stanford University.

Typical deliberative polls have three main stages. First, a traditional public opinion poll is conducted of the population of interest, for example, all voting-age adults in the United States. A probability sample of this population is selected and respondents, who agree to participate in all the stages, are asked standard survey questions on selected issues along with some background and demographic questions. Respondents are then sent briefing materials that provide information about these same issues. In the second stage, respondents travel to a given location to deliberate on these issues. The deliberations take the form of small group discussions and can include sessions where participants are able to question experts. Some more recent deliberative polls have used online deliberations. In the third stage, the participants are interviewed again using traditional survey techniques to see whether their views changed as a result of their deliberative participation. Fishkin's view is that this second survey shows what public opinion would look like if the entire population were more informed and able to engage in deliberations on these issues.

The first national deliberative poll in the United States (called the National Issues Convention) was conducted in Austin, Texas, in January 1996, at a cost of about $4 million. A second National Issues Convention was conducted in Philadelphia, Pennsylvania, in January 2003, which was followed by the first online deliberative poll. Some utility companies in the United States have also used deliberative polling at the local level to get public input on energy policies. Deliberative polls have also been conducted internationally in such countries as Australia, Britain, Bulgaria, China, Denmark, Greece, Italy, and Northern Ireland.

Some public opinion researchers have raised scientific concerns about deliberative polling. One challenge is getting a representative sample of survey respondents to participate in the deliberations. In the 1996 National Issues Convention, older respondents, those with less education, and the less politically active were less likely to travel to Austin for the weekend of deliberations. However, selection differences were less prevalent on the issue questions.

Another concern is whether group discussions are the best approach for disseminating information. Deliberative poll participants generally take the group discussion task seriously, but criticisms have been raised about the quality of the discussions and the accuracy of information exchanged in them. A related criticism of the discussions is the potential impact of group dynamics. In group situations, people can be influenced by normative factors unrelated to the strength or merits of the arguments. In addition, differences in discussion participation rates can also have an impact on opinions. Not everyone is equally motivated or has the same ability to participate in group discussions. The more vocal and persuasive members of the group may have a disproportionate influence on the outcome of the deliberative poll.

There also has been debate about the amount of opinion change that is produced by deliberative polling. For example, in the 1996 National Issue Convention, Fishkin pointed to a number of statistically significant shifts in aggregate opinion as a result of participation in that deliberative poll. Other researchers have argued that there were relatively few meaningful changes in aggregate opinion after this significant effort to educate members of the public and have them participate in extensive deliberations. This was taken as evidence of the robustness of public opinion as measured by traditional public opinion polls that can be conducted at a fraction of the cost of a project like the National Issues Convention Deliberative Poll. Larger shifts in aggregate opinion have been found, for example, in deliberative polls conducted for utility companies on esoteric issues for which opinions are weakly held or nonexistent and public interest and knowledge are very low.

Demographic Measure

Demographic measures are questions that allow pollsters and other survey researchers to identify nonopinion characteristics of a respondent, such as age, race, and educational attainment. Demographic measures typically are used to identify key respondent characteristics that might influence opinion and/or are correlated with behaviors and experiences. These questions are usually found at the end of a questionnaire. Reasons for this are (a) to engage or otherwise build rapport with the respondent by asking substantive questions of interest earlier in the questionnaire; (b) to lessen the likelihood that asking these personal questions will lead to a refusal to continue completing the questionnaire (i.e., a breakoff); (c) to prevent priming the respondent; and (d) to allow the respondent to answer the core questions before possibly boring him or her with the mundane demographic details.

Demographic measures are important because numerous studies have demonstrated that opinions are formed primarily through an individual's environment. This environment socializes us to think and behave in accordance with community norms and standards. As a result, by identifying these demographic measures, pollsters are better suited to understand the nature of public opinion and possibly how it might be formed and modified.

Demographic measures are also very important because they allow researchers to know how closely the sample resembles the target population. In a national sample of U.S. citizens, for example, researchers know what the population looks like, demographically, because the federal government conducts a census every 10 years and updates those data annually thereafter until the next census. As such, researchers know the percentages of the population based on race, gender, age, education, and a whole host of other demographic characteristics. A simple random sample of the population ideally should resemble the population, and demographic measures allow researchers to see how well it does. For example, because survey nonresponse often correlates with educational attainment, most surveys of the public gather data from proportionally far too many respondents who earned college degrees and far too few respondents who did not graduate from high school. Knowing the demographic characteristics of the sample respondents (in this case, educational attainment) allows the researchers to adjust (weight) their sample to the known population characteristics. This can be done with greater confidence and accuracy if the wording of the demographic question in the survey matches the wording of the question for the same characteristics that was used to produce the universe estimates (e.g., the wording used by the U.S. Census).

The length of the questionnaire often limits the number of demographic questions asked. Accordingly, demographic measures must be carefully selected to best allow further analysis. There are a number of standard demographic questions that are nearly always asked, including questions about age, gender, income, race, Hispanic ethnicity, and education. Questions designed to identify these characteristics have become fairly standardized and often follow the ways the federal government gathers these data in the census and/or other surveys they conduct. Other common demographic measures identify the respondent's political party, political ideology, marital status, religious preference, church attendance, voter registration status, geographic place of residence, and number of children. Occasionally, the nature of a poll or other survey might cause specific other demographic questions to be asked, such as questions about military service, union membership, sexual orientation, type of employment, type of housing unit, and years lived in one's neighborhood.

These demographic measures also allow for simple breakdowns of the survey results into subgroups. Although it might be nice to know that 48% of the country approves of the job the president is doing, it may well be more informative to know that 88% of Republicans and 15% of Democrats approve of the president's job performance. Regardless of the purpose of the questionnaire, demographic measures provide a clearer picture of public preferences, dispositions, behaviors, and experiences. For instance, a marketing firm might find that men between the ages of 30 and 40 are the most likely to use a particular product. Marketers can then use this information to design advertisements that would appeal to that particular group. In short, demographic measures allow for a more nuanced understanding of the public by allowing researchers to examine the details that are absent at the aggregate level by filling in the background information.

Dependent Interviewing

Dependent interviewing is a method of scripting computer-assisted survey questionnaires, in which information about each respondent known prior to the interview is used to determine question routing and wording. This method of personalizing questionnaires can be used to reduce respondent burden and measurement error. The prior information can be incorporated reactively, for in-interview edit checks, or proactively, to remind respondents of previous answers.

Dependent interviewing exploits the potential of scripting computer-assisted questionnaires such that each interview is automatically tailored to the respondent's situation. This can be done using routing instructions and text fills, such that both the selection of questions and their wording are adapted to the respondent's situation. Both routing and text fills are usually based on responses to earlier questions in the questionnaire. Dependent interviewing in addition draws on information known to the survey organization about the respondent prior to the interview. In panel surveys, where dependent interviewing is mainly used, this information stems from previous waves of data collections. For each panel wave, prior survey responses are exported and stored together with identifying information (such as name, address, and date of birth) used by interviewers to locate sample members eligible for the round of interviewing.

The previous information can be incorporated into the questionnaire script to reduce respondent burden and measurement error. In panel surveys, a set of core questions are repeated at every interview. For respondents whose situation has not changed between interviews, it can be frustrating and lengthen the interview unnecessarily to have to answer the same questions repeatedly. With dependent interviewing, information from previous waves can be used to verify whether a respondent's situation has changed. If not, and if the responses given in the previous interview still accurately reflect the respondent's situation, the questionnaire script can automatically route the respondent around unnecessary redundant questions. Responses from previous waves can then be filled in for the current wave. For open-ended questions such as those regarding occupation, this not only reduces the length of the interview, but also of coding time.

In general, the purpose of asking the same questions at different points in time is to generate data that can be used to investigate individual-level change. Estimates of change from panel surveys, however, tend to be biased. This is because responses about the reference period reported in one interview tend to be internally consistent but are not necessarily consistent with responses given in earlier interviews. These longitudinal inconsistencies can be due to respondent errors (such as simple variation in the way the respondent understands a question or describes her or his situation, recall errors, or estimation strategies used to compute responses), or interviewer errors, coding errors, or processing errors.

A consequence of these inconsistencies is the phenomenon called the "seam effect." Dependent interviewing can be used to remind respondents of previous responses or for edit checks to verify whether apparent changes are true. The hope is that this will reduce response variance, improve respondent recall, and catch interviewer errors. Routing around redundant open-ended questions and imputing codes from previous waves further increases longitudinal consistency. Dependent interviewing has been shown to effectively reduce, although not completely eliminate, seam effects.

The prior information can be incorporated into the questionnaire in one of two ways: (1) reactively or (2) proactively. With *reactive dependent interviewing*, respondents are first asked an independent question, without reference to prior data. The computer script then compares the response with the prior data. If the responses differ (e.g., in the case of categorical variables) or differ beyond a pre-defined threshold (e.g., in the case of continuous variables), the computer script prompts a follow-up question to verify whether the change is true (valid). For example, if reported earnings differ by more than +/–10% from the previous interview, the respondent could be asked:

> *May I please just check?—So your earnings have changed from* <fill: amount a> *to* <fill: amount b> *since we last interviewed you on* <fill: date of interview>?

In addition, the respondent could be asked to clarify the reason for the difference, and this information could later be used for data editing.

With *proactive dependent interviewing*, the previous response is incorporated into the question text. This can be used as a boundary before asking the independent question. For example, respondents may be asked:

> *Last time we interviewed you on* <fill: date of interview>, *you reported receiving* <fill: $amount of unemployment benefits> *each month. Have you continued to receive* <fill: $amount unemployment benefits> *each month since* <fill: date of interview>?

Alternatively, the respondent can be asked to confirm the prior information before being asked about the current situation. For example:

> *According to our records, when we last interviewed you on* <fill: date of interview>, *you were* <fill: employment status>. *Is that correct*?

The prior information can also be used to explicitly ask about change. For example:

> *Last time we interviewed you on* <fill: date of interview>, *you said you were working for* <fill: employer name>. *Are you still working for* <fill: employer name>?

Dependent interviewing is mainly used for factual questions. Respondents generally react positively to interviewers acknowledging information they have provided in earlier waves of interviewing. Cognitive studies suggest that the fact that the interviewer has access to their data does not worry the respondent. However, there are precautions that researchers need to take. For example, confidentiality concerns may arise in surveys that allow proxy reporting. Respondents are not always comfortable with the data they have provided being "fed forward" to a different household member in the future wave of interviewing, were some other member to serve as their proxy. In addition, care also needs to be taken that the wording of reactive dependent interviewing questions that query inconsistent responses do not put respondents off. Finally, the added complexity of the questionnaire script means that implementing dependent interviewing is resource intensive, both in terms of programming and script testing.

Dependent Variable

A dependent variable is a variable that is explained by one or more other variables, which are referred to as "independent variables." The decision to treat a variable as a dependent variable may also imply a claim that an independent variable does not merely predict this variable but also shapes (i.e., causes) the dependent variable. For example, in a survey studying news consumption, exposure to television news could serve as a dependent variable. Other variables, such as demographic characteristics and interest in public affairs, would serve as the independent variables. These independent variables can be used to predict television news exposure and also may be investigated as to whether they also cause one's exposure level.

Researchers often face challenges in establishing causality based on survey data. In causal inference, the dependent variable indicates an outcome or effect, whereas the independent variable is the cause of the outcome or effect. In order to conclude that the dependent variable is caused by the independent variable, the relationship between the two must meet three criteria. First, the two variables must be correlated. That is, a change in one variable must be accompanied by a change in the other. In the case of a positive correlation, one variable increases as the other increases. In the case of a negative correlation, one variable increases as the other decreases. For example, higher levels of education may be associated with lower levels of television news viewing, and if so, there would be a negative correlation between the two variables. If the two variables are not correlated, then there is no causal relationship between them.

Second, the dependent variable must follow the independent variable in the timing of its occurrence. For example, a researcher who seeks to show that one's level of education influences one's level of television news viewing would need to show that changes in the latter occurred *after* changes in the former. In some instances, it is relatively easy to ascertain the temporal order of the variables. For instance, if a researcher investigates the relationship between children's academic performance and their parents' education levels, then he or she may be fairly confident in claiming that the former happened after the latter. In other cases, however, the time order is less clear. For example, it may be difficult to determine the temporal ordering of political knowledge and television news viewing.

Third, the observed correlation between the two variables must be genuine—that is, it cannot be explained by other variables. Even if watching television news is positively associated with political knowledge, the relationship may be spurious, from a causal standpoint, if it can be accounted for by another variable, such as political interest. If the positive correlation between television news viewing and political knowledge is due to the fact that the two variables are both positively related to political interest, then the causal relationship may not be valid, and thus is only one of noncausal covariation.

In establishing a causal relationship between a dependent variable and an independent variable, it is not necessary for the independent variable to be the only cause of the dependent variable. In other words, the independent variable can be one of many factors that influence the dependent variable. For example, education levels may influence the amount of television news one consumes even if many other variables (e.g., interest in politics) also affect news watching.

In survey data, causal relationships between a dependent variable and an independent variable are typically probabilistic rather than deterministic. In other words, the relationship will not necessarily be true for all the cases or even for most cases. For example, if education is found to exert a negative influence on television news viewing, this does not mean that each and every highly educated person watches less television news than each and every less educated person. Thus, finding the cases that violate the relationship does not falsify the causal inference.

Researchers usually face two major challenges while using survey data to establish a causal relationship between the dependent variable and the independent variables(s): (1) ascertaining which variable takes place first, and (2) whether the relationship is genuine. For example, a researcher may find that people who behave aggressively watch more violent television programs but be unable to disentangle the causal direction in the relationship. This is especially likely to be true for analyses using cross-sectional survey data in which the two variables in question are measured at the same time rather than at different points in time and are not measured as part of an experimental design. Moreover, one must rule out other plausible factors that may account for the relationship to ascertain that the observed relationship between the two variables is possibly a causal one. If a nonexperimental survey does not measure all variables that may explain the relationship, then the researcher may not be able to rule out alternative explanations.

Surveys do lend themselves to experimental designs in which the causal relationships between the dependent variable(s) and independent variable(s) can be tested formally. For example, survey researchers can examine experimentally whether response rates are influenced by different levels of incentives or new alternative forms of interviewer persuasion techniques. However, too often survey researchers do not deploy such experimental designs, thus missing the opportunity to better understand the dependent variable(s).

DESIGNATED RESPONDENT

Designated respondents are the individuals chosen specifically to be interviewed for a survey. Surveys often are conducted in two stages: first, selecting a sample of household units and, second, selecting persons within the households with whom to speak. Survey researchers' and interviewers' jobs would be easier if they could question the persons first answering the phone or first coming to the door or simply any adult resident in the unit who was willing to talk. This usually is an acceptable idea only if the researchers simply need to know the basic characteristics of the household; however, much of the time researchers need to gather data from one specifically chosen person in the household—that is, translate the sample of units into a sample of individuals. In contrast, if the respondent is merely the most likely person to answer the phone or to be home, his or her characteristics may be overrepresented in the sample, meaning that the sample will be biased. These more willing or available individuals tend to be older and/or female. Such biases mean that survey researchers are likely to get an inaccurate picture of their samples and can come to some incorrect conclusions. Information quality depends on who is providing it.

Researchers try to avoid such bias by using a within-household selection procedure likely to produce a more representative sample at the person level. These tend to be more expensive than interviewing any available person in the household, but they are also more precise. It takes more time to find the "right person" and to gain an interview when that person is available. As a result, refusal rates can, and often do, increase. The informant (person who answers the door or phone) may be put off by some of the questions interviewers have to ask in order to pick the designated respondent—for example, a complete list of household residents—and may refuse to proceed further. If informants are cooperative but are not the designated respondent, a handoff must occur, and interviewers may have to keep calling back if the designated respondent is not immediately available. Survey researchers have to make trade-offs when they choose a respondent selection method. Different kinds of respondent selection methods have been devised to identify the correct person for interviewing and obtain his or her cooperation, and each has advantages and disadvantages with respect to costs and precision.

Respondent designation techniques have consequences for errors of nonresponse, such as not finding the correct person, inability of the person selected to participate because she or he does not qualify (e.g., because of language barriers, ill health, illiteracy), or that person's unwillingness to be interviewed. Ways to compensate for these problems exist, such as callbacks, interviewing a secondary person in the household who also meets appropriate criteria (e.g., speaks English, is able-bodied, literate), or weighting responses by appropriate criteria. Among principal concerns are within-unit coverage errors; for instance, when the wrong types of respondents consistently are interviewed or when the selected respondents consistently do not meet the survey requirements and another qualified person is available but not interviewed. Survey researchers need to think out solutions to these issues in advance.

Many studies have compared two or more different within-unit selection methods to aid researchers in decisions about procedures that will best fit their needs, although more research on these issues is desirable. This is because some methods of respondent selection violate the principle of random sampling but appear to provide age and sex or other demographic distributions that approximate those in the population of interest. In addition, random sampling should best represent the population of interest, but this does not always happen for a number of reasons.

Usually, the least desirable method is no selection; that is, interviewing whoever answers the phone or door, if age 18 or older (usually adults are the population desired). Although the least expensive method, its common age and gender biases hinder generalizing to the larger population. Data are likely to be less accurate if topics are related to the biases.

The Council of American Survey Research Organizations strongly recommends that market research and attitude studies collect information only by designating a respondent scientifically or according to an appropriate function. Randomness is less of a concern when the designated respondent is, for example, the man of the house, the female head of household, the principal shopper, or the health care decision maker. In cases where informants may indicate that more than one household member qualifies, a random method or other predetermined systematic and unbiased technique will be needed to decide among those qualifying. An example of research on this issue, in 1963, found no significant differences among the four designated respondent procedures that were employed to collect data on home owners' alterations and repairs. The four procedures used in the 1963 study were (1) the head of household, (2) the wife of the head, (3) both together, and (4) any adult in the household with knowledge of these costs. Joint interviews were more difficult to obtain simply because one or the other was more likely to be available than both being available at the same time, and interviewing both persons did not produce a fuller picture than interviews with either one. The researchers speculated that allowing interviewers to ask for the adult best-informed about these consumer expenditures might have been preferable.

Design-Based Estimation

Design-based estimation methods use the sampling distribution that results when the values for the finite population units are considered to be fixed, and the variation of the estimates arises from the fact that statistics are based on a random sample drawn from the population rather than a census of the entire population.

Survey data are collected to estimate population quantities, such as totals, means, or ratios of certain characteristics. Other uses include comparing subpopulations—for example, estimating the average difference between males and females for certain characteristics. In addition to these descriptive quantities, for many surveys the data are used to fit statistical models, such as linear regression models, to explain relationships among variables of interest for the particular population. In any case, statistics derived from the sample are used to estimate these population quantities, or *parameters*. The basis for assessing the statistical properties of such estimates is the sampling distribution (the probability distribution) of the estimates—the distribution of the estimates that would arise under hypothetical repetitions using the same randomization assumptions and the same form of the estimate.

In design-based estimation, the probabilities used to select the sample are then used as the basis for statistical inference, and such inference refers back to the finite population from which the random sample was selected. These selection probabilities are derived using the particular survey sampling design (e.g., multi-stage, clustered, stratified). In design-based estimation methods, sampling weights are used to account for the possibly unequal probabilities of selection used to draw the sample.

Survey practitioners can also make use of alternative estimation methods including model-based approaches. Pure *model-based estimation* methods assume that the values for the finite population, $Y_1, Y_2, \ldots, Y_N$, are the realization of a random variable from a statistical model, and that the observed outcomes, $y_1, y_2, \ldots, y_n$, can be thought of as having been generated from either that same statistical model or from a statistical model that has been modified to take into account how the sample design has affected the sampling distribution for the sample data. The observations from the sample are used to predict the unobserved units in the population. In contrast, in design-based estimation methods, the values for the finite population units, $Y_1, Y_2, \ldots, Y_N$, are treated as fixed but unknown quantities, and the sampling distribution for the observed outcomes, $y_1, y_2, \ldots, y_n$, arises from the probabilities used to select the units for inclusion into the sample.

Another framework can be used that combines the model and design-based estimation methods and is referred to as a "model-design-based framework" or a "combined distribution." Within this framework, the values for the finite population, $Y_1, Y_2, \ldots, Y_N$, are considered to be the realization of a random variable from a statistical model, and the probability distribution for the outcomes, $y_1, y_2, \ldots, y_n$, is determined by both the statistical model for the population values and the probabilities used to select the units in the sample. Under the model-design-based framework, fitting statistical models to data obtained through a complex survey design, using design-based estimation methods, will often give protection against violation of the model assumptions and any misspecification that may be made with respect to the sampling distribution of the observed data, especially for large sample sizes and small sampling fractions.

Survey-Weighted Estimates

One common outcome in design-based methods is the generation of point estimates that serve to estimate the finite population parameters of interest, such as a population mean, total, proportion, and so on. Such estimates are derived using the sampling weights that are computed in part from the sampling design itself. A simple example to consider here would be the case of selecting a random sample with unequal probabilities of selection from a finite population, where there are no nonresponse and no response errors. In this case, the survey population consists of all units in the population that were eligible for selection in the sample survey design. One assumes that the target population is the same as the survey population. For each unit in the sample, a sampling weight is constructed based on the sampling design. Including this weight for each unit allows one to account for the unequal selection probabilities. When, for each unit in the sample, this weight is equal to the reciprocal of the probability that the unit is included in the sample, the survey-weighted estimate will provide an *unbiased* estimate of the population total. For *multi-stage sampling* designs, the sampling weight is constructed to account for the probabilities of selection at each stage of sampling. An informal interpretation of these weights is that, for each respondent, the weight is approximately equal to the number of units in the population represented by the respondent.

For example, to estimate the population total, $Y = \sum_{i=1}^{N} Y_i$, one could use the survey-weighted estimate given by the statistic $\hat{Y} = \sum_{i=1}^{n} w_i y_i$, where the w_i's are the sampling weights for the observed units. The estimate of the *variance* of this statistic will be based on the design-based sampling distribution of the observations. Statistical inference for large samples (or a large number of primary sampling units in the case of a multi-stage survey design) can be obtained by using the design-based estimate and its estimated design-based variance in conjunction with the normal distribution as an approximation to the sampling distribution of the estimated total. This normal approximation would be the basis for estimating confidence intervals or for conducting statistical hypothesis testing.

The finite population quantities of interest may be more complex than a population total. For example, when the population size is not known, the estimate of a population mean would be the ratio of the survey-weighted estimate of the population total and the survey-weighted estimate of the population size. In this case, the estimate of the population mean would be approximately unbiased. Since the bias tends to zero for large sample sizes, the estimate is said to be *asymptotically design unbiased.* Asymptotically unbiased estimates will be close to their quantities of interest for large samples. Estimates for subpopulations or domains are handled by setting to zero the observed values for all units that fall outside of the domain. Common quantities of interest are domain means or differences between the means of two domains, such as the average difference between males and females for some characteristics of interest.

In practice, there is usually nonresponse, and there may be deficiencies in the sampling frame, such as undercoverage or overcoverage. To account for these deficiencies, adjustments or calibrations are often made to the survey weights. The guiding principle behind such adjustments are to ensure that the survey-weighted estimates are approximately unbiased for the population totals, and possibly to reduce the variance of the estimates. One such example involves using auxiliary data, such as age-sex distributions for the population, to improve the accuracy of the estimates through post-stratification, ratio, or regression estimation.

Analytical Quantities of Interest

When the population of inference is finite, the population quantities of interest are descriptive. However, when fitting a statistical model to survey data, the population of inference is often conceptually infinite, although the population from which samples are drawn are finite. The population of inference is represented by a statistical model from which the values for the finite population units have been generated. The population of inference is larger than the population targeted by the researcher. The quantities of interest are related to the statistical model assumed to have generated the population targeted by the survey taker. In this case, the quantities of interest are analytic, not descriptive.

Design-based estimates for many statistical models are asymptotically design unbiased for the finite population quantities of interest that are associated with the statistical model based on a completely observed finite population. These finite population quantities of interest are usually approximately model unbiased for the parameters of the statistical model. Therefore, the design-based estimates are consistent for the model parameters of interest under the combined or model-design-based framework. The model-design-based variance for the design-based estimate of the model parameter will be close to the design-based variance when the sampling fractions are small and the sample size is large. Therefore, design-based inference for the model parameters of interest would also be valid in the model-design-based or combined framework. Modifications to the design-based variance would be required for cases where the sampling fractions are not negligible.

There are some statistical models for which design-based estimation will not be consistent under the model-design-based framework. These include estimates of the variance components associated with random effects models, mixed effects models, structural equation models, and multi-level models. The fixed effects in these models can usually be estimated consistently, but not the variance components associated with the random effects, unless certain conditions on the sample sizes apply. However, for most models, such as generalized linear models (including linear regression and logistic regression) and proportional hazards models, the parameters of interest can be estimated consistently.

Informative Sampling

The issue of whether a pure model-based estimation approach, as opposed to a design-based estimation approach, is appropriate when estimating quantities from a sample that has been obtained from a complex design is related to whether or not the sampling design is informative. If the sampling distribution of the observations is the same under the model-based randomization assumptions as the sampling distribution under the model-design-based (or combined) randomization assumptions, then the sampling is noninformative. Stratification and clustering in the sample design can lead to informative samples.

When the sampling is informative, the observed outcomes may be correlated with design variables not included in the model, so that model-based estimates of the model parameters can be severely biased, thus leading possibly to false inferences. On the other hand, if the sampling is noninformative, and a design-based estimation approach is used, then the variances of the estimates will usually be larger than the variances of the estimates using a model-based approach.

Design Effects (*deff*)

The design effect (*deff*) is a survey statistic computed as the quotient of the variability in the parameter estimate of interest resulting from the sampling design and the variability in the estimate that would be obtained from a simple random sample of the same size.

In large-scale sample surveys, inferences are usually based on the standard randomization principle of survey sampling. Under such an approach, the responses are treated as fixed, and the randomness is assumed to come solely from the probability mechanism that generates the sample. For example, in simple random sampling without replacement, the sample mean is unbiased with randomization-based variance given by

$$V_{SRS}(\bar{y}) = (1 - f)\frac{S^2}{n},$$

where n, N, and $f = n/N$ denote the sample size, the population size, and the sampling fraction, respectively, and S^2 is the finite population variance with the divisor $N - 1$. Usually f is negligible and can be dropped from the formula. In any such case, the equality displayed provides a conservative formula for the variance.

In most cases, however, complex sampling designs (indicated by the subscript *CSD* in the following) are applied rather than simple random sampling. In such a situation, $\bar{y}$ can still be an unbiased estimator under the usual randomization approach if the sampling design is one in which each sampling unit in the finite population has the same chance f of being selected. However, $V_{SRS}(\bar{y})$ usually underestimates the true randomization variance of $\bar{y}$ under the complex sampling design, say $V_{CSD}(\bar{y})$. To account for this underestimation, Leslie Kish proposed the following variance inflation factor, commonly known as the design effect:

$$DEFF_R = \frac{V_{CSD}(\bar{y})}{V_{SRS}(\bar{y})}, \tag{1}$$

where subscript R denotes the perspective of the randomization framework. Although in the vast majority of empirical applications, the design effect is considered for the usual sample mean, the ratio in Equation 1 can be defined more generally for the variances of any estimator, θ, under any complex design. In practice, $DEFF_R$ is unknown, and some approximations and estimations are employed to assess its magnitude.

To give an example, consider a population of $N = 9$ elements from which one wishes to select $n = 3$ into the sample. Let the y_i, $i = 1, \ldots, 9$, values be given by 10, 18, 32, 11, 21, 33, 12, 21, 31. If one samples the elements using systematic sampling, as an instance of a complex sample design, exactly three samples are possible: $s_1 = \{10, 11, 12\}$, $s_2 = \{18, 21, 21\}$, $s_3 = \{32, 33, 31\}$. Given these extreme data, it can already be seen, without doing any calculations, that the variance of the sample mean is inflated compared to a simple random sample of three elements. If one calculates the variance of the sample mean given the systematic sample design ($CSD = SYS$), one gets

$$V_{SYS}(\bar{y}) = 74. \tag{2}$$

And, for the variance of the sample mean under simple random sampling,

$$V_{SRS}(\bar{y}) = = \left(1 - \frac{3}{9}\right) \times \frac{84.5}{3} \approx 18.78. \tag{3}$$

Thus the design effect of this example is

$$DEFF_R = \frac{74}{18.78} \approx 3.94, \tag{4}$$

which means that the variance of the sample mean, when choosing the sample by systematic sampling, is nearly 4 times as large as the variance of the same estimator under simple random sampling. This indicates a considerable loss of precision (i.e., larger variance for the same sample size).

It must be noted that the magnitude of the design effect depends on the y values. A different ordering of the values of the study variable in this example yields a different design effect. Now consider the y_i values in the following order: 11, 12, 10, 21, 21, 18, 31, 33, 32, and the possible systematic samples of size 3: $s_1 = \{11, 21, 31\}$, $s_2 = \{12, 21, 33\}$, $s_3 = \{10, 18, 32\}$. Under this ordering of the study variable, the variance of the sample mean given the systematic sample design is

$$V_{SYS}(\bar{y}) = \frac{2}{3} \approx 0.6667,$$

and thus the design effect for the reordered data is

$$DEFF_R = \frac{\frac{2}{3}}{\frac{169}{9}} \approx 0.0355,$$

which implies that in this case systematic sampling is more efficient than simple random sampling (i.e., *design effect* < 1). The reason for these enormous differences lies in the relative homogeneity of the y values within and between the samples.

Systematic sampling is a special case of cluster sampling. The design effect for cluster sampling of n clusters from a population of C clusters, each of size M, can be computed as

$$DEFF_R = \frac{C \cdot M - 1}{M(C - 1)}[1 + (M - 1)\rho], \tag{5}$$

where ρ is the well-known intraclass correlation coefficient (ρ), which is defined as

$$\rho = \frac{\sum_{c=1}^{C} \sum_{j=1}^{M} \sum_{\substack{i=1 \\ j \neq i}}^{M} (y_{ci} - \bar{Y}_c)(y_{cj} - \bar{Y}_c)}{(M - 1)(C \cdot M - 1)S^2}, \tag{6}$$

where y_{cj} denotes the y value of the jth unit in cluster c in the population, and $\bar{Y}_c$ their mean in cluster c. S^2 is the finite population variance of the $C \cdot M$ y values.

The intraclass correlation coefficient can be interpreted as a measure of homogeneity. It ranges from $-\frac{1}{M-1}$ to 1. High values of ρ indicate more homogeneity of y values within the clusters, whereas a low value of ρ indicates less homogeneity. Moreover, negative values indicate a gain in efficiency of the complex design compared to simple random sampling. However, in most empirical applications, ρ takes on small to intermediate values (0.02 to 0.20) depending on the variable under study. In the previous examples, ρ would be computed as 0.978 and –0.487, respectively. Using these values in Equation 5 along with $C = 3$, $n = 1$, and $M = 3$ yields the design effects computed for the original and reordering of the set of 9 y-values, respectively.

In general, design effects that exceed 1 imply less precision per sampled unit for the complex sampling design relative to a simple random sample of the same size, while design effects that are less than 1 imply a gain in precision per sampled unit.

Use of Design Effects

There are several potential uses of design effects. First, design effects are routinely used for the determination of the sample size of a complex survey from knowledge of sample size requirement for a simple random sample design of equal precision. This approach is followed in the European Social Survey (ESS), as described by Peter Lynn, Sabine Häder, Siegfried Gabler, and Seppo Laaksonen. In this context, an important quantity that can be derived from $DEFF_R$ is the effective sample size, n_{eff}, which is defined as

$$n_{eff} = \frac{n}{DEFF_R}. \tag{7}$$

It denotes the corresponding sample size of a simple random sample (more precisely a simple random sample with replacement) that has the same variance as the complex sample design. Usually, n_{eff} is smaller than n, which indicates a loss in precision caused by the complex design. When an overall design effect is known, n_{eff} can be used to compute the sample size, n, of a complex sample, which is required to ensure a pre-defined precision.

In the absence of any direct survey data on the response variables, historical data as well as information from similar surveys are used in conjunction with the information available on the survey under consideration such as average cluster size, number of clusters, and so on.

The second possible use of design effects is for variance computation from complex surveys in situations in which standard variance estimation techniques cannot be employed—either due to unavailability of appropriate software, especially in developing countries, or due to unavailability of actual cluster identifiers to protect the confidentiality of survey respondents. For this use, survey researchers and practitioners often publish design effects of core items together with survey data.

Estimation of Design Effects

In practice, the design effect depends on unknown population quantities that have to be estimated from sample data. Hence, the numerator and denominator of the right-hand side of Equation 1 have to be estimated from the sample data. Estimating the numerator leads to the classical variance estimation problem. In the case of stratified random sampling or cluster sampling, adequate variance estimators are available. However, in complex surveys with unequal probability sampling, second-order inclusion probabilities π_{ij} have to be available. Since the computation of the π_{ij} may be extremely cumbersome, adequate approximations may have to be considered.

The generalization of Equation 1 to calibration estimators or nonlinear statistics generally leads to applying residual or linearization techniques, as discussed by A. Demnati and J. N. K. Rao and by J. C. Deville. Alternatively, resampling methods, such as the jackknife or bootstrap, can be applied in order to build the sampling distributions via estimating from adequate subsamples from the original sample.

The estimation of the denominator of Equation 1 leads to estimating the variance of the given estimator under simple random sampling with the given sample. However, this sample was drawn using a complex sampling design and cannot be directly used for variance estimation under simple random sampling. One way to compensate for unequal probabilities is to estimate S^2 by

$$\hat{S}^2 = \frac{1}{\sum\limits_{i \in S} \pi_i^{-1} - 1} \sum_{i \in S} \frac{1}{\pi_j} \left(y_i - \frac{1}{\sum\limits_{i \in S} \pi_i^{-1}} \sum_{j \in S} \frac{y_j}{\pi_j} \right)^2. \tag{8}$$

Alternatively, one may wish to estimate the population distribution and from this an estimator of S^2.

Model-Based Approach to Design Effects

Model-based estimation differs from the design-based approach mainly in the assumptions about the data-generating process and hence the way estimators of population parameters have to be considered. This approach is mainly helpful in the design stage of a sample survey when no data are available.

A model-based version of the design effect has been suggested by Gabler, Häder, and Parthasarathi Lahiri. Let b_c be the number of observations in the cth of C clusters. Hence, $\bar{b} = \frac{1}{C}\sum_{c=1}^{C} b_c$ is the average cluster size. Taking into account the usual design-based estimator of the population mean, $\bar{y}_w = \frac{\sum_{c=1}^{C}\sum_{j=1}^{b_c} w_{cj}y_{cj}}{\sum_{c=1}^{C}\sum_{j=1}^{b_c} w_{cj}}$, let us assume the following model (M1):

$$Var_{M1}\left(y_{cj}\right) = \sigma^2 \text{ for } c = 1, \ldots, C;\ j = 1, \ldots, b_c \quad (9)$$

$$Cov_{M1}\left(y_{cj}, y_{c';j'}\right) = \begin{cases} \rho\sigma^2 & \text{if } c = c'; j \neq j'; \\ 0 & \text{otherwise} \end{cases} \quad (10)$$

A second model (M2) specifies the distribution of the y_{cj} in the following way:

$$Var_{M2}\left(y_{cj}\right) = \sigma^2 \text{ for } c = 1, \ldots, C; j = 1, \ldots, b_c \quad (11)$$

$$Cov_{M2}\left(y_{cj}, y_{c';j'}\right) = 0 \text{ for all } (c, j) \neq (c', j'). \quad (12)$$

Let $Var_{M1}(\bar{y}_w)$ be the variance of the weighted sample mean under model M1 and let $Var_{M2}(\bar{y})$ be the variance of the overall sample mean, $\bar{y} = \frac{\sum_{c=1}^{C}\sum_{j=1}^{b_c} y_{cj}}{C\bar{b}}$, under M2. Under M2, the variance of $\bar{y}$, however, turns out to be given by $Var_{M2}(\bar{y}) = \frac{\sigma^2}{n}$. Then the model-based design effect is defined as

$$DEFF_M = \frac{Var_{M1}(\bar{y}_w)}{Var_{M2}(\bar{y})}. \quad (13)$$

After some algebra, it turns out that $DEFF_M$ can be expressed as

$$DEFF_M = n\frac{\sum_{c=1}^{C}\sum_{j=1}^{b_c} w_{cj}^2}{\left(\sum_{c=1}^{C}\sum_{j=1}^{b_c} w_{cj}\right)^2} \times [1 + (b* - 1)\rho], \quad (14)$$

where

$$b* = \frac{\sum_{c=1}^{C}\left(\sum_{j=1}^{b_c} w_{cj}\right)^2}{\sum_{c=1}^{C}\sum_{j=1}^{b_c} w_{cj}^2}. \quad (15)$$

The first term of Equation 14 is the design effect due to unequal selection probabilities, $DEFF_P$, and the second term is the well-known design effect due to clustering, $DEFF_C$. Thus, Equation 1 can equivalently be written as a product of $DEFF_P$ and $DEFF_C$:

$$DEFF_M = DEFF_P \times DEFF_C. \quad (16)$$

The quantity ρ again servers as a measure of homogeneity. The usual analysis of variance (ANOVA) estimator of $\rho||\text{I}||$ is given by

$$\hat{\rho}_{ANOVA} = \frac{MSB - MSW}{MSB + (K - 1)MSW}, \quad (17)$$

where

$$MSB = \frac{SSB}{C - 1}$$

with $SSB = \sum_{c=1}^{C} b_c(\bar{y}_c - \bar{y})^2$, $\bar{y}_c$ the sample mean of the y values in the cth cluster, and

$$MSW = \frac{SSW}{n - C}$$

with $SSW = \sum_{c=1}^{C}\sum_{j=1}^{b_c}(y_{cj} - \bar{y}_c)^2$ and

$$K = \frac{n - \frac{\sum_{c=1}^{C} b_c^2}{n}}{C - 1}.$$

In simulation studies, the ANOVA estimator is usually found to be an approximately unbiased, efficient, and consistent estimator of ρ, as discussed by S. R. Paul, K. K. Saha, and U. Balasooriya. These empirical findings, together with its appealing intuitive interpretation and its computational simplicity, are the reasons why it is used in the estimation of design effects in many surveys (e.g., the ESS).

The model described has the advantage that it applies to many real-world situations. In the ESS, for example, the model-based design effect is estimated according to the above formula in countries where sampling was done using (a) unequal selection probabilities, (b) clustering, or (c) both. What makes it even more useful is that it can also be applied to multiple design samples. Gabler, Häder, and Lynn showed that Equation 1 has a generalized form that allows a weighted average to be calculated over multiple domains in a sample.

Software

Today, most of the popular statistical software packages offer an option for data analyses to allow for complex designs—either by providing an estimate of the design effect or by their capability to account for the complex design in the variance estimation. These include STATA, SUDAAN, and WesVar PC.

Diary

A diary is a type of self-administered questionnaire often used to record frequent or contemporaneous events or experiences. In *diary surveys*, respondents are given the self-administered form and asked to fill in the required information when events occur (event-based diaries) or at specified times or time intervals (time-based diaries). Data from diary studies can be used to make cross-sectional comparisons across people, track an individual over time, or study processes within individuals or families. The main advantages of diary methods are that they allow events to be recorded in their natural setting and, in theory, minimize the delay between the event and the time it is recorded.

Diaries are used in a variety of domains. These include studies of expenditure, nutrition, time use, travel, media exposure, health, and mental health. Expenditure surveys usually have a diary component in which the respondent has to enter expenditures on a daily basis for a short period of time, such as a week or 2 weeks. An example of this is the Consumer Expenditure Survey in the United States, in which one household member is assigned two weekly diaries in which to enter household expenditures. Food and nutrition surveys use diaries to record food consumption over a fixed period of time. An example is the 1996 Food Expenditure Survey in Canada.

Types of Diaries

Time-use diaries usually have shorter reference periods than expenditure diaries. The most common methodology is a diary where the respondent accounts for all his or her activities in a period of 24 hours. If different respondents get assigned different days, the data are used to construct a synthetic week using data from other respondents with similar characteristics. Sometimes, respondents are asked to record their activities at random times during the day when they are signaled by an electronic device. In other time-use surveys, the diary is used as a recall aid for in-person or phone interviews. Time-use researchers have often found that when people are asked about what they spend time on, they often overestimate or underestimate time spent relative to what they actually record in diaries.

Travel surveys use diaries to record trips. Some examples are the 2001 National Household Travel Survey, which recorded information about one travel day, and the 1995 American Travel Survey, which was a 3-month travel survey structured in the form of a calendar. Media exposure diaries are used by companies in the United States like Nielsen and Arbitron to measure the size and composition of the television and radio audiences, respectively, in specific geographic media markets. The Nielsen TV Diary covers television tuning and viewing for all household members in their home for a 7-day week, while the Arbitron radio diary is for one person and covers radio listening anywhere it may take place during a 7-day week.

Diaries are also widely used in health, mental health, and by researchers in various areas of psychology. Diary studies have been used to investigate symptoms, medications, pain levels, substance use, unsafe sexual practices, depression, anxiety, addictions, use of health services, and many other medical issues.

Paper-and-pencil diaries are the oldest kind of diary instrument and can be structured in different ways depending on the type of survey. Paper-and-pencil diaries can be of a journal type (which are unstructured), product type (in categories), outlet type (by place), or day/time type (which covers each hour or minute of each day in the measurement period). An ideal paper-and-pencil diary would be portable, incorporate simple instructions, and have an appropriate level of structure and organization. Though they are very easy to use, paper diaries can be problematic. Respondents often forget to fill them out in a timely manner and later make recall errors. The burden of data entry and processing can be heavy for these diaries. Augmented paper diaries are sometimes used in time-based surveys, when respondents record in a paper diary, and a device like a beeper or pager, programmable wristwatch, or phone call reminds them to fill out the diary.

Advantages and Disadvantages

Recent technological innovations in diary studies include the use of handheld devices, voice activated recorders, scanners, and Web-based diaries. Some devices now in use include handheld computers, personal digital assistants, and electronic diaries. Electronic devices have the benefit of being portable, can have time and date stamps, and are easy to program to allow for signaling or other kinds of customization. Although data entry is easier, the costs of training, program development, hardware, and repairs can be quite high.

There are several problems with diary surveys in general. Since participation often involves a large time commitment, response rates are can be very low. Additionally, there are problems with accuracy of data entry by respondents. Errors include forgetting to fill the diary or filling it in erroneously because of recall problems caused by delay. The process of having to fill out a diary may also affect the respondent's behavior. For instance, respondents may change their levels of food consumption in food surveys or purchase fewer items in expenditure surveys during the time they are participating in the diary survey merely because they know they are being measured. Finally, diary studies can be expensive both because of the cost of the technological devices and also the costs of interviewers having to make repeated visits to train respondents to use the diary, monitor respondents to ensure that they fill it out, and pick it up at the end of the survey.

DIFFERENTIAL ATTRITION

Panel studies are subject to *attrition*, which is unit nonresponse after the initial wave of data collection. Attrition affects the results of analyses based on panel data by reducing the sample size and thereby diminishing the efficiency of the estimates. In addition, and more important, attrition also may be selective; differential or selective attrition occurs when the characteristics of the panel members who drop out of the panel because of attrition differ systematically from the characteristics of panel members who are retained in the panel. Differential attrition may introduce bias in survey estimates. However, the amount of bias depends both on the amount of attrition and on the selectivity of attrition, or in other words, on the association between the variables from which the estimate is constructed and the attrition propensity of the panel units. If an estimate is not associated at all with the attrition propensity, then the data are not biased. However, if an estimate is associated with the propensity to participate in the panel, the data are biased.

The propensity to participate in a panel survey (or alternatively, the propensity to be contacted, and given contact, the propensity to agree to participate in the panel survey) is influenced by many different factors, from characteristics of the survey design, survey-taking climate, and neighborhood characteristics to sociodemographic characteristics of the sample persons, the sample persons' knowledge of the survey topic, and their prior wave experiences. For example, the "at-home" patterns of a household and its members, and thus also their propensity to be contacted, are a function of sociodemographic attributes (e.g., number of persons in household) and lifestyle (e.g., working hours, social activities). If one person lives alone in a housing unit, contact is completely dependent on when he or she is at home. Likewise, the lifestyles of younger people may involve more out-of-home activities than those of other groups, and this also means that they will be harder to contact. Consequently, for example, when studying the extent of and changes in social contacts as teenagers grow into adulthood and later when they start their own families, the results are likely to be biased because the survey disproportionally loses (due to attrition) young individuals with more out-of-house activities. A similar logic underlies how error related to refusals is generated. For example, some studies of panel attrition provide evidence that a pleasant survey experience enhances the chance that people will participate in subsequent surveys, whereas those without such an experience are less likely to participate. Participating in a survey is a negative experience when one lacks the cognitive ability to perform the respondent task. We can assume that respondents with low socioeconomic status, including lower educational attainment, might have more difficulties in performing the respondent task; consequently, the interview is an unpleasant or bad experience, and these respondents will be less motivated to participate again in the panel survey. Since socioeconomic status is an important explanatory variable in many panel data analyses, it may be expected that at least some of the conclusions of these studies will be based on biased estimates due to the resulting differential attrition.

Attrition may also be selective with respect to the recent behavior of panel members or recent changes in their position, for example, a divorce transition. Several attrition studies have shown that noncontact is more likely after a household move. However, the move itself is usually precipitated by a particular set of circumstances, and specific events, such as marriage or divorce, affect the likelihood of moving. A divorce is also a stressful situation and can cause a family crisis, which may prevent panel members from participating in a new wave of the panel survey. Since there might be a relationship between the propensity to undergo the change being analyzed, that is, getting a divorce, and the propensity to leave the panel survey, the divorce propensity estimated on the basis of the panel data is most likely an underestimate of the real divorce propensity.

Differential Nonresponse

Differential nonresponse refers to survey nonresponse that differs across various groups of interest. For example, for many varied reasons, minority members of the general population, including those who do not speak as their first language the dominant language of the country in which the survey is being conducted, are generally more likely to be nonresponders when sampled for participation in a survey. Thus, their response propensity to cooperate in surveys is lower, on average, than that of whites. The same holds true for the young adult cohort (18–29 years of age) compared to older adults. This holds true in all Western societies where surveys are conducted.

Ultimately, the concern a researcher has about this possible phenomenon should rest on whether there is reason to think that differential nonresponse is related to *differential nonresponse error*. If it is not, then there is less reason for concern. However, since nonresponse error in itself is difficult to measure, differential nonresponse error is even more of a challenge.

In considering what a researcher should do about the possibility of differential nonresponse, a researcher has two primary options. First, there are things to do to try to avoid it. Given that noncontacts and refusals are typically the main causes of survey nonresponse, researchers can give explicit thought to the procedures they use to make contact with respondents (e.g., advance letters) and those they use to try to avoid refusals from respondents (e.g., refusal conversation attempts)—in particular as these procedures apply to key groups from whom lower levels of contact and/or cooperation can be expected. For example, the use of differential incentives to persons or households known from past research to be harder to contact and/or gain cooperation from has been shown to be effective in lowering differential nonresponse. However, some have argued that it is not "equitable" to provide higher incentives to groups that traditionally have low response rates because it fails to fairly "reward" those who readily cooperate in surveys.

However, an unpleasant paradox exists for those who argue that differential strategies aimed at reducing differential nonresponse are inequitable to those respondents who are easier to contact and/or more readily cooperate. When a new treatment (e.g., higher noncontingent incentives) is implemented across the board to raise response rates—so that everyone gets the same treatment—it often increases the gap in response rates between the lowest responding groups and the highest responding groups rather than narrowing the gap between the two groups. This results in an *increase in the size of the differential nonresponse.*

The second option for researchers is to use a variety of post-survey adjustments to their raw data to account for differential nonresponse. If there is no differential nonresponse error associated with the differential nonresponse, then these adjustments will likely be adequate. However, too often it is not known whether there is any error associated with the differential nonresponse, and thus researchers cannot know with confidence whether their adjustments have accomplished anything to help make the survey more accurate.

Directory Sampling

Directory sampling is one of the earliest versions of telephone sampling. Telephone directories consist of listings of telephone numbers. The residential numbers are generally placed in a section of the directory separate from business numbers. Each telephone listing is generally accompanied by a name and an address, although the address is not always present. Households may choose not to have their telephone number published in the directory. These are referred to as *unpublished numbers*, most of which also are *unlisted numbers*.

In the original application of directory sampling, a set of telephone directories covering the geopolitical area of interest to the survey were assembled. After the sample size of telephone numbers was determined, a random selection procedure was used to draw the required number of residential directory-listed telephone numbers for each directory. The actual selection method ranged from using systematic random sampling of listed telephone numbers to first selecting a sample of pages from the directory and then sampling one or more telephone numbers from the selected pages.

Directory samples provide samples only of telephone numbers that are directory listed. Directory samples will yield biased samples of a population, because all unlisted households are given a zero probability of selection, and unlisted households generally differ from listed households on key characteristics. For example, persons with unlisted numbers are more likely to be minorities, recent movers, and single female adults. In some geographic areas, a substantial percentage of households may have unlisted telephone numbers, for example, larger central city areas and Western states.

Today, directory-listed sampling is rarely used alone, having been replaced by list-assisted random-digit dial sampling. But in other ways, directory sampling has made a comeback. Telephone directories are now entered into national databases of listed residential telephone numbers that are updated on an ongoing basis. A fairly common random-digit dialing sample design involves forming two strata. The first stratum consists of directory-listed residential telephone numbers. The second stratum consists of telephone numbers in the list-assisted sampling frame that are not residential directory-listed telephone numbers. Thus two mutually exclusive strata are formed, and a sample of telephone numbers is drawn from each stratum.

The presence of an address for most residential directory listed telephone numbers in national databases makes it possible to assign geographic codes to the addresses. Typical geographic codes include county, zip code, census tract, block group, and census block. This makes it possible to sample directory-listed telephone numbers from small geographic areas, for example, from a *reverse directory*. The presence of a name with each listed number also enables the matching of the names to lists of ethnic surnames. This makes it possible to sample directory-listed households with specific surnames.

Disclosure

Within the context of survey research, *disclosure* can be used with two distinct meanings. In the first meaning, a researcher is required to provide full disclosure of his or her own identity and purpose in collecting data. In the second meaning, a researcher is required to prevent disclosure of information that could be used to identify respondents, in the absence of specific and explicit informed consent allowing the researcher to disclose such information.

However, in some research settings, full disclosure of the research objectives may jeopardize the objectivity of results or access to research participants. Observational research of behavior in public settings, for example, may be exempt from rules of informed consent, since the public nature of the behavior itself implies consent. Nevertheless, in this situation, the researcher ideally should provide detailed justification for the data collection methodology in any research proposal or data presentation, and the methodology should be subject to peer and ethical review. In addition, the participants' right to privacy, anonymity, and confidentiality gains additional importance in such cases, since respondents have not given explicit consent and are not cognizant of the purpose or objective for which they "provide" information. Whenever possible, participants should be debriefed as to the research objectives and use of data after completion of the research or observation and given the opportunity to refuse participation.

Another situation that challenges many researchers in the effort to fully disclose their role and objective as researchers is one in which gatekeepers are involved. When gatekeepers control access to the participants of the research, full disclosure to the gatekeeper is necessary but not sufficient to gain access to the research participant. Permission obtained from the gatekeeper may not be substituted for the need to take separate and full informed consent of the participants. The rights of participants in such situations are the same as in all other cases and need determined protection.

In the second use of the term, disclosure of a respondent's identity or identifying information is prohibited in the absence of specific, informed consent. Research for which disclosure of the subject's identity and/or responses could put the individual at risk of criminal or civil liability or damage the subject's financial standing, employability, or reputation is especially problematic and is generally subject to review by an institutional review board.

Disclosure risks may involve a direct risk, when the disclosure of a respondent's identity or responses may cause harm to the respondent because of the nature of the data themselves, or the risk may be indirect, when risk involves the potential for combining the collected data with an external database through which individuals may be identified and confidential information exposed. This indirect disclosure risk is becoming far more problematic nowadays with the availability of many various data sources, and respondent protections are increasingly focused on this second type of disclosure risk.

Recent expansion in the aggregation of data from a variety of sources that link individuals using identifying information has increased researchers' concerns about confidentiality protection and the disclosure of research subjects' identity. Although confidentiality is promised in the data collection process, the obligations of those disseminating "cleaned" data sets are often less formal and less clear. As commercial databases that include names, addresses, and other sensitive information have become more accessible, the potential for misuse has grown.

When data sets are made public or disseminated, any codes or variables that can be used in combination to isolate and identify a small population subgroup or class pose a risk of disclosure. Ethnicity, for example, in combination with age, gender, and a detailed occupational group or specific geographic identifier may provide sufficient information to disclose an individual identity. Some protections to reduce the likelihood that this form of disclosure may occur include the following:

1. *Coarsening* the data set involves disguising identifying information within a data set. Variables such as age may be rounded in order to remove the precision that might allow for identification. Income is a visible and highly sensitive characteristic that may be top and bottom coded, so that each income extreme, whether for households, persons, or families, including total income and its individual components, is combined into "over" and "under" categories.

2. *Microaggregation* is the process of creating artificial respondents synthesized from averaged responses. For the Substance Abuse and Mental Health Services Administration's Alcohol and Drug Services Study (ADSS) groups, cases in sets of three for problematic variables could potentially be linked to other files or could be used to identify an individual or organization. The average of the three records for each grouping is then recorded as the record for each case in the group.

3. *Suppression* is the removal of any estimate or value in which cells are below a certain size. For example, the Census Bureau and National Center for Health Statistics require that all geographic areas identified must have at least 100,000 persons in the sampled area (according to latest census or census estimate). Other variables, such as duration of residence, migration specifying movement from one type of area to another, distance of a residence from an identified geographic area, or the existence of a particular service or utility (such as well water, septic tanks, and cable TV) for which only a small area has or does not have this type of service are also treated as sensitive variables capable of disclosing respondent

identity and suppressed from publicly disseminated data files.

Laws generally do not protect researchers from disclosure in the ways that journalist–sources, lawyer–client communications, and doctor–patient relationships are often exempted from required disclosures of identify and content of communication. Researchers are ethically required actively to protect respondents' identities, particularly when data sets may be distributed, combined, or used in other, unforeseen ways.

Disclosure Limitation

Survey researchers in both the public and private sectors are required by strong legal and ethical considerations to protect the privacy of individuals and establishments who provide them with identifiable information. When researchers publish or share this information, they employ statistical techniques to ensure that the risk of disclosing confidential information is negligible. These techniques are often referred to as "disclosure limitation" or "disclosure avoidance" techniques, and they have been developed and implemented by various organizations for more than 40 years.

The choice of disclosure limitation methods depends on the nature of the data product planned for release. There are specific disclosure limitation methods for data released as micro-data files, frequency (count) tables, or magnitude (point estimates) tables. Online query systems may require additional disclosure limitation techniques, depending on whether the data underlying these systems are in the form of micro-data files or tables.

The first step in limiting disclosures in data products is to delete or remove from the data any personal or "direct" identifiers, such as name, street address, telephone number, or Social Security number. Once this is done, statistical disclosure limitation methods are then applied to further reduce or limit disclosure risks.

After direct identifiers are deleted from a micro-data file, there is still a possibility that the data themselves could lead to a disclosure of the individual, household, or business that provided them. Some people and some businesses have unique characteristics that would make them stand out from others. Applying micro-data disclosure limitation methods reduces the possibility of locating these unique records. Some of these methods are data reduction (delete data fields or records), data swapping, micro-aggregation, data perturbation, and imputation.

Protected micro-data produce protected tables. However, sometimes there is interest in producing tables without changing the underlying micro-data. Disclosure limitation methods for tables are applied directly to the tables. These methods include redesign of tables (collapsing rows or columns), cell suppression, controlled and random rounding, and synthetic data substitution.

The application of most disclosure limitation methods will result in some loss of information. Survey researchers should carefully select the appropriate disclosure limitation methods not only to maximize the information retained and the benefits accrued through data release but also protect confidential information from disclosure. However, when judging the risks of disclosure against the loss of information and the benefits of data release, survey researchers should recognize that there is no way to ensure complete elimination of disclosure risk short of not releasing any tables or micro-data files.

Disk by Mail

Disk by mail is a survey administration technique in which a selected respondent is mailed a computer disk that contains a questionnaire and a self-starting interview program. The respondent runs the program on his or her own computer and returns the disk containing the completed questionnaire. In some instances, the disk may provide an option for the person to transmit his or her responses over the Internet. Although disk-by-mail surveys can be conducted with the general public, the approach is most effective for targeted populations such as professional or business groups for whom computer access is nearly universal.

Disk by mail is one of a variety of computer-assisted self-interview (CASI) techniques. As such it has some of the advantages of a computerized survey. These surveys have the capability of guiding the respondent interactively through the questionnaire and including very complex skip patterns or rotation logic. This approach can also offer many innovative features beyond traditional mail and telephone surveys, but it does require costs and time in terms of programming and distribution of the survey. Because the approach is computer based, it allows the researcher to enhance the survey forms with respect to the use of color, innovative screen designs, question formatting, and other features not available with paper questionnaires. They can prohibit multiple or blank responses by not allowing the participant to continue on or to submit the survey without first correcting the response error.

Disk by mail also shares some of the advantages of mail surveys. It is less expensive than telephone surveys since there are no interviewer costs incurred, eliminates the potential for interviewer bias, provides respondents with greater "perceived" anonymity that may lead to more truthful answers, especially on sensitive questions; and allows respondents to complete the survey on their own time, that is, when it is most convenient.

Disk by mail does have some drawbacks as a survey technique. It is restricted to those having access to a computer and limited by the technological capacity or make of the respondent's computer. Although disk-by-mail surveys allow for much more innovative features than paper-and-pencil mailed surveys, some respondents may have difficulty accessing the survey due to poor computer skills and will not be able to respond. Furthermore, some people are not accustomed to the process used to respond to an electronic survey (e.g., selecting from a pull-down menu, clicking a radio button, scrolling from screen to screen) and will need specific instructions that guide them through each question and the manner in which they should respond. As with other computer-based survey tools, respondents are often concerned about confidentiality and may be reluctant to download files in fear that they may contain viruses. Additionally, disk by mail typically requires a longer fielding period than some other methods (such as telephone) to complete the project, can make it difficult for the respondent to ask questions or seek clarification, can be limited by low literacy rates among some populations, and provides researchers with little control over who actually completes the survey, thus leading to the possibility of within-unit coverage error.

Dispositions

Sample dispositions (codes or categories used by survey researchers to track the outcome of contact attempts on individual cases in the sample) provide survey researchers with the status of each unit or case within the sampling pool and are an important quality assurance component in a survey, regardless of the mode in which the survey is conducted. Sample dispositions are used for three reasons: (1) to help the survey researcher control the sampling pool during the field period, (2) to calculate response rates, and (3) to help assess whether the sample might contain nonresponse error. Sample dispositions usually are tracked through the use of an extensive system of numeric codes or categories that are assigned to each unit in the sampling pool once the field period of the survey has begun. Common sample dispositions include the following:

- Busy (telephone survey)
- Fast busy (telephone survey)
- Callback
- Completed interview
- Household refusal
- Ineligible respondent
- Ineligible household
- Language barrier
- Nonresidential address or number (in-person, mail, and telephone surveys)
- Nonworking number (telephone survey)
- Partial interview
- Privacy manager (telephone survey)
- Respondent refusal
- Ring–no answer (telephone survey)
- Unable to participate
- Unavailable respondent
- Unpublished number (telephone survey)
- Vacant housing unit (mail and in-person surveys)

Sample dispositions usually are assigned each time a case is contacted during the field period of a survey, and final sample dispositions are assigned once the field period of a survey has been completed (and the final status of each case in the sampling pool is known). For example, the disposition code of each telephone number in the sample for a telephone survey is updated after every call that is made to the number by an interviewer. In the case of a mail survey, sample dispositions may be updated as completed survey questionnaires are returned to researchers by respondents or as the postal service brings mail "returned to sender" back to the researchers in the case of incorrect addresses or respondents who have moved. In an Internet survey, sample dispositions may be updated as email invitations are sent to individuals in the sampling pool, as email nondelivery messages are returned to the sender after not being able to be delivered (in the case of an incorrect or nonworking email address), as respondents log in to complete the Web survey, and as respondents complete the questionnaires. In an in-person household survey, sample dispositions may be updated as field interviewers visit addresses listed in the sampling frame.

Uses of Sample Dispositions

Controlling the Sampling Pool

A primary purpose of sample dispositions is to assist researchers in controlling the sampling pool during the field period for a survey. For example, if interviewers in an in-person survey were allowed to choose neighborhoods and households to visit from the sampling pool, nonresponse error would be likely because the resulting sample would include a disproportionately large number of households in neighborhoods that are easy to reach, consist primarily of single-family houses, and have higher socioeconomic statuses (and thus may be safer to visit). Sample dispositions make it possible for survey managers to ensure that all cases in the sampling pool are contacted at a variety of days and times and that specific appointments are kept. In this way, sample dispositions help researchers maximize the efficiency of interviewers. In telephone, mail, Internet, and in-person surveys, sample dispositions make it possible for survey managers to ensure that nonresponding cases in the sampling pool are targeted by follow-up mailings, reminder emails, telephone calls, or visits by interviewers.

Calculating Response Rates

Another important purpose of sample dispositions is to calculate survey response rates. It is standard practice for survey researchers to compute a survey's response rates at the end of the field period. Response rates are a common measure of survey quality, and it often is assumed that the higher the response rate, the higher the quality of the survey data. Because sample dispositions categorize the outcome of each case (or unit) in the sampling pool, sample dispositions make it possible for survey researchers to calculate survey response rates.

Assessing Nonresponse Error in the Sampling Pool

A third important purpose of sample dispositions is to assess potential nonresponse error in the sampling pool. Correct or not, a common assumption is that there is more nonresponse error in survey samples with lower response rates than in survey samples with higher response rates. Although determining the amount of nonresponse error in survey data requires more than just knowing the survey response rate, calculating survey response rates is an important first step in understanding whether nonresponse error is present in survey data.

Disproportionate Allocation to Strata

One type of random sampling employed in survey research is the use of disproportionate allocation to strata. Disproportionate allocation to strata sampling involves dividing the population of interest into mutually exclusive and exhaustive strata and selecting elements (e.g., households or persons) from *each* stratum.

Commonly used strata include geographic units; for example, high-minority-density census tracts in a city are put into one stratum and low-minority-density census tracts are put into another stratum. In epidemiology case-control studies, strata are used where persons in one stratum have a condition of interest (e.g., Type I diabetes) and persons without the condition are put into a second stratum. After dividing the population into two or more strata, a "disproportionate" number of persons are selected from one stratum relative to others. In other words, the persons in one stratum have a higher probability of being included in the sample than are persons in the other strata.

This type of sampling can be used to create a more efficient sample design with more statistical power to detect key differences within a population than a simple random sample design or a proportionate stratified sample design. An example of a difference within a population is the comparison of older and younger persons with respect to some characteristic, such as having health insurance. However, a disproportionate allocation can also produce some results that are much more inefficient than a simple random sample or a proportionate stratified sample design.

Disproportionate allocation to strata as a technique can be more efficient than a simple random sample design. Efficiency is determined by whether the sample variances are smaller or larger than they would have been if the same number of cases had been sampled using a simple random sample.

Researchers use disproportionate allocation to strata in order to increase the number of persons with important characteristics within their final study sample and to increase the efficiency of the sample design over simple random sampling. When making estimates using a sample that has used disproportionate allocation to strata sampling, it is important to control for the differences in the probabilities of selection into the sample. Persons from some strata will have been more likely to be included than persons from other strata. To accomplish this task, survey weights are used to adjust each person for their probability of selection into the sample when making estimates of specific characteristics for the entire population.

Disproportionate allocation to strata can make some estimates more (or less) efficient than if the same number of cases had been selected using simple random sampling. Efficiency is gained to the extent that the variables used to stratify the target population are related to the characteristic being studied. For example, when stratifying a health insurance survey by age into two strata—those 65 years of age and older and those under 65 years—the outcome variable of interest, "health insurance coverage," is strongly related to the variable used to stratify. People 65 years of age and over are much more likely to be insured than those under 65 years. The same is true for case-control studies where the condition of interest is used to stratify the target population and the resulting sample is more efficient for studying differences between those with a condition and those that are known to have the condition than would have been possible through a simple random sample of the population.

By the same token, the survey that was more effective for some estimates as a result of stratification may be less efficient for other estimates than a simple random sample would have been. For example, when studying political party preference using a survey stratified by age—65 years and over versus 18- to 64-year-olds—will not yield nearly as efficient an estimate as it did for health insurance coverage, because party preference is not as correlated with being over 64 years as health insurance coverage is. This situation also varies by how much more likely people in one stratum were to be selected into the sample. The worst case scenario is when the strata are completely unrelated to the variables being examined and the two (or more) strata were selected with vastly different probabilities of selection (say 1 in 10 in one strata and 1 in 100,000 in the other). In this case, disproportionate allocation to strata produces an inefficient sample design.

A key aspect of disproportionate allocation to strata is the importance of the estimates for the entire sample versus the estimates for population domains. In our example we have decided to oversample older adults relative to younger adults so that we can compare these two domains with respect to a characteristic such as health insurance. The study will, however, also produce an estimate of health insurance coverage for the entire population, and the oversampling of older adults introduces unequal weights into the sample design that in most cases will reduce the precision of the estimates for the entire population. This type of trade-off needs to be carefully considered at the design stage.

Do-Not-Call (DNC) Registries

A do-not-call (DNC) registry is a listing of people who have requested that they not receive any telephone calls from telemarketers on their residential telephone number(s). In the United States, these registries are maintained by the federal government and by government agencies in the majority of states. Survey research organizations are *not* prohibited from calling the numbers on the DNC registries, but many citizens fail to understand this, which causes them to be less willing to agree to participate when sampled for a telephone survey.

The birth of DNC registries has its roots firmly in the groundswell of public reaction in the United States to certain practices of the telemarketing industry that began in the 1980s and escalated considerably until 2003, when the national registry was implemented. The sheer volume of calls, telemarketers' penchant for calling in early evening hours (i.e., dinner time), and their abusive use of predictive dialing equipment all served to overwhelm the repeated attempts of the Direct Marketing Association and the American Telemarketing Association to gain industry agreement and compliance on self-policing measures. This failure of industry standards led to a snowballing of political sentiment that in turn led to legislation in 40 states and ultimately an umbrella National Do Not Call Registry overseen by the Federal Communication Commission (FCC) and the Federal Trade Commission (FTC).

The do-not-call registry guidelines and restrictions generally do not directly affect the survey research industry—in fact, survey research is *specifically exempted* from the law. So, only in rare cases does the legislation ever have the chance of affecting the research industry. However, there is always the potential for interference by an overzealous prosecutor in some potential gray area, and consumers often do not recognize the difference between a telemarketing call and a request to participate in a survey. Indirectly, and through public ignorance, the DNC registries cause some sampled residents whose number is listed on the registry to refuse to participate in telephone surveys, at least in part because they mistakenly believe that survey researchers are restricted from calling their number.

Most citizens associate the DNC with the federal registry that was established in 2003. However, the first state-level DNC was put in place more than 15 years earlier, in Florida in 1987. The federal DNC was established under the 1994 Telemarketing and Consumer Fraud and Abuse Prevention Act directing the FTC, and the 1991 Telephone Consumer Protection Act providing authority to the FCC, to establish such a registry. Proposed rules and public discussions involving the establishment of the DNC began in 1999, with the first registrations taken in October 2003. In total, 40 states enacted their own DNC laws by the time the federal DNC began operation. In most cases, each state set up their own registration procedures for residents of their respective jurisdictions. During the ensuing 5 years since the federal DNC was established, all but one state (Pennsylvania) has folded their registries into the federal database. It is worth noting that the Direct

Marketing Association, the largest telemarketing industry group, had their own do-not-call service, the Telephone Preference Service (TPS), for many years prior to establishment of the federal DNC; the likelihood is that they will follow the lead of the states, ceding their efforts to the federal DNC.

As of the fall of 2007, the U.S. federal DNC totaled approximately 150 million distinct telephone number listings. Only about 55% of these telephone numbers fell within the normal telephone landline random-digit dialing (RDD) sampling frame, another 37% were cellular phone numbers, with the remainder being likely business numbers.

There is one area where the federal DNC can directly affect survey research. In some cases, a telephone survey sampling design may utilize compiled lists of various types to supplement or as an aid in stratifying the sample frame. Most list compilers and vendors are part of the direct marketing world rather than the survey research world. Hence because of their internal business rules, they may eliminate records with telephone numbers that are also on the DNC. Consequently, a telephone survey researcher who buys a sample from such a vendor must question the supplier carefully and in many cases be required to sign a release before the vendor will supply those records to the survey researcher.

There is not much empirical evidence on what effect the DNC registries have had on telephone survey response rates. One study, using large national RDD survey databases compiled in late 2003 and early 2004, indicated that those households whose telephone numbers were listed on the national DNC actually were *more likely to agree to participate in a telephone survey* when they were sampled than were households whose home number was not listed on the registry.

Don't Knows (DKs)

"Don't Know" responses (DKs) occur when respondents report that they do not know or are uncertain about the answer to a survey question, whether it be about their behavior, attitudes, beliefs, perceptions, or a factual question. Don't Knows are often considered to be nonsubstantive responses and a form of item nonresponse. A high level of DKs is sometimes used as an indicator of poor data quality. DKs also create problems for statistical analysis. Researchers often treat DKs as missing data and often exclude cases in which respondents said "Don't know" from their analyses.

Respondents may say they don't know in response to a survey question for a number of reasons. They may genuinely not have an opinion or belief to report. Alternatively, satisficing theory suggests that respondents may report that they don't know because it is a strategy for providing acceptable (satisfactory) answers to survey questions without going through the mental processes necessary to provide a careful response. Finally, some respondents may say they don't know to avoid answering an uncomfortable, embarrassing, or politically charged question.

Don't Know responses are one example of a larger category of no-opinion responses, which reflect that respondents do not have a judgment to report. "Don't know" is sometimes included with the list of substantive response options that are offered to respondents in survey questions that use a closed-ended response format—for example, *or don't you know?* When presented in a survey question with a list of response options that does not include an explicit don't know option, respondents may volunteer "don't know" responses to interviewers in telephone and face-to-face surveys and may write them in on self-administered surveys.

Thus, respondents can report that they don't know the answer to a survey question regardless of whether such an option is explicitly offered to them. However, explicitly including such an option to respondents dramatically affects the proportion of respondents who say they don't know. The inclusion of an explicit

Don't Know response option has been found to substantially increase (from 5 to as much as 30 percentage points) the proportion of respondents who report that they don't know, particularly for questions about issues with which respondents may not be familiar.

Because including an explicit Don't Know option can have a dramatic impact on responses, the decision about whether to explicitly offer such a response option is a very important one for researchers when creating a survey instrument. Two perspectives—nonattitude and satisficing—provide competing theoretical arguments about this decision.

The nonattitude perspective suggests that respondents who genuinely do not know an answer nevertheless may choose a substantive response option when no other option is available. The nonattitude perspective comes from Philip Converse's observation that survey interviews may exert implicit pressure on respondents to appear to have an opinion on a wide range of topics. When respondents are faced with a question to which they genuinely do not know the answer, many may be uncomfortable admitting that they know little about the topic or that they do not know the answer, and this may be particularly true when multiple questions for which they are uninformed are included in a survey interview. Respondents who do not have attitudes on an issue may respond to a question about the issue essentially by randomly selecting responses from among the choices offered. Including an explicit Don't Know response option would provide these respondents with a way to accurately report that they do not know how to answer the question.

In contrast, as noted previously, the satisficing perspective suggests that respondents may choose an explicitly offered Don't Know response option as an alternative to completing the work necessary to choose a substantive response that they would otherwise be able to provide. Thus, the satisficing perspective suggests that Don't Know responses should not always be viewed as accurate reports of nonattitudes. This perspective on Don't Know responding is based on the argument that answering survey questions is a demanding cognitive task. When answering each question in a survey, respondents must understand and interpret the question, search their memory for relevant information, integrate that information into an opinion, and translate that opinion into an understandable response. This "work" may overwhelm respondents' abilities or motivation. In such situations, some respondents may satisfice by seeking out ways to avoid doing this work while still appearing as if they are carrying on a survey interview appropriately. When respondents satisfice, they look for a cue in the question suggesting how to do so. An explicitly offered Don't Know response option provides such a cue, allowing respondents who are otherwise disposed to satisfice to do so by saying, "Don't know." If a Don't Know option was not offered (and the question provided no other cue about how to satisfice), these respondents might be pushed to do the cognitive work necessary to carefully answer the survey question.

Evidence about why respondents choose to report that they do not know generally supports the satisficing perspective. Omitting Don't Know response options from survey questions does not appear to substantially reduce data quality. There is little evidence that explicitly offered Don't Know response options provide an advantage to researchers.

Double-Barreled Question

A double-barreled question asks about more than one construct in a single survey question. Best practices for questionnaire design discourage use of certain types of questions. Questions with unknown terms or complicated syntax should not be used when designing a questionnaire. Foremost among these recommendations is to avoid double-barreled questions.

The word *and* is a hallmark of a double-barreled question. Double-barreled questions most frequently arise in attitudinal questions. In these types of questions, two attitude targets (e.g., political candidates and policy decisions) are asked as one construct (e.g., *Do you favor candidate X and higher taxes or candidate Y and lower taxes?*). Response formation problems arise when the respondent prefers candidate X and lower taxes or candidate Y and higher taxes. Statements that align two different constructs also are double-barreled (e.g., *Do you agree or disagree with the following statement: Managers in my organization are helpful, but the lack of diversity in the organization is disappointing*). The word *but* plays the role of the conjunction *and*, linking two divergent question constructs into one double-barreled question.

Double-barreled questions require more time for respondents to answer than single-barreled forced choice questions. Comprehension breakdowns are responsible for part of the problems with double-barreled questions. Respondents struggle to understand exactly which construct among the multiple constructs that appear in the question wording is the most important, resulting in higher rates of requests for clarification for double-barreled questions than in single-barreled questions. Breakdowns may also occur when generating a response and in mapping the retrieved or generated response to the response options. As a result, higher rates of item nonresponse and unstable attitudes are likely to occur with double-barreled questions. This also leads to analytic problems and questions of construct validity, as the analyst does not know which "barrel" led to the respondent's answer.

Some double-barreled questions ask about one construct in the question wording, but introduce a second construct through the response options. These questions are sometimes called "one-and-a-half-barreled questions." For example, *Do you agree or disagree with Candidate Z's views on alternative fuels?*, with response options of "Agree," "Agree, and I agree with Candidate Z's stance on tax breaks for hybrid vehicles," "Disagree," introduces the idea of tax benefits from owning hybrid cars only in the response options. As with double-barreled questions, one-and-a-half-barreled questions lead to questions of construct validity. In this example, endorsing "Disagree" can be seen as disagreeing with the candidate's views on alternative fuels, tax benefits for hybrid vehicles, or both.

Turning a double-barreled question into two forced choice questions or two separate statements are common repairs for this questionnaire design problem. Many double-barreled questions mimic forced choice questions but differ in question wording. In a forced choice question, the respondent is asked to choose between two constructs. However, each construct in a forced choice question is asked as a separate idea (e.g., Candidate A versus Candidate B; higher taxes versus lower taxes). Hence, repairs for double-barreled questions can be accomplished by identifying the multiple constructs in the question, deleting irrelevant constructs, and separating relevant constructs into two or more questions.

Double Negative

A *double negative* refers to the use of two negatives in one statement or question. In questionnaire design, this is almost always a situation to be avoided. A double-negative usually creates an unnecessary amount of confusion in the mind of the respondent and makes it nearly impossible for the researcher to accurately determine what respondents were agreeing or disagreeing to.

Such a question can increase item nonresponse by increasing the percentage of respondents unable to understand the question. A more insidious problem is an increase in the number of responses from people who have misunderstood the question and responded based on that misunderstanding. Both item nonresponse and misunderstanding contribute to the type of survey error know as *measurement error*.

Sometimes the questions sound sufficiently confusing that no serious researcher would include them in a questionnaire. For example, *Are you likely to vote for or against a candidate who is opposed to the proposed ordinance to prohibit smoking in public places?*

However, the second of the two negations often appears in the answer options. It is in these cases when a double negative question may seem perfectly clear to researchers, particularly those who are caught up in issues of the moment. For example, members of the media who support release of the names of jury members might wish to ask:

> *Please tell me whether you agree or disagree with this statement: "The names of jury members in capital trials should not be withheld from the media."*

Perhaps the most infamous example of a double-negative occurred in November 1992 in a survey conducted by the prestigious Roper Organization, a respected survey research center founded in 1947. Roper was commissioned by the American Jewish Committee to conduct a survey of adults in the United States to measure public attitudes and beliefs about Jews. The following question slipped through the usual quality control steps:

> *The term* Holocaust *usually refers to the killing of millions of Jews in Nazi death camps during World War II. Does it seem possible or does it seem impossible to you that the Nazi extermination of the Jews never happened?*

The published results of the survey implied that one third of adults in the United States felt it was possible that the Holocaust never occurred. The outrage and confusion resulting from the release of the study results prompted several other studies conducted with the specific aim of avoiding the double-negative problem. The other studies worded their survey questions to avoid double negatives. Results from these studies revealed that fewer than 10% of the population felt it was possible the Holocaust had never occurred.

The double-negative problem is difficult to avoid in questionnaire design for attitude and opinion surveys because researchers are often presenting choices to respondents that represent positives and negatives. One approach to avoiding double negations is to make every effort to present the issue without using any negative statement. If the double negative must be used, cognitive interviewing should be employed during pretesting to ensure that respondents have a clear understanding of the question.

Drop-Down Menus

Drop-down menus are often used in Web surveys and are one of the basic form elements in HTML (hypertext markup language) used for closed-ended survey questions, in addition to radio buttons and check boxes. They are also referred to as "drop-down lists" and "drop-down boxes."

Drop-down menus commonly display a single option that can be left blank, and other response options become visible after clicking on the side of the box. A response is selected by then clicking on one of the displayed choices, and multiple selections can be allowed (i.e., "check all that apply"). They are suitable and used for long categorical lists, such as lists of states or institutions, but they can be used for shorter and ordinal lists. While radio buttons and drop-down menus can fulfill the same purpose, there are some key differences. Drop-down menus take less space, as all the options do not need to be visible at all times. They also require two clicks, instead of a single click, to select a response option.

Experimental studies show no difference between radio buttons and drop-down menus in terms of time and break-off rates, but find higher rates of item nonresponse and nonsubstantive responses in drop-down menus.

Dual-Frame Sampling

Dual-frame sampling designs are a subset of multiple-frame designs in which units within the population of interest are selected via independent probability samples taken from each of two frames. These two frames make up the population of interest, and they typically overlap. The dual-frame sampling approach is often useful when the amount of undercoverage from using a single frame is substantially improved by the introduction of two (or more) frames. The degree of overlap in the two frames is usually not known a priori to the sampling, but should this information be available, estimates of the amount of undercoverage to be expected from the dual-frame approach can be assessed more accurately. The resulting estimates from each of the two frames in the dual-frame sampling design are combined to form a single composite dual-frame estimate of the population parameter(s) of interest. A generic figure illustrating the basic structure of a two-frame design is provided in Figure 1.

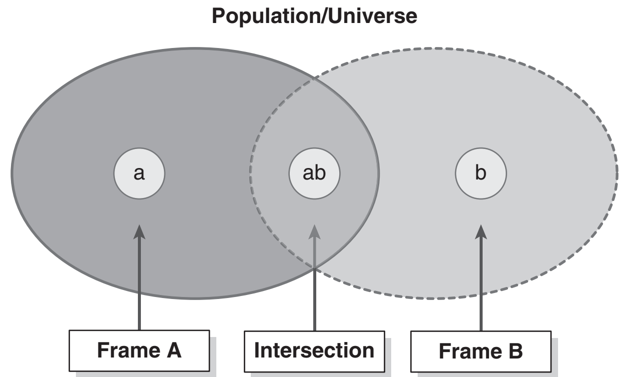

Figure 1 Illustration of two frames for a dual-frame sampling design

Considering this figure, we can see that there are three possible "overlap" situations that may occur when using two frames in the sampling design, including the following:

1. Illustrated in Figure 1 is the circumstance in which neither of the two frames is completely included in the other, implying that Frame A and Frame B have some degree of overlap (i.e., like cell phone and landline phone ownership). This approach serves to improve the overall coverage of the target population, thus reducing undercoverage; this situation is very common for dual-frame designs in practice. Another spin on this approach comes when estimates from a rare population are desired. For example, using random-digit dialing (RDD) to survey the state to estimate the quality of life of breast cancer survivors one year beyond their cancer diagnosis is possible through the use of a health eligibility screener—however, within a given state, the proportion of adult citizens who are one-year breast cancer survivors may be small, making the screener approach alone prohibitively expensive. The State Cancer Registry, however, provides a list of those diagnosed with cancer and is considered "complete" somewhere around 2 years post-diagnosis. So using this frame at the one-year point would certainly be accompanied by a degree of undercoverage and may contain errors in diagnosis, in general but it would include more individuals from the target population of interest. Using a dual-frame approach with an RDD frame with a health screener along with the cancer registry frame may be a more viable and precise approach for estimating the quality of life parameter of interest.

2. Not illustrated in Figure 1 is the circumstance in which Frame A is a complete subset of Frame B (i.e., a rare segment of the population, like homeless, institutionalized, or members of a health maintenance organization who were prescribed a particular type of drug). In this case, Frame B may provide complete coverage of the population frame (i.e., complete household address list for customers within a business district of a large retail corporation), while Frame A may consist of a subset of population units from

Frame B (i.e., an email register of frequent shoppers). If the company wanted to select a random sample of customers, it may be more expensive to sample solely from Frame B based on costs associated with in-person or mailed surveys; to reduce expected costs, a sample from Frame B could be augmented with a sample from Frame A, since emailed versions of the survey would be less expensive to administer than mailed versions.

3. Also not illustrated in Figure 1 is the circumstance in which Frame A and Frame B have no overlap (i.e., list frame of hospital addresses in the northern region and a telephone directory of hospitals in the southern region of the country). In this case, the dual-frame sampling design would simplify to a stratified sampling design in which two strata (northern and southern regions) use different mechanisms for sampling (using addresses versus phone numbers, for example).

A very common estimator of a population total based on a dual-frame sampling design is the *composite* estimator first proposed by H. O. Hartley. This estimator combines estimates of regions (a) and (b) of Figure 1 with a linear combination of two estimates of region 2 derived from the probability samples taken from frames A and B, respectively. Specifically, the estimator is given by

$$\hat{Y} = \hat{Y}_a + \hat{Y}_b + \lambda\hat{Y}_{ab} + (1-\lambda)\hat{Y}_{ba}, \quad (1)$$

where $\hat{Y}_a$ is the estimate of region (a) derived using elements of the first sample that only belong to Frame A, while $\hat{Y}_b$ is the estimate of region (b) derived using the elements from the second sample that belong only in Frame B; similarly, $\hat{Y}_{ab}$ is the estimate of region (ab) derived using the portion of the sample from Frame A that also belongs to Frame B and $\hat{Y}_{ba}$ is the estimate of region (ab) derived from the portion of the sample from Frame B that also belongs to Frame A. The mixing parameter, λ, lies between 0 and 1 and is optimally derived to minimize the variance of the population total estimate as a function of the costs associated with sampling in each of the two frames.

Another form of this estimator was proposed by W. A. Fuller and L. F. Burmeister and makes use of estimates of the population size of the overlap in Frames A and B (i.e., size of region (ab) in Figure 1) but requires estimating two parameters for combining information from the two frame samples. While the form of the estimators is straightforward, the optimal parameters for combining information across the two frames must be estimated separately for each possible outcome variable Y for which population totals are desired. C. J. Skinner and J. N. K. Rao proposed an alternative *pseudo-maximum likelihood* estimator that relies on a single set of global weights that can be universally applied for any outcome variable for which population total estimates are desired. Regardless of the estimator used, there are some overall advantages and disadvantages of dual-frame sampling designs, including the following:

Advantage 1: Increased coverage than what is afforded using only a single frame—using multiple frames generally removes undercoverage bias that is accompanied with only one (incomplete) frame.

Advantage 2: Flexibility in sampling designs per frame (i.e., stratified design in one frame and simple random sample in another, depending on the type of frame).

Advantage 3: Improved coverage of rare populations at lower cost—by using a second frame for the "rare" population units, screeners on the larger, more general frame can be reduced and optimal cost allocation models can be derived based on the distribution of rare population elements.

Disadvantage 1: More complicated estimators and weighting scheme—the composite estimator proposed by Hartley shown in Equation 1, for example, is one such composite dual-frame estimator that requires computation of at least four estimates of the population parameter that will be combined to form the overall dual-frame estimator. Additionally, nonresponse adjustments and other weighting adjustments may be done on the overall composite weights, or separately per frame, then used in the composite estimator. If done separately, control totals and other aspects of the weighting adjustments will be required for each type of frame.

Disadvantage 2: Requires estimation of the "mixing" parameter to deal with how the two estimates of the intersection of the two frames will be combined—estimates usually need to be derived iteratively from the data.

Disadvantage 3: Dual frame designs may have more administrative costs associated with them—that is, two types of surveying required or screeners required for the two frames; different types of collection required to be compatible with frame type (i.e., when using an

Table 1 Example for computing dual-frame estimate for the total purchases made by "rewards program" members based on samples from telephone and email frames

Sample Unit	*Selected from Frame:*	*In the Overlap?*	*Used in:*	*Sampling Weight*	*Annual Purchases for Selected Unit*
1	A	No	$\hat{Y}_a$	16	\$354.39
2	A	No	$\hat{Y}_a$	16	\$205.76
3	A	No	$\hat{Y}_a$	16	\$329.39
			$\hat{Y}_a$ **Estimate: \$14,232.40**		
4	A	Yes	$\hat{Y}_{ab}$	16	\$255.53
5	A	Yes	$\hat{Y}_{ab}$	16	\$264.48
			$\hat{Y}_{ab}$ **Estimate: \$8,320.13**		
1	B	No	$\hat{Y}_b$	10	\$408.70
2	B	No	$\hat{Y}_b$	10	\$415.37
3	B	No	$\hat{Y}_b$	10	\$479.48
4	B	No	$\hat{Y}_b$	10	\$437.05
5	B	No	$\hat{Y}_b$	10	\$311.97
6	B	No	$\hat{Y}_b$	10	\$360.17
			$\hat{Y}_b$ **Estimate: \$24,127.44**		
7	B	Yes	$\hat{Y}_{ba}$	10	\$357.44
8	B	Yes	$\hat{Y}_{ba}$	10	\$394.40
9	B	Yes	$\hat{Y}_{ba}$	10	\$439.34
10	B	Yes	$\hat{Y}_{ba}$	10	\$494.85
			$\hat{Y}_{ba}$ **Estimate: \$16,860.23**		

area frame, personal interviews may be required as compared to telephone interviews used for the landline frame).

For example, consider the population of interest to customers who are registered for a small company's "rewards program." Interest is given in estimating the total annual purchases from the company for registered customers. Customers can register for the rewards program by providing either their landline telephone number or email address; providing both forms of contact is not necessary, and telephone numbers and email addresses are kept separate for marketing purposes. So, in this case, the size of the overlap in Frame A (telephone list) and Frame B (email list) is unknown unless additional steps are taken to match customer information across the two frames. Assume that the telephone frame (A) has 80 numbers from which a simple random sample of 5 numbers is taken, and assume that the email frame has 100 numbers from which a simple random sample of size 10 is selected. For illustration, assume that the costs associated with data collection in each frame for these sample sizes is similar and that there is no survey nonresponse; also assume that $\lambda = 0.5$. For this example, region (a) of Figure 1 refers to customers who provided only a telephone number, while region (b) refers to those customers who provided only an email address, and, finally, region (ab) refers to those customers who provided both a telephone and email address (i.e., appear in both databases). Using estimates from Table 1, we see that the composite estimate based on this dual-frame sample for the total annual purchases for customers in the rewards program is

$$\hat{Y} = 14{,}232.40 + 24{,}127.44 + (0.5 \times 8{,}320.13) + ((1 - 0.5) \times 16{,}860.23) = \$50{,}950.03.$$

Another application of dual-frame designs that is currently being applied in survey practice involves the revision of traditional random-digit dialing designs that attempt to "cover" the telephone population. Because current trends in cell phone only households have created intolerable levels of undercoverage for single landline frame designs both locally and nationally within the United States, the use of a cell phone only frame in conjunction with a landline telephone number frame has been proposed and implemented in practice. Specifically, J. Michael Brick and others reported in 2006 an application of the dual-frame approach for sampling both cell phone and landline telephones to improve overall coverage of the telephone population that incorporated different weights in the landline, cell phone, and combined estimates to adjust for nonresponse bias.

Duplication

Duplication refers to the prevalence of an element more than one time on a sampling frame, assuming that the element appears only once in the target population but appears more than once in the sampling frame. As straightforward as this problem and its solution may appear to be, its detection and correction can be complicated, time-consuming, and/or costly.

For example, a sampling frame made up of names of members of a professional organization may list the same person more than once if the professional organization has not cleaned its list well, so that all but one of the variants of the same name are purged—as in trying to narrow down the following names to only one listing: "Joan F. Smithers," "Joan Smathers," "J. F. Smithers," "J. Smythers," and so on. Whether or not all the names in this example are the same person is not certain, but it serves to demonstrate the challenges the issue of duplication raises.

Other times, when there is no real list serving as a sampling frame, such as in random-digit dialing (RDD) telephone sampling, the concept of duplication is somewhat more abstract, since the initial sampling unit in such a survey is a household, and many households can be reached by more than one telephone number. Thus, an RDD frame contains a lot of duplication as it relates to the existence of telephone numbers that reach particular households or businesses. In telephone surveying, this is further complicated by the growth of cell phone ownership, which leads to even more telephone numbers that can reach members of the same household.

The major problem that duplication creates is that it leads to unequal probabilities of selection. Probability samples require that elements have a known, but not necessarily an equal, probability of selection. Thus researchers who want to maintain their probability samples must gather information regarding how many "chances" a selected respondent has to be sampled. With a sampling frame that can be cleaned of duplication, it is incumbent upon the researchers to do this as well as possible before the sample is drawn. Then all elements have similar chances of being selected assuming a simple random sample is drawn. But with other sampling frames, in particular with RDD telephone frames, measures must be taken upon reaching a household or business to determine how many other telephone numbers that exist in the frame could also have reached the household or business. This information can then be used to adjust (weight) the database prior to conducting analyses in order to “correct” the issue of duplication and reduce the potential bias it may create.

E

e

e is a term used in the calculation of survey response rates; it represents the proportion of sampled cases with unknown eligibility that are estimated to be eligible cases.

To determine response and other outcome rates for surveys, all cases in the sample first need to be classified into one of four categories: (1) completed cases; (2) eligible cases, no interview (nonrespondents); (3) cases of unknown eligibility, no interview; and (4) not eligible cases (out of sample). Then the eligibility status of the unknown cases needs to be estimated. The proportion of unknown cases that is estimated to be nonrespondents (i.e., eligible cases with no interviews) is known as the *e*-rate and is represented as *e* in equations. For example, in the formula for Response Rate 3, according to the standards of the American Association for Public Opinion Research (AAPOR), the response rate is the number of complete interviews (I) divided by the number of complete interviews (I) plus the number of partial interviews (P), plus the number of nonrespondents due to refusals (R), noncontact (NC), and other reasons (O), plus the number of unknown known cases (unknown if household (UH) and other unknowns (UO)) times their estimated eligibility rate (*e*):

$$RR3 = I/(I+P) + (R+NC+O) + e(UH+UO).$$

So if 55% of the cases in the unknown category were estimated to be eligible cases, *e* would be .55, and 55% of the unknown cases would appear in the base (denominator). The 45% estimated not to be eligible would be excluded from the calculation of this response rate.

In estimating *e*, AAPOR requires that "one must be guided by the best available scientific information" and "one must not select a proportion in order to boost the response rate." AAPOR has documented eight general methods for estimating the eligibility rate:

1. Minimum and maximum allocations
2. The proportional allocation or CASRO method
3. Allocation based on disposition codes
4. Survival methods using either (a) the number of attempts only or (b) the number of attempts and other attributes of cases
5. Calculations of the number/proportion of eligible population compared to same in the realized sample
6. Contacting databases or information sources, such as telephone companies
7. Linking to other records, and
8. Continued interviewing, especially after the close of the data collection period

Cases of unknown eligibility are rare in some types of surveys, such as in-person, area probability samples, but are common in other surveys, such as random-digit dialing (RDD) samples, and mail and Internet samples. In RDD samples in general and especially in RDD samples with minimal callbacks, the number of cases of unknown eligibility (due to "ring–no answer" and "busy" outcomes) will be appreciable, and as a result calculating the response rate will be notably influenced by estimates of *e*. The same will be the case in mail and Internet surveys because of those sampled cases for which nothing is ever heard back by the researcher.

Ecological Fallacy

The ecological fallacy is a type of faulty reasoning that sometimes is made in the interpretation of results that come from the analysis of aggregate data. This mistake occurs when data that exist at a group or aggregate level are analyzed and interpretations are then made (generalized) as though they automatically apply at the level of the individuals who make up those groups. For example, if a researcher used zip code level census data to determine that the proportion of women in the labor force was inversely correlated with the prevalence of mobile homes in that zip code, it does not necessarily follow that women who live in mobile homes are less likely to be employed than are women who do not live in mobile homes. It is possible that the same relationship between employment and type of housing exists at the level of individuals, but just because it was found to exist at the aggregate level does not assure that it holds at the individual level.

The ecological fallacy can come into play for survey researchers who merge aggregate level data onto their survey data sets—original data that are gathered in a survey from the individual respondents. For example, if a survey of adult residents in a metropolitan area were conducted about race relations, the researchers may want to enhance their analyses by merging zip code or block group census data onto each case in the data set; for example, merging area-level variables such as the percentage of residents in the zip code or block group who are white and the percentage who are black with each survey respondent's individual-level data. These variables can serve many purposes, including being used as statistical controls. They also can allow the researchers to generate new variables by using both the individual-level data gathered in the survey and the aggregate area-level data merged onto the data set; for example, creating a new variable that indicates whether the respondent lives in a zip code or block group in which her or his own race is the majority race. There is nothing inherently wrong with doing any of this, and it does not constitute an instance of committing the ecological fallacy.

Instead, the problem of committing the ecological fallacy occurs when researchers go beyond the precision and applicability of their data to draw conclusions that the data simply do not justify. If the findings are based only on variables that exist at the aggregate level, then no conclusions should be generalized to the individual level. That is not to say the researchers cannot speculate that the same relationships may exist at the individual level. But that is as far as the researchers should go, and it should be labeled explicitly as speculation due to the possibility of the ecological fallacy. If a researcher believes it is important to determine whether the relationship holds at the individual level, it is her or his responsibility to investigate it by conducting a new study that gathers appropriate data at the individual level or by conducting secondary analyses of existing individual-level data.

ECONOMIC EXCHANGE THEORY

As it applies to survey research, economic exchange theory provides a possible explanation for why certain types and levels of survey incentives do or do not work to (a) raise the response propensity of a sampled respondent to participate in a survey, (b) improve the quality of the data provided by the respondent, (c) reduce nonresponse bias, and/or (d) lower total survey costs. The central premise in economic exchange theory, as it relates to survey research, is that respondents make at least a partially rational decision about whether or not they will participate in a survey, and the rational part of this decision takes into account the "costs" of participating versus the "benefits" gained from participating. One of those presumed benefits is the value to the respondent of any incentive that may be given her or him by the researchers. Economic exchange theory suggests that if the perceived benefits are equal to or exceed the perceived costs, then the sampled respondent will be positively disposed to participating because she or he will perceive that she or he is being treated equitably by the researchers.

Past research on why people do not want to participate in a survey consistently has shown that "no time" and "no interest" are the two most frequently mentioned reasons for not participating. Consistent anecdotal feedback from survey interviewers indicates that some respondents specifically complain that their time is worth much more than whatever incentive is being offered to them. Thus, some portion of the "No Time/No Interest" constellation of refusal reasons appear to be linked to respondents who rationally are calculating the cost of their time and effort to cooperate versus what is in it for them in return. In most cases the monetary value of survey incentives that have been used throughout the history of survey research has been far too small to approach what most respondents would perceive as an equitable economic exchange for financially offsetting the costs to them for participating.

This reasoning notwithstanding, there are no consistent empirical data that support economic exchange theory as being a driving force in explaining whether certain types of survey incentives will work to raise respondent cooperation and compliance. Part of the reason for this may be that the unconfounded and robust experiments that are required to adequately test economic exchange theory have not been conducted as yet.

That such rigorous research should be conducted is indicated by the results of a provocative study on this topic that was reported by P. M. Biner and H. J. Kidd in the 1990s. This research provided evidence that the manner in which an incentive is framed (i.e., explained to respondents) will affect response rates beyond the mere value of the incentives. Following from personal equity theory, Biner and Kidd used an experimental design that showed that telling sampled respondents that they were being given a small, noncontingent cash incentive as "payment" for participation in the survey—that is, the respondents reasonably were assumed to perceive that they were being "undercompensated" for their time and effort—led to significantly *lower* response rates than telling another group of respondents that the same low-value incentive was being given as a "token of appreciation." In contrast, with larger value noncontingent incentives—especially ones that a respondent likely would view as overcompensation for the time and effort involved in performing the survey task—respondents who were told that they were being given the larger value noncontingent cash incentive as "payment" for participation in the study had significantly *higher* response rates than other randomly assigned respondents who were told that the higher-value incentives were being given as a "token of appreciation."

Many appear to view economic exchange theory as though it is in competition with the long-revered social exchange theory in explaining why incentives work to motivate sampled respondents to cooperate and comply with survey requests. However, it may turn out that the two theoretical perspectives complement each other, but that will await a more rigorous and valid testing of the two theories than heretofore has been conducted.

Effective Sample Size

Complex sample surveys rarely result in a set of independent and identically distributed observations, because of sample design features such as stratification, clustering, and unequal weighting that are necessary for efficient data collection. Such features affect the resulting variance of survey estimates. The effective sample size is one of several useful measures of the effect of the complex sample design on the resulting precision of the estimates.

A general definition of the *effective sample size* is the sample size for a simple random sample selected with replacement that yields the same variance for an estimate as the variance obtained from the sample design used to collect the data. A simple random sample selected with replacement yields a set of independent observations and is the simplest comparison sample design. It is immediately obvious that there is not a single effective sample size for any one study, since the variance for each outcome, analysis domain, and type of estimate (e.g., mean or regression coefficient) will be different. For example, the effective sample size, n_{eff}, of the mean is the sample size such that $S^2/n_{eff} = Var(\bar{y})$, where S^2 is the population variance of the variable in question and $Var(\bar{y})$ is the variance of the estimate under the sample design used to collect the data. Consequently, $n_{eff} = S^2/Var(\bar{y})$.

A related concept is the *design effect (deff)*, which is the ratio of the variance under the sample design used to collect the data to the variance of a simple random sample selected with replacement of the same sample size. Assuming that the sampling fraction for the simple random sample is small, the design effect of the mean is $DEFF = Var(\bar{y})/(S^2/n)$, where n is the sample size from the sample design used to collect the data. Thus, we see that $n_{eff} = n/DEFF$. This latter expression is often used as the definition of the effective sample size. However, the definition presented herein more directly relates to the underlying concept of the effective sample size, whereas its relationship to the $DEFF$ is a consequence of the concept.

To better understand the effective sample size, it is useful to consider the four major aspects of complex sample design that impact the variance of an estimate and hence the $DEFF$ and n_{eff}.

1. *Stratification*. Stratification is the process of dividing the population into mutually exclusive and exhaustive groups and then selecting a separate independent sample from each stratum. When the observations within each stratum are more homogenous than those between the strata, the variance of the resulting estimate will be reduced. If the observations are approximately linearly related to the stratification variable, then the variance of the mean will be reduced by approximately $D_S = (1 - r^2)$, where r is the correlation between the variable under study and the stratification variable.

2. *Clustering*. When clusters, or groups, of observations are selected together rather than single observations, the variance of an estimate is usually increased, since the observations within a cluster are most often positively correlated. In a two-stage sample design, where clusters are sampled first followed by individual observations within each cluster, the amount of increase in the variance of the estimated mean is approximately $D_C = 1 + (m-1)\rho_y$, where m is the number of observations selected per cluster from the analysis domain and ρ_y is the intracluster correlation between two observations in a cluster. This model assumes that the same number of observations is selected within each cluster and that there is a constant intracluster correlation within all clusters. For regression coefficients, the inflation, or possible deflation, in variance is approximately $D_C = 1 + (m-1)\rho_y\rho_x$ where ρ_y and ρ_x are the intracluster correlation coefficients for the dependent

variable and the independent variable, respectively. For certain designs and regression models, it is possible for ρ_x to be negative, resulting in a decrease in the variance of the estimated coefficient.

3. *Unequal weighting*. When the sample is selected with unequal probabilities, the variance of the estimated mean is increased above that of an equal probability sample of the same sample size due to the variability in the weights unless the selection probabilities are approximately proportional to the values of the associated observations or otherwise optimally allocated to minimize the variance. The amount of this increase, often called the "effect of unequal weighting," is approximately $D_W = n\sum_i w_i^2/(\sum_i w_i)^2$, where w_i is the sampling weight for the i^{th} observation. When the weights are all equal, D_W is minimized and equal to 1.

4. *Finite population sampling*. When selecting a sample from a finite population, the variance is reduced when the sample size becomes a substantial fraction of the population size. For a simple random sample selected without replacement, the variance is reduced by the finite population correction factor (fpc) equal to $(1 - f)$, where f, the sampling fraction, is n/N and N is the population size. It is often the case that f is quite small and can be ignored. In the following, we do not consider the fpc since the impact of the other three factors usually dominates the design effect and the effective sample size.

The overall design effect can usually be modeled as $DEFF = D_S D_C D_W$, and the effective sample size by $n_{eff} = n/D_S D_C D_W$, where the impact of sample designs that use stratification, clustering, and unequal weighting are given by D_S, D_C and D_W, respectively. Thus, we observe that effective stratification will increase n_{eff} as r^2 increases. On the other hand, clustering will usually reduce the effective sample size of the mean, since ρ_y is almost always positive. For a regression coefficient, the reduction in n_{eff} due to clustering is often less than that for a mean, since $\rho_y\rho_x \leq \rho_y$ when both intracluster correlations are nonnegative. However, for an independent variable that groups whole clusters together, a so-called between-cluster covariate, $\rho_x = 1$ and ρ_y, again dominates the reduction in n_{eff}. Also, it is possible to make ρ_x negative when the covariate is experimentally manipulated, as in a cross-over design within clusters, and n_{eff} will be increased due to clustering. Finally, the effective sample size for the mean is usually decreased when the variability in the sampling weights is not due to a nearly optimal sample size allocation to minimize the variance or the weights are not inversely proportional to the outcome variable.

In the situation in which clustering has the dominant impact on n_{eff}, there is a very enlightening simple example for the mean estimated from a two-stage design. Consider a two-stage design where 10 $(= m)$ sampling units are selected from each of 50 sampled clusters for a total sample size of 500. If $\rho_y = 1$, then $DEFF = 10$ and $n_{eff} = 50$, the number of clusters. This is the situation where the observations within a cluster are perfectly related and no further information is gained by selecting more than one observation from each cluster. Thus, the effective sample size is the number of clusters. On the other hand, if $\rho_y = 0$, then the observations within each cluster are unrelated, $DEFF = 1$, and $n_{eff} = 500$. This is the situation of independent observations, all of which contribute equal information to the estimate. When ρ_y is between 0 and 1, the effective sample is between 50 and 500.

Last, the effective sample size can be used to estimate power or precision when planning a survey or to calculate the power of an existing survey. In the former situation, n_{eff} can be approximated using the relationships described above for D_S, D_C and D_W combined with data from previous studies to approximate n_{eff} and then used in the appropriate power/precision formula or software package to determine the approximate power or precision. Likewise, the effective sample size can be estimated from an existing survey as $n_{eff} = n/DEFF$ and used in the same way to approximate power or precision.

800 Poll

An 800 poll is a one-question unscientific "survey" that is taken by having daily newspaper readers, television viewers, and/or radio listeners call into a toll-free 1-800-number that involves *no cost to the caller*. A different 800-number is given for each "response" that the poll allows the self-selected respondents to choose as their answer to whatever the survey question is. These polls are typically sponsored over a one-day period (or part of a day) by media organizations that produce news. For example, callers who "agree" and those who "disagree" with whichever issue position is being surveyed use separate 800-numbers. It is possible to offer callers more than two answer choices, and thus more than two 800-numbers, but typically the polls utilize only two choices.

Such polls have no scientific standing because there is no way to know what target population is represented by those who choose to dial in. Since this is a nonprobability sample, there is no valid way to calculate the size of the sampling error. Additional threats to their validity include the possibility that the same person will call in more than once. Also, because the response choices normally are limited to two, the question wording and the response choices often are not well crafted.

Nonetheless, they offer a vehicle through which media organizations can provide their audience with a feeling of involvement in the news, since the poll results are typically reported by the news organization within the next day of the poll being conducted. In some cases, the news organizations acknowledge that the poll results they are reporting are unscientific, and in other cases they do not.

With the widespread use of the Internet by the general public, 800 polls have been mostly replaced by similar one-question unscientific surveys on the homepages of news media organizations' Web sites.

It is important to understand that these unscientific 800 polls are entirely unrelated to the scientific use of 800-numbers by some survey organization as a mode of allowing scientifically sampled respondents to "opt into" a mail survey rather than completing a questionnaire and mailing it back. That is, some survey organizations that conduct mail surveys provide their respondents with a toll-free 800-number to call in to complete the questionnaire with a telephone interviewer.

Election Night Projections

Election night projections are made in the United States on the night of major primaries and major elections to help project the winners of key political races (e.g., president, senator, governor) and issue referenda. A small group of survey research experts make up the Election Night decision teams that make these projected calls. The same basic methods are used to project the winners by the National Election Pool (NEP), a consortium of ABC, CBS, CNN, FOX, NBC, and the Associated Press. Each media organization makes its own projection decisions but relies on common data using this procedure and occasionally supplemented with its own. The method has evolved over the years, but it is essentially the same model developed and implemented in 1967 by Murray Edelman and Warren Mitofsky (then with CBS News) based on their work in probability methods at the U.S. Census Bureau.

Sources of Information

There are four possible sources of information about the election outcome in any given state that are used to make Election Night projections for that state: (1) the actual vote at sample precincts, (2) a statewide exit poll of voters at those precincts, (3) a statewide telephone poll of absentee (early) voters, and (4) the tabulated vote reported by counties throughout the state.

Precinct Sample

Like all estimation, the election night projections start with the sample. In each state where a projection is desired, a sample of voting precincts must be taken. Depending on the size and diversity of a state, a sample of 60 to 120 precincts is taken as the basis of a projection. This procedure for sampling is known as a *stratified systematic sample proportionate to size*.

Each state is broken into three to five geographic areas (geo-strata) based on their historical voting patterns. For example, Figure 1 shows the geographic areas (strata) for New Jersey, while Figure 2 shows an example of New Jersey's historical voting patterns.

A recent past general election in a state is used as the base race for selection for that state. There are three important attributes in choosing the base race: (1) being recent, so as to minimize the geographic boundary changes that may occur from election to

election; (2) being competitive, so that it shows a reasonable distribution of the vote; and (3) being typical, in that it reflects the ideology of the political parties that the candidates represent.

A listing of all precincts and vote counts in that past election is obtained and geographic codes are added. The precincts are sorted by geographic area and placed in order of total vote. The precincts in each area are then broken down into two separate size groups (usually at the median of accumulated total vote in the geographic strata). The two size groups are used to minimize the bias that can occur when sampling probability proportionate to size. The precincts in each group within a geographic area are ordered by their percentage of Democratic vote in the base race. A sample of precincts is then selected from each group proportionate to the size of their total vote in the base race with an exception in only one state. There are a couple of precincts in New Hampshire that are larger than the interval of selection, and in those cases the precincts are selected with probability of one (1.0). This procedure gives an excellent probability sample of the state for the past race.

It is the job of the research team to properly translate this sample of precincts from a past election to one reflecting the current names and boundaries of the precincts in the upcoming election of interest. This involves talking to county officials to determine if the sampled precinct has had any boundary changes between the selection (base) year and the current year. When there is a boundary change, an effort is made to determine the precinct in the current year that best represents the voters in the precinct that was selected. Once the precincts have been selected, the vote in other past races is obtained to improve the estimation. The current registration in the precinct and its county is also obtained to be used in an estimate of turnout. The selected precincts are then staffed with reporters whose job is to phone in to NEP the actual vote count of the precinct on election night as soon as possible after the polls have closed. They obtain the vote at the actual precinct or at the county where the election results are centrally counted.

The listing of all of the precincts in the state is also used to form a stratification by party. All of the precincts are sorted by their Democratic vote in the *base race*, and different cutoffs are made from High Democratic to Low Democratic.

Exit Poll Data

In most states, an exit poll is also taken. A subsample of between 15 and 60 precincts are selected for the exit poll in each state; the actual number used depends on the importance of the race. The subsampling is done in such a way as to preserve the state's original order and stratification. The interviewers at the exit poll precincts tally the questionnaires three times during the day: morning, afternoon, and about an hour before the polls close in that state. These tallies are the first data used in the projection models.

Early Voting and Absentee Polls

Early and absentee voting is becoming a substantial part of the vote in many states. In Oregon, elections are totally absentee, and in Washington State more than 70% of voters cast absentee ballots. Other states with a large absentee vote are California, Texas, Tennessee, and Arizona. An estimate of the size of the absentee vote is made by an NEP analyst who looks at the size of the absentee vote in past elections along with changes in rules and current requests for absentee ballots in the state. In states with a large absentee vote, it is essential to supplement the exit poll with an absentee poll. These are regular random-digit dialed (RDD) telephone polls with random selection of respondents and multiple callbacks to improve response rates that are conducted before the day of the primary or the election. Respondents are asked if they have already voted or plan to vote before Election Day. If so, they are interviewed using the basic exit poll questionnaire, slightly modified for telephone use. These data are weighted and used to estimate the absentee vote in the state. The sample sizes of these "early voter" RDD surveys range from 400 to 800 depending on the importance of the absentee vote.

In states where there is not an absentee poll, an estimate of the current absentee vote is made when possible using an estimate from past years of the difference between the absentee vote and the Election Day vote. This is, of course, the default method used when the absentee is not sizable or the race in the state is not seen as having enough editorial (news) importance for the substantial expense of an absentee poll.

Vote Tabulation

Once the polls in a state close, a preliminary tabulation is conducted by the state. Many states now put the results by county on their Web sites in a timely manner. But in all states, the vote results, broken down by county, are provided by the Associated Press and are used directly in the election projection models.

Models Used

Models With Precinct Data

There are two basic models used in estimation. The "simple" estimate uses the current proportion of the vote for each candidate in the precinct, averaged over all precincts that have reported in each stratum. At that point, these average proportions are weighted by the size of the strata.

The "ratio" estimate is the average just described using the current vote divided by a similar average of proportions, based only on the past vote in the same precincts that have reported, multiplied by the actual past proportion for the same candidate in that stratum. This stratum estimate is then weighted by the size of the stratum.

There are two stratifications for each of these methods of estimation and hence four estimates: (1) simple geo, (2) simple party, (3) ratio geo, and (4) ratio party. Prior to poll closing all are based on the relative sizes of the strata in a past election. In the two geo estimates after poll closing, the current sizes of the strata are estimated, using an average of the total current vote divided by registration in each reported precinct and multiplied by the total registration in that stratum. In the two party estimates, no current estimate of stratum size is available, so this estimate is used more cautiously when there appear to be any deviations from usual voting trends.

These models are used with the exit poll tallies and then later with the reported votes from the sample precincts. The variance of these estimates uses the standard form of the computation of variance of a stratified random sample.

Models With County Data

Unlike the precinct data, which is a sample of precincts, the county data is an "evolving census" of the vote count. Most counties start with a trickle of precincts approximately a half-hour after the polls close in a state and eventually reach 100% of the precincts, often many hours later. In some states, the absentee vote is counted with the precinct Election Day vote; in other states, it is counted separately and added to the vote, sometimes at the beginning of the night and other times at other irregular intervals. In a few states, at least some of the absentee vote is not counted until days later. An analyst trying to make a projection from the county reports has to be cautious when estimating how much vote has come in at a given time, since the vote count only roughly follows the proportion of precincts reported. In addition, even when a county has 100% of the vote reported, it can still have errors of as much as 0.5%.

A county estimate is made by inflating the votes in the county based on the inverse of the percentage of the precincts reported. Then the counties are cumulated by stratum and inflated to the stratum size to account for counties that have not reported yet. The stratum estimates are then added and the votes percentaged at the state level. An error term on this estimate is formed by using a regression equation that is based on historical data over different time intervals and elections relating the percentage of precincts reporting in a county at a given time to the deviation of the candidate percentages from the final outcome. The estimates of the individual county errors are combined by stratum and then adjusted to the relative sizes of the strata to form an estimate of the error of the overall state estimate.

When the Information Is Used

Prior to Poll Closing

On Election Day, prior to poll closing, the only sources of voting information are the exit and absentee polls. As mentioned, the exit poll interviewers report in three waves, typically in the morning, afternoon, and about an hour before poll closing. At each of these points, both simple and ratio model estimates are made. These are combined with the absentee estimate when available based on the estimated relative size of both types of vote. The estimates are rank ordered based on the variance of each, with the estimate with the smallest variance considered the "best" statewide estimate. The variance of this estimate is computed and a critical value is formed. When the critical value is high enough that the there are only 5 chances in 1,000 ($p = .005$ or less) of being wrong, a call can be made. Judgment always weighs in here because of the possibility of nonrandom error, such as that produced by nonresponse.

Usually there is a pre-election or "prior" estimate of the outcome based on the pre-election polls as combined by political experts. The analyst would always have that prior expectation in the back of her or his mind when considering a projection. Although a combination of the prior and exit poll estimates is not used for projection, the two are composited, using the inverses of their errors, and used for reference.

Shortly After Poll Closing

Once the polls have closed in the state, the vote in the sample of precincts gradually becomes available and is used in the model with the poll data. As each exit poll precinct reports, the actual vote replaces the exit poll tally information in the model. The same stratified estimates are calculated now with the combination of exit poll tallies and actual votes in the precincts and the same decision model employed. When the precinct vote is available in at least eight of the exit poll precincts, it is also possible to estimate the possible error (bias) in the exit poll. This is used as a guide by the Election Night decision teams in evaluating the accuracy of the estimate.

After about an hour, there typically is enough actual vote reported by county to make an estimate from it. This estimate is combined with the best precinct estimate using the inverse of their error so that the more accurate estimate dominates. For the geographic stratification, another estimate, called the "integrated model" becomes possible when there are enough counties reporting in each stratum. This is formed by creating a composite estimate in each stratum of the precinct estimate for the stratum combined with its county estimate. The strata estimates are weighted to their size and summed to obtain an estimate for the state. This estimate is usually the one watched most often by the decision team once there are enough actual votes reported to get an estimate for each stratum.

As the Vote Straggles In

With more than 90% of the vote reported, there is yet another way to view the reported vote. One can look at the outstanding vote by county. For example, if the vote yet to be reported is from counties where the Republican is ahead in the tabulated vote, one would be more confident that the Republican would win. This method, however, has to be used judiciously. Estimates of the outstanding vote in a county depend on assuming that the precincts yet to report are of comparable size to the ones that have already reported and that the candidate vote to be reported is similar to the vote already reported.

Eventually the vote tabulation will reach 100%, but, as already mentioned, even then the state count can be off by as much as a half of one percentage point. Some errors in the vote may persist even after the vote is officially certified by the state months later.

ELECTION POLLS

Election polls are surveys that are taken before, during, and after election season and are used to predict and explain election outcomes. The media conduct election polls to satisfy their viewers' and readers' desire for "horse race" journalism and to help editors and reporters plan their coverage of elections and politicians. Candidates and political parties use them for strategic purposes, including fund-raising and helping to position their campaigns in the best possible light. Political scientists and other academics conduct election polls to understand the influence of campaign dynamics on voting behavior.

Election polls employ various survey methods and come in a variety of types. In the United States over the past few decades, most election polls have been random sample telephone polls, drawn from various target populations, such as the entire adult population, registered voters, or so-called likely voters. Few are conducted face to face, but a growing number are conducted via the Internet. Respondents are usually asked a series of standardized questions designed to measure their opinions on issues and candidates. Election polls influence political campaigns in a number of ways and are an important component of the election news coverage. There are several different types of election polls that are conducted at various times during a political campaign, from before the primaries to the day of the election.

Pre-Primary and Primary Surveys

Surveys are conducted early in a campaign to help benchmark baseline information about voter demographics and the public's perceptions of the candidate's image, message, and issue positions. The most useful benchmark questions for a candidate concern name recognition, strengths compared to challengers, and performance while in office (if the candidate is an incumbent). The results of these surveys are circulated within a candidate's campaign organizations and help shape strategy.

These surveys are conducted before and during the season of the primary elections, when campaigns are striving to demonstrate the viability of their candidate. The results are used by the candidates to stimulate fund-raising efforts, and may be leaked to the news media if favorable to the candidate and/or unfavorable to the opponent(s). The value of these pre-primary polls depends on their timing. If conducted too early, respondents may not know enough about a candidate. If conducted too late, the results may have little value to the candidates.

Trial Heat Pre-Election Surveys

The primary focus of these pre-election surveys is to gather trial heat data that essentially take the form, *If the election were held today would you vote for A or B?* The reliability of these questions also depends on the timing of the survey. If they are asked too early in the campaign, these questions are more likely to measure name recognition, not voter intentions. The results are prone to considerable fluctuation related to the changing campaign conditions. For example, a Fox News/Opinion Dynamics trial heat survey conducted in August 2004 gave Democratic presidential candidate John Kerry a 6-point lead over Republican George Bush, but the same survey conducted 2 months later in October gave Bush a 4-point lead, a swing of 10 percentage points. Such surveys are at the heart of what has become known as "horse race" journalism, which refers to the perceived obsession of the news media to focus overly on who is likely to win an election.

Tracking Polls

Tracking polls produce up-to-date estimates of campaign leaders and are typically conducted over the last few weeks of the campaign. They are used by the media to complement its horse race coverage and by candidates to monitor late shifts in support, especially any shifts that may occur after a campaign-staged event or other newsworthy events that may arise. They produce a rolling average estimate derived from daily samples, usually 100–200 interviews each, that typically are aggregated across 3-day periods (e.g., Monday–Tuesday–Wednesday, Tuesday–Wednesday–Thursday, Wednesday–Thursday–Friday). Tracking polls have been criticized for employing inconsistent sampling procedures; they are often conducted only in the evenings, rarely attempt to deal with hard-to-reach respondents, and select respondents based on whoever answers the phone rather than randomly within the household. Tracking polls can be very expensive compared to other pre-election surveys.

Exit Polls

Probably the most controversial of election polls are exit polls. Exit polls have two primary purposes: helping project winners on the evening of Election Day and helping explain election outcomes in the days following the election. These polls consist of interviews of voters as they leave sampled polling places; they are asked a short list of questions concerning vote decision, issue positions, and voter demographics. Exit polls use multiple-stage sampling methods. First, the polling organization randomly samples counties in the states of interest, and then precincts within counties, and then interviewers in the sampled precincts select respondents based on a pre-determined systematic sampling selection method. Respondents usually complete a survey form and place it in a "ballot box" themselves. ABC, CBS, NBC, CNN, Fox, and the Associated Press (AP) conduct the most widely know U.S. exit poll: previously through a consortium called the Voter News Service, and recently through a partnership between Edison Media Research and Mitofsky International. Through the 2006 election, the *Los Angeles Times* offered the main alternative source of national exit poll data but decided not to continue this for the 2008 election. Interviewer bias, differential response, faulty data, and the timing of results reporting are often cited as the major problems associated with exit polls.

The largest benefit of exit polling is that it provides critical data for analyzing the meaning (or so-called mandate) of the election—data that sometimes contradicts the political explanations for a candidate's victory. For example, Republicans often attribute George Bush's 2004 victory over John Kerry as due to the votes of Christian Evangelicals, when in fact exit poll data indicated that middle-class, suburban whites were Bush's largest group supporters.

Influence of Election Polls on Voters and Journalists

The influence of election polls on voters is mixed. On the one hand, some studies indicate that election polls deter some registered voters from voting and sometimes may mislead candidates on the effectiveness of their campaign. Other studies suggest that bandwagon and underdog effects driven by news about pre-election poll standings can change voting preferences within the electorate. Election polls may also bias media coverage toward frontrunners—especially at the time of the primaries, when candidate "viability" often appears to help determine news coverage assignments—leading journalists and thus voters to pay less attention to trailing candidates and more attention to leaders. Election polls have also been argued to influence campaign fund-raising, with donors more likely to give money to frontrunners. On the other hand, studies have consistently found that election polls help inform the public about election and candidates and also get people interested in the political process. Despite the various criticisms, polls can be expected to grow in use and popularity in future elections.

Elements

Within the context of survey research, an *element* is the basic unit that represents whatever is being sampled and from which survey data are to be gathered. Thus, the elements used in different surveys will depend on the purpose of the survey and may be adults, children, households, employees, businesses, students, teachers, schools, school districts, uniformed personnel, civilian personnel, police districts, libraries, books within libraries, pages within books, or many other things.

Within a target population, all the members of that population are its elements. Within a sampling frame, all the elements from the target population that can be listed constitute the frame. All the elements that are selected for study from the sampling frame make up what is commonly called "the survey sample." However, all the selected elements from which data are gathered also are commonly referred to as the "sample."

Eligibility

Eligibility refers to whether or not a sampled unit is eligible to have data gathered from it—that is, is the unit part of the survey's target population or is it not? For example, the target population for a survey might be all adults who are 18–34 years of age. As such, if a household is sampled and screened via random-digit dialing and no one living there fits the age criteria, then the household is ineligible. If there is at least one person ages 18–34 years, then the household is eligible. Ultimately, eligibility versus ineligibility is central to the issue of how well a sampling frame and a sample drawn from that frame "cover" the target population and whether or not coverage error results. Eligibility also is linked to survey costs, since samples drawn from frames that contain a large portion of ineligible units are much more costly to process. As straightforward as it may appear to determine eligibility for a survey, it often is not at all easy to do and many mistakes (errors) may occur in the process. Mistakes in determining eligibility may lead to coverage bias.

For example, most surveys have geopolitical boundaries for their samples, as they are not national in scope. In each of these surveys, the target population typically is limited to those residents living within the geopolitical boundaries (e.g., a particular county). If the mode of sampling and data collection is the telephone, as it often is, then some form of geographic screening must be instituted for interviewers to determine the eligibility of the household or person being contacted. In the case of boundaries that are commonly known and well understood by the public (e.g., one's county of residence), eligibility is readily determined without many errors, as long as the respondent does not know what answer will make her or him eligible or ineligible for the survey. (If the respondent knows this in advance of answering the screening questions, some respondents will self-select themselves in or out of the interview erroneously.) On the other hand, if the geographic boundaries that define eligible residency are not well know, (e.g., a school district or a police district), then screening a sample for eligibility via the telephone can be fraught with error. Some people will mistakenly say, "Yes," they live within the boundaries when asked the screening question(s) when in fact they should have said, "No" (errors of commission), and others will say, "No," when they should have said, "Yes" (errors of omission). This will occur even if the screening sequence carefully defines the eligibility boundaries, because many people are "geographically challenged" and will not understand the boundaries they are being asked about.

There are many other criteria than geography that are used to define eligibility in various surveys. For example, a major health survey conducted annually since 1994 for the U.S. government interviews only parents of children ages 19–35 months to learn about the immunization history of the children. (The exact eligibility definition for a household in this survey essentially changes every day of interviewing, since children age each day.) Researchers therefore must pay very careful attention to how eligibility is defined and how it is explained to respondents, whether that be in an interviewer-administered survey (e.g., in person or telephone) or via a self-administered survey (e.g., via mail or Internet).

Eligibility directly affects two important aspects of survey quality. First, coverage problems and possible nonnegligible coverage error will result if eligibility status is not accurately determined throughout a survey. Second, the response rates that are calculated for a survey will be affected by how well the eligibility of the sampled units is determined. The response rates will be depressed if too many ineligible units are deemed erroneously to be eligible, because these units will then be included in the denominator of the fractions used to calculate the response rates when in fact they should be excluded. This too is a complex issue, especially with telephone, mail, and Internet surveys, since the data collection period often ends with the eligibility status of many cases remaining unknown (e.g., those numbers that are always busy during a telephone survey). To accurately calculate response rates, the researchers must make informed judgments about the proportion of these cases with unknown eligibility that are likely to be eligible. This matter is so important that the standard definitions for calculating response rates promoted by the American Association for Public Opinion Research include specific instructions about how to estimate eligibility among those cases that end with a status of "unknown eligibility" (which is referred to as *e*).

Email Survey

An email survey is one that sends the survey instrument (e.g., questionnaire) to a respondent via email and most often samples respondents via email. These electronic mail surveys first came into use in the late 1980s, and many scholars at the time thought that they represented the future of survey research. Since then, Web (Internet) surveys have become the predominant model for electronic surveying, because of the relatively poor performance of email surveys in terms of ease of use and response rates.

Email Survey Procedures

Similar to a Web survey, a survey conducted via email most typically uses electronic mail to contact members of the sample. With Web surveys, the user is directed in the contact email to a Web site containing the questionnaire. With email surveys, the contact email contains the survey questionnaire and no survey Website is referenced. Generally, the email survey approach takes one of three forms: (1) a software file attached to the email, (2) an electronic document attached to the email, or (3) questionnaire text embedded in the email itself.

Some commercial vendors have offered survey software that will attach an executable file to each email sent to sample members. The file is downloaded by the user and executed on his or her personal computer; a software program then prompts the user to fill out the questionnaire and records their responses. A more common and simpler approach is to attach a copy of the questionnaire to the email as an electronic document, using a common format such as Microsoft Word. Users open the document, type their responses in the appropriate places, save the document on their computer, and then reattach the document to an email that is sent back to the surveyor. Alternatively, a text or HTML (hypertext markup language) copy of the questionnaire can be embedded directly in the contact email. By hitting "reply" in their email software, users create a copy of the questionnaire into which their responses can be typed. Responses are given either by inserting Xs into a set of brackets by the appropriate response for text emails or by marking radio buttons for HTML emails, and the email is sent to the surveyor.

Emails from respondents are then collected and entered into a database, either by hand or through the use of survey software. With both the electronic document approach and the embedded text approach, users are often given the option of printing off the questionnaire and mailing it back to the surveyor via regular mail. Research indicates that few respondents use this option when it is offered.

Advantages and Disadvantages

Email surveys share many of the same advantages and disadvantages of Web surveys. For example, email surveys are less costly than other survey modes, because of the lack of printing, postage, or interviewer costs, and they enable the surveyor to collect data quite rapidly. Thus, the potential for interviewer effects are eliminated due to self-administration of the survey. Email surveys also share the same coverage issues as Web surveys, in that not everyone has an email address (nor are there national directories of email addresses), as well as the same measurement error issues, arising from the format of the questionnaire appear differently on different computer and software configurations. There is also evidence that respondents to email surveys may differ from respondents to mail surveys in terms of having higher socioeconomic status; similar results have been found for Web surveys.

The main issue with email surveys, especially when compared to the alternative of Web surveys, is the difficulty of use for both the respondent and the surveyor. With the attached software approach, users must not only know how to run an executable file but also be comfortable with running such files on their personal computers. Given that computer viruses are often spread via executable files, it is likely that many respondents are uncomfortable with this approach. Different computer configurations among the target population, as well as variance in file size limitations among email servers, may also hamper the use of this approach.

With the use of attached electronic documents, users must know to save the document on their computer after entering their responses, generate an email to the surveyor, and reattach the saved document to the email before sending. As with attached software, respondents may be wary of opening an electronic document from an unknown sender. While attached documents would appear to offer the advantage of more formatting and graphics compared to embedded text surveys, methodological research studies indicate that email surveys with embedded text yield higher response rates than attaching an electronic document.

With the embedded text approach, users must hit the "reply" button to generate a copy of the survey; not all email programs are set to create a copy of incoming messages (and thus the questionnaire) when users hit the reply button. While email programs that read HTML-based emails are becoming more popular, many individuals still use email programs that can only read text-based emails. Many of these issues could theoretically be overcome with detailed instructions for the respondent, but the increased complexity of the email survey process is a likely cause of the low survey response rates reported by researchers.

An often overlooked issue with email surveys is their confidentiality. Unlike Web use, many businesses and Internet service providers routinely monitor and/or electronically back up their email traffic. Even when businesses closely monitor Web use, such monitoring usually consists of a record of Web sites accessed rather than a record of every keystroke used or Web form submitted. Confidentiality concerns can thus be higher for email surveys, as copies of the respondent's answers may be made on both their personal computer as well as their email server, unlike in Web or mail surveys. In addition, respondents may be wary of replying to an email, fearing that the surveyor is a spammer and is using the survey to verify email addresses for future spamming. This is less of a concern in Web surveys, which generally involve clicking on a hyperlink rather than giving an email address.

Email surveys can also increase the burden for the surveyor. With the electronic document and embedded text approaches, users can drastically alter the survey document by deleting the special symbols (such as brackets) that are used to designate the beginning and end of each item response. When this occurs, the response must be processed by hand because the survey software cannot process the response. Such processing can be resource intensive. For example, M. P. Couper, J. Blair, and T. Triplett found that nearly half of their email survey responses required some sort of clerical action before they could be added to the survey response database.

In order to keep track of respondents, a unique identifier must be included in each document or email; these can easily be deleted by the respondent. Duplicate submissions may then become a problem. Some researchers have tried using email addresses as the unique identifier, but this does not always work in practice. For example, respondents have email forwarded to other accounts, from which they then reply to the survey, making respondent tracking difficult. Respondents may also forward email surveys to individuals outside the target population.

The literature reveals numerous studies comparing email surveys to mail surveys; the majority of studies show higher response rates for mail surveys. Research is mixed as to whether data quality is higher for mail or email surveys. Interestingly, there is little research comparing email surveys to Web surveys.

The Future of Email Surveys

As HTML-based email programs become more popular, email surveys may become more prevalent. Given that their major drawback lies in the complexity of the process, an HTML-based questionnaire could be constructed in an email such that the respondent could fill it out and submit his or her responses without having to access an external Web site. This involves fewer steps than the typical Web survey, for which respondents must click on a URL (uniform resource locater, or Web address) in the contact email to open the survey in a Web browser. Yet until there is more commonality across email programs, which in turn will allow consistency in design, email surveys will likely fill a small niche in the survey researcher's toolbox. Simply put, email surveys face significant issues in terms of how respondents complete and return the instrument, and how the surveyor processes and analyzes completed surveys. Conversely, Web surveys offer the same advantages as email surveys in terms of cost and speed and relatively few of the disadvantages.

Email surveys are likely to be successful when use of a Web survey is impractical and costs preclude the use of other modes. For example, some organizations may limit their workers' access to the Web. Use of an email survey to query employees would be a viable alternative in this situation, especially considering that employees for an organization are likely to use the same email program.

Encoding

Encoding information is the cognitive process through which experiences are translated into memory. However, for the social sciences, *encoding* often means the process of translating thoughts, ideas, or questions into words. Different phrases and words, definitional and connotative frameworks may conflict given different audiences and contexts. In survey research, the encoding of widely understood and definitive meaning into a question is essential to valid measurement. Researchers must be cognizant of how different groups will interpret (or decode) their questions. A strong survey instrument ensures that the researcher and the respondent share the same understanding of both the questions asked and the answers given. Compounding problems emerge when a respondent is conditioned by the survey questionnaire or must choose between response options with similar meanings.

One example of poor encoding might be translating an idea into a question that the respondents interpret inconsistently as a group, interpret differently from the researcher, or both. For example, a survey question might ask how respondents feel about democracy. In order to interpret responses to this question, a researcher must assume that everyone in the sample shares the same definition of *democracy* as everyone in the sample population and also shares the surveyor's definition. Further, the researcher must receive the respondent's answers with the same understanding that the respondent delivers it. In survey projects, consistent encoding and decoding is essential to relaying the respondents' true responses. Failing to anticipate how different groups of people will interpret the survey instrument will affect both the internal and external validity of a research project.

There are several sources of differential encoding and decoding in survey research. A survey or researcher may ask questions in a second or translated language and may confuse meanings in the second language. Values, ideas, and definitions may differ across cultures or within cultures. Common usage and events may affect how groups understand and the questions or answers in the survey. Also, some ideas are inherently more complex than others. Complex concepts in either the question or the answer can result in multiple interpretations of their meanings.

Encoding may also occur in the questionnaire itself. As sampled people respond to different elements of the questionnaire, they may begin to develop a set pattern based on either the questions asked or the list of possible answers. In this instance, the respondent has been conditioned to the questionnaire itself. She may have encoded a set of answers per question type, established an opinion or mood toward the survey instrument, or may skim over similar questions, believing (correctly or incorrectly) that she has an answer. Hence, the respondent may assume a set of values within the research project that may not accurately reflect her true opinion, preference, actions, and so on that exist outside the particular research study.

Researchers work to minimize encoding and decoding differentials in many different ways. One way to guard against individuals sharing different conceptions is by thoroughly explaining difficult and important parts of the questionnaire. Explicitly stating and defining questions and answers within the study helps homogenize how the respondents respond. Also, the researcher can construct straightforward and simple questions and answers. From these simple responses, the researcher then may develop insight into theoretically deeper questions. Last, to gain external validity, the descriptions in the study should be congruent with other scholarly works, environments, or surveys.

In order to minimize encoding and false reflexive responses based on the questionnaire, the researcher can develop a complex survey instrument that varies questions and responses. When the language, structure, and the order of the questions vary, the subject is less likely to create a fixed response. Such a questionnaire forces the subject to thoughtfully engage the questions and be more apt to respond accurately. Encoding is not necessarily detrimental to research. It is a characteristic of thought and social relations of which researchers must be aware.

EPSEM Sample

Sampling involves the selection of a portion of the population being studied. In probability sampling, each element in the population has a known, nonzero chance of being selected through the use of a random selection procedure. *EPSEM* refers to an *equal probability of selection method*. It is not a specific sampling method such as systematic sampling, stratified sampling, or multi-stage sampling. Rather it refers to the application of a sampling technique that results in the population elements having equal probabilities of being included in the sample. EPSEM samples are self-weighting; that is, the reciprocal of the probability of selection of each element in the selected sample is the same. Thus the base sampling weighting for each selected element in the sample is a constant equal to or greater than one (1.00).

The most common examples of equal probability of selection methods are (a) simple random sampling, (b) unrestricted random sampling, (c) systematic random sampling, (d) stratified sampling, and (e) proportionate stratified sampling. *Simple random sampling* refers to equal probability of selection element sample without replacement. *Unrestricted random sampling* refers to equal probability of selection element sample with replacement. *Systematic random sampling* refers to the selection of elements using a sampling interval and a random start. *Stratified sampling* refers to the formation of mutually exclusive and exhaustive groupings of elements. *Proportionate stratified sampling* then entails selecting a sample from the strata so that the proportion of the total sample allocated to each stratum equals the proportion of the total elements in the population in each stratum. So for example, if a stratum contains 25% of the population elements, 25% of the sample would be selected from that stratum.

A multi-stage sample can also be an EPSEM sample. The simplest example is a multi-stage design based on equal probabilities of selection at each stage of sampling. A more common practical example is a multi-stage design that results in an overall equal probability of selection of each element in the population, but at each stage the probabilities of selection are not equal. In two-stage sampling the clusters are usually of unequal size (i.e., the number of elements in the clusters vary from cluster to cluster, with some small clusters and some large clusters). If a probability proportional to size (PPS) sample of clusters is drawn, the larger the cluster the greater its probability for selection. So, at the first stage, the probabilities of selection are unequal. At the second stage of sampling, an equal number of elements are selected using simple random sampling from the sample clusters. So, at the second stage, the within-cluster probability of selection of an element is higher if the cluster is smaller. However, the product of the first-stage selection probability of the cluster and the second-stage probability of selection of the element within the cluster is a constant for all elements in the population. Thus, an EPSEM sample is achieved.

Equal Probability of Selection

Survey samples can be chosen in many ways, and one common approach is to use a technique that provides an equal chance of selection to all elements in the sampling frame. One type of equal probability sample is a simple random sample, but there are many others.

Morris H. Hansen, William N. Hurwitz, and William G. Madow appear to have been the first to refer to them as *EPSEM samples* ("equal probability selection method"), but the term was so often used by Leslie Kish that some have misattributed the coinage to him. Others have used the phrase *self-weighting sample*, although some eschew this term, given that weighting typically involves nonresponse adjustment and some form of calibration such as ratio adjustment or raking, and these lead to unequal weights even when all elements of the sample have been selected with equal probability. Typically, the *equal* in the title refers only to marginal inclusion probabilities. Joint probabilities of selection vary across pairs of units for designs other than simple random samples.

The variation across pairs of units is caused most often by systematic selection, stratification, clustering, or some combination of these, although it can also be caused by other sampling systems, such as controlled selection and maximization (or minimization) of overlap with other samples. The purpose of varying the joint probabilities of selection is to improve efficiency by exploiting auxiliary information. The reasons to keep the marginal inclusion probabilities constant are less compelling and largely involve tradition.

One of the innovations that was introduced in the 1940s at the U.S. Census Bureau is a scheme for multi-stage sampling that preserves equal probabilities and is very efficient. In this design, clusters are stratified into strata that, in addition to being internally homogenous, are nearly equal in population. Two clusters are then selected with probability proportional to population from each stratum. Within sample clusters, second-stage probabilities of selection are calculated so as to achieve an EPSEM sample. Given reasonably accurate population measures, this procedure will result in nearly equal-sized cluster workloads, convenient for a local interviewer to handle. Attendant reductions in the variation in cluster sample size and in sampling weights also improve efficiency.

Also, in the 1940s, it was much harder to deal with unequal weights at the analysis phase. Now, with software like SUDAAN, WesVar, and various SAS procedures that are readily available and designed to cope with unequal weights, there is less reason to design EPSEM samples. There are, however, still some reasons to consider them. Some are articulated by advocates of inverse sampling, a procedure whereby an EPSEM sample is extracted from a larger sample. Certainly, if one is interested in multi-level modeling, then an EPSEM sample can still be advantageous because there is considerable debate about how to use sampling weights in fitting such models. Another advantage arises in the context of hot-deck item imputation. If probabilities of selection are equal, then the contentious question of whether to use the weights in donor selection is avoided.

Despite these analytic and workload advantages, samplers should feel free to vary probabilities of selection using optimal allocation when advance knowledge of strata characteristics is available. This is particularly important for oversampling of minority populations in the United States.

Error of Nonobservation

Errors of nonobservation refer to survey errors that are related to the exclusion versus inclusion of an eligible respondent or other sample record. This term principally refers to sampling error, coverage error, and nonresponse error. This is distinguished from errors of observation, which refer to errors that are related to the measurement of the content of surveys.

The term *errors of nonobservation* is based on the language and assumptions of survey methodology. It is similar to the concepts that psychometricians use to call the errors that impact external validity and, in some respects, is similar to what economists call "selection bias."

Within the total survey error perspective, errors of nonobservation can impact both random error and systematic error. Traditionally, however, coverage error and nonresponse error have been seen as being most problematic in terms of systematic error or bias. In contrast, in probability samples, sampling error is primarily seen as impacting variability, although systematic bias can also result from nonprobability samples or from inappropriate data adjustment or weighting of data from probability samples.

Sampling Error

Inference from sample surveys assumes that an underlying population is being studied and that samples are taken from this underlying population. Sample statistics, including sampling errors, are calculated to determine the variability of a statistic as measured in a survey compared to the actual or true value of that statistic in the population.

Since not all members of a population are included in a sample, survey statistics are usually different from population values. For any population, there are all sorts of possible combinations of records that might be included in any particular sample. In many cases, the results of a survey will be close to what would be found in an underlying population; in some cases they may be far off. The sampling error is traditionally taken as a measure of how the statistics obtained from any particular survey might differ or vary from those of the actual underlying population.

In terms of understanding errors of nonobservation, sample errors from probability samples primarily refer to errors regarding certainty about how close a survey statistic comes to the actual value of the statistic in an underlying population. That is, nonobservational errors due to sampling primarily impact the variability of survey statistics or the precision of the survey measure. Although there is almost always error in the form of variance, because survey results are rarely exactly in line with population statistics, these variable errors are random and thus cancel each other out across many samples.

The characteristics of sampling error are primarily mathematical and are based on several assumptions. Sampling statistics assume that a sample of respondents or other units is taken from an underlying collection, list, or frame of all members of a population.

Sampling statistics also assume that data are collected from all selected records. Moreover, probability sampling assumes that all sampled records have a known, nonzero probability of being selected.

Nonprobability samples select respondents in ways that do not permit the understanding of the specific probability that sampled members of the population are included in the sample. Convenience samples, for example, select respondents that are easily accessible to the researcher while excluding others. These sampling methods can lead to bias, when the results of measured statistics systematically differ from population values, usually in unknown ways. Bias or systematic error can also occur in scientific samples when different sample records are selected with varying likelihoods or probabilities of selection, but this bias can be adjusted for with simple mathematical adjustments known as *sample weights*.

Coverage error and nonresponse error, in contrast, come about when the sample frame does not well match the underlying population or when data are not collected from all valid sample records. In these cases, population members are not included in a survey either because they do not have a chance of being included in samples or because eligible sampled respondents do respond to a survey for various reasons.

Coverage Error

Coverage error refers to the error that occurs when the frame or list of elements used for a sample does not correspond to the population a survey is intended to study. This can occur in several ways. For example, some sample records might correspond to multiple members of a population. In contrast, some sample records might be duplicates or correspond to the same member of a population. The most problematic situation is undercoverage, where a sample frame excludes some members of the population it is intended to cover.

The primary danger involved in coverage error is coverage bias, which can occur when a sample frame systematically differs from the population it is intended to include. The extent of coverage bias depends both on the percentage of a population that is not covered in the sample frame and the differences on any statistic between those included in the sample frame and those excluded from the sample frame. For example, household surveys systematically exclude persons who are homeless, telephone surveys systematically exclude persons who do not have telephone service, and most telephone surveys have systematically excluded people who have cellular (mobile) telephone service but not traditional residential landline telephone service. In cases where the excluded proportion of a survey's target population is small, and where differences between sampled respondents and others are small, researchers usually do not have to worry about bias in results because of these exclusions. However, if the magnitude of this coverage error is large, or if the differences between covered and noncovered respondents are great, or if a survey is attempting to make very precise estimates of the characteristics of a population, then nonignorable coverage bias may result.

Nonresponse Error

Nonresponse error refers to error that occurs when persons or other elements included in a sample fail to respond to a survey. There are two types of nonresponse to surveys: unit nonresponse and item nonresponse. *Item nonresponse* (i.e., missing data) occurs when a respondent who completes a survey fails to provide answers to a question. Many Americans, for example, refuse to tell survey researchers their income. *Unit nonresponse*, in contrast, occurs when sampled respondents fail to respond to a survey at all.

Unit nonresponse occurs for a variety of reasons. Some respondents are unable to complete a survey, for example, because of a health condition or because they speak a language other than the ones a survey is administered in. Other respondents are unavailable to complete a survey, for example, because they are not at home when an interviewer calls. Still other respondents refuse to complete surveys and thus are not included in final data.

The primary danger involving survey nonresponse is potential bias in results. Similar to coverage error, the magnitude of nonresponse error depends both on the percentage of the population who fail to respond to a given question and the differences between respondents and nonrespondents on any survey statistic.

Errors of Commission

Errors of commission are sometimes also called "false positives." They refer to instances in which someone or something is erroneously included for consideration when they or it should have been excluded. In survey research, this error typically occurs when the eligibility of a unit is determined. For example, when someone is screened at the start of interviewer contact to determine whether or not he or she is eligible, and the person answers erroneously in a way that makes the interview proceed as though the person were eligible for data collection when in fact the person is not eligible, then this is an error of commission. In these cases, data are gathered and analyzed for someone who should not have been interviewed.

Errors of commission occur for many reasons, but most are due to questionnaire-related error, interviewer-related error, and/or respondent-related error. The introduction to a questionnaire, where eligibility screening is typically carried out, might be worded poorly and thus cause incorrect data to be gathered, leading to people who in fact are not eligible being erroneously treated as eligible. An interviewer may administer an eligibility screening sequence poorly, thus causing the respondent to misunderstand what is being asked, leading to answers that result in an ineligible person being treated as eligible. Finally, a respondent may be unable to understand the eligibility screening questions and thus may give incorrect answers. Or the respondent may not be paying enough attention to the screening questions or may not be willing or able to give an accurate answer. In fact, some respondents will give an answer they believe will disqualify them even if it is not true for them, whereas others will do the opposite just so they can take part in the survey.

An example of errors of commission routinely occurs when people in the United States are sampled via telephone by the Nielsen Company to ask them to participate in a week-long TV diary survey. In the age of time shifting, when many people have digital video recorders (DVRs) that allow them to shift the time they view television programming, a special diary has been devised to measure programming that is time-shifted. This diary places much more of a cognitive burden on respondents who receive it than does the regular TV diary that does not measure time shifting. Thus, it would be ideal if only those people who have DVRs were sent the special diary. However, despite extensive R&D testing of the eligibility questions that are used to determine whether or not someone has a DVR, many people (especially older adults) appear not to be able to accurately answer the questions and therefore incorrectly are sent the special diary when they should receive the simpler diary.

Another example of errors of commission concerns the current situation in the United States when interviewing people reached via cell phone. Currently there are federal regulations affecting number portability that allow people to take their cell phones to another state without changing their numbers when they move. If, for example, a telephone survey of residents of New York were to be conducted without adequate screening to determine whether or not the person reached was in fact a New York resident, then all those people who had cell phones with New York area codes but now were living in other states would incorrectly be treated as eligible.

How to reduce the chances that errors of commission will occur is an important issue for researchers to think carefully about. It is not likely that such errors can be eliminated completely from surveys, and sometimes it is very expensive to institute the procedures that will keep these errors to a minimum.

Errors of Omission

Errors of omission are also sometimes called "false negatives." They refer to instances in which someone or something is erroneously excluded from consideration when they or it should have been included. In survey research, this error typically occurs when the eligibility of a unit is determined. For example, when someone is screened at the start of interviewer contact to determine whether or not he or she is eligible, and the person answers erroneously in a way that keeps the interview from proceeding as though the person were ineligible for data collection when in fact the person is eligible, this is an error of omission. In these cases, data are not gathered from someone who should have been interviewed.

Errors of omission occur for many reasons, but most are due to questionnaire-related error, interviewer-related error, and/or respondent-related error. The introduction to a questionnaire, where eligibility screening is typically carried out, might be worded poorly and thus cause incorrect data to be gathered, leading to people who in fact are eligible being erroneously treated as ineligible. An interviewer may administer an eligibility screening sequence poorly, thus causing the respondent to misunderstand what is being asked, thus leading to answers that result in an eligible person being treated as ineligible. Finally, a respondent may be unable to understand the eligibility screening questions and thus may give incorrect answers. Or the respondent may not be paying enough attention to the screening questions or may not be willing or able to give an accurate answer.

An example of an error of omission occurs whenever a survey screening sequence is worded in such a way that it is readily apparent to the respondent what answers will qualify her or him for the interview and what answers will disqualify her or him. Since many people are reluctant to directly refuse to participate in surveys in which they have little or no interest, such screening sequences are an easy way for the respondent to get out of doing the survey without outright refusing the interviewer. Thus, it is very important for researchers to structure their eligibility screening questions in ways that do not telegraph to the respondents what answers will make them eligible or ineligible.

How to reduce the chances that errors of omission will occur is an important issue for researchers to think carefully about. It is not likely that such errors can be eliminated completely from surveys, and sometimes it is very expensive to institute the procedures that will keep these errors to a minimum.

Establishment Survey

An establishment survey is a survey that seeks to measure the behavior, structure, or output of organizations rather than individuals. Establishment surveys include surveys of business that are critical to our understanding of trends in the economy, such as the Economic Census conducted by the U.S. Census Bureau. However, establishment surveys also include surveys of universities and colleges, hospitals, and nursing homes. There has been considerable discussion about the best practices involved with conducting establishment surveys in recent years, as the response rates achieved by many establishment surveys have declined similar to those of household surveys. This reduction in response rates has spurred the development of a more robust literature on conducting establishment surveys, as well as investigation of how to increase cooperation through improved questionnaire design and contacting procedures. Understanding establishment surveys requires examining the ways in which they are different from household surveys by focusing on the unique sampling, survey, and questionnaire design issues that need to be considered when studying establishments, as well as effective strategies for contacting the appropriate respondents within establishments to complete these surveys.

Differences Between Establishment and Household Surveys

Establishment surveys differ from household surveys in a number of notable ways, creating some unique challenges and considerations for survey researchers who are conducting establishment surveys. The most fundamental difference between establishment and household surveys is the unit of analysis. Whereas in a household survey, the unit of analysis is the household, family unit, or an individual, the unit of analysis for an establishment survey may be either an establishment or an enterprise. An establishment could be a business operating in a particular location, a business entity reporting unemployment insurance claims, a hospital or clinic location, and so on. An example of an enterprise would be a corporation that includes one or more locations or establishments. The term *establishment survey* is used as a generic or umbrella term to refer to surveys that collect data at either the establishment or enterprise level.

A second important distinction between establishment and household surveys is the use of informants. Whereas informants to a household survey are generally selected as part of the sampling design, informants to establishment surveys are often the person or people within an organization who are the most knowledgeable about the subject matter of the survey or those who have access to the required information. Also, although household surveys generally rely on one person to answer questions about the household overall or others living in the household, there may be multiple informants to an establishment survey, depending on the survey topics and the complexity of the establishment.

The complexity of selecting proper informants to respond to establishment surveys is usually correlated with the complexity of the sampled organizations. An example of an establishment with a simple structure for identifying a proper informant would be a nursing home, where the administrator of the nursing home would generally be the desired informant. Establishments with more complex structures, such as universities or larger businesses, may have a more decentralized structure that requires additional effort to determine who is the most appropriate informant and may include multiple informants. Surveys of larger or more complex establishments conducted via telephone may require additional time to identify appropriate informants; this is especially true of establishments for which there is no contact name provided from the sample frame. For this reason, some survey firms have invested in the additional effort of pre-contacting the establishment to obtain the name of a contact person (and potential informant) prior to the full survey being fielded. Given that the informants completing establishment surveys are answering questions about the organization as a whole, or about others within the establishment, survey questions for the establishment that ask for hard, factual data about the operations of the establishment tend to be more appropriate than questions that ask opinions or require subjective evaluation.

A further difference between establishment and household surveys is related to respondent burden, which is measured differently in establishment surveys than in surveys of household or individuals. The burden of completing a household or individual survey is generally limited to the number of questions asked of a respondent (although there are some examples of household surveys requiring respondents to obtain records prior to the interview, this is not the norm), and the questions are usually designed to be answered by recall. In contrast, an establishment survey often will have some questions that require more time to answer because of the need to compile the required information. Researchers also must consider that those responding to an establishment survey most likely are doing so during working hours, which may be discouraged by establishments because it takes time away from work tasks. This is true of both mandatory and voluntary surveys, although completion of government mandatory surveys that establishments regularly complete tends to become one of the regular work functions of certain staff members. Due to the burden issues inherent in many establishment surveys, limiting the number of survey topics involved with completing the questionnaire is an important factor in achieving high response rates.

Establishment Survey Design

Like all surveys, the design of establishment surveys requires careful consideration of a number of issues to ensure unbiased estimates of the population being studied. Several of these issues warrant discussion, as they have implications that are specific to establishment surveys, including sampling, survey design and development tools, questionnaire design, choice of mode, and effective data collection techniques.

Sampling

Establishment survey samples are generally drawn from list frames, such as business registers, or lists of other types of organizations created from multiple data sources. The sample design of many establishment surveys uses probability proportionate to size (PPS) sampling or simple random sampling with some stratification. Surveys using stratification only also tend to use the size of the establishment, since the size of the establishment generally contributes much of the variance in these list samples. For example, large surveys of establishments collecting employment data have found that employment is skewed heavily toward larger establishments, meaning that the sampling design must account for this to obtain an accurate estimate. Establishment surveys often tend to employ a second sampling stage in which those within the establishment (employees, patients, etc.) are sampled within the establishment unit.

Survey Design Issues and Development Tools

Surveying establishments requires a thorough understanding of the workings of the organizations being studied, so that the limitations on the types of data that can be collected are understood and so that the most successful approaches to obtaining cooperation can be employed. During the design phase of an establishment survey, it is useful for researchers to understand the types of data the sampled establishments are able to provide, and in what format these data tend to be kept by establishments. Similar to household surveys, the terms and definitions used in questionnaires, instructions, and other materials related to the questionnaire should be reviewed carefully to ensure they are understood in the same way by different establishments in the population. Terms that are confusing or can be understood in different ways by different respondents tend to increase item nonresponse and increase response bias by encouraging respondents to estimate answers to survey questions in ways they would not if the terms and definitions were clear. Qualitative tools such as expert panels, site visits, focus groups, and cognitive interviews, that have been used extensively in household surveys, have become more common in designing and improving establishment survey questionnaires.

Establishment surveys often rely on expert panels or stakeholders' meetings to review proposed survey items and to help researchers use language and terminology in the questionnaire and other materials that will be relevant and appropriate. This is especially important for establishment surveys of populations that use very specific terminology (such as medical practices), so that the language used in communication with sample members mirrors that used among the establishment professionals themselves.

The design of many establishment surveys has gone beyond expert review to include site visits to potential establishment respondents, and these site visits can provide researchers valuable information about the survey response process. Specifically, conducting site visits can shed light on a number of issues related to the questionnaire design process, including how establishments in the population fulfill requests to complete surveys and who in the organization handles the requests. Another potential discussion topic for site visits is the recordkeeping system or systems typically employed by establishments in the survey population, because knowing how information is recorded and stored at the establishments will help researchers to align the data requests with what establishments can provide with the highest quality and smallest possible burden. Finally, since establishment surveys often collect data about specific time periods, it is important to understand how any "reference" dates the survey plans to use mesh with how establishments in the sample receive, update, and store those data. Site visits could include unstructured one-on-one interviews, focus groups, or in-depth discussions with potential survey informants about the barriers to responding to a survey of their establishment. Surveys using these techniques prior to developing the questionnaire tend to get a solid grounding in how requests for certain data in a questionnaire will be received, whether the definitions used are in common usage and are understood in a consistent way, and the burden involved in assembling and reporting the data.

Questionnaire Design and Pretesting

There are questionnaire design issues that are particular to establishment surveys. With surveys of all types, shorter questionnaires generally produce higher response rates. Given the amount of time required by the establishment to collect information to respond to some surveys, limiting the number of data items will increase the likelihood of response by the sampled establishments. There has been increased attention to the appearance of establishment survey questionnaires in recent years, and methodological studies of the effects of layout and other visual cues have improved the usability of many establishment surveys. Improving the layout and visual presentation of establishment surveys has been shown to increase the likelihood of response by reducing the perceived burden of completing the questionnaire. Due to the number and complexity of the terminology used in the instructions, some establishment surveys have placed sets of complex definitions and instructions in a separate document to avoid the cluttered appearance that placing these items in the questionnaire itself can create.

Similar to household surveys, pretesting establishment survey instruments prior to fielding can identify problems with comprehension and survey flow and can also validate improvements made to the instrument as a result of previous design steps. Also, the use of cognitive testing has increased in recent years as researchers have realized the extent to which terms and definitions can be understood differently by respondents. Methodological work on cognitive interviewing on establishment surveys has shown how both concurrent and retrospective think-aloud techniques can be used to improve questionnaires in establishment surveys.

Mode Considerations

The modes that are used in establishment surveys have evolved considerably in recent years. For many years, mail was the predominant mode used when surveying businesses and other institutions due to the low cost of mail surveys. Similar to recent trends in household surveys, surveys offering sampled establishments a choice of modes are now common. The increasing popularity of offering a Web survey response option to selected establishments is primarily due to the fact that Web access in workplaces is now widespread. Also, the use of combinations of mail, Web, and other modes such as touchtone data entry in a survey reduces mode effects, since these modes are self-administered and questions can be displayed in essentially the same format. Surveys using mail and Web have also employed telephone contacts with establishments as reminder prompts or to collect the data as a last resort. In contrast, for voluntary surveys or surveys among populations that have shown themselves to be reluctant to participate in surveys in the past, the combination of a Web and telephone mode offering is often necessary so that interviewers can personally persuade sample members about the benefits of participating in the survey, communicate effectively with gatekeepers, and allay concerns about confidentiality.

Data Collection

As discussed previously, the level of burden associated with completing establishment surveys has depressed response rates in recent years, and maintaining similar response rate levels on periodic surveys has been accomplished only through more intense follow-up efforts and the employment of more effective data collection techniques. One of the techniques employed in establishment surveys is ensuring that the initial contact to respondents in establishment surveys is personalized, professional, and succinct. Personalizing an advance mailing by sending it to an individual rather than to the establishment at large increases the probability that the mailing will be opened, and if the targeted contact is not the most appropriate person to respond to the survey, he or she is more likely to pass along the materials to someone else at the establishment who is better able to provide the information. However, efforts to direct materials to specific individuals at the establishment are dependent on the information available from the sampling frame or on prefield efforts to identify appropriate respondents.

The design of a successful establishment survey includes a thorough understanding of the terminology used among the establishments studied, as discussed earlier. In the same vein, successful contacting of establishments during data collection should be done by staff who are familiar with this terminology and can provide relevant information about the value of completing the survey. Organizations conducting establishment surveys that include telephone interviewing or prompting have found it useful to provide additional specialized training to interviewing staff in order to avoid refusals and increase survey response. Also, a highly trained and knowledgeable staff will be better able to negotiate with gatekeepers, who tend to be more prevalent in establishment surveys due to the nature of organizations and the need for decision makers to insulate themselves from communication not central to their organizations' missions.

Use of Incentives

Similar to household surveys, the use of incentives in establishment surveys has increased, and it is generally considered necessary to provide incentives to populations that are studied regularly or that typically have low participation rates, such as physicians and business executives. Incentives for respondents at establishments tend to be more effective in fostering participation when they are explained as being "tokens of appreciation" rather than payment for the respondent's time, since busy (and highly compensated) respondents may not see the incentive as equitable value for their time spent responding.

Longitudinal Establishment Surveys

Many establishment surveys are conducted regularly to enable time-series data analyses, and often the same set of businesses is asked to complete surveys at regular intervals, such as annually. These longitudinal surveys face additional challenges, such as respondent fatigue, and the survey instruments used are generally changed very little between rounds of the survey in order to maintain time-series continuity. Even though questions on these surveys remain fairly static over time, pretesting (including cognitive interviews prior to data collection or response behavior follow-up surveys after respondents complete the survey) can identify areas of confusion that respondents may encounter while completing the survey. The decision to change survey items on longitudinal surveys should factor in the potential impact on respondents, some of whom complete the survey in multiple years and may be frustrated by changes in the measures or definitions. That concern must be balanced with the knowledge that there will also be respondents completing the survey for the first time, either due to staff turnover or because of new establishments added to the sample. Longitudinal surveys should strive to accommodate both situations to ensure similar response rates between establishments that are new to the sample and those completing the survey multiple times.

Ethical Principles

In the discipline of survey research, *ethical principles* are defined as the standard practices for privacy and confidentiality protection for human subject participants. Ethical principles in survey research are in place to protect individual participant(s) beginning at the start of study recruitment, through participation and data collection, to dissemination of research findings in a manner that is confidential, private, and respectful. These principles guide accepted research practices as they apply to the conduct of both quantitative and qualitative methods in survey research.

Background and Historical Perspective

The need for adequate protection of the individual participant and the adoption of stricter ethical principles in practice has been shaped by several historical events. One of the worst cases of ethical misconduct by researchers in the United States was the Tuskegee Syphilis Study (1932–1972) conducted by the U.S. Public Health Service with 399 black men in Macon County, Alabama, to study the natural history of syphilis. Following incidents of research malpractice such as the Tuskegee Study and the increased concerns of the public, the Nuremberg Code, the Belmont Report, and the Declaration of Helsinki were adopted.

The *Nuremberg Code* declares the need for voluntary consent by human subjects, disclosure of study procedures, and protection for vulnerable populations. The *Belmont Report*, released in 1979 by the U.S. National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research, emphasizes three basic ethical principles to guide practice: (1) respect for persons, (2) beneficence, and (3) justice. The principle of respect for persons emphasizes that researchers acknowledge autonomy (an individual's ability to independently make decisions) and the protection of those with diminished or restricted autonomy (individuals who are not capable of self-determination) to enter into research participation informed and voluntarily. Beneficence exemplifies the ethical treatment of persons by securing their protection from harm or risk involved with participation and the disclosure of benefits associated with study involvement. The third principle, justice, encourages equal treatment and provision of advantages and access associated with research to all persons. The *Declaration of Helsinki*, adopted in 1964, was designed to guide physicians in biomedical research involving human subjects to safeguard the health of people.

Respondent/Participant

Informed Consent

Informed consent is designed to protect survey participants' rights to voluntary participation and confidentiality and thus relates to basic concerns over respect, beneficence, and justice, as discussed previously. To make an informed decision to participate, individuals must understand that the survey involves research and the purpose of the research. The consent statement should communicate the expected burden (typically for survey research, the length of commitment) and any potential discomfort that may result from participation, such as distress resulting from the sensitivity of questions. The consent statement likewise should describe potential benefits that the survey may have on the individual and society. Informed consent requires an explanation of the voluntary and confidential nature of the study.

The consent statement must be understandable to potential study participants and thus avoid jargon and complex language. In some survey situations, study participants may be asked to agree to several activities, such as answering questions in a survey and being audiotaped. Each individual activity should be presented on its own and consent obtained separately.

Voluntary Participation

Participation in survey research is fully voluntary, meaning that individuals have the right to decide themselves whether they wish to participate. Once that decision is made, participants have the right to withdraw from the survey at any time or refuse to answer any question. The voluntary nature of participation requires that such decisions be made without negative consequence or withdrawal of benefits to the participant.

Confidentiality and Privacy

Survey participants have the right to control the disclosure of information about themselves that they may consider private. Information that is considered private may vary across communities and individuals. Survey researchers have the responsibility to treat any information shared in an interview setting or on a self-administered questionnaire as confidential. All individuals involved in collecting data should be fully trained in confidentiality practices and be required to adhere fully to such protocols without exception.

The design of the survey instrument itself affects the protection of privacy. At times, surveys may ask about sensitive topics that participants may view as intrusive to their privacy. The consent form should clearly divulge the topics covered in the interview, and the survey design itself should allow participants to choose not to answer any question. The storage of survey data, including audio- and videotapes, clearly impacts the process of maintaining confidentiality. The first consideration is whether participant identifiers need to be kept. If so, survey practitioners should consider options for protocols that limit access and prevent inadvertent disclosure.

In some situations, private data can be protected from subpoena by third parties. Studies that collect information potentially harmful to individuals if disclosed, such as substance abuse, other illegal behaviors, or sexual practices, may be granted a *Certificate of Confidentiality* issued by the National Institutes of Health that offers protection against disclosure. Any study, regardless of funding or source of funding, can apply for a Certificate of Confidentiality. Limitations to confidentiality in a survey study do exist. For example, some states require the reporting of child abuse and neglect or intent to harm oneself or others. In survey situations that may uncover such events, the interviewer may be required to report this to her or his supervisor, who in turn would follow the survey organization's procedure for such cases.

Incentives

Incentives in survey research are often used as a vehicle for thanking study participants for their contributions or as a means for initially motivating interest and participation. Incentives may pose ethical conflicts when their appeal is too strong (i.e., coercive) and thus misrepresent the voluntary nature of the study or bias the participants' decision to participate.

Vulnerable Populations

Some study populations may be more vulnerable to violation of their rights to informed consent and voluntary participation. Such populations include minors, prisoners, cognitively disabled individuals, economically and educationally disadvantaged individuals, and those with mental health conditions. Survey researchers have responsibility to build in additional protections for these individuals. For example, such protections may include building in an oral consent requirement when literacy levels are low in a study population or, in the case of research with children, obtaining parental consent.

Researcher/Investigator

Ethical principles also provide a foundation to guide the researcher in the design of a study. The principles supply a standard for practice that is used to guide research design, conduct, analysis, and reporting of findings. Applied and ethical theories are the basis for several codes of professional ethics and practices (e.g., American Association for Public Opinion Research [AAPOR] and Council of American Survey Research Organizations [CASRO]) that are based on teleological, deontological, and casuistical ethics. Teleological ethics in professional practice guide the practice and development of research studies that aim to answer a set of questions in a manner that is valid and reliable with an outcome that is meaningful for a population. Deontological ethics are those that are inherently and morally correct (protection of confidentiality, voluntary participation). The codes of professional ethics and practices guiding research are established on accepted principles that model best practices in the field of survey research and are casuistical.

Research Design, Practice, Reporting, and Disclosure

Survey researchers should aim to design research that protects participants through methods and practices that are approved by institutional review boards (IRB), or their equivalent in the private sector, and comply with ethical principles. Survey researchers should be committed to the conduct of research of the highest integrity that carefully weighs and accounts for participant benefits, risk, and protection. Ethical principles extend beyond recruitment and data collection to the management of data, analysis, and the report of findings. Analysis of data collected should not include identifying variables that could lead to a violation of survey participant confidentiality.

Survey practitioners have ethical obligations to the public to share their methods and findings. Disclosure of the study design and methods furthers the goals and advancement of science generally, but more specifically, allows for others to reflect carefully on the strengths and limitations of the study itself and allows for replication of research and validation of findings.

The findings released from a survey should accurately reflect the survey data. Misrepresentation of survey results can violate society members' rights to respect and justice, and in some situations result in harm to community standing, access to services and programs, and personal freedoms.

Researchers are required to report study methods that include procedures of participant recruitment, data collection (participant and nonparticipant characteristics), data management (editing and coding), and analysis that allow for adequate peer review, replication and validation of research findings, and the evaluation of the quality of published studies. Full disclosure of a survey and its findings should include several key pieces of information, such as (a) research sponsorship and name of the organization that conducted the survey; (b) a description of survey objectives; (c) sampling frame and sampling methodology; (d) dates of the study; and (e) exact wording of the questions. The reporting of survey methods in a manner that protects participant confidentiality yet allows for professional evaluation of the quality of survey research avoids the creation of publication bias and misinterpretation and misleading conclusions. Survey researchers are expected to avoid falsification of findings and plagiarism.

As new methods of data collection (e.g., Web surveys) are introduced and accepted into practice, ethical principles must be modified and implemented to assure the protection of participants. Analysis techniques (e.g., Hierarchical Linear Modeling and Geographic Information Systems) continue to evolve and allow survey researchers to report and illustrate findings in ways that assure participant confidentiality and informed consent.

Through practice, survey researchers have learned that ethical principles not only protect individual rights in research participation but contribute to better research methods that may increase the trust between survey participants and research interviewers and result in better rapport and quality of data collected. Ethical principles have also improved confidence in the value of research within specific communities as well as overall public trust.

EVENT HISTORY CALENDAR

The event history calendar is a conversational interviewing approach that is designed to collect retrospective reports of events and the timing of their occurrences for reference periods that can range from several months to an entire life course. Different researchers have used different terms, including *life history calendar, life events calendar, crime calendar, life events matrix*, and *neighborhood history calendar*.

Key Components

The primary aim of the event history calendar approach is to maximize the accuracy of autobiographical recall. Just as event history calendars represent the past both thematically and temporally, the structure of autobiographical knowledge is believed to be organized in a similar fashion. Theoretically, the thematic and temporal associations of events within the structure of autobiographical knowledge afford retrieval cues that can be implemented in event history calendar interviewing and aid respondents to reconstruct their pasts more completely and accurately. One type of retrieval cue involves the sequencing of periods of stability and the transitions between them with regard to what happened earlier and later in time within the same timeline. For example, one may remember that one's employment period in one company immediately preceded another period of employment with a different company. In between these periods resides the transition point from one period to another, and both the length of periods and the timing of transition points are recorded within event history calendar timelines. In addition to sequential retrieval, the use of parallel retrieval cues involves the remembering of events across timelines and domains that happened contemporaneously, or nearly so. For example, one may remember a period of unemployment that was contemporaneous with a change in residence from one location to another. Parallel retrieval is particularly effective if the timing of one of the events is especially memorable, as this memory will locate the timing of the other event as well. It is the use of the respondents' own remembered events as cues to recall less easily retrieved information that is hypothesized to lead to benefits in data quality, and it is this requirement that necessitates conversational flexibility in interviewing.

Other key components of event history calendar design include representing thematic aspects of the past into domains, such as residence and labor, and the capturing of temporal changes by the inclusion of one to several timelines within each domain. For example, a labor history domain may include separate timelines to collect temporal changes in the amount of work, periods of unemployment, and periods in which one had been out of the labor force. In addition to the length of the reference period, instrument designers need to determine the smallest units of time in which life events are to be located, whether years, months, or in some instances, thirds of a month. For longer reference periods, larger time units should be used, so as to provide participants with a level of temporal detail that is best matched to how finely tuned the timing of events can be reconstructed in memory and to lend to both interviewers and respondents a manageable number of units. The first domains that should be queried are those whose events are most easily remembered, to motivate responding and also to lay out a framework in which more easily remembered events can be used as cues in the remembering of events that are queried later in the interview. Requesting respondents to provide "landmark events," such as the timing of holidays and birthdays, can be an effective first domain when used in this fashion, but landmarks appear most beneficial for shorter reference periods. With longer reference periods, it may be best to ask respondents to trace their residential histories, which helps respondents to map temporal locations with physical ones. As part of their use of flexible conversational interviewing, event history calendars can be implemented by allowing interviewers and respondents to return to domains once covered, although usually the interview flows by proceeding from one domain to the next.

Background

The first administrations of the event history calendar interviewing methodology can be traced to 1969, with the Monterrey Mobility Study of 1,640 men ages 21–60 in Monterrey, Mexico, and with the Hopkins Study that recruited a U.S. national probability sample of 953 men ages 30–39. The method became more widely recognized as a viable approach to questionnaire design in the late 1980s, with its implementation in the University of Michigan's Study of American Families. Complementing these earliest efforts in the fields of demography and sociology, the event history calendar has been administered by researchers in a variety of disciplines, including criminology, economics, nursing, psychiatry, psychology, epidemiology, social work, and survey methodology. It has been successfully used to collect mobility, labor, wealth, partnering, parenting, crime, violence, health, and health risk histories. Although aptly used in scientific investigations seeking to uncover the causes and consequences that govern well-being within populations, it has also been used in more qualitative efforts, including those in clinical settings that examine an individual's patterns of behavior to assess potential beneficial interventions.

Event History Calendar Versus Standardized Interviews

Several studies have directly compared the quality of retrospective reports engendered in event history calendar and standardized interviews in experimental and quasi-experimental designs. In most, but not all, instances, the event history calendar has been shown to lead to more accurate retrospective reports. Some of the differences in data quality between interviewing methods have been impressive. For example, in reports of intimate partner violence, the event history calendar has been shown to be effective in eliminating an age-cohort bias in reports of first exposure to violence that is observed in standardized interviews. Whereas standardized interviewing leads to older women reporting the first exposure to intimate partner violence at older ages due to the failure to report earlier instances, such an age-cohort bias is not observed in event history calendar interviews. The advantages of event history calendar interviewing have yet to be isolated as the result of the use of more effective retrieval cues, the ability of conversational flexibility to repair misunderstandings and to clarify question objectives, or some combination of both retrieval cuing and conversational interviewing. Ongoing verbal behavior coding studies that document the occurrence of different types of retrieval cues and conversational mechanisms may uncover which types of verbal behaviors produce better data quality. Such work is likely to lead to improvements in interviewer training.

That event history calendars show mostly encouraging gains in data quality in comparison to standardized interviewing indicates that it is not a panacea that will "cure" all ills associated with forgetting, and that there are also likely beneficial aspects to standardization that are not utilized in event history calendar interviews. The very few studies that have been conducted have shown that event history calendar interviewing leads to modest increases in interviewer variance in most, but not all, instances. The event history calendar also usually leads to modest increases in interviewing time, at present on the order of 0%–10% longer than standardized interviews. Interviewers show overwhelming preference for event history calendar interviewing in ease of administration. As an attempt to acquire the "best of both worlds," hybrid event history calendar and standardized interviewing instruments have also been designed.

Administration Methods

Event history calendars have been administered in a variety of methods, including as paper-and-pencil and computer-assisted interviewing instruments, and in face-to-face, telephone, and self-administered modes. The method has mostly been implemented in the interviewing of individuals, but the interviewing of collaborative groups has also been done. The computerization of event history calendars affords the automation of completeness and consistency checks. Web-based applications are also being explored.

EXHAUSTIVE

Exhaustive is defined as a property or attribute of survey questions in which all possible responses are captured by the response options made available, either explicitly or implicitly, to a respondent. Good survey questions elicit responses that are both valid and reliable measures of the construct under study. Not only do the questions need to be clear, but the response options must also provide the respondent with clear and complete choices about where to place his or her answer. Closed-ended or forced choice questions are often used to ensure that respondents understand what a question is asking of them. In order for these question types to be useful, the response categories must be mutually exclusive and exhaustive. That is, respondents must be given all possible options, and the options cannot overlap. Consider the following question, which is frequently used in a number of different contexts.

Please describe your marital status. Are you…
Married
Divorced
Widowed
Separated
Never married

This question does not provide a response option for couples who are in committed relationships but are not married, whether by choice or because of legal barriers. For example, a woman who has been with a female partner for 5 years would be forced to choose either married or never married, neither of which accurately describes her life situation. Without a response option that reflects their life circumstances, those respondents may be less likely to complete the questionnaire, thus becoming nonrespondents. This question is easily improved by the addition of another response category:

A member of an unmarried couple

In situations in which the researcher cannot possibly identify all response options a priori, or cannot assume a single frame of reference for the subject matter, an "Other [specify]" option can be added. For example, questions about religion and race always should include an "Other [specify]" option. In the case of religion, there are too many response options to list. For race, traditional measures often do not adequately capture the variety of ways in which respondents conceptualize race. Thus, an "Other [specify]" option allows respondents to describe their race in a way that is most accurate to them.

EXIT POLLS

Exit polls are in-person surveys in which data are gathered immediately after people have engaged in the behavior about which they are being surveyed, such as voting in an election. The survey methods that are used in exit polls apply to the measurement of a wide variety of behaviors, but in the minds of most people exit polls are most closely associated with what is done on Election Day to help project the winning candidates before the final vote tally is announced. Although political exit polling is done in many countries, it is the exit polling conducted for elections in the United States that is covered here.

How Exit Polling Is Conducted and Used in U.S. Elections

The exit polls that are conducted nationwide and in most individual states for the general election in the United States are among the largest single-day surveys that are conducted anywhere, with data from more than 100,000 respondents being gathered, processed, and analyzed within one 24-hour period.

To estimate the outcome of an election in a particular geopolitical area of the United States, which most typically is done at the state level, a stratified random sample of voting precincts within the area is selected, and at least one interviewer is sent to each of the sampled precincts. In the 2004 U.S. general election, there were 1,469 sampled precincts nationwide, and in 2006 there were 993. Those exit polls were conducted by Edition Media Research and Mitofsky International, the organizations that were hired to gather the exit poll data for their news media funders (ABC, the Associated Press [AP], CBS, CNN, Fox, and NBC). On a systematic basis, and in order to obtain a completed questionnaire, the exit poll interviewer stops (i.e., intercepts) people who just finished voting as they exit from their voting places. For example, the interviewers may do this with every 10th person who comes out of the voting place. In each sampled precinct, an average of approximately 100 voters is interviewed over the course of Election Day. Not all exiting voters who are stopped agree to complete the exit poll questionnaire, but in those cases the interviewer records basic demographic information about these refusing voters. This information is used later as part of analyses that investigate the nature of exit poll nonresponse. Interviewers at each sampled precinct telephone in the data they are gathering at three scheduled times on Election Day: mid-morning, early afternoon, and within the hour before voting ends in the precinct.

In order to gather the exit poll data, the interviewer typically hands the selected voter a questionnaire on a clipboard and asks her or him to complete it and then deposit it in a survey "ballot box." The questionnaire gathers three types of data: (1) it measures who the sampled citizen voted for in the day's key election contests (e.g., president, senator, and governor); (2) it measures various attitudes held by the voter that the news media sponsors believe will be associated with the votes cast by the sampled voter; and (3) it measures key demographic and lifestyle characteristics of the voter to further help explain why he or she voted as he or she did. All of these data are gathered via a questionnaire comprised of 20–25 questions that fit onto one piece of paper, which is printed on the front and back sides.

The survey data gathered by exit polls are used for two major purposes by the news media who sponsor them. First, exit polls are used to project the outcome of races on Election Night. However, these projections are not based solely on exit poll data. Rather, the statistical models that have been devised to help make accurate election projections utilize a variety of data, depending in part on how close is the election contest that is being projected. In a "landslide" election contest, a projection can be based with confidence on (a) the prior expectations (e.g., from preelection polls and past election history for the geopolitical area) with which the statistical models are "primed," (b) any "early voter" survey data that may have been gathered, and (c) the exit poll data. In very close elections, a confident decision cannot be made on the basis of just these three types of information, and the projection model is supplemented with additional data as actual vote counts from the sample precincts become available after voting has ended. And, then later, countywide actual vote counts are used in the models as those data become available throughout the night of the election and into the early morning of the next day. In the case of the actual vote count from the sample precincts, the projection model also takes into account the match or lack there of between the exit poll data for a precinct and the actual vote in the precinct to calculate a *bias estimate* in the exit poll data for that precinct. These bias estimates are also taken into account by the model and by the human decision makers who ultimately make the final decision about when to "call" a race in very close contests. Thus, despite what many people believe, the election projections announced on television in many cases are based very little, or even not at all, on the exit poll data.

Although it is these projections of election winners that most people think of when they think of exit polls, the second use of exit poll data is arguably more influential on the geopolitical entity and the citizenry being measured. Thus, exit polls are important, not so much because they are used to help make the projections reported by the major television networks on Election Night, but because the information they gather about the voters' demographics and attitudes toward the candidates and the campaign issues provides very powerful and important explanations about *why* the electorate voted as it did. It is only through the use of accurate exit poll data that the so-called mandate of the election can be measured and reported accurately without relying on the partisan spin that the candidates, their campaign staff, and political pundits typically try to put on the election outcome. For example, in 1980, Ronald Reagan's strategists described his sound defeat of Jimmy Carter as a "turn to the right" by American voters and as an impetus for a conservative legislative agenda for the new Congress. In contrast, 1980 exit-poll data showed there was no ideological shift among American voters. Instead, they were primarily concerned about President Carter's inability to influence the economy and settle the Iran hostage crisis, and they wanted a new president whom they hoped would do a better job in reducing inflation. As another example, in the 1998 exit polls, voters indicated that they were basing their votes for Congress on evaluations of their local candidates and not on any concerns about the allegations regarding President Bill Clinton and Monica Lewinsky contained in Kenneth Starr's report.

The Evolution of Exit Polling in the United States

Exactly when the first election exit poll was conducted is debatable. Warren J. Mitofsky, who is recognized as the father of exit polling, believed it took place in November 1967 and was conducted by CBS News for a gubernatorial election in Kentucky. In contrast, I. A. "Bud" Lewis, former pollster for *The Los Angeles Times*, believed it was in June 1964 when NBC News gathered data from California voters exiting polling places in 21 sampled precincts on the day of that state's primary election.

Starting in the late 1960s and until 1990, ABC, CBS, and NBC conducted their own exit polls for major elections. In 1990, these networks joined with CNN to create and sponsor a new entity, Voter Research and Surveys (VRS), to gather exit poll data they all would share. In 1994, a further consolidation took place, and this joint operation became the Voter News Service (VNS) when the VRS exit polling operations were merged with the News Election Service, which heretofore had been responsible for gathering actual vote counts. The four television networks and the AP, which joined as a sponsor in 1994, shared the same VNS database on election nights from 1994 through 2002, although each media organization (with the exception of the AP) used its own methods, models, and expert consultants to produce its projections of winners. Fox News joined the group as a VNS sponsor in 1996. VNS provided high-quality data through the 2000 election prior to its dissolution after the November 2002 election. In 2003, the six major sponsors of VNS contracted with Edison Media Research and Mitofsky to create the 2004 National Election Pool (NEP) service. With Mifotsky's sudden death in the summer of 2006, Edison Media Research took over sole responsibility for the 2006 exit polls and continued with that responsibility for the 2008 exit polls. Through the 2006 election, only *The Los Angeles Times* (which started its own exit polling in 1980) conducted an alternative national exit poll in presidential election years.

Exit Polling and Total Survey Error

Exit polls provide survey researchers with unique data to help understand survey accuracy. Exit polls that measure election outcomes generate survey data that generally can be validated against the actual vote count in an election within a day after the exit poll data are gathered. Thus, unlike almost all other surveys, there is a "gold standard" that allows exit pollsters to calculate how right or wrong the exit poll data were and to investigate why they were not more accurate.

From the standpoint of coverage error and sampling error, the exit polls planned and implemented by Mitofsky and his colleague, Murray Edelman, during the past 3 decades have had nothing to fault them. The sampling design is an exceptional one for the purposes to which the data are to be put. The stratified samples that are drawn in each state traditionally have covered the electorate very well, and the sample sizes have provided adequate statistical power for the uses that are made of the exit poll data, both in terms of helping to project the election outcomes and to analyze why the electorate voted as it did. However, a growing coverage threat to exit poll accuracy stems from the "early voter" phenomenon. As proportionally more and more voters in certain states (e.g., Oregon, Washington, California, Florida) choose to vote before the day of an election, the electorate that must be measured is not all available on Election Day for sampling by exit polls. And, to the extent that early voters differ in their voting behavior and motivations from those who vote on Election Day, exit pollsters must field accurate pre–Election Day surveys (e.g., telephone surveys) of these early voters to combine those data with the data gathered via exit polls on Election Day. A problem with this is that telephone surveys of early voters are not as accurate a survey methodology as are same-day in-person surveys such as the exit polling done on the day of an election.

From a nonresponse error standpoint, research reported by Mitofsky in the early 1990s and additional research reported by Daniel M. Merkle and Edelman in the late 1990s has shown that the exit poll error that exists at the level of the sampled precinct—that is, the difference between the exit poll election outcome data for a precinct and the actual vote count in that precinct—is *uncorrelated* with the exit poll response rate at the precinct level. In the exit polls conducted by VRS, VNS, and NEP, the precinct-level response rate generally falls within the 30%–70% range. What this nonresponse research has shown is that whether the response rate is on the low side or the high side is not related to the size of the bias for how people have voted in a precinct. However, because of the great need for exit poll data to remain as accurate as possible, continued investigations in the possibility of nonresponse bias are needed. This is necessary, if for no other reason than to help counter partisan claims that exit polls are biased because voters of certain political persuasions are more likely to refuse to participate when they are sampled for exit polls.

From a measurement error standpoint, a great advantage of exit polls in controlling respondent-related error is that the election behaviors and attitudes of interest are being measured at almost the exact time they occurred. That is, it is just a few minutes after a respondent has made her or his final decisions about how to vote that she or he is asked in the exit poll questionnaire to answer questions about these voting behaviors and attitudes. Thus, there is essentially no chance that an exit poll respondent will have forgotten how she or he voted, and there is little chance that her or his attitudes on key matters will have changed between the time of voting and the time of completing the exit poll questionnaire. Furthermore, because the questionnaire is self-administered and is placed into a "ballot box" by the respondent, there is little chance for social desirability to bias the answers the respondent provides, since the exit poll interviewer is unaware of any of the respondent's answers. All this notwithstanding, the effects of interviewer-related error and questionnaire-related error on the measurement accuracy of exit polls is yet to be understood as well as it needs to be, and thus continued research into these topics is needed.

Experimental Design

Experimental design is one of several forms of scientific inquiry employed to identify the cause-and-effect relation between two or more variables and to assess the magnitude of the effect(s) produced. The independent variable is the experiment or treatment applied (e.g., a social policy measure, an educational reform, different incentive amounts and types) and the dependent variable is the condition (e.g., attitude, behavior) presumed to be influenced by the treatment. In the course of the experiment it is necessary to demonstrate the existence of covariation between variables, its nonspuriousness, and to show that the cause occurred before the effect. This sort of inquiry can take the form of an artificial experiment, carried out in a laboratory scenario, or a natural experiment implemented in a real-life context, where the level of control is lower. For both cases, the literature presents several taxonomies, from which four main types are considered: (1) true or classical experimental, (2) pre-experimental, single-subject experimental, and (3) quasi-experimental. In addition, there are a number of variations of the classic experimental design as well as of the quasi-experimental design.

In a true or classic experimental design, there are at least two groups of individuals or units of analysis: the experiment group and the control group. Participants are randomly assigned to both groups. These two groups are identical except that one of them is exposed to the experiment or causal agent, and the other, the control group, is not. In many instances, a pretest and a posttest are administered to all individuals in the two groups; but the pretest is not a necessary aspect of the true experiment. If there is a significant difference between members of the two groups, it is inferred that there is a cause-and-effect link between that treatment and the outcome.

The pre-experimental design does not have a control group to be compared with the experiment group. There is a pretest and a posttest applied to the same participants. In a single-subject experimental design, there is only one participant, or a small number, that is analyzed over a period of time. In quasi-experimental designs, participants come from naturally assembled or pre-determined groups (e.g., a family, a school class, a professional category, or inhabitants of a neighborhood) and are not therefore assigned randomly to the control and treatment groups.

An experimental design has to fulfill several conditions. The variables must be measured with accuracy and precision, and the statistical test must be defined before starting the experiment. If necessary, it must be possible to repeat the experiment in order to confirm that the outcome is statistically significant and that no other factors, other than the independent variable(s) the researcher manipulates, are responsible for the outcome. In practice, however, not every experiment meets all these conditions. Internal and external validity can be affected by several factors. For example, internal validity (cause-effect relation) can be influenced by the length of the time between the pretest and the posttest, by changes in the measurement instruments, the influence of the pretest on subsequent behavior, and so on, but can be improved with matching procedures and by randomization. External validity can be enhanced by the use of a representative sample and by avoiding artificial experiment settings lacking mundane realism

Experimental design is used in biological, physical, and social sciences and can be combined with other forms of scientific inquiry (e.g., experimentation can test hypotheses contained in a formal model). However, in contrast to biology, chemistry, physics, and medicine, where experimentation is widely used, in many cases experimental design is not practicable in social science research. An exception is in psychology and behavioral branches of other social sciences, such as behavioral economics or political research on voting behavior and voter decision-making processes. Due to concerns about external validity, social factors often are too complex to be validly represented in an experiment. Furthermore, due to concerns about fundamental ethical principles, other ways of assignment to ameliorative treatments (rather than randomization) may introduce biases in the selection of participants. As a consequence, experimental design has not been a dominant mode of inquiry in the social sciences. However, in survey research, it is an ideal approach for testing the effects of methodological innovations.

Experimental design with human subjects, in both social and biological sciences, raises several ethical issues, some of which may even preclude the use of experiments. For example, a study of the long-term effects of unemployment cannot be done by assigning people randomly to an employed control group and an unemployed experiment group. It would be unethical to do so and instead the study should be done with data obtained from nonexperimental studies, such as longitudinal surveys. In other cases, the experience is ethically acceptable only if the event occurs naturally. The reluctance of human participants to be used as material for experiments is another factor that makes the use of experimentation in social science more difficult. Finally, issues of informed consent and deception in research with human participants need to be addressed even more carefully in the case of a social experimental design.

Experimental designs have a number of advantages over other forms of empirical inquiry whose primarily aim is to determine the cause-effect relation between variables. It is the best research device from the point of view of internal validity, since it can reduce, at least in theory, the partiality that exists in all other forms of inquiry based on observational data. It can provide answers about causal relations that other forms of inquiry do not, and as such it is important for the development of explanations of complex social behavior (e.g., response/nonresponse to surveys). It is also useful in those circumstances when it is necessary to validate formal models or to produce evidence to support fundamental arguments.

However, experimental design also has some weaknesses: (a) it is not suitable for all kinds of studies (e.g., longitudinal studies often are better for situations of mutual causal effects); (b) it assumes that once random assignment has been adopted it will always generate valid results; (c) it can artificially produce the expected results (this weak point can be somewhat reduced by the use of double-blind practices); (d) it may shape reality quite artificially and does not fully consider other relevant factors, assuming a particular variable (treatment, information, policy measure, etc.) as the cause of the observed differences between the two groups; and (e) it is often too expensive. In social sciences, besides these general difficulties, there are additional ethical constraints that affect this model of inquiry.

Within survey research, experimentation is commonplace when investigating questionnaire effects such as wording, ordering, and formatting. It also is used routinely to study the effects of different types and amounts of incentives and other treatments (e.g., advance letters; special introductions for interviewers) to counter survey nonresponse.

Pure or classic experimental design is, under certain conditions, the most powerful form of inquiry for the identification of causal relations. However, some of those conditions, like randomization and experimental control, make its application in social science, including survey research, more problematic than in the biological or physical sciences for technical and ethical reasons. Other forms of experimental inquiry, such as quasi-experimental design, that do not involve random selection of participants can be useful research tools for the study of causal mechanisms in a myriad of social situations in geography, planning, political science, sociology, and in other disciplines as well.

EXTERNAL VALIDITY

External validity refers to the extent to which the research findings based on a sample of individuals or objects can be generalized to the same population that the sample is taken from or to other similar populations in terms of contexts, individuals, times, and settings. Thus, external validity is generally concerned with the generalizability of research results and findings to the population that the sample has been taken from. It is a very important concept in all types of research designs (true experimental, quasi-experimental, and nonexperimental) including ones that use surveys to gather data. Therefore, assuring the external validity and the generalizability of the findings should be one of the primary goals of the survey researcher.

The language of survey research often does not include the term *external validity*. However, that concept includes what survey researchers refer to as nonresponse error and coverage error, in that each of these types of survey error is related to how well the findings from a survey can be generalized to the target population the survey purports to represent.

Threats to External Validity

Threats to external validity are the characteristics of any type of research study design, including survey research, that can influence and limit the generalizability of the research findings. These threats may include (a) sample characteristics, (b) setting characteristics, (c) temporal characteristics, (d) pretesting effects, (e) multiple-treatment interferences, (f) high dropout (attrition) rates, and (g) low response rates. Avoiding and/or controlling these threats help a survey research study increase the level its external validity and thus the generalizability of the results.

Sample Characteristics

If the results of the survey apply only to the sample, rather than to the target population from which the sample was selected, then one might question why the survey was conducted in the first place, as the results are not likely to have any value. In order to avoid this situation, the researcher should make certain that the sampling design leads to the selection of a sample that is representative of the population. This can be accomplished by using an appropriate probability sampling method (e.g., simple random sampling, systematic sampling, stratified sampling, cluster sampling, multi-stage sampling) to select a representative sample from the target population. Generally this means drawing a sample that has sample characteristics (gender, age, race, education, etc.) that closely match the parameters of the target population. Nonprobability samples generally have little or no external validity.

Setting Characteristics

This threat to external validity refers to the characteristics of the survey study's setting that may limit the generalizability of the results of the study. The major concern with this threat to the external validity is that the findings of a particular survey research study may be influenced by some unique circumstances and conditions, and if so, then the results are not generalizable to other survey research studies with different settings. The research site, specific experimental setting arrangements, intervention delivery method, and experimenter's competency level are examples of such possible setting factors that well can limit the generalizability of the results.

One of the methods that can be used for minimizing the survey research setting threat is replicating the study across different sites with different individuals and in different times. Thus, in order for the results of a survey to be externally valid, it should be generalized across settings or from one set of environmental conditions to another. This concept is also referred to in the literature as *ecological validity*.

Temporal Characteristics

This threat to external validity refers to whether the same survey results would have been obtained if the intervention were implemented (e.g., in an experimental study) and/or the data were gathered at a different point in time. In order for a survey to be characterized as externally valid, the results should be generalizable and essentially remain invariant across different points in time. Failure to consider the time variable, including possible seasonal fluctuations, can threaten the external validity of survey research.

However, there are many surveys in which the "window of time" to which their results are meant to generalize were quite brief. Examples of these surveys are those conducted for news purposes by the media on topics for which opinions well may change on a daily or weekly basis. In these cases, the temporal aspect of external validity can be an ephemeral one.

Survey Research Study Awareness

This threat to external validity refers to the possible impact on respondents of knowing that they are participating in a survey research study. This impact is known in the social science literature as the *Hawthorne effect* or *reactivity*. Thus, the participants' awareness of their participation in a survey and their thoughts about the study's purpose can influence the study's outcomes and findings. Performance, achievement, attitude, and behavior are examples of such outcomes that may be affected. The research findings may be different if the participants were unaware of their participation in the study, although this generally is not practical when using survey research. Nevertheless, the prudent researcher and researcher consumer keeps this threat to external validity in mind when deciding how well the survey results generalize beyond the study itself.

One of the methods that can be used for avoiding the awareness threat in an experimental study is by giving the participants in the control group a placebo treatment and giving the participants in the experimental group the new treatment. However, it is important to stress the fact that the researcher who uses a placebo treatment in a survey study must consider the following ethical issues:

1. Should the participants in the study be informed that some of them will be given the placebo treatment and the others will be given the experimental treatment?
2. Should the participants be informed that they will not know which treatment (placebo or experimental) they have received until the conclusion of the study?
3. Should the participants be informed that if they initially received the placebo treatment, they will be given the opportunity to receive the more effective treatment at the conclusion of the study if the results of the experimental study indicate the effectiveness of the experimental treatment?

Multiple-Treatment Interferences

This threat to external validity refers to survey research situations in which the participants are administered more than one intervention, treatment, training, testing, or surveying either simultaneously or sequentially within the same larger study. In these situations, it will be difficult to determine which one of these interventions, treatments, training, testing, and surveying is responsible for the results of the survey study unless the various treatments all are controlled with an experimental design, which often is impractical. For example, if a study were conducted within a survey to try to raise response rates and several interventions were combined (e.g., higher incentives, new recruitment scripts, special interviewer training) to form a "treatment package" for the experimental group of respondents, the researchers would not have confidence in knowing which of the interventions or their interactions brought about any observed increase in response rates. Thus, any observed effects could not generalize to other studies that did not use *all* of the same interventions in the same combination.

Pretest-Treatment Interactions

This threat to external validity refers to the effects that pretesting or pre-surveying the respondents might have on the posttest and the data gathered in the survey at the conclusion of the intervention, treatment, or program. In many types of research (e.g., longitudinal research), individuals are surveyed during a pretest to provide a baseline measure of an outcome against which the effects of the intervention can be compared at the conclusion of the study to assess the effectiveness of the intervention.

Pretesting is considered a threat to external validity because exposure to the pretest and/or pretest surveying may affect the data respondents subsequently provide in future waves of surveying. Thus, the results would be generalizable only to the population if and only if the individuals are pretested. This threat could be minimized in survey studies by extending the time lapse between the pretest and posttest administrations to decrease the pretest or pre-survey effects on the posttest or post-survey results or by using a Solomon four-group design.

Survey Research Attrition Effects

This threat to external validity refers to the effects that the dropout of the sampled individuals (i.e., attrition) might have on the results of the survey panel study and the generalizability of these results. The individuals who drop out from a multi-wave research study might have specific characteristics that are different from the individuals who did not drop out from the study, as occurs when differential attrition occurs. Consequently, the survey results would be different if all the individuals stayed in the survey study and completed the survey instruments.

The dropout threat to external validity can be avoided and minimized by keeping attrition rates as low as possible. There are many different methods to minimize attrition; for example, providing participants special incentives to encourage them to remain in the study.

Survey Nonresponse Effects

This threat to external validity refers to the effects of the individuals' nonresponse to the survey request or to certain items on the questionnaire. The respondents who do not respond at all and those who do not complete the survey instrument might have specific characteristics that are different from the individuals who respond and complete the entire survey instrument. Thus, the survey results would be different if all the individuals responded and returned the survey instrument.

The nonresponse threat to external validity may be avoided and minimized by maximizing the response rate of the survey. There are different methods for maximizing the response rates of a survey research study, including: sending follow-up surveys, sending reminder notes to return the survey, and providing different kinds of incentives. But recent research by Robert Groves and others suggests that even with high response rates, there can be considerable nonresponse error at the item level, and thus the external validity for those results would be very low.

EXTREME RESPONSE STYLE

Extreme response style (ERS) is the tendency for survey respondents to answer categorical rating scales in the extreme, end-most intervals, across a wide range of item content. ERS can particularly affect surveys that use Likert and semantic differential scales. ERS is a source of survey error that distorts people's true attitudes and opinions. People with relatively higher ERS will tend to have relatively high or low scores, since they tend to mark extreme intervals, while those with low ERS will tend to have more moderate scores. Thus, apparent differences in survey data and observed scores between people or groups can be an artifact caused by differences in their ERS rather than by differences in their true attitudes and opinions. ERS can also distort the relationship between variables, including survey statistics such as correlations or regression slope coefficients. Distortion from ERS increases when the mean sample response is further from the scale midpoint. ERS is positively correlated with some response styles, such as yea-saying, naysaying, response range, and standard deviation, and negatively correlated with midpoint responding.

ERS is related to demographic, personality, cultural, and national variables, which makes ERS of particular concern when making comparisons across different countries or cultures. ERS tends to increase with age and decrease with education and household income, or when a person has a more collectivist versus individual orientation. People in Southern European countries tend to have higher ERS than those in Northern European ones. ERS tends to be higher for cultures that are more masculine or that place greater emphasis on differences in power and authority.

ERS depends on characteristics of survey items. ERS tends to be higher when an item is more meaningful to respondents, is worded in the first rather than third person, or written in the respondent's primary rather than secondary language. It can also vary with the scales themselves, such as the number of intervals in the scale.

Several methods have been proposed to measure individuals' ERS and then adjust their observed survey data to compensate, as a means to remove the measurement error induced by ERS. These methods share the common goal of measuring ERS across items probing a range of uncorrelated constructs, to ensure that people's true scores on a particular construct do not unduly affect their ERS scores. One method uses a dedicated battery of items specifically designed and pretested to measure ERS. Other methods allow researchers to use item sets designed for more general survey purposes, provided the items involve several constructs. Several statistical methods have been proposed to isolate observed score variation due to ERS from variation due to differences in attitudes and opinions and other sources of response variance. These methods include structural equation modeling combined with multi-group factor analysis, item response theory, and hierarchical Bayesian ordinal regression.

Face-to-Face Interviewing

The face-to-face interview, also called an in-person interview, is probably the most popular and oldest form of survey data collection. It has continued to be the best form of data collection when one wants to minimize nonresponse and maximize the quality of the data collected. Face-to-face interviews are often used to solicit information in projects that can be considered to be very sensitive, for example, data collection on sexual behaviors. This entry describes the advantages and disadvantages of face-to-face interviewing along with basic operational considerations for successful interviews.

Advantages

By far, the main advantage of the face-to-face interview is the presence of the interviewer, which makes it easier for the respondent to either clarify answers or ask for clarification for some of the items on the questionnaire. Sometimes, interviewers can use visual aids (e.g., so-called show cards) to assist respondents in making a decision or choice. Properly trained interviewers are always necessary lest there be problems such as interviewer bias, which can have disastrous effects on the survey data. Relatively high response rates and an almost absence of item nonresponse are also added bonuses. The opportunity for probing exists where the interviewer can get more detailed information about a particular response.

Disadvantages

In face-to-face interviewing, respondents often are not afforded the time to provide answers that might be thought out thoroughly as compared to a mail or Internet survey. Respondents essentially are expected to give an answer on the spot, which may not be very convenient or very accurate. Privacy issues continue to be a main concern in face-to-face interviews. Respondents need to be able to develop trust in the interviewer in order to disclose sensitive information. Furthermore, it is not nearly as feasible to monitor face-to-face interviews compared to what can be done with telephone interviews. The time to complete a survey project that uses face-to-face interviewing is appreciably longer than that of other data collection modes. In addition, the cost of carrying out face-to-face interviewing can be exorbitant depending on the sample size and the amount of information being collected.

Basic Operational Considerations

Advance Letter

An advance letter should be sent ahead of time so that the respondent knows when the interviewer will arrive and has sufficient time, if necessary, to prepare for the interview. If the location of the interview is somewhere other than the respondent's home, this also should be communicated clearly. The letter also must describe the study's purpose, explain the procedures to be followed, and strive to motivate cooperation. One must create a letter that is precise. A successful letter should be on one page and printed on professional letterhead. It should have a contact address, toll-free telephone number, or both, and should grasp the reader's attention in its first sentence. The aim of the letter should be cogent to the respondent. It should identify why the survey is important, why it is important to participate, who is being asked to participate, and if it is confidential or not. It should be simple to read.

Administrative and Structural Considerations

Establishing proper administration of face-to-face interviewing is integral to the success of the overall process. In particular, interviewer training and ample supervision can lead not only to higher response rates but also to the collection of higher-quality data. For example, supervisors can randomly check (validate) some interviews to ensure the reliability of the data being collected.

Types of Face-to-Face Interviewing

There are three different formats that face-to-face interviewing can take:

- Structured interviews
- Semi-structured interviews
- Unstructured interviews

Each format has particular advantages and disadvantages and is suited for particular purposes. The purpose of the study, the length of the interview, and the cost constraints are all factors to consider.

In structured face-to-face interviews the interviewer asks each respondent the same questions in the same way. This is the most basic and most common face-to-face survey type. A structured interview may include open-ended and closed-ended questions. This type of interview is usually used for large projects for which the researcher wants the same data to be collected from each respondent.

Semi-structured face-to-face interviews mainly consist of open-ended questions based on topics the researcher wants covered in the interview. Although the interview focuses on key topics, there is also the opportunity to discuss, in more detail, some particular areas of interest. The interviewer has the opportunity to explore answers more widely or other areas of discussion spontaneously introduced by the respondent. The face-to-face interviewer may also have a set of prompts to help respondents if they struggle to answer any of the questions. For example, this is particularly helpful if a respondent cannot make a decision because she or he is deficient in some knowledge of the topic.

In unstructured face-to-face interviews the interviewer has a limited number of pre-defined topics to discuss in an open-ended fashion. This type of interviewing is usually what is done in focus group environments where respondents are free to talk in a free-flowing fashion with the interviewer or moderator. The interviewer then asks questions around these topics and bases later questions on the respondent's or group's responses.

Before the Interviewing Begins

Before interviewers are sent to conduct face-to-face interviews, there are some tasks that must be accomplished. One of these is to craft an introduction to inform respondents about the interview. They may want to know about the reason(s) for conducting the survey, how the information will be used, and how the results may impact their lives in the future. The respondent usually will want to know the length of time that the interview will take. Last but not least, the respondent must be given information to trust the interviewer and the introduction should set this into motion.

Immediately before the interview, the interviewer does a check to ensure that she or he has all the equipment and materials needed. She or he should review the questionnaire, as needed. The place chosen to do the interview should be as serene as possible and be exempt from unnecessary disruptions. If respondents believe that their answers are confidential, then they will be less hesitant to respond. To increase the sense of confidentiality, names and addresses should not be placed on the questionnaires (where the respondent could see them). Instead, the researchers should use code numbers on the questionnaires and keep the names and addresses in a separate document. Also, there should be no other people present—only the interviewer and the respondent.

Incentives can improve response rates, so researchers need to decide on these beforehand. This can take the form of rewarding respondents before (noncontingent incentives) or after (contingent incentives) filling out questionnaires, or both before and after. Deployment of either form of incentive can be immediate when doing face-to-face interviewing; thus, gratification is essentially instant. Cash money is the simplest and most direct reward. It has been found consistently to be more effective when prepaid (noncontingent; e.g., sent along with an advance letter) than when promised (contingent). The larger the rewards are, the higher the response rates will be. Respondents can be rewarded with other things rather than money. Rewards can vary from ballpoint pens to movie tickets. The purposes are to express appreciation for the respondents' efforts and thus encourage participation. Prepaid incentives, in theory, contribute to the trust that should be developed between the researcher (and interviewer) and the respondent.

The Interview

The interviewer should get very comfortable and help make the respondent comfortable, possibly by using some friendly banter to establish positive rapport with the respondent. The interviewer should begin with a brief recap of the main purpose and goals of the survey project. Explanation of the confidentiality aspects of the data collection process may be the most important part of the discussion prior to the commencement of the interview.

During the face-to-face interview, the interviewer should be aware of her or his body language, as the respondent might be very suspicious of any abnormal body language. Humans communicate a great deal of information through their body language, and only a small portion of a conversational message is attributable to the words that are spoken. A higher degree of cooperation is likely if the tone of the interview is relatively informal and the respondent feels comfortable enough to give private information. An interviewer's observance of any abnormal body language on the part of the respondent should be immediately addressed during the course of the interview. During the interview, the interviewer should speak clearly and use proper grammar, but not in an overly formal or overly educated fashion.

Probing

Face-to-face interviews allow the researcher the ability to have interviewers gather detailed information about attitudes and behavior toward a particular topic. Whenever one wants to find out more about an issue or explore an answer, interviewers should be trained how to probe to gather unbiased detailed responses. Face-to-face interviewing is more compatible with gathering long and detailed answers and clarifying ambiguous answers than is telephone interviewing.

Wrapping Up the Interview

Upon finishing a questionnaire and immediately thanking the respondent, a face-to-face interviewer often will recap the information given by the respondent and reassure her or him that the information will be held in confidence. The interviewer also may remind the respondent of the use that the data will be eventually put to. The respondent also should be given the interviewer's contact details just in case there are any questions after the interviewer has left. After departing from a face-to-face interview, the interviewers should write up any relevant notes and complete any additional paperwork required by the researcher linked to the interview as soon after the interview as possible, to ensure that the interviewer can remember all the details.

Factorial Design

Factorial designs are a form of true experiment, where multiple factors (the researcher-controlled independent variables) are manipulated or allowed to vary, and they provide researchers two main advantages. First, they allow researchers to examine the main effects of two or more individual independent variables simultaneously. Second, they allow researchers to detect interactions among variables. An interaction is when the effects of one variable vary according to the levels of another variable. Such interactions can only be detected when the variables are examined in combination.

When using a factorial design, the independent variable is referred to as a *factor* and the different values of a factor are referred to as *levels*. For example, a researcher might examine the effect of the factor, medication dosage, of different levels (Factor 1 with three levels: low, medium, or high) for two different types of psychotherapy (Factor 2 with two levels: Type 1 and Type 2). Because this is a form of true experiment, it requires that subjects or respondents be randomly assigned to each of the conditions.

In the literature, factorial designs are reported according to the number of variables and the number of levels in the variables. The example described in the previous paragraph is a 3×2 factorial design, which indicates that there are two factors, where Factor 1 has three levels and Factor 2 has two levels. The total number of groups (or cells or conditions) in the design is the product of the number of levels. For a 3×2 design this is six groups. In general, an $m \times n$ design has mn groups, so a 5×6 design requires 30 groups.

To make the explanation more concrete, let us consider, in detail, the simplest type of factorial design: a 2×2 design with equal numbers of people randomly assigned to each of the four groups. Suppose the researcher is testing the effect of two different forms of psychotherapy (Type 1 and Type 2) and medication dosage (low or medium) on level of symptom improvement (the dependent variable) measured on a scale of 1 (showing no improvement) to 20 (showing a great deal of improvement). Thus, there are four groups in this design to which subjects are randomly assigned: (1) Type 1 psychotherapy and low medication dosage; (2) Type 1 psychotherapy and medium medication dosage; (3) Type 2 psychotherapy and low medication dosage; and (4) Type 2 psychotherapy and medium medication dosage. The clearest way to examine the data for main effects is to put the group means in a table (see Table 1). The row and column marginals are used to examine for main effects of each of the independent variables. To examine the main effect of medication dosage on symptom improvement, the table is read across and the means are compared in the low dose row versus the medium dose row. These data show a main effect of dose with patients receiving the medium level showing greater symptom improvement compared with the low dose medication group (10 vs. 15). To examine the main effect of type of psychotherapy on symptom improvement, the table is read down by column, comparing the overall means for the two groups receiving Psychotherapy 1 versus the two groups receiving Psychotherapy 2 (15 vs. 10). The data show that patients receiving Psychotherapy 1 showed greater symptom improvement compared with patients receiving Psychotherapy 2.

Table 1 Means from a 2×2 factorial study on medication dosage and type of psychotherapy

	Psychotherapy		
	1	*2*	*Row means*
Low dose	15	5	10
Medium dose	15	15	15
Column means	15	10	12.5

To determine whether an interaction exists, we examine whether the size of the Factor 1 (type of psychotherapy) effect differs according to the level of Factor 2 (medication dosage level). If so, an interaction exists between the factors. In this example, the effect of dose differs according to which therapy the patient received. Thus, there is an interaction between type of psychotherapy and medication dosage. For patients receiving the low dose medication, there was significantly less improvement under Psychotherapy 2 than under Psychotherapy 1. But dosage level made no difference when given with Psychotherapy 1.

Because the effect of the individual variables differs according to the levels of the other variable, it is common practice to stress that any significant main effects must be interpreted in light of the interaction rather than on their own. In this example, while drug dosage showed a main effect with the medium dose leading to greater symptom improvement, on average, this effect held only for patients receiving Psychotherapy 2. The outcome of a study using a factorial design can also be depicted graphically. Figure 1 shows a bar chart and a line chart of the group means. For the bar chart, an interaction is apparent because the difference between the bars for low dosage is larger than the difference between the bars for medium dosage. For the line chart, an interaction is apparent because the lines are not parallel. Line charts should be used only with factorial designs when it makes sense to talk about

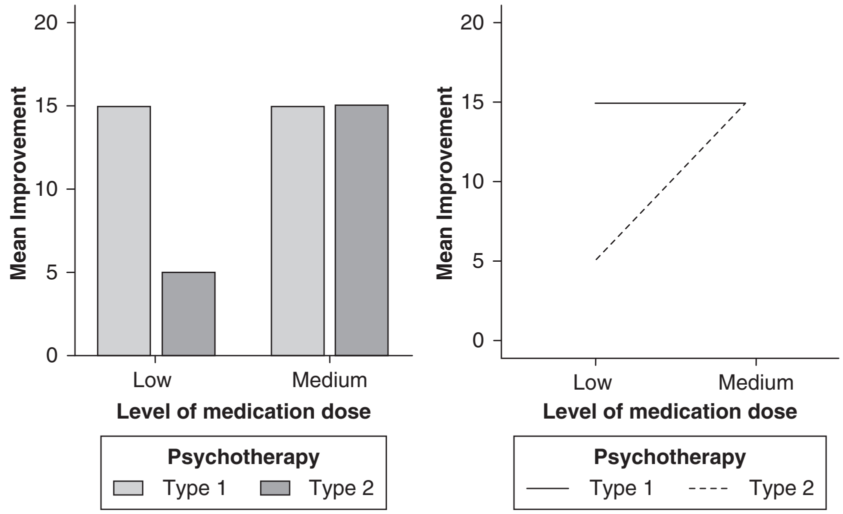

Figure 1 Graphical representations of the outcome of a factorial study: bar chart (left) and line chart (right)

intermediate values between the levels. In the present example, researchers could have given a dose halfway between low and medium; therefore, it makes sense to interpret intermediate values along the line. If the x-axis differentiated types of psychotherapy, this would probably not have been valid.

Factorial designs can take on more complex forms than that of the example presented here. They can have several factors, each with a different number of levels. Thus, a $2 \times 2 \times 3$ factorial design has three factors, two of which have two levels and one of which has three levels. This design requires 12 different groups of randomly assigned participants. With designs that have more than two factors, several different interaction effects are possible. With a three-factor design, one can have three different two-way interactions (Factor 1 with Factor 2, Factor 1 with Factor 3, and Factor 2 with Factor 3) and a three-way interaction (Factor 1 with Factor 2 with Factor 3). With these more involved factorial design studies, the nature of interactions can be determined by comparing group means to determine if a unique condition stands out or differs from other patterns of means. As the number of factors increase, it often is difficult to provide a theory to account for these higher-order interactions. Often they can arise through measurement artifacts (e.g., a floor or a ceiling effect), so caution is urged.

As the number of factors and levels increases, the number of groups also increases. A $4 \times 3 \times 4 \times 5$ design would require 240 groups. Sometimes the number of groups is too large to be practical, and rather than do a full factorial design, where there are subjects or respondents assigned to every possible condition, a *fractional factorial design* (i.e., nested design) is used, in which some groups are vacuous (empty). The choice of which conditions should be vacuous is determined by which effects the researcher does not wish to measure, and usually these are the higher-order interactions because they are often difficult to interpret. Factorial designs can also include within-subject factors, where participants take part in all levels of the factor. Further, there can be restrictions to modeling group means. Factorial designs can be used to model other statistics; in particular, when the response variable is categorical, the odds of a particular response are usually modeled.

General statistical software (such as SPSS, SAS, SYSTAT, R) will give relevant output to inform the user about the size of the main effects and interactions and whether they are statistically significant. The analysis is usually done with some form of least squares regression, often within the ANOVA framework, which has evolved with factorial design beginning with R. A. Fisher in the 1920s. There are more detailed adjustments to account for different numbers of people in groups and complex designs.

Factorial Survey Method (Rossi's Method)

Rossi's factorial survey method, proposed by sociologist Peter Rossi, is a technique that uses vignettes to explore individuals' beliefs and judgments. The method begins with a particular view of human nature. In this view, humans seek to know the causes of things, and they judge (evaluate) the "goodness" or "badness" of things. The drive to understand the way the world works produces positive ideas, and the drive to judge the world produces normative ideas. These positive and normative ideas can be represented by equations, termed, respectively, the *positive-belief equation* and the *normative-judgment equation*. In the positive-belief equation, also known as a "what is" equation, the individual-observer is acting as a lay scientist, whereas in the normative-belief equation, also known as a "what ought to be" equation, the individual-observer is acting as a lay judge. Rossi's factorial survey method makes it possible to estimate these equations-inside-the-head.

For example, individuals form ideas about the causes of healthiness and marital happiness, about what generates earnings and produces social harmony, and about many other matters. And they make judgments about fair compensation for workers and chief executive officers, just prison sentences, policies on trade and immigration, and so forth.

Because people differ in their life experience, social location, and information—and also in personality and culture—they may have differing perceptions about the actual world and different ideas about the just world. Thus, the positive-belief and normative-judgment equations are linked to a further equation, which describes the determinants of components of the beliefs or judgments: This equation is called a *determinants equation*.

For example, the lay scientist's view of the causes of marital happiness may be influenced by childhood observation of parental behavior, and the lay judge's view of the just prison sentence may be influenced by religious experience.

Moreover, beliefs and judgments influence many behaviors. Thus, the positive-belief and normative-judgment equations are linked to another equation, this one describing the consequences of components of the beliefs or judgments. This is called a *consequences equation*.

For example, the decision to stop smoking or the choice of a marital partner may be influenced by the positive-belief equations about healthiness and marital happiness, respectively. And the decision to participate in a strike or to make a contribution to a lobby group may be influenced by the normative-judgment equations about societal and institutional arrangements.

These four equations—(1) the positive-belief equation, (2) the normative-judgment equation, (3) the determinants equation, and (4) the consequences equation—constitute the basic set of equations in the factorial survey method. They are known, respectively, as Type II, III, IV, and V equations. (Type I is reserved for scientific approximation of the way the world works. Thus, a Type I equation represents a collective and systematic approximation to "truth," and a Type II equation represents a solitary and less explicitly systematic approximation—a Platonic "appearance" as seen by a given individual.)

The links between the four basic equations may be represented diagrammatically:

$$\text{Determinants} \rightarrow \text{Beliefs and Judgments} \rightarrow \text{Consequences}$$

Thus, the positive-belief equation and the normative-judgment equation each may join with a determinants equation to form a multi-level system of equations. Similarly, the positive-belief equation and the normative-judgment equation each may join with a consequences equation to form another (possibly multi-level) system of equations.

Note, however, that if all observers can be described by the same Type II positive-belief or Type III normative-judgment equation, then there are no determinants or consequences to study via a Type IV or Type V equation. Accordingly, the pivotal tasks in the factorial survey method are estimation of the equations-inside-the-head and assessment of the extent to which people hold the same beliefs or reach the same judgments.

Rossi pioneered the factorial survey method and developed it with several associates. Rossi's factorial survey method provides an integrated framework for estimating the positive-belief and normative-judgment equations-inside-the-head, testing for interrespondent homogeneity, and estimating the determinants and consequences equations. As comprehensively described by Guillermina Jasso in 2006, the current factorial survey framework assembles a set of tools for estimating Type II and Type III equations and carrying out the corresponding homogeneity tests and for estimating Type IV and Type V equations—incorporating such advances as seemingly unrelated regression estimators and random parameters estimators for the Type II and Type III equations and joint multi-level estimation for the pair of equations formed by a Type IV equation and a Type II or Type III equation.

All elements of the research protocol are designed with the objective of obtaining estimates with the best possible properties of the positive-belief and normative-judgment equations and the determinants and consequences equations.

Data Collection

Each respondent is asked to assign the value of a specified outcome variable (such as healthiness, marital happiness, actual wage, just wage, or fairness of an actual wage) corresponding to a fictitious unit (e.g., a person or a family), which is described in terms of potentially relevant characteristics such as age, gender, study or eating habits, access to medical care or housing, and the like. The descriptions are termed *vignettes*. One of Rossi's key insights was that fidelity to a rich and complex reality can be achieved by generating the population of all logically possible combinations of all levels of potentially relevant characteristics and then drawing random samples to present to respondents. Accordingly, the vignettes are described in terms of many characteristics, each characteristic is represented by many possible realizations, and the characteristics are fully crossed (or, in some cases, to avoid nonsensical combinations, almost fully crossed). Three additional important features of the Rossi design are (1) in the population of vignettes, the correlations between vignette characteristics are all zero or close to zero, thus reducing or eliminating problems associated with multi-colinearity; (2) the vignettes presented to a respondent are under the control of the investigator (i.e., they are "fixed"), so that endogenous problems in the estimation of positive-belief and normative-judgment equations arise only if respondents do not rate all the vignettes presented to them; and (3) a large set of vignettes is presented to each respondent (typically 40 to 60), improving the precision of the obtained estimates. The rating task reflects the outcome variable, which may be a cardinal quantity (e.g., earnings), a subjective continuous quantity (e.g., the justice evaluation of earnings), a probability (e.g., probability of divorce), a set of unordered categories (e.g., college major), or a set of ordered categories (e.g., verbal happiness assessments).

Data Analysis

The analysis protocol begins with inspection of the pattern of ratings, which, in some substantive contexts, may be quite informative (e.g., the proportion of workers judged underpaid and overpaid), and continues with estimation of the positive-belief and normative-judgment equations. Three main approaches are (1) the classical ordinary least squares approach; (2) the generalized least squares and seemingly unrelated regressions approach, in which the respondent-specific equations may have different error variances and the errors from the respondent-specific equations may be correlated; and (3) the random parameters approach, in which the respondents constitute a random sample and some or all of the parameters of the respondent-specific equations are viewed as drawn from a probability distribution. Under all approaches, an important step involves testing for interrespondent homogeneity.

Depending on the substantive context and on characteristics of the data, the next step is to estimate the determinants equation and the consequences equation. Again depending on the context, the determinants equation may be estimated jointly with the positive-belief and normative-judgment equations.

Prospects

For many years Rossi's method was somewhat difficult to implement, given the computational resources required to generate the vignette population and to estimate respondent-specific equations. Recent advances in desktop computational power, however, render straightforward vignette generation, random samples, and data analysis, thus setting the stage for a new generation of studies using Rossi's method.

Research teams around the world are exploring several new directions, building on the accumulating experience of factorial surveys on many topics and in many languages and countries. These include (a) presenting two rating tasks to the same set of respondents; (b) presenting two rating tasks to two randomly selected subsets of a set of respondents; (c) presenting two vignette worlds to randomly selected subsets of a set of respondents; (d) computerized implementation; (e) Web-based implementation; (f) pictorial vignettes and videos; and (g) systematic linkage to parallel vignette-based approaches, such as conjoint analysis and cross-national and cross-cultural measurement strategies.

Fallback Statements

Oftentimes when interviewers first make contact with a sampled respondent, the respondent is hesitant or otherwise reluctant to agree to participate in the survey. In most surveys, researchers can anticipate the nature of the concerns that will be expressed by respondents, and, as such, the researchers can train their interviewers to use targeted persuasion to try to convince the respondents to cooperate. The verbiage that interviewers are encouraged to use to persuade respondents has been termed *fallback statements*, as the interviewers must "fall back" to them in order to be successful with the respondent.

For example, respondents sampled in RDD (random-digit dialing) surveys who express reluctance to participate often will ask the interviewer, "How did you get my number?" Knowing that this question is one that commonly is asked, the researchers can provide interviewers a suggested response that they can tailor to individual respondents. A fallback statement for this particular respondent question might be something along the following lines:

> Your number was chosen by a technique called random-digit dialing. All the three-digit telephone prefixes that ring in your area were put into a computer and the computer added four more random digits to make up the seven-digit number that we used to reach you. We use this technique because it's important that we speak with people throughout your area, regardless of whether their numbers are listed or unlisted. That's the only way we can do a survey that will fairly represent the opinions of the different residents in your area.

In addition to providing interviewers with a fallback statement to help them explain how someone's telephone number or address was chosen, other topics that interviewers commonly have to explain to respondents, and thus are ones that fallback statements should address, include (a) the purpose of the survey, (b) how the data will be used, (c) additional details about how the data will be kept confidential, (c) why only one designated respondent is chosen for each household contacted, and (d) who at the survey organization can be contacted if the respondent wants to verify the legitimacy of the survey.

If any of these concerns were expressed by the majority of respondents, then it would behoove researchers to build explicit details about it into the standard introductory spiel that interviewers provide to all respondents when they first make contact. However, not every respondent has such concerns, and even among those who do, they do not necessarily share the same concerns. Thus, the survey introduction needs to be a more generic one, with the interviewers having targeted fallback statements to deploy for those respondents who express specific concerns.

FALSIFICATION

Interviewer falsification, the act by a survey interviewer of faking an interview or turning in falsified results as if they were the real thing, is a well-known, long-standing, and recurrent problem that has drawn occasional attention in the research literature since the early days of the field's development. It has traditionally been referred to as *curbstoning*, a term that captures the image of the interviewer, out on field assignment, who settles on the street curbing to fill interview forms with fabricated responses instead of knocking on doors to obtain real interviews.

In recent years, the problem has drawn renewed attention because the U.S. federal government's Office of Research Integrity (ORI) made clear in 2002 that it considers interviewer falsification in any study funded by the U.S. Public Health Service to be a form of scientific misconduct. Because that designation can invoke potentially grave consequences for researchers and their organizations, a summit conference of representatives of governmental, private, and academic survey research organizations was convened in Ann Arbor, Michigan, in April 2003 by Robert M. Groves (with ORI support) to compile "best practices" for the detection, prevention, and repair of interviewer falsification. This entry draws freely on the statement generated from those meetings, which has been endorsed by the American Association of Public Opinion Research and by the Survey Research Methods Section of the American Statistical Association. This entry defines falsification, discusses its prevalence and causes, and outlines methods of prevention and control. This entry also covers actions to be taken when falsification is detected, suggests that control methods should be covered in reports of survey methods, and considers which falsification events can be handled internally.

Falsification Defined

Interviewer falsification means the intentional departure from the designated interviewer guidelines or instructions, unreported by the interviewer, which could result in the contamination of data. *Intentional* means that the interviewer is aware that the action deviates from the guidelines and instructions; honest mistakes or procedural errors by interviewers are not considered falsification. This behavior includes both fabrication (data are simply made up) and falsification (results from a real interview are deliberately misreported). It covers (a) fabricating all or part of an interview, (b) deliberately misreporting disposition codes and falsifying process data (e.g., recording a refusal case as ineligible or reporting a fictitious contact attempt), (c) deliberately miscoding the answer to a question in order to avoid follow-up questions, (d) deliberately interviewing a nonsampled person in order to reduce effort required to complete an interview, or (e) intentionally misrepresenting the data collection process to the survey management.

Prevalence, Seriousness, and Causes

Interviewer falsification is uncommon but not really rare. Because most survey organizations have practices in place to control falsification (e.g., interviewer monitoring), its prevalence is quite low. Nevertheless, any survey organization with several years of experience doing surveys is likely to have encountered one or more incidents, especially if the organization conducts face-to-face surveys that are carried out by a dispersed field staff. The consensus among practitioners is that falsification is rare in surveys that are conducted from centralized telephone facilities, because such facilities have effective monitoring controls in place to prevent and detect falsification.

In ethical terms, falsification is always a serious matter, but the seriousness of the practical consequences varies greatly. The most serious cases seem to occur in small studies by researchers who do not have professional survey services at their disposal. For example, a university professor may hire one or two graduate students to conduct all of the interviews for a small study, only to find out later that all the cases assigned to one of the students have been fabricated. The result is irreparable damage to the integrity of the research findings. In contrast, in a large study involving thousands of cases and scores of interviewers, if one interviewer is found to have falsified some of her or his cases, the relatively small number of bad cases can usually be removed without serious damage to the accuracy of the overall result.

The causes of falsification include both the characteristics of interviewers and features of the situation in which they conduct their work. As with embezzlers and others who commit breaches of trust in organizational settings, interviewers who falsify their data may have no previous records of dishonest behavior, and they sometimes are individuals suffering from financial problems, family pressures, or health issues. However, as Leo Crespi stated in a seminal 1945 article, "The Cheater Problem in Polling," cheating is not so much a problem of interviewers' morals as it is one of interviewers' morale and the factors that affect that morale. Some organizational factors that may facilitate interviewer falsification are inadequate supervision, lack of concern about interviewer motivation, poor quality control, piece-rate pay structures, and off-site isolation of interviewers from the parent organization. The design of the survey itself may play a role, as falsification seems to be more likely when interviewers are called upon to deliver cash incentives to respondents; when compensation is closely tied to production rates; when interviews are overly long, complex, or burdensome; when sample members are difficult to find; and when a too-short field period increases the pressures to produce.

Prevention and Detection

Data integrity is both a product and a reflection of organizational integrity. Researchers can enhance measures to prevent interviewer falsification by creating an organizational environment that encourages honesty, discourages falsification, enhances morale, and promotes data quality. Managers must demonstrate their commitment to data quality in both word and deed. When hiring interviewers, reference checks are recommended, and criminal background checks may be advisable despite the hiring delays and costs involved. Newly hired interviewers should be required to sign a pledge of ethical behavior that clearly states the consequences of falsification, including the threat to research and the personal consequences for the falsifier. Interviewer workloads and production goals should be realistic. The risk of falsification may increase where large incentives are offered to respondents and when interviewer pay is based on interviewer completions. These protocols are necessary in some situations, but the level of control procedures applied should reflect the increased risk.

As Groves and colleagues have outlined in their textbook, *Survey Methodology*, there are three main ways to detect interviewer falsification: (a) observational methods, (b) recontact methods, and (c) data analytic methods.

Observational Methods

Observation means that another staff member hears and/or sees the interview take place. In centralized phone facilities, observation usually takes the form of silent audio monitoring (listening to the phone interview as it takes place), sometimes coupled with video monitoring through screen capture of the computerized interview in progress. These tools significantly enhance the power of simple, direct observation of the interviewer by the floor supervisor, and where such tools are regularly employed it is virtually impossible for telephone interviewers to falsify without being promptly detected. Only a portion of the interviewing activity is monitored, but it is important that interviewers be aware that they may be monitored and not be aware of precisely when they are being monitored.

In-person field interviews have traditionally been shielded from such direct observation, but with the advent of computer-assisted personal interviewing (CAPI), the built-in microphone of the laptop computer can be programmed to digitally record random portions of the interview. These recordings can then be checked by supervising staff for indicators of falsification.

Another form of observation is to have supervisory personnel validate some or all completed interviews as soon as possible after they are completed. Experience suggests that it is very difficult to falsify data in a way that is consistent enough to appear plausible if someone else (a supervisory staff member) is looking carefully through an entire questionnaire to validate that an interview was completed properly. This form of validation is much more practical and effective in a centralized telephone facility than it is with face-to-face interviewing.

Recontact Methods

In dispersed field interviewing, the most usual means of checking for falsification is for a supervisor to communicate with the respondent after the interview is completed, to verify that the interview actually took place and that it was properly conducted. (Some telephone surveys also include verification follow-up calls, especially if the interviewers are not working from a centralized location subject to monitoring.) Recontacts can be undertaken in person, by telephone, or through the mail. Recontact methods face two challenges: (1) It can be difficult to achieve a high rate of response to the recontact attempts, and (2) it is not always clear that falsification has occurred if a respondent to the recontact should fail to recall or verify circumstances of the interview. Face-to-face recontact methods are the most expensive but generate the highest response rates; mail recontact is the least expensive but generates the fewest useful responses. Some studies mix the modes of recontact. As with monitoring, verification is undertaken only on a sample of the completed interviews, a sample that should be chosen so as to subject all interviewers to a real possibility of validation. The verification interview should go beyond simply asking if an interview takes place; it also should verify key demographic items and solicit respondent feedback on the interview experience. If a recontact fails to produce a confirmation of an interview from one of the completions submitted by an interviewer, the supervisor will typically undertake recontacts of more of that interviewer's cases, to achieve greater certainty as to whether the interviewer actually engaged in falsification.

Data Analytic Methods

Interviews and process data can sometimes be verified by examining the data record. CAPI and CATI (computer-assisted telephone interview) programs typically record interview duration and the timing of specific questions, so that complete interviews of exceptionally short duration can be flagged as suspect. Discovering an interviewer with an exceptionally high rate of production, or an unusually low rate of refusals by respondents, might lead to closer examination of that interviewer's completed interviews or call records and could lead to a decision to recontact to verify some of the contacts or interviews. Interviews could also be flagged for verification if they have unusual patterns of response, logically inconsistent responses, responses that cause the interview to skip lengthy or burdensome question sequences, or answer patterns that seem to be invariant in relation to question content (suggesting an interviewer who repeatedly selects the same response in order to speed through the fabrication process). Joe Murphy and his colleagues at the Research Triangle Institute presented a paper in 2004 describing how certain data analytic methods were deployed to detect cheating in the National Survey on Drug Use and Health. All of these techniques work best as preventives if analysis of closed and completed cases is undertaken while a survey is still in the field.

Repair and Reporting of Falsification

If falsification is suspected, survey managers should conduct an investigation by reviewing the work of the interviewer. If there is some evidence of falsification, that interviewer should be removed from data collection activities until the issue is resolved. The organization should retrospectively review all other work submitted by the suspect interviewer to check for further, previously undetected falsification. An interviewer who is found to have falsified results should be subjected to disciplinary actions under the organization's personnel policies that are appropriate to serious misconduct—in most cases, the policy is permanent dismissal.

It is obviously unethical for a survey organization to deliver data that are known to be falsified. All data known to be falsified, and any data collected by the suspect interviewer that cannot be confirmed, should be removed and—where possible—replaced with valid data from the same or from equivalently sampled cases. However, the contaminated data records need to be preserved, in a separate file from the valid results, in order to maintain an audit trail for administrative review of the misconduct episode and for any subsequent personnel actions or required reports.

Despite the potential embarrassment involved, survey organizations are obliged to report falsification episodes as an important component of understanding the quality and accuracy of a survey. The technical documentation for a survey should include a description of how monitoring or verification was carried out and a summary of the results of the efforts to detect falsification. The response rate for validation recontact efforts should be reported, along with the number of cases found to have been falsified. Efforts at cleaning, repairing, or replacing the data with valid cases should be described, and any related personnel actions should be mentioned (without naming individuals). If researchers make reports of falsification a standard part of their survey documentation, awareness of the problem and its potential solutions will be raised in the profession.

Organizations that accept funding from the U.S. Public Health Service are required to have research integrity procedures in place that require the reporting of research misconduct to the institution's research integrity officer, who is required to notify ORI in most cases and may initiate a formal inquiry. The 2003 summit, and a follow-up summit convened by Groves at Ann Arbor in 2005, sought to define a de minimus standard that would allow minor interviewer falsification incidents to be handled locally by the survey organization, using industry best practices as approved by the research integrity officer, while more serious incidents would be subject to the full scrutiny of the ORI process. The recommended threshold is that an event would exceed the de minimus standard if, in a single study, a single interviewer or a group of colluding interviewers allegedly falsifies either more than 50 interviews or more than 2% of the cases. This recommendation represents the current industry consensus. Survey organizations that follow best practices in the prevention, control, and repair of interview falsification can expect that incidents rising above this threshold of seriousness will continue to be rare.

Fast Busy

A fast busy is a survey disposition that is specific to telephone surveys. It occurs when an interviewer dials a number in the sampling pool and hears a very rapid busy signal. Fast busy signals are sometimes used by telephone companies to identify nonworking telephone numbers, but they occasionally occur when heavy call volumes fill all of the local telephone circuits. Telephone numbers in the sampling pool that result in a fast busy disposition usually are considered ineligible. As a result, fast busy case dispositions are considered final dispositions and typically are not redialed by an interviewer, although in some cases they may be dialed again in case the fast busy condition is only temporary.

From a telephone interviewing standpoint, the practical difference between a fast busy signal and a normal busy signal is that the pace of the fast busy signal is noticeably faster than that of a normal busy signal. It is important to note that the disposition of fast busies is different from that of busies, and thus fast busies need to have a survey disposition code that is different from the code used for normal busies. As a result, telephone interviewers need to understand the difference between busies and fast busy signals, along with the different dispositions of cases that reach normal busies and fast busy signals. This knowledge will ensure that interviewers code the fast busy cases appropriately and will prevent interviewers from making unnecessary additional call attempts on these cases.

If cases with a fast busy disposition are redialed later in the field period of a survey, it is possible that a small proportion of these numbers may no longer have a fast busy signal on the line. This may occur when a telephone company assigns the number to a new customer or puts the number (back) into service.

Favorability Ratings

A favorability rating is a statistical indicator that is produced from data that typically are gathered in political polls. These ratings indicate whether the public's overall sentiment toward a politician is favorable (positive), unfavorable (negative), or neutral. Journalists often report favorability ratings as part of their coverage of political campaigns and elections.

A favorability rating about a politician is calculated by using data gathered in so-called approval questions. These questions ask poll respondents whether they "approve or disapprove of X," where X typically is the name of a politician. The favorability rating for that person is calculated by subtracting the proportion of those interviewed who say they disapprove of the person (or her or his policies, or both) from the proportion that say they approve. That is, the disapprove (negative) percentage is subtracted from the approve (positive) percentage; if there are more who disapprove than approve, then the favorability rating will be a negative number.

For example, if 65% of the people polled said they disapproved of the job George W. Bush was doing as president, while 30% said they approved (with 5% undecided), the favorability rating for Bush would be $30 - 65 = -35$. The –35 score would indicate that there are substantially more people who disapprove of the president than approve. In contrast, if 45% of those polled said they approved of Bush, 40% said they disapproved, and 15% remained undecided, the president's favorability rating would be a $+5$ $(45 - 40)$, or very slightly positive.

Favorability ratings are best understood within some comparative context. Typically this context is either to compare the favorability rating of one politician with that of another or to compare the current favorability rating of a politician with her or his previous favorability ratings. Because favorability ratings are produced by contrasting two percentages, the absolute value of the rating indicates almost nothing about the underlying dynamics of public opinion toward the politician's job performance. For example, a favorability rating of –10 can result from many varied underlying differences in public sentiment, such as 5% of the public being positive about the politician, 15% being negative, and 85% having no opinion either way; or from 55% being negative and 45% being positive. These examples are two very different circumstances and reflect great differences in what the public as a whole believes. As such, a favorability rating by itself is difficult to interpret beyond merely knowing that proportionally more people feel one way than feel the other.

Finally, as a measurement technique in polls and surveys, favorability ratings are not limited in use only to the assessment of opinions about politicians. They can be used to assess the overall valance toward any person, place, or thing. Nor do they need to be calculated from a survey item that measures the extent of approval versus disapproval that the public holds. Instead, any survey item that is evaluative—in the sense that the closed-ended response scale ranges from "good" to "bad"—can be used to compute a favorability rating.

Federal Communications Commission (FCC) Regulations

The Federal Communications Commission (FCC) regulates many of the telecommunications survey and marketing researchers use through the rules under the Telephone Consumer Protection Act (TCPA), which directed the FCC to balance the fair practices of telemarketers with consumer privacy concerns.

Although some TCPA provisions apply only to commercial and sales-related communications—for example, the Junk Fax Prevention Act (JFPA), the National Do Not Call Registry, and restrictions on call abandonment and time of day—they still impact researchers. However, the TCPA restrictions on "war dialing," artificial or prerecorded messages, and cellular phone calling apply to all callers, including survey researchers.

Junk Fax Prevention Act (JFPA)

The federal JFPA amends earlier fax regulations in the TCPA to reduce the amount of unsolicited facsimile advertisements sent to businesses and residences. The law does not apply to researchers faxing surveys, collecting data via fax, or recruiting respondents via fax. The FCC defines unsolicited fax advertisements as "any material advertising the commercial availability or quality of any property, goods, or services which is transmitted to any person without the person's prior express invitation or permission, in writing or otherwise." Of course, survey researchers that fax unsolicited advertisements seeking to sell their services are bound by the JFPA.

However, individuals and businesses may send unsolicited fax advertisements to other business or residential subscribers where an *established business relationship* is present; this relationship is defined as "a prior or existing relationship formed by a voluntary two-way communication between a person or entity and a business or residential subscriber with or without an exchange of consideration, on the basis of an inquiry, application, purchase or transaction by the business or residential subscriber regarding products or services offered by such person or entity, which relationship has not been previously terminated by either party." Alternatively, fax advertisements can be sent if the recipient gives prior express consent.

All fax advertisement senders must provide a clear and conspicuous opt-out notice on the first page of the ad, and a telephone number, fax number, and a cost-free mechanism (including a toll-free telephone number, local number for local recipients, toll-free fax number, Web site address, or email address) to opt out of faxes. These numbers and cost-free mechanism must permit consumers to make opt-out requests 24 hours a day, 7 days a week.

Although survey research is outside the scope of the JFPA, professional organizations generally recommend that all researchers adopt fax policies addressing respondent opt-out requests to promote respondent cooperation.

Do-Not-Call (DNC) Registry

The FCC TCPA rules first required that companies maintain their own internal do-not-call registries; subsequently, the TCPA was amended to create a federal DNC registry operated by the Federal Trade Commission in conjunction with the FCC. Telemarketers and sellers are required to search the registry at least once every 31 days and drop from their call lists the phone numbers of consumers who have registered.

Calls placed to registered lines are allowed with prior written consent or under established business relationship rules similar to those of the JFPA.

The DNC registry does not apply to survey research calls; however, a researcher that accesses the DNC registry, for whatever reason, becomes legally bound by it—that is, responsible for scrubbing their calling lists of registrants, just like a telemarketer.

Call Abandonment

The TCPA prohibits telemarketers from abandoning more than 3% of all telemarketing calls that are answered live by a person. A call is considered abandoned if it is not connected to a live sales representative within 2 seconds of the called person's completed greeting. Although these restrictions apply only to telemarketing calls, professional associations recommend that researchers strictly limit their call abandonment rates.

Time of Day Restrictions

The TCPA restricts the time of day for sales and fund-raising calls to between 8:00 a.m. and 9:00 p.m.

(local time for the called consumer). Although researchers are exempt from such restrictions, professional associations generally recommend abiding by these restrictions as a best practice.

War Dialing

War dialing is the practice of using automated equipment to dial telephone numbers, generally sequentially, and software to determine whether each number is associated with a fax line or voice line. The TCPA prohibits anyone from doing so. However, the restriction only applies if the purpose of the call is to determine whether the line is a facsimile or a voice line. For example, calling a number already known to be a voice line for the purpose of determining if it is a working or nonworking number could be outside the scope of the TCPA.

Artificial or Prerecorded Messages

The TCPA prohibits telemarketing calls to any residential phone using an "artificial or prerecorded voice to deliver a message without the prior express consent of the called party."

Although that does not apply to survey researchers, the TCPA requires all artificial or prerecorded messages to disclose (at the beginning of the call) the identity of the business, individual, or other entity initiating the call, and if a business is responsible for initiating the call, the name under which the entity is registered to conduct business with the State Corporation Commission (or comparable regulatory authority) must be stated.

Messages must state clearly the telephone number (other than that of the auto-dialer or prerecorded message player that placed the call) or address of such business, entity, or individual. Furthermore, the telephone number provided during the disclosure may not be a 900 number or any other number for which charges exceed local or long-distance transmission charges.

Calling Cellular Phones

In only limited circumstances is it legal to call cell phones for survey research purposes.

Under the TCPA, automatic telephone dialing systems (including auto-dialers and predictive dialers) cannot be used to call a 911 line, an emergency line of a hospital, a doctor's office, a health care facility, a poison control center, a fire department, a law enforcement agency, a paging service, a cellular telephone, or any service where the called party is charged for the call, or in such a way that two or more telephone lines of a multi-line business are engaged simultaneously. The TCPA rules allow for such calls to cellular phones only in cases of emergency or where there is express consent of the called party. The FCC has acknowledged that "persons who knowingly release their phone numbers have in effect given their invitation or permission to be called at the number which they have given, absent instructions to the contrary . . . . Hence, [callers] will not violate our rules by calling a number which was provided as one at which the called party wishes to be reached." The TCPA restrictions apply to both intrastate calls (calls made and originating from within the same state) as well as interstate calls (calls from one state to another), and the FCC can impose monetary penalties for violation of this restriction.

This means that automatic dialing systems are prohibited from dialing cell phones, and there is no good faith exception for inadvertent calls to cell phones. But based on the current scope of the law, survey research calls to cell phones are not prohibited outright. If a researcher is not using an automatic system but calls cell-phone numbers manually or has consent from the called party to call his or her cell phone, that researcher may be outside the scope of the law's restrictions.

Most random-digit dialing sample providers identify and remove numbers assigned to wireless carriers from their frames. To ensure the removal of landline phone numbers that have been ported to a wireless service, NeuStar as the North American Numbering Plan Administrator, the National Pooling Administrator, and the Local Number Portability Administrator licenses a database of these ported numbers that can be used for scrubbing.

Federal Trade Commission (FTC) Regulations

The Federal Trade Commission (FTC) regulates various aspects of telemarketing and the collection, use, and dissemination of personally identifiable information (PII). Under the Telephone and Consumer Fraud and Abuse Prevention Act (TSR), the FTC regulates telephone solicitation. The Children's Online Privacy Protection Act (COPPA) delineates how Web site operators (including researchers) may collect and use PII from children under the age of 13 online. Under the Controlling the Assault of Non-Solicited Pornography and Marketing Act (CAN-SPAM), the FTC regulates commercial emails. Further, the FTC writes the rules enforcing consumer financial privacy thanks to the Gramm-Leach-Bliley Act. Finally, deceptive practices are regulated according to the law that originally established the FTC.

Telemarketing and Consumer Fraud and Abuse Prevention Act (TSR)

This federal act, also know as the Telemarketing Sales Rule or TSR, established rules in 1994 to prohibit certain deceptive telemarketing activities, and it regulates sales and fund-raising calls to consumers, as well as consumer calls in response to solicitation by mail. The TSR also prohibits activities commonly known as SUGing and FRUGing. *SUGing* is the practice of selling under the guise of research, while *FRUGing* is fund-raising under the guise of research. Selling, in any form, is differentiated from survey research, and the FTC recognizes that in the TSR. Occasionally, survey research companies will offer an incentive or gift to the respondent in appreciation of his or her cooperation. Such an incentive or gift could be a cash donation to a charity, a product sample, or a nominal monetary award. But sales or solicitation is not acceptable or permitted in legitimate and professionally conducted survey research and violates federal law.

Telemarketers have various restrictions in the TSR but perhaps the best-known provisions relate to the National Do Not Call Registry. To enforce the law, the TSR allows consumers to bring private civil lawsuits in federal district courts.

Children's Online Privacy Protection Act (COPPA)

The federal COPPA, signed into law in 2000, applies to the online collection of personal information from children under the age of 13. The primary goal is to place parents in control over what information is collected from their children online. The rules spell out what a Web site operator must include in a privacy policy, when and how to seek verifiable consent from a parent, and what responsibilities an operator has to protect children's privacy and safety online. The rules cannot be sidestepped by simply including a disclaimer, making the collection of PII optional, or surreptitiously inviting children to falsify their age.

COPPA applies to operators of commercial Web sites or online services directed to children under the age of 13 that collect personal information from children, operators of general audience sites that knowingly collect personal information from children under 13 years of age, and operators of general audience sites that have a separate children's area and that collect personal information from children under 13 years of age.

PII under COPPA includes full name; physical address; email address; Social Security number; phone number; screen name revealing an email address; persistent identifier, such as a number held in cookie, which is combined with personal information; and information tied to personal information, such as age, gender, hobbies, or preferences.

The FTC applies a sliding scale approach to the practice of collecting PII from children. It balances the level of information sought from a child and the level of information needed from the child's parent. Information that the Web site operator will keep for internal purposes requires simpler consent methods than information that might be externally shared with the public or a third party.

Although COPPA applies only to children under 13, professional research and marketing associations generally recommend that researchers seek parental consent for any respondents under the age of 18.

Controlling the Assault of Non-Solicited Pornography and Marketing Act (CAN-SPAM)

The federal CAN-SPAM Act, signed into law in 2003, established commercial email distribution requirements, penalties for violation of the law, and consumers' rights to opt out of future emailings.

The law bans false or misleading header information, meaning that emails must contain accurate "From" and "To" fields and routing information, including the originating domain name and email address. It also prohibits deceptive subject lines. Commercial email must be identified as an advertisement or solicitation and include the sender's valid physical postal address, as well as explicitly state that recipients can opt out of future emails.

The law requires not only that emails include a method for recipients to opt out but also that senders strictly honor such requests within 10 days, and for at least 30 days after sending the commercial email. In addition, CAN-SPAM prohibits the sale or transfer of the opted-out email address.

The CAN-SPAM Act applies to those that distribute commercial email messages. However, survey research emails may be covered under the false or materially misleading header provision—usually not an issue for the profession, give the ethical nature of research contacts. However, researchers using email to solicit business or sell goods or services are bound by the law. Survey researchers that are recruiting or inviting respondents to participate in a survey are not legally required to abide by the opt-out provisions or email identification provisions of the CAN-SPAM Act because recruiting and taking surveys are not commercial or sales-related activities. However, as part of best practices, researchers are encouraged by professional associations to include opt-out notices in all email distributions, regardless of whether the message is commercial or noncommercial in nature.

The Gramm-Leach-Bliley Act

The federal Gramm-Leach-Bliley Act, signed into law in 1999, includes provisions regulating the privacy and security of consumer financial information, which are overseen by the FTC and a variety of financial regulatory agencies.

The law restricts the disclosure of consumers' "nonpublic personal information" by "financial institutions" and requires explicit notices to customers about information-collection and information-sharing practices. The Gramm-Leach-Bliley Act allows for consumers to opt out of having their information shared with third parties, and all financial institutions are required to provide notice and opt-out opportunity before they may disclose information to nonaffiliated third parties (with certain caveats).

The FTC defines the term *financial institution* as any institution engaged in the business of providing financial services to customers who maintain a credit, deposit, trust, or other financial account or relationship with the institution. An institution must be "significantly engaged" in financial activities to be considered a financial institution.

Thus, for researchers to acquire customers' PII from financial institutions, the institutions must either (a) provide customers notice of such disclosure and their ability to opt out of it or (b) utilize an exception in the law. Under this exception, the financial institution is still required to provide notice to its customers about its information-sharing practices, but PII can be disseminated without the opt-out provision to third parties who provide services for the financial institution—for example, survey researchers conducting research for the financial institution. To take advantage of this exception, survey researchers would have to enter into a contractual agreement with the financial institution to keep the PII confidential.

Deceptive Practices

The FTC regulates survey researchers in a broad way—breaking promises can mean breaking the law. Violating stated privacy policy can be actionable under Section 5 of the original FTC authorization act (15 U.S.C. §§ 41–58) as an unfair or deceptive trade practice, as well as under similar laws at the state level.

Feeling Thermometer

The feeling thermometer is a common survey tool used by researchers to determine and compare respondents' feelings about a given person, group, or issue. Feeling thermometers enable respondents to express their attitudes about a person, group, or issue by applying a numeric rating of their feelings toward that person, group, or issue to an imaginary scale. Using a feeling thermometer, respondents express their feelings in terms of degrees, with their attitudes corresponding to temperatures. A rating of 0, very cold, indicates that a respondent does not like a given person, group, or issue at all; a rating of 100, very warm, translates to the respondent liking that person, group, or issue very much. In general, researchers consider ratings below 50 to indicate a respondent dislikes or has a negative view of a person, group, or issue; conversely, respondent ratings above 50 are indicative of positively held feelings or attitudes. The midpoint of the feeling thermometer, 50, is reserved to indicate that a respondent's feelings toward a person, group, or issue are completely neutral: He or she does not like or dislike, approve or disapprove, have positive or negative feelings toward the person, group, or issue.

Despite the seemingly simple and straightforward concept of feeling thermometers, they are susceptible to high levels of variance due to a variety of reasons associated with how individuals respond to feeling thermometers. Studies have found that some respondents tend to be "warmer" than others in applying the scale, whereas other respondents tend to be "colder." Further, they explain that some respondents, for whatever reason, restrict their ratings to relatively small portions of the thermometer, whereas others are just more open to using the entire spectrum. Additionally, an inverse relationship has been found between respondents' levels of education and thermometer ratings, with higher ratings associated with the less educated respondents.

Feeling thermometers were first used in the 1964 American National Election Study. Because feeling thermometers were introduced in an election study, people commonly associate the use of feeling thermometers with political science research. Although political scientists do utilize feeling thermometers in a wide variety of studies, many researchers in other disciplines, including psychology and sociology, frequently employ feeling thermometers in their research as well. Beyond social sciences, feeling thermometers are often used in medical fields to allow respondents, or patients, to rate their health or health-related quality of life.

Feeling thermometers are important survey instruments because they allow researchers to gather information about the direction, as well as the intensity, of respondents' attitudes and feelings toward specific people, groups, and issues. Additionally, feeling thermometers have proven to be indispensable in longitudinal studies such as the American National Election Study because they allow researchers to observe and document how peoples' feelings and attitudes about certain public figures, groups, or issues change over time.

Field Coding

Field coding involves the use by an in-person or telephone interviewer of a standardized listing of response options to categorize open-ended responses given by respondents to questions that provide no specific response options to the respondent. This approach differs from the administration of a closed-ended question, where the response options are read to the respondent, and differs from the administration of open-ended questions, where the response is typically recorded verbatim.

With field coding, an interviewer typically asks the respondent an open-ended question and waits for a response. As the respondent replies, the interviewer records the information into one or more of the predetermined response options. Should the respondent give an answer that is not on the interviewer's list of response options, the interviewer either must interpret the answer as close as possible to one of the predetermined response options or ask follow-up probes to clarify the response. Creating as inclusive a set of response options as possible is important, which means that the researcher must anticipate (or know from previous research studies) how the sample population might respond to the particular survey questions administered in this manner. As a last resort, when an interviewer cannot map an open-ended response to a pre-specified response option, the researcher should provide the interviewer with an "other" response choice and ask that some verbatim specification of what the respondent said be written by the interviewer.

By allowing respondents to reply in their own words, field coding techniques help to establish a dialogue between the respondent and the interviewer that more closely resembles a conversation than is typically the case with the administration of closed-ended survey questions. A positive rapport can help facilitate more sincere and detailed answers from the respondent. Additionally, the use of a predetermined set of response categories allows for greater standardization of the process than might be the case with recoding of verbatim responses, which can often be incomplete or unrelated to the actual question asked. A researcher must anticipate possible responses by the respondent, which requires development of an inclusive but mutually exclusive set of response options. Pretesting of the initial response options helps create the set of possible responses to use in the coding list.

Use of a standardized set of response options may, however, limit the capture of more complex responses, those which do not fit into the predetermined categories. In this respect, field coding may produce data that are less comprehensive than the recording of full verbatim responses or the taking of field notes by the respondent. Because the interviewer takes an active role in "creating" the respondent's response, field coding is susceptible to reactivity (i.e., changes in the respondent's answers caused by interaction with the interviewer or the setting) and to coder variance (variation in how an identical response is coded across a number of different interviewers). Further, the respondent may take a longer time to reach the same answer than he or she would have had the response options been presented as part of the question. This can increase the cost of conducting a survey.

To properly administer field coded questions, interviewers must be well trained and conscientious. For example, a respondent's answer may deviate from the wording of the response options in the questionnaire (which the interviewer sees but the respondent does not), leaving the interviewer to determine how best to code the response. The choice of a category may be selected by the interviewer based on his or her interpretation of the response, or the interviewer may ask follow-up questions to help determine the best fitting response. In doing the latter, however, the interviewer should not suggest one response over another, but rather allow the respondent to choose. The techniques and questions for probing the respondents' answers can either be standardized before the interview takes place or be determined by the interviewer. A skillful interviewer will allow respondents to express their responses within the parameters of the study.

Field Director

In the survey research community, the title Field Director is commonly used to denote the person with overall responsibility for the data collection component of a survey that uses off-site interviewing personnel as data collectors. Not to be confused with the Principal Investigator or the Project Director, which may be positions held by other staff on the project, the Field Director role is commonly limited in functional scope to all aspects of collecting data in the field. The Field Director also may be called the Field Manager or Data Collection Task Leader. (The Field Director title is sometimes used to refer to the person in charge of data collection in a centralized telephone call center, although some consider this a less appropriate use of the term.)

A Field Director typically has overall responsibility for the preparation, staffing, training, implementation, monitoring, and controlling of the field operation and ensures the task is completed on schedule, within budget, and in accordance with the project objectives and quality specifications. On large surveys, the Field Director often is supported by in-house survey specialists, who assist with data collection preparations before collection begins, as well as Regional Supervisors and Field Supervisors. In this organizational model, the Field Supervisors oversee the field data collectors and report to Regional Supervisors, who in turn report to the Field Director. The Field Director is a senior member of the project management team and typically reports directly to the Project Director or Principal Investigator.

An effective Field Director should be a functional expert in two areas: project management and field survey methodology. Given the breadth of responsibilities, a person must be experienced and skilled in both areas.

Project management skills are needed to develop and implement the data collection plan and to monitor and control the execution of the plan. The Field Director should be proficient in developing work plans, work schedules, staffing plans, communication plans, quality plans, and budgets. He or she must have managerial skills to oversee the implementation of the various plans and the leadership skills to establish and maintain an effective and committed team of support staff. Finally, the Field Director must be skilled at monitoring and controlling the technical work, the logistics, the schedule, and the project budget. These project management skills are necessary to bring the field operation to a successful conclusion on schedule and within budget.

Survey methodology expertise is needed to ensure that the data collection plan incorporates appropriate survey operational methods, procedures, and systems that will result in a successful data collection outcome that meets project specifications and expectations within budget and time constraints. Areas of required expertise include development of instrumentation and forms, training plans, data collection protocols, validation and quality assessment procedures, and post–data collection processing of the collected data.

The Field Director must be a skilled negotiator, problem solver, manager, and team player who is able to interact effectively with other members of the project team as both a peer and a supervisor. He or she must coordinate field data collection activity with other project task managers, such as those in charge of sample design, systems and programming, weighting and estimation, and analysis. As noted earlier, the Field Director will often be responsible for a task team consisting of survey specialists, Regional Supervisors, Field Supervisors, and data collectors. Depending on the size, duration, and complexity of the data collection operation, the Field Director may assign task leaders to specific field data collection components, such as development of field manuals and training programs, instrumentation, field supply logistics, field staff recruiting, validation and quality, and so on. Overall responsibility for the completion and coordination of all tasks on schedule and within budget, however, lies with the Field Director.

Field Period

The field period of a survey is the time frame during which the survey instrument is "in the field," as opposed to the time when the survey instrument is under development or review in the office. It is the period during which interviews are conducted and data are collected for a particular survey. Originally, it referred to the period of time when personal face-to-face interviews are being conducted by "field interviewers." Over the course of years, the field period has come to be regarded as the period of days or months over which data for a survey were gathered from respondents, regardless of the mode of data collection that was used.

The purpose of the survey is directly related to the field period that is established. A field period might be as short as a few hours for an overnight public opinion poll or a few days for time- or event-sensitive surveys. For surveys in which the subject is less time- or event-sensitive, the field period might extend for several weeks or months. In establishing the field period for a survey, the purpose of the survey is perhaps the most significant factor. To the extent that a survey is designed to gauge public opinion in response to a specific event or activity, a short field period is appropriate. This is often the case in political polling such as voter preference. It might also be appropriate in those surveys designed to gauge health risks and behavior, such as the impact of flu shots on influenza.

In addition to the purpose of the survey, another consideration is what events are taking place during the proposed field period. For example, surveys of high school students may be more difficult during certain times of the year, such as summer vacation and holiday breaks. Buying patterns may be quite different during the weeks immediately preceding the beginning of a school year than they are at the beginning of summer vacation. Holidays and traditional vacation periods may make contacting potential respondents more difficult and result in additional costs to reach the target population.

Administering surveys with a short field period can be more costly, in part because of the number of attempts that must be made for each completion. For computer-aided telephone interviews, this cost is related to the number of calls that must be made to reach the numbers of completions required. A short field period might also require the use of a large number of interviewers to ensure that sufficient call attempts are made. For mail surveys, there may be additional costs associated with either pre-notification or follow-up mailing to encourage completion of the survey. Shorter field periods may also increase the cost of data processing (such as coding and data transformation) needed to meet the turnaround time required for reports or public release of the results.

Because shorter field period surveys make it difficult to make multiple attempts to those households that are not contacted on the first attempt, there is a greater potential for sample bias. Statistical weighting can be used to overcome some of this bias. Longer field periods can allow more attempts to be made to those difficult-to-reach households and reduce the potential nonresponse bias that may result.

For those survey designs that require the use of interviewers, longer field periods can create the potential problem of interviewer turnover. This will require that a sufficient number of trained interviewers are readily available to ensure that the survey continues to be administered in a consistent manner throughout the field period. To address this concern, it is sometimes possible to cross-train interviewers on a number of surveys so that they can be reassigned as needed. The alternative is ongoing training and, if necessary, hiring of additional interviewers.

Every survey design must include determination of the field period during which useful data can and will be collected. Careful consideration of the possible sources of bias, additional cost, and implementation issues related to administration of the survey instrument can help ensure that the data collected will accurately reflect the opinions and concerns of the population being interviewed.

Field Survey

The term *field* is used in survey research to refer to the geographical setting where data collection takes place. Typically this refers to in-person interviewing and thus the name, field survey.

One of the key decisions when designing a survey is the choice of the mode of data collection. Field interviewing is one of three traditional modes of survey data collection (along with telephone and mail). In field surveys, which are also referred to as face-to-face or personal-visit surveys, an interviewer visits the respondent's home or office (or another location) and conducts the interview. This entry outlines the major advantages and disadvantages of field data collection and the variations that are found in modern survey research and concludes with a brief overview of the development of present-day field surveys.

Advantages and Disadvantages

Field surveys have several advantages over other modes of data collection. Lengthy, complex instruments are easier to administer in a face-to-face interaction in which the interviewer can clarify questions, present visual aids, probe responses, and assess respondent fatigue. In countries like the United States that do not maintain a national registry of residents, selecting neighborhood blocks and listing the housing units on selected blocks, as is often done for field surveys, provides more complete coverage of the household population than do studies based on telephone numbers or mailing addresses. Response rates are typically higher in face-to-face surveys.

On the other hand, field interview costs are very high relative to other modes of data collection, sometimes 5 to 10 times those for telephone surveys. Large field data collections involve significant time for planning and implementation and require hiring, training, and supervising a large, geographically dispersed field staff. In terms of data quality, the presence of an interviewer may cause respondents to adjust their answers to survey items in order to report socially appropriate or desirable responses.

Variations

Field surveys can be implemented in a number of ways and can be used to collect a wide range of data. It is common to record interviewer observations on characteristics of the neighborhood and housing unit. In surveys that ask for sensitive information such as drug use or sexual behavior, some questions may be self-administered; that is, respondents read and answer the questions on their own either during or after the interview. For example, the National Survey on Drug Use and Health, a large annual field survey of approximately 70,000 U.S. persons 12 years old and older, which is sponsored by the U.S. Substance Abuse and Mental Health Services Administration and conducted by RTI International, uses ACASI (audio computer-assisted self-interviewing) in which respondents listen to questions using earphones and enter their responses on a laptop computer.

Field survey protocols may include the administration of tests of physical performance (e.g., walking speed, grip strength) or cognitive ability (e.g., memory tasks, word recognition) or the recording of physical measurements (e.g., height, blood pressure). Biological specimens such as blood or saliva or environmental specimens such as soil or dust may be taken as part of the in-person visit, as is done, for example, in the National Health and Nutrition Examination Survey. In mixed-mode studies, sample members may first be asked to complete the survey using mail, Internet, or telephone modes. Only those sample members who do not respond via these modes are followed up with a more expensive field survey request. In panel studies that collect data from the same persons at multiple time points, like the Current Population Survey, field interviewing may be used in the initial interview to motivate sample members to participate and report accurately. Later rounds of interviews are then completed using less expensive telephone interviews.

Development of Present-Day Field Studies

The roots of modern field survey research can be found in part in the studies of the poor carried out by Charles Booth and colleagues in London during the late 19th and early 20th centuries.

In the decades to follow, the use of field surveys grew dramatically as there were attempts to systematically record and analyze sample survey data on a variety of phenomena, from consumer preferences to unemployment. However, in the private and academic sectors, field surveys would later be replaced by mail and telephone surveys that were cheaper and expected to yield similar data based on methodological studies. Today, most national field data collections are sponsored by the federal government.

Historically, field interviews were completed using paper-and-pencil questionnaires, but by the end of the 20th century, most large field studies in the United States had transitioned to computer-assisted personal interviewing (CAPI) instruments that were administered using laptop computers. The first national household survey to use CAPI in the United States was the 1987 Nationwide Food Consumption Survey, conducted by National Analysts.

FIELD WORK

Field work encompasses the tasks that field staff, such as field interviewers or telephone interviewers, perform before or during the data collection field period of a survey. Field work refers to both telephone and in-person studies. For telephone interviewing, field work is usually restricted to the field period. For in-person studies, field work may take place before, during, and after the field period for the study.

The field work for telephone studies usually involves working at a telephone survey center with computer-assisted telephone interviewing (CATI) stations. In RDD (random-digit dialing) surveys, the computer at the CATI station dials randomly generated telephone numbers that are programmed into the CATI system. Given that the telephone numbers are randomly generated, part of the telephone interviewer's field work is to screen the telephone numbers to determine whether they are eligible for the study sample. For instance, if a study is sampling members of households, the interviewer has to determine whether the phone number dialed reaches a household, a business, or is a nonworking number. Usually, the interviewer samples eligible respondent(s) at the household by asking the person who answers the phone questions designed to randomly select a person or persons in the household. The telephone interviewer then administers the CATI questionnaire to the sampled respondent over the telephone or makes an appointment for a callback when the designated respondent will be available. In case of a refusal, the telephone interviewer uses his or her knowledge about the study and about refusal conversion skills to convince the respondent to participate. If not successful, the interviewer records the reason for the refusal in detail so that the case can be contacted again for refusal conversion.

The field work for in-person studies is more extensive than for telephone interviewing. Field work conducted in preparation for the field period for random sampling studies can include listing of dwelling unit addresses, which is performed by *listers* or *enumerators*. These field staff members work at the selected geographical areas for the study identifying eligible units and listing their addresses for sampling. For list samples, field work may involve contacting institutions to obtain lists of employees, members, or clients for sampling.

Field work for an in-person interviewer (or enumerator) during the study's field period may include locating the sampled units on a map and planning the most efficient way to travel to the area to conduct the interviews. Once in the area, the field interviewer contacts the sampled unit to request participation in the study. Field work may involve screening households or businesses to identify eligible respondents using a screening questionnaire. Once the eligible respondents are identified, the field interviewer administers the main questionnaire to the sampled respondents usually via computer-assisted in-person interviewing (CAPI) but also sometimes via a paper questionnaire. In some studies, field work also involves administering literacy assessments, collecting samples (e.g., hair, urine), and taking other health measurements of respondents, such as height and weight, in addition to administering a CAPI questionnaire. Field interviewers also ensure that respondents fill out any required study forms such as consent forms. Field interviewers may also call respondents to schedule appointments for additional interviews or assessments as part of their field work. Field interviewers may plan and implement refusal conversion strategies to convert refusals incurred by the interviewer or transferred from another interviewer.

Other tasks that are part of field work for in-person interviewers are recording the result of contacts on a computer or case folder and submitting completed work via mail and online data uploads. Field interviewers report to a field supervisor or to a home office in person or via telephone conference call on a regular basis to discuss field work in progress. Field interviewers keep track of the hours they spend doing field work and traveling to and from the field and expenses incurred while in the field and submit those on a timely basis to their supervisor. They also keep track of their supplies to ensure that they have the study materials in the field when they need them. Field work for some interviewers may involve traveling to other sampled locations in the study to help to convert refusals or screen households.

For longitudinal studies, field work usually includes locating respondents who moved since the last wave of the study: This is known as tracking and tracing. Quality control procedures to monitor the work of phone or field interviewers are also considered part of field work.

FINAL DISPOSITIONS

Final dispositions (or final sample dispositions) are a set of codes or categories used by survey researchers to document the ultimate outcome of contact attempts on individual cases in a survey sample. Assigned after field work on a survey has been completed, final dispositions provide survey researchers with a terminal, or ending, status of each unit or case within the sampling pool. Survey researchers use final sample dispositions for two reasons: (1) to calculate response rates and (2) to help assess whether the sample might contain nonresponse error.

One important purpose of final dispositions is to calculate survey response rates. It is common practice for survey researchers to compute the response rates at the end of a survey's field period. Response rates are a common measure of survey quality, and typically it is assumed that the higher the response rate is, the higher the quality of the survey data is. Because the final dispositions categorize the outcome of each case (or unit) in the sampling pool, final dispositions make it possible for survey researchers to calculate survey response rates.

A second important purpose of final dispositions is to assess potential nonresponse error in the sampling pool. Correct or not, a common assumption is that there is more nonresponse error in survey samples with lower response rates than in survey samples with higher response rates. Although determining the amount of nonresponse error in survey data requires more than just the survey response rate, calculating survey response rates requires final dispositions and is an important first step in understanding whether nonresponse error is present in survey data.

Types of Final Dispositions

At the end of a survey field period, survey cases generally can be classified into four groups: (1) completed interviews, (2) eligible cases that were not interviewed or who did not complete the survey questionnaire (nonrespondents), (3) cases of unknown eligibility (some of which are likely to be nonrespondents), and (4) cases that were ineligible for the interview. In order to categorize the variety of possible outcomes of survey cases into each of these four broad categories, researchers usually use a more extensive and refined system of subcategories that are assigned to each unit in the sampling pool during the field period. In an effort to permit reporting of comparable final dispositions across survey organizations and survey projects, survey-related professional organizations such as the American Association for Public Opinion Research have developed standardized definitions for final dispositions.

Completed Interviews

Final dispositions for completed interviews divide the category into two subgroups: completed (full) interviews and partial interviews. Full interviews are interviews in which the respondent has provided data for each question in the survey instrument. The definition of a partial interview tends to vary across survey organizations but commonly includes those cases for which the respondent has provided data for a majority of questions in the survey instrument, including questions that are key variables for the purpose of the study.

Eligible Cases With No Data Gathered

Final dispositions for eligible cases from which no data were gathered divide the category into refusals, breakoffs, noncontacts, and "other cases." *Refusals* are cases in which some contact has been made with the sampled unit or named respondent, and the named respondent or a responsible member of the sampled unit has declined to participate in the interview. *Breakoffs* are cases in which data collection began, but the respondent refused or was unable to complete the interview (for in-person and telephone modes) or the questionnaire (for Internet and mail modes). The definition of *noncontact* varies depending on the mode of interviewing. For in-person interviews, a noncontact results when an interviewer is unable to gain access to a building, when no one is reached at a housing unit, or when the named respondent is away or unavailable. For telephone interviews, a noncontact results when the selected respondent is never available or when only an answering machine can be reached, but the message confirms that the telephone number is that of a household unit. "Other cases" include cases in which the respondent is located and does not refuse the interview but is unavailable or unable to complete the interview because of death, illness, physical or mental limitations, language problems or barriers, or other uncommon reasons.

Cases of Unknown Eligibility

Cases of unknown eligibility include situations in which it is not clear whether an eligible household exists and also situations in which a household unit exists, but it's not clear whether an eligible respondent is present within the household unit. For in-person interviews, cases of unknown eligibility include cases that were not attempted or worked by an interviewer, cases that could not be reached or that were in an unsafe area, and cases for which a valid address could not be located. For telephone surveys, cases of unknown eligibility include telephone numbers that are always busy, numbers in which no one ever answers, answering-machine messages that do not indicate whether the number belongs to a household unit, and technical phone problems that prevent the call from ever being completed properly. For mail and Internet surveys, unknown eligibility includes all sampled addresses from which the researcher receives neither a response nor any feedback about whether the survey invitation was ever received.

Ineligible Cases

For in-person household surveys, ineligible cases consist of household units included in the sample by error, nonresidential units, vacant households, household units with no eligible respondent, and situations where quotas have been filled. In addition, for telephone household surveys, ineligible cases include fax or data lines, nonworking numbers, or nonresidential numbers.

Converting Temporary Dispositions to Final Dispositions

At the end of a survey field period, many cases will already have reached a logical final disposition. These cases include completed interviews, refusals, and ineligible numbers, among others. However, some cases will not have reached a final disposition and will still have a temporary disposition code. (Temporary disposition codes are used to record the outcomes of contact attempts when the contact has not resulted in a final disposition.) Examples of temporary disposition codes include maximum call limit met, callback, no callback by date of collection cut-off, ring-no-answer, busy, and appointments that were not kept by the interviewer or the respondent.

Temporary disposition codes must be replaced with final case dispositions before these cases can be included in the calculation of response rates. For these cases, researchers must assign final dispositions by reviewing the pattern of disposition codes and call/contact outcomes recorded for each individual case and using this information to determine the final disposition code that "best" describes the case. (Computer algorithms can be written to make most, if not all, of these decisions.) In considering the proper final disposition code to use, survey researchers must consider the best information from all contact attempts. Because the information across contact attempts might be contradictory, three factors merit special attention: (1) the case's situation on status day (usually the first day of the field period or the first day that a case was contacted); (2) the certainty of the information on case contact attempts (information across contact attempts might be uncertain and researchers in these cases most often should take the conservative approach of assuming a case is eligible or possibly eligible unless there is reliable information to suggest otherwise); and (3) the hierarchy of disposition codes (disposition codes in which there was human contact take precedence over others, and generally in these cases, the last disposition in which there was human contact will serve as the final disposition). For example, if the last contact attempt with a sampled household results in a noncontact disposition, but a previous contact resulted in a refusal, most survey researchers would consider the final disposition of this case to be a refusal.

Finite Population

Most statistical theory is premised on an underlying infinite population. By contrast, survey sampling theory and practice are built on a foundation of sampling from a finite population. This basic difference has myriad ramifications, and it highlights why survey sampling is often regarded as a separate branch of statistical thinking. On a philosophical level, the theory brings statistical theory to a human, and thus necessarily finite, level.

Before describing the basic notion of finite population sampling, it is instructive to explore the analogies and differences with sampling from infinite populations. These analogies were first described in Jerzy Neyman's seminal articles in the 1930s and are discussed in basic sampling theory textbooks such as William Cochran's in the 1970s. In the general framework of finite population sampling, we consider samples of size n from a finite population of size N, that is, a population with N elements or members.

The bridge of finite to infinite population sampling is also seen in terms of a finite population correction (fpc) that applies to the variances under most sampling designs. Finite population sampling typically begins with simple random sampling (SRS), the simplest form of sampling design, which can be considered with replacement or without replacement. For SRS designs, the fpc may be expressed as $1 - n/N$, or $1 - f$, where f is the sampling fraction or the sampling rate, $f = n/N$. Clearly, the fpc does not materially affect variances when sampling from large populations, particularly when the sample is not too large itself.

Finite population corrections are applicable for estimation but may not be necessary for many inferential uses such as statistical testing (e.g., comparisons between subgroups). In many instances, it is more sensible to consider an underlying infinite population when comparing subgroup parameters. In general, an infinite population approach to sampling has been developed that is based on superpopulation models. The superpopulation approach treats the value associated with a population unit as the realization of a random variable rather than as a fixed number.

Finite Population Correction (fpc) Factor

The finite population correction (fpc) factor is used to adjust a variance estimate for an estimated mean or total, so that this variance only applies to the portion of the population that is not in the sample. That is, variance is estimated from the sample, but through the fpc it is used to assess the error in estimating a mean or a total, which is due to the fact that not all data from the finite population are observed.

This concept is found throughout sample survey statistics, but this entry concentrates on the simplest of design-based sample survey statistics, simple random sampling (without replacement). A sample of n observations for a data element of interest, say, pairs of shoes sold, are randomly selected from the N members of the universe, say, of all shoe stores or dwellings, respectively, in a geographic region. (This can also be done by strata in stratified random sampling. Other strategies can be more complex. Also, this concept can be applied to ratios of totals, such as price per unit.) An estimated mean or total will be found by extrapolating from the sum of the n observations in the sample, $\sum_{I=1}^{n} y_i$, to an estimate, $\hat{T}$, of the sum of these values for the universe, $T = \sum_{I=1}^{N} y_i$, where this total is estimated for the part of the population not in the sample. (If $\hat{T}$ represents an estimate of the total, T, then we can write $\hat{T} = \sum_{I=1}^{n} y_i + \sum_{I=n+1}^{N} \hat{y}_i$. This will be considered later.) Therefore, there is an error associated with making this leap, and that is the sampling error. There are nonsampling errors to consider, such as poorly constructed survey measures, data processing errors, and reporting errors, but here we concentrate on the error due to the fact that not all data were observed, only the data for members of the sample. (Note also that there is a model-based analogy to this, but the fpc is considered to be part of a design-based approach.) Nonresponse by members of the sample can be handled in more than one way, but again, here we concentrate on simple random sampling, without regard to nonsampling error, or nonresponse. This applies straightforwardly to stratified random sampling where simple random sampling is accomplished within each stratum (group). Other designs become more complicated.

Consider the estimation of a total, $\hat{T}$, as previously shown. (Means and ratios follow from there. Here, totals are discussed.) For a stratified random sample design, survey weights are used—often adjusted to calibrate for auxiliary information or in some other way—and the finite population total is estimated within each stratum by adjusting from the sample total within that stratum, to account for the data not collected. We can consider one stratum at a time and, therefore, consider simple random sampling.

To estimate the variance of an estimated total, we use the estimated variance within the sample, and accepted practice is to apply it only to the part of the population that was not in the sample, $\sum_{I=n+1}^{N} \hat{y}_i$. This may seem odd at first, but it has a certain logic, if we ignore variance due to nonsampling error to some extent. If we can estimate variance for data within a population, it must be based on the sample data, as those are all the data available. If we consider a finite population, then the variance of the estimate of a total is due to the data that are not in the sample. In other words, error in estimating a finite population data element total will be considered as being due to failure to observe all data, and instead, estimating for some of it. Thus the estimated variance is applied only to the part of the population not sampled, assuming that the variability of the data available is the same as would be found in the data not collected. Therefore, any variance estimate for a finite population total has to be adjusted downward, because the data observed are considered to have no contribution to the variance of that estimated finite population total. Thus we regard the n observations made for a given data element (say, pairs of shoes sold) to be completely known, so the variance of the estimated total will only be derived from the $N-n$ cases in the subtotal, $\sum_{I=n+1}^{N} \hat{y}_i$, shown previously, that are not known.

The fpc factor, in the case of SRS, can be written as a single adjusting factor, applied to the estimated variance of a total, and written as $\frac{N-n}{N}$. This is the ratio of unobserved members of the finite population to total population size. It represents the fraction of the finite population to which we consider variance to be relevant here. This factor can also be written as $1-f$, where $f = \frac{n}{N}$ is the sampling fraction. Therefore, for simple random sampling, $\text{fpc} = \frac{N-n}{N} = 1-f$. It is therefore the *fraction* of the finite population that is *not sampled*. (That is, f is the sampling fraction, and $1-f$ is the fraction not sampled.) Because the fpc is literally a factor in the calculation of an estimate of variance for an estimated finite population total or mean, that estimated variance is reduced to zero if $n = N$ and approaches "full value" if $n \to 0$. This leads to the following:

$$\text{If } n \to N \text{ then fpc} \to 0.$$

$$\text{If } n \to 0 \text{ then fpc} \to 1.$$

In many sample surveys of very large populations, f is very small, and the fpc may be eliminated (i.e., considered as though $\text{fpc} = 1$). However, for a complete census, fpc = 0, and the variance of the finite population total, mean, or ratio is zero.

Focus Group

A focus group is a qualitative research method in which a trained moderator conducts a collective interview of typically six to eight participants from similar backgrounds, similar demographic characteristics, or both. Focus groups create open lines of communication across individuals and rely on the dynamic interaction between participants to yield data that would be impossible to gather via other approaches, such as one-on-one interviewing. When done well, focus groups offer powerful insights into people's feelings and thoughts and thus a more detailed, nuanced, and richer understanding of their perspectives on ideas, products, and policies.

This entry begins by describing the historical background of focus groups. The entry then discusses issues that researchers might consider in choosing to use focus groups, including their strengths and limitations. Next, the entry describes the types of focus groups; the steps taken to prepare for focus groups; and the analysis of, and reports pertaining to, the data gathered. Finally, the entry addresses some ethical considerations in relation to focus groups.

Background

Focus groups first appeared in academic research in the 1920s. At that time, scholars such as Walter Thurstone used group interviews to develop survey instruments. During World War II, Robert Merton and Paul Lazarsfeld used them to develop propaganda and other war time materials for the U.S. government. Between the 1950s and 1980s, focus groups became increasingly prominent in marketing and yet were rarely used in academic research. Marketers began to refer to them as *group depth interviews*, in which professionals trained in probing sources of behavior could work to uncover customers' psychological motivations.

In the 1980s, focus groups became more prominent in scholarly circles. This renewed attention was due both to work in social marketing (researching public health concerns) and the emergence of scholarly articles and books on focus groups as a method in the mid-1980s and 1990s by David Morgan, Richard Krueger, and others. Today, focus groups are common for academic research, product marketing, evaluation research, and quality improvement. In these arenas, they are used to help identify problems, to assist in the planning process, to aid the implementation of ideas and programs, and to assess data and outcomes.

Considerations for Choosing Focus Groups

Focus groups thrive in marketing because they provide a useful format to learn about people's reactions to concepts. These group conversations are most appropriate when participants, as a group, are asked to respond to stimuli and then share and compare their responses with and against others in the group. Focus groups provide insight into individuals, such as how they think and feel (as well as how often and deeply they think and feel) about ideas or products, when and under what conditions their thoughts and feelings lead to behaviors, when complicated or contradictory thoughts and behaviors emerge in response to topics or products, and how diverse groups view a specific idea or product. Moreover, this method allows researchers to assess more subtle feelings people may harbor about topics, to test pilot ideas, to shed light on previously collected data, and to aid in the construction of future large scale quantitative survey studies. In all of these instances, it is important to allow data to "emerge" freely from participants and to listen for the deeper understanding of the range of ideas.

In other situations, focus groups are not an appropriate choice for researchers. Group interviews should be avoided when participants are not comfortable with each other or with the topic, when a project requires rigorous statistical data, when consensus or emotionally charged information is desired, or when confidentiality is necessary. Additionally, focus groups should not be used when the act of holding a group, and soliciting opinions and reactions on a potentially sensitive issue, implies a commitment to a group of participants that cannot be kept (i.e., those who use this method have a special obligation to be sensitive to the suggestive "force" of this method as well as the communities with whom they work).

Relative to other qualitative methods, focus groups most closely resemble open-ended interviewing and participant observation. As in open-ended interviews, focus group moderators approach groups with a protocol of questions and encourage participants to focus on an identified topic. Unlike open-ended interviews, however, focus group moderators can be flexible with how the questions are asked and should use the conversation (as opposed to the individual interview) as the unit of analysis. Like participant observation, focus groups afford the opportunity to observe interaction among individuals and require that moderators surrender some power, at least, to the group. Unlike participant observation, though, focus groups produce large amounts of data on the researcher's specific interest in a short period of time. Two criteria, then, help researchers discern if focus groups are a good methodological choice for them relative to these closely aligned approaches: Would the research project be better off with the additional individual-level data acquired from interviews (than the group-level conversation data from focus groups)? Would the research project be better off with the contextual information afforded by naturally occurring events witnessed during participant observation (than the focused, yet less naturalistic, data gathered during a focused group conversation)?

Strengths and Limitations

As with all research methods, focus groups have both strengths and limitations. Strengths of this approach include how groups provide for exploration and discovery (to learn more about ideas or people who are poorly understood), context and depth (to discover the background behind thoughts, experiences, and differences), interpretation (to uncover how things are as they are and how they got that way), and sharing and comparing across participants (to offer and sharpen ideas and perspectives through the group process). In all of these instances, researchers benefit from listening and learning from a conversation across individuals.

The limitations of focus groups are similar to those of other qualitative methods and stem from the inherent flexibility of the group interview format. Focus groups have been critiqued for not yielding generalizable findings (as they typically employ small samples—three or four focus groups—that rarely are selected using probability sampling techniques). Focus group procedures can be viewed with suspicion, as questions are not asked the same way each time with regard to ordering or phrasing, and responses are not independent (and thus the unit of analysis becomes the group). Focus group data can be nettlesome, as the results are difficult to quantify and conclusions depend on the interpretations of researchers.

Types

Many focus group experts acknowledge that these group conversations can take several forms. Perhaps the most common type is a *full group*, in which a group of 6 to 10 participants (who are recruited because they share at least one commonality of relevance to the researcher) are gathered together and led by one moderator (possibly with the aide of a facilitator who helps with procedural aspects of the focus group) for 90 to 120 minutes. Other types of groups involve at least one derivation from this approach. *Two-way focus groups* allow for one group to watch another focus group and to discuss the observed interactions and conclusions.

Dual moderator focus groups feature two moderators in which one guides the conversation and another makes sure that all desired topics are covered. *Dueling moderator focus groups*, unlike dual moderator groups, feature two moderators that encourage these two leaders to intentionally take opposite sides on the issue under discussion (and then watch the conversation that emerges as a response from the group). *Respondent moderator focus groups* invite one or more of the participants to act as the moderator on a temporary basis in order to add another layer of perspective to the conversation. *Client participant focus groups* enable one or more clients of the group to engage in the discussion, either covertly or overtly, to add their desired perspective to the discussion. In addition to these takes on the standard format, focus groups can also feature fewer participants (*mini-groups* are composed of four or five participants), *teleconference focus groups* encourage interaction over a telephone or network, and *online focus groups* rely on computers and Internet networks to facilitate a conversation between participants.

Preparation Steps

Focus group preparation involves the following steps. First, researchers must decide what kind of people should be studied, how many groups should be conducted, what type of group plan should be adopted for each group type (e.g., per group recruited on at least one variable of interest to the researcher), and how participants will be recruited or sampled. Although it is rarely used, a probability sampling design can be used to sample participants. Often recruitment is done via telephone. It is recommended that at least three to four groups per group type be conducted.

Deciding upon how large an incentive should be offered is an important decision as offering too low an incentive will increase recruitment costs (because many people will refuse), possibly to the level where it would have been cost-effective to start out with a larger incentive in the first place. In deciding about the amount of incentive, consideration should be given to travel time and travel cost for the participants to come to the focus group facility.

Second, researchers should decide on a moderator. Moderators should not be of an age, ethnic background, or gender that might inhibit group members from participating in the conversation; must be comfortable with the reality that participants will have varying levels of comfort in speaking in front of the group; and must be mindful of their nonverbal behaviors (so as not to affect the group conversation).

Third, researchers should decide upon the desired level of structure for the group and on the scope of the protocol (also called a questioning route, topic guide, or discussion guide). Generally speaking, the focus group protocol should feature 10 to 12 questions for a 90-minute group.

Fourth, basic logistical issues of recruitment and compensation of participants must be considered. Participants should be selected on a variable of interest to the researchers, and efforts must be made to ensure that these individuals possess the desired background knowledge or experience to yield valuable data for the project (while also not having so much experience that they will silence other members of the group). Researchers should create careful screeners that outline the desired characteristics of group members. Researchers can also attempt to overrecruit participants for each group and then, after the participants have arrived to the location, selectively tell potentially problematic group members that the group is overenrolled (and thank such members and send them home with any promised compensation). While it might seem wasteful to pay an individual for not participating in the group, it can be far more costly to keep that individual in the group if there is a risk that he or she will threaten the group dynamics. It also is a good policy to invite one or two more people to participate than may be needed because of no-shows.

Fifth, moderators should attend to the best practices of facilitating the session. Sessions should be held around a round (or oval or rectangular) table. The moderator should be in a position to see all participants to help control the flow and content of the conversation, and if the session is being video recorded, the recording device should be behind the moderator. Name cards (with first names only) can be placed around the table to assign the participants to specific places and to facilitate the recognition of names through the conversation and during potential transcription.

Sixth, focus group data can be obtained in a variety of ways. Full transcription is the most costly but the most accurate means of generating a record of the group conversation and lends itself to myriad ways of content analyzing it. Other options include tape-based coding (in which researchers take notes from audio- or videotapes searching for pre-established themes); note-based coding (in which researchers rely on their field notes; in such instances the same researcher and moderator should be employed to ensure consistency across the field notes); and memory-based coding (recommended only for experienced moderators who have a strong sense of what they are looking for in group conversations).

Data Analysis and Reports

Most of the focus group analysis in the field of marketing is impressionistic and strives to understand and explain the motivations behind people's attitudes, responses, and feelings. Scholarly research advances a few more systematic approaches to analyzing data. The *grid technique* encourages scholars to create a table to summarize the responses of each group per question in order to compare answers per item across groups. Basic *coding techniques* advise researchers to note all mentions of a given code (derived from the research questions or topic of interest behind the project), whether the code was mentioned by all participants, and whether the code appeared in all of the groups conducted. *Indexing* is a procedure in which all extracts of data that are important to a theme, topic, or hypothesis are marked (and then the coder assigns index codes that allow researchers to attend to both themes in the data as well as the context of such themes).

Although there are no hard and fast rules, focus group reports generally include the following types of information: (a) a cover page, (b) an executive or top line summary, (c) a table of contents, (d) purposes and procedures, (e) results and findings, (f) summary of conclusions, (g) recommendations, and (h) an index. Most reports also feature a balance of direct quotations from the participants and a summary of the discussion.

Ethical Considerations

There are several ethical considerations with focus groups. One consideration involves judging if participants are at risk. Researchers can protect participants by providing them with a statement of informed consent (e.g., clarifying that participants are over 18 years of age and aware that they are participating in a study). Another ethical risk involves attending to basic privacy issues. Researchers can protect the privacy of their participants by restricting access to information that reveals their identities, for example, protecting identifying information, referring to participants only by their first names or pseudonyms, protecting access to the transcripts and tapes of the focus groups, removing or modifying identifying information on transcripts, protecting them against the sponsor of the group, and encouraging the moderator to remind participants not to overdisclose during group discussions. Yet another risk lies in the discussion of potentially stressful topics. Researchers can protect participants against stress by emphasizing how participation is voluntary, setting boundaries for the group conversation, preparing an information sheet with experts and sources in case the discussion raises issues the participants want to pursue in greater detail, and trying to include someone on the research team who has experience with germane areas of stress.

Forced Choice

Forced choice refers to a specific format for response options in survey questionnaires. In a forced choice format, respondents are not given a specific option to reflect a "nonresponse" type choice, such as "no opinion," "don't know," "not sure," or "not applicable." Respondents must select a response choice that provides a specific answer to the survey item.

The elimination of item "nonresponse" choices in the forced choice format increases the number of survey records with responses that are usable for analysis. Survey designers use the forced choice format to encourage respondents to provide an actual response. The forced choice format is common in key survey questions, especially qualifier (screener) questions. For example, question items about household income and number of household members might use forced choice response formats in a survey of households below the poverty level so as to make certain that everyone provides an answer to allow the researchers to determine whether a given respondent is eligible or ineligible for the survey.

Interviewer-administered surveys sometimes use a more flexible version of the forced choice format where the item nonresponse choices are available for the interviewer to see, and thus to code, but are not explicitly read to respondents. This approach allows respondents to give these types of responses but only if they take the initiative to volunteer one of them. At the other extreme, some surveys require a valid response and terminate or discard the interview rather than accept a nonapplicable response.

As an example, response choices on a satisfaction survey might include a response scale of 1 to 7 where 1 is very dissatisfied and 7 is very satisfied. With a forced choice format, there would be no response choice to indicate a lack of opinion (though a response choice of 4 would indicate a neutral opinion). Some surveys will use a forced choice format with an even number of responses, such as a scale of 1 to 6 with no true midpoint included among the response options, rather than 1 to 7 in which 4 is the midpoint. This forces respondents to provide a response with a clear direction.

Although useful for some survey items, the forced choice format has disadvantages. The primary disadvantage is that it can contribute to measurement errors, nonresponse errors, or both. Whereas the forced choice format can discourage respondent laziness and encourage them to provide a thoughtful response, the requirement of a response can encourage respondents to answer a question in a way that does not truly reflect what they think and feel. Some respondents really may not know how they feel about an issue or may not know the information requested, and forcing a response would result in the collection of erroneous data. Also, by "forcing" a response by not providing a respondent a valid response option that indicates that she or he does not have an opinion or does not care to provide an answer to a specific question, the researcher may be increasing the chances that some respondents will be frustrated and offended and thus terminate their participation before they complete the questionnaire.

Frame

A frame is used to identify elements in the population. Elements are the fundamental unit of observation in the survey. A frame may look very different depending on how the population of interest is defined and how its elements are defined. A well-defined appropriate frame is essential to the sampling process, the development of weights for use in analyses of survey data, the minimization of coverage error, and the understanding of what coverage error may exist. This entry describes the basic concept of a frame; the impact it has on sampling, weighting, and coverage; and how it is developed in relation to the survey population and the survey sample. It also discusses several commonly used frames and their specific issues.

A major goal of most surveys is to describe a specific population. For example, the U.S. government conducts two surveys specifically to estimate the rate of unemployment in the country each month: the Current Employment Statistics program (a survey of business establishments) and the Current Population Survey (CPS; a survey of people). Each month, the U.S. Census Bureau interviews a sample of people for the CPS. However, selecting that sample is difficult as there is no accurate, up-to-date list of people in the United States with contact information. Without such materials, it is difficult to draw a sample. But the U.S. Census Bureau can construct a frame of housing units in the country using various sources (the decennial census, building permits, etc.). Therefore, the U.S. Census Bureau defines the survey population as people living in housing units. This revised definition of the survey population is important because it allows for a better frame to be constructed. Of course, a disadvantage is that the homeless are not included, but this is judged to be acceptable to meet the goal of this survey.

Among the domains of research that use statistical techniques, survey research is unique in assigning so much importance to the source of sample units. Whereas most statisticians view sample units as a way to describe a process of interest, survey statisticians view sample units as a way to describe a population of interest. Other statisticians would only be interested in elements that are missing from the frame if the missing elements were informative of the process under study. For example, in sampling to study the effect of a certain drug, if the sample had no women, this would be a concern only if women reacted differently from men to the drug under study. The survey statistician may not be interested in whether women reacted differently to the drug but would want women proportionally represented in the sample frame so their role in the population could be described.

From Population to Frame

Surveys are often interpreted as applying to a general population, without any specific statements about time or relatively small subpopulations being excluded. This population, to which results are inferred, is often too simply defined for conducting a survey.

The next step for a survey researcher is to define a target population. This is often similar to the inferential population (population of inference) but excludes some elements that would be very difficult or costly to include on the frame. For example, many surveys exclude the homeless in order to use a housing unit frame, and many surveys exclude households without telephone service to use a telephone-based frame. Elements in the inferential population but missing from the target population should be easy to describe and note in the survey documentation. The target population can be thought of as the ideal survey frame.

The survey frame is an attempt to list the units in the target population. The frame may be a list of units. For example, a large company may conduct a survey of its employees, and the list may be readily available. Alternatively, the frame may be a set of procedures, materials, or both, to generate the sample. This is the case for telephone surveys that use random-digit dialing in the United States: A computer generates random 10-digit phone numbers using known working area codes (first three digits) and exchanges (next three digits). All elements of the target population should be represented on the frame, giving each element a nonzero probability of selection for inclusion in the survey sample. This probability of selection is calculated using the information on the frame and details about the sampling procedure. Because probability of selection is used in developing analysis weights, the accuracy of the survey frame (and complete documentation of it) is vital to drawing valid conclusions from data collected by the survey.

Differences between the target population and the survey frame are often referred to as coverage error. Elements that are missing from the survey frame are sources of survey undercoverage (e.g., a new employee missing from the list, telephone numbers in a new area code). Elements may also be on the survey frame more than once, leading to overcoverage (e.g., perhaps an employee with two names or a household that has two telephone numbers). Generally, undercoverage is a bigger problem for the survey researcher as identifying missed elements is difficult and costly. Overcoverage can usually be detected on the frame and fixed before sampling (e.g., removing recently terminated employees, removing business phone numbers), or detected during the interview and fixed by having good survey procedures (e.g., asking about the employee's status, asking about other phone numbers at the household).

Survey frame elements may need to be "mapped" to target population elements. For example, the CPS uses households as the frame elements, but the target population consists of people. In the CPS, when a household is selected for the survey, all the eligible residents of that household are selected for the survey, and one "reference" person answers the questions for the entire household. Other surveys treat the household as a primary sampling unit in a cluster sampling approach and subsamples only one person in each household.

Often, complex sampling procedures can reduce the burden of frame development. The CPS uses a stratified multi-stage cluster sampling approach: Within each state, the CPS samples counties, then blocks (within the sample counties), then households (within the sample blocks). In locations where address lists are incomplete, an area frame approach is used according to which lists of housing units within each block are required for the final stage of sampling. By selecting only a subset of counties, and then only a subset of blocks within those counties, the CPS only has to list housing units within the selected blocks.

Some Common Frames

One of the most common frames is a simple list of population elements. This type of frame is often used in surveys of well-defined populations, such as employees of a company or students at a school. As mentioned previously, use of lists can be combined with a complex sampling scheme, for example, by using a list of elementary schools in an area for the first level of sampling and then using lists of students within only the selected schools. Often, the successful use of a list (or lists) depends on the quality of the source of the list and having a relatively short amount of time between the list generation and survey data collection.

Beyond lists, there are two very common types of frames of households. An area frame consists of sampling defined geographic areas, then listing the housing units in those areas, then taking a sample of those housing units, and finally conducting the survey (usually with in-person interviewers). Area frames are used widely by large-scale surveys sponsored by governments because they provide good coverage by not depending on telephone service and not relying on potentially flawed lists (that may be out of date or incomplete). The major drawback to area frames is the cost associated with the in-person listing and face-to-face interviewing. Because of the high costs, multistage clustered sampling is often used, which reduces the precision of survey estimates (unless the sample size can be increased).

The second common type of household frame is telephone based. Telephone frames work well when (a) the vast majority of households in the population have telephone service and when (b) the exclusion of households that do not have telephone service is not expected to affect survey statistics. For example, one would expect fewer coverage problems when conducting a market research survey in the United States with a telephone frame compared to conducting a health survey in a developing nation. Random-digit dialing (RDD) in the United States uses a relatively simple frame: Generate a 10-digit number that is a valid telephone number (does not have a 0 or 1 in the first or fourth positions, among other criteria). So-called list-assisted RDD frames attempt to reduce the number of nonworking and business telephone numbers by first sampling area codes and exchanges that are known to have household telephone numbers (by using publicly available telephone books). This leaves only the last four digits to be randomly generated.

Frames of business establishments are often quite different from those of households. Lists are generally easily available from public directories or tax records. Many governments, including the U.S. government, maintain business registers. An important consideration for business surveys is the unit of analysis, as businesses can be thought of at different levels. At the establishment level, physically separate establishments are the basic elements of the survey. At the enterprise level, entire corporations are the basic elements of the survey, whether they consist of one establishment or thousands of establishments. A closely related decision is how to handle complex relationships in the business world (wholly owned subsidiaries, joint ventures, partnerships, etc.). Additionally, surveys of businesses often use sample designs that require measures of size on the frame. A commonly used measure of size in government business surveys is revenue reported on tax records.

Frequency Distribution

A frequency distribution is a tabular representation of a survey data set used to organize and summarize the data. Specifically, it is a list of either qualitative or quantitative values that a variable takes in a data set and the associated number of times each value occurs (frequencies).

The frequency distribution is the basic building block of statistical analytical methods and the first step in analyzing survey data. It helps researchers (a) organize and summarize the survey data in a tabular format, (b) interpret the data, and (c) detect outliers (extreme values) in the survey data set.

For example, the following are the scores of a group of 25 students on a final math exam: 83, 75, 95, 100, 83, 85, 85, 83, 98, 89, 84, 65, 95, 98, 80, 95, 89, 75, 65, 80, 89, 80, 75, 98, and 69. The students' math scores are not listed in any order to make sense of the data or to help provide a descriptive and summary statement about the scores. From these data, as they are displayed here, it is difficult to answer questions such as the following: How many students had math scores between 80 and 90? What percentage of students had a score of 70 or less? To answer the first question, the researcher has to count up all the scores between 80 and 90. How difficult or easy this task is depends on how many math scores the researcher has. To answer the second question, the researcher needs to know how many math scores are 70 or less in the data compared to higher math scores.

To summarize this data set, the researcher needs to put the data in some sort of logical order and tally the number of times each value occurs. This simple frequency distribution is called *raw* (or *ungrouped*) *frequency distribution*. The necessary steps in creating the raw frequency distribution are as follows:

- Identify the lowest and highest variable values in the data set.
- List in ascending order all single values in the data set from the lowest to highest (e.g., see the column labeled "Score" in Table 1).
- Tally the number of the times the variable values occurred (e.g., see the column labeled "Tallies" in Table 1).
- Count the number of tallies for each variable value (e.g., see the column labeled "Frequency" in Table 1).

Thus, the simple frequency distribution of the listing of the 25 students' math exam scores will look like Table 1. (Of note, this table does not contain any percentages, which could be added to the table and are what is called *relative frequency*.)

In some situations, this simple frequency distribution tabulation is unpractical, even impossible, or simply not needed by the researcher, for instance, when the variable under consideration has continuous values with decimal points (e.g., 88.5, 75.6, 94.4) instead of discrete values (e.g., 88, 75) or when the number of possible data points (values) is too large to construct such simple frequency distribution.

Table 1 Simple frequency distribution of math scores

Score	*Tallies*	*Frequency*	*Cumulative Frequency*
65	//	2	2
69	/	1	3
75	///	3	6
80	///	3	9
83	///	3	12
85	///	3	15
89	///	3	18
95	///	3	21
98	///	3	24
100	/	1	25
Total		25	

In such situations, a different kind of tabulation, based on the range (interval) of values instead of a set of single values, is used. The data values are grouped into different intervals and the number of data values that belong to each interval is determined. Thus, instead of listing single variable values and tallying the frequencies for each listed value, as was done in creating the raw frequency distribution in Table 1, the researcher could use ranges (intervals) of variable values and count the frequencies for each interval. This tabulation scheme is called *grouped frequency distribution*.

The steps involved in creating the grouped frequency distribution are as follows:

- Find the range of the data, which is the difference between the largest and smallest variable value. For the math scores example, the data range is $100 - 65 = 35$.
- Find the interval width. Divide the range from step 1 by the desired number of intervals. For the math scores example, if the researcher desired 5 intervals/groups, the interval width is $35/5 = 7$, that is, 7 is the number of numeric values in an interval.
- Determine the starting point of the lowest interval. For the math scores example, the smallest score is 65 and the starting point of the lowest interval should begin with 65.

Table 2 Grouped frequency distribution of math scores

Score Intervals	*Tallies*	*Frequency*	*Cumulative Frequency*
65-71	///	3	3
72-78	///	3	6
79-85	/////////	9	15
86-92	///	3	18
93-100	///////	7	25
Total		25	

- Determine the ending point of the lowest interval. This step involves adding the interval width to the lower boundary and subtracting 1 $(65 + 7 - 1 = 71)$. Thus, 71 is the value at which the lower interval should end.
- List all the needed equivalent intervals to include the largest value in the data set. For the math scores example, list 65–71, 72–78, . . . , 93–100.
- Tally the values within each interval.
- Indicate the frequencies from the tallied values.

The grouped frequency distribution of the previous listing of the 25 students' exam scores will look like that shown in Table 2.

FRUGing

When a survey is not conducted to gather valid information but instead to stimulate fund-raising for a cause or organization, this practice is know as FRUGing ("fund-raising under the guise of research") and rhymes with "tugging." In a FRUGing solicitation, the answers a respondent gives to the putative survey are of lesser or no importance compared to the main goal of eliciting donations.

The effect of FRUGing on the survey enterprise is a deleterious one. On average, response rates to surveys have been declining. Reasons for this are varied but include the unethical practice of conducting false surveys for an ulterior motive; FRUGing is one such practice.

The full extent and effects of FRUGing calls, mailings, and interviewing is difficult to estimate, although empirical research on nonresponse in Canada has indicated that one quarter of citizens have received a FRUGing call or mailing. Market and survey research associations in several countries have taken the lead in public education, advocating for anti-FRUGing legislation and confronting organizations that conduct FRUGing.

FRUGing solicitations are different from legitimate surveys in that the questions are not designed to accurately understand respondents' beliefs and perceptions but rather to facilitate and lead up to a request for a donation. For that reason, FRUGing questions may be overly brief, simplistic, and often are biased in favor of the issues that are important to the organization behind the FRUGing and assumed to be important to those who are being "FRUGed" by that organization.

For example, imagine a FRUGing solicitation aimed at raising money to combat climate change that might ask the following question: *How much more could you do to fight the soon-to-be catastrophic and life-changing effects of global warming? (1) A little more, (2) A good deal more, or (3) A lot more*. This type of question wording obviously attempts to predispose the respondent to positively respond to the later solicitation for a donation to combat global warming. It also uses dramatic wording to play upon the concerns of those who are being FRUGed.

Because the sample that is "surveyed" during a FRUGing solicitation is likely to have strong opinions and to be skewed about the topic of the survey, any use of the data from the survey can result in intentionally misleading or biased findings, which the funding organization may then attempt to use to influence public opinion or public policy.

Survey researchers who find themselves in a situation where they are encouraged to attach a solicitation to a survey should take the opportunity to educate their client on the unethical aspects of this practice and the research consequences of such an action. Furthermore, in addition to being an unethical practice, FRUGing telephone calls are also illegal in the United States under the Federal Trade Commission's 2003 Telemarketing Sales Rule.

In Canada, FRUGing is known as SUGing ("soliciting under the guise of research"), leading to confusion in the United States, the United Kingdom, and continental Europe, where SUGing is defined as "selling under the guise of research."

F-TEST

An *F*-test is any statistical hypothesis test whose test statistic assumes an *F* probability distribution. The *F*-test is frequently associated with analysis of variance (ANOVA) and is most commonly used to test the null hypothesis that the means of normally distributed groups are equal, although it can be used to test a variety of different hypotheses. The *F*-test was devised as an extension to the *t*-test: *F* is equal to the squared value of *t* ($t^2 = F$). Although the *F*-test produces the same information as the *t*-test when testing one independent variable with a nondirectional hypothesis, the *F*-test has a distinct advantage over the *t*-test because multiple independent groups can easily be compared. Survey researchers often use the *F*-test because of its flexibility to compare multiple groups and to identify whether the relationship they are studying among a set or combination of independent variables has occurred by chance.

For example, if a survey researcher hypothesizes that confidence in government varies between two groups of persons with different levels of education (e.g., those with a college degree and those without a college degree), a *t*-test and an *F*-test would produce the same results. More often, one is interested in comparing multiple or subsets of independent variables. The *F*-test gives researchers the ability to examine the independent (main) effects of education and the combined (main) effects of a set of socioeconomic status (SES) variables (e.g., education, income, and occupation) as well as the potential effects of the interaction among these variables on confidence in government.

F-tests are also often used to test the effects of subsets of independent variables when comparing nested regression models. For instance, the researcher could compare the *F*-tests from a model with only the SES variables, a model with a set of variables measuring satisfaction with government services (e.g., police, fire, water, and recreation), and an overall model with both sets of variables to determine whether, as a group, the SES and government services variables make a statistically significant contribution to explaining differences in confidence in government.

The *F*-test compares the observed value to the critical value of *F*. If the observed value of *F* (which is derived by dividing the mean squared regression by the mean squared error) is larger than the critical value of *F* (obtained using the *F*-distribution table), then the relationship is deemed statistically significant and the null hypothesis is rejected. There are two types of degrees of freedom associated with the *F*-test: The first is derived by subtracting 1 from the number of independent variables and the second by subtracting the number of independent variables from the total number of cases. In output tables from statistical software packages, such as SPSS, SAS, or STATA, the *F* value is listed with the degrees of freedom and a *p*-value. If the *p*-value is less than the alpha value chosen (e.g., $p < .05$), then the relationship is statistically significant and the null hypothesis is rejected. It is important to note that the *F*-test is sensitive to non-normality when testing for equality of variances and thus may be unreliable if the data depart from the normal distribution.

G

Gallup, George (1901–1984)

One of the pioneers of the polling field in the United States, George Gallup became the living personification of the industry during the first half century of its development. He was a trained research methodologist who also had a flair for promotion, and he parlayed both into a series of the most successful polling firms in the United States. As an undergraduate, he was interested in journalism and became a student reporter and editor. His interest in, and understanding of, the newspaper business was instrumental in the development of his polling business.

George Gallup was born on November 18, 1901, in Jefferson, Iowa. He earned three degrees from the University of Iowa, including a Ph.D. in psychology. He had a strong interest in audience and attitude research, and his dissertation involved the development of a new technique for measuring newspaper readership. This work resulted in academic positions at Drake University and Northwestern University, but in 1932 he moved to New York to join Young & Rubicam as its research director and also to serve on the journalism faculty at Columbia University. His early work in New York and Princeton focused on market research designed to improve the quality of newspapers and magazines based upon the preferences of their readers, and by 1937 he was working full time in the advertising research business.

Even at this early stage of his career, he developed an interest in social and political issues as well as elections. This started when he was a student and was enlisted to help his mother-in-law run for statewide office in Iowa. She won her first election by the narrowest of margins, but Gallup began to survey her constituents and used the resulting information to help her build increasing electoral margins. He was known as a person of high ethical standards, and as his political polling work expanded and became more public, he stopped voting in presidential elections so his published polls would be free of any allegations of personal preference or bias.

During this period, he formed the American Institute of Public Opinion, from which he began to conduct national surveys of public opinion and produce a newspaper column. He also founded the Audience Research Institute where he did work on the response of film audiences to new releases, including the development of an innovative method to measure consumer reactions to films and new products at the Mirror of America, a converted theater in Hopewell, New Jersey. He became a vice president of Young & Rubicam and served in that capacity until 1947 when he turned full time to the other businesses he had developed. He managed three firms in Princeton, New Jersey. The American Institute of Public Opinion conducted the Gallup Poll and produced three syndicated newspaper articles a week from it. A second firm, Gallup and Robinson, conducted market research for a number of clients. In addition, a third firm, the Gallup Organization, conducted special surveys tailored to the interest and needs of individual clients.

Gallup catapulted to fame in 1936 because of his belief that he could apply face-to-face interviewing with well-designed quota samples to produce better estimates of election outcomes than could *The Literary Digest*. He was so confident of the superiority of these methods that he offered his main client, *The Washington Post*, a money-back guarantee if he did not outperform the magazine's mail survey. When he proved to be more accurate than *The Literary Digest* in correctly predicting a Roosevelt victory in 1936, his business was off and running.

Gallup had good results from his 1940 and 1944 pre-election polls, but disaster struck in 1948 when he and several other pollsters estimated that Thomas Dewey would beat Harry Truman. A number of factors were identified as contributors to the error, including quota sampling and the use of mailed questionnaires to interviewers and their return by mail, which meant stopping interviewing too early. Gallup resolved to devote additional time and resources to improving the methodology of pre-election polls. In addition to adopting probability sampling methods, the Gallup Organization also pioneered techniques for identifying likely voters; these techniques became widely used in the polling industry. The Gallup Organization never made an incorrect call of the winner in an American presidential election after 1948, and it had one of the most accurate records of estimation in the industry.

At heart, Gallup was a populist who believed in the civic function of polls and their ability to serve as plebiscites between elections. He was an advocate for measuring the "voice of the people" and making it known to elected officials and other policy makers. From the start, he wrote extensively on the role and function of public polls in a democratic society, starting with *The Pulse of Democracy: The Public Opinion Poll and How It Works*. His written work promoted the polling method as much as specific findings, and it generally served to propel the development of the field by increasing its visibility and potential.

In addition to his central role in the American polling industry, Gallup also developed a network of foreign associates under the umbrella of the Gallup International Research Institutes. They were at one time responsible for conducting polls in more than 70 countries overseas. He was involved in the founding of the Roper Center at Williams College and in the National Council of Public Polls. He received numerous honors for his work including the AAPOR Award from the American Association for Public Opinion Research and election to the Advertising Hall of Fame and the Market Research Hall of Fame, as well as several honorary degrees. He died in Tschingel, Switzerland, on July 27, 1984.

Gallup Poll

The Gallup Poll is the longest continuous measure of public opinion in the United States, having been conducted for more than 70 years, and is the most widely recognized brand name in the field of survey research.

On Sunday, October 20, 1935, George Gallup officially launched his "scientific" polling operation nationwide with "America Speaks: The National Weekly Poll of Public Opinion." About three dozen newspapers carried his first release, including *The Washington Post*, whose editor heralded the event by hiring a blimp to pull a streamer over the city to announce the new column. Gallup called his operation the American Institute of Public Opinion, which he located in Princeton, New Jersey, where he also lived. To attract subscribers, he made a money-back guarantee that his poll-based prediction of the 1936 presidential election would be more accurate than that of *The Literary Digest*, which had correctly predicted Herbert Hoover's win in the 1928 election within less than one percentage point of the election outcome. Gallup made good on his promise, predicting Franklin Delano Roosevelt would beat Alf Landon, while the *Digest*'s final poll predicted a Landon landslide.

Gallup kept the name American Institute of Public Opinion for more than 20 years, but within a very short time, his poll was known simply as the Gallup Poll. He, too, used that name, giving souvenir cards to cooperative respondents with the announcement, "You have been interviewed for THE GALLUP POLL—The American Institute of Public Opinion."

The Gallup Poll increased its newspaper subscribers substantially over the years, though it suffered a minor setback after the 1948 election, when Gallup and almost all of the other scientific pollsters of the day predicted Thomas Dewey to beat Harry Truman. By the 1950s, Gallup had more than 200 newspaper subscribers. In 1963, he encountered his first serious competitor, Louis Harris, who began syndication of his own column. For almost a decade and a half, the Harris Poll and the Gallup Poll were the two competing sources for news about American public opinion.

In the 1970s, the major news media organizations began forming their own public opinion polls, and by the 1980s subscriptions to the Gallup Poll had fallen considerably. Gallup died in 1984, and 4 years later, his organization was bought by a small research company in Lincoln, Nebraska, called Selection Research, Inc. (SRI). By this time, Gallup polls were rarely covered in the national news media. The president and chief executive officer of this new SRI-owned Gallup Organization negotiated with CNN to form a media partnership to cover the 1992 election campaign season. They included CNN's occasional polling partner, *USA Today*, and for the first time in Gallup's history, the poll was no longer completely independent. But the new CNN/*USA Today*/Gallup Poll gained what Gallup had mostly lost after the emergence of the media polls: immediate nationwide dissemination of Gallup Poll results.

The partnership worked to all the partners' satisfaction in 1992 and was renewed several times. In 2006, the Gallup Organization refused to renew the partnership with CNN, resulting in a messy public break-up. Gallup continues to partner with *USA Today*.

In the early years of polling, George Gallup supported researchers from around the world who were interested in establishing their own polls. He freely allowed the use of his name, if researchers thought it might help gain credibility in their own countries. In 1947, he helped found the Gallup International Association, originally with 11 members and him, though today the organization has close to 60 members and interviewing capabilities in more 100 countries. That generosity posed problems for the SRI-owned Gallup as it expanded its polling business overseas. In many countries, the U.S.-based Gallup Organization could not use "Gallup Poll," because the name was owned, or claimed, by another polling organization. In several countries, the U.S.-based Gallup Organization was able to buy back its name or get court orders to allow it to legally reclaim sole ownership of the "Gallup Poll" name. But the Gallup International Association remains a viable organization. A Gallup Poll in the United States clearly refers to the original operation founded by George Gallup. But reports from "Gallup International," and even from a "Gallup Poll" in some countries, are not necessarily from the U.S.-based Gallup Organization.

Gatekeeper

A gatekeeper is a person who stands between the data collector and a potential respondent. Gatekeepers, by virtue of their personal or work relationship to a respondent, are able to control who has access, and when, to the respondent. Furthermore, they may be encountered on both field (in-person) and telephone data collection surveys. They may also be encountered in mail surveys in which a respondent's material must be sent to, or in care of, another individual for distribution to the respondent (e.g., sending materials to a parent for distribution to a respondent away at college or in the military, or sending materials to an employer for distribution to sampled employees).

Gatekeepers can take many forms, including guards or doormen at secured residential or business complexes; secretaries, administrative assistants, or office managers in businesses; family members, housekeepers, and so forth. For studies in which children are the intended respondents, parents may be considered gatekeepers in that their consent must be obtained for the child's participation in the study.

A single respondent may have multiple gatekeepers that must be contacted by the data collector. In a secured apartment complex, the security guard may prevent access to an individual apartment unless the data collector has obtained permission from the complex manager. The latter is now a second gatekeeper who must be convinced to grant access to the selected housing unit. If successful there, the data collector may then encounter a third gatekeeper at the housing unit in the form of a parent, other family member, or housekeeper.

It is important to consider that a single gatekeeper may control a data collector's access to not just one but many respondents. For example, in the case of an area probability sample, a security guard at a large apartment complex may prevent access to multiple sampled housing units. An establishment survey wishing to sample multiple employees at a large company may have an administrative assistant standing in the way of gaining access to the director of human resources for the company (who could also be considered a secondary gatekeeper).

Regardless of their relationship to a respondent, gatekeepers must be successfully yet carefully negotiated in order to further the research objectives. Data collectors must walk a fine line between giving gatekeepers enough information about the survey and its sponsorship to motivate them to grant access to the respondent while, at the same time, not revealing sensitive information that could violate the respondent's privacy or reflect negatively on the person. Further, data collectors must be cognizant and respectful of all local laws and regulations regarding trespassing, solicitation, and so on.

Data collectors must assess each controlled access situation and note as many relevant details as possible. For example, when refused entry by a security guard, data collectors can note the guard's name or demographics and then plan to return when another, possibly more cooperative guard is on duty. They can check locked building entrances at other times of the day when they might be open to the public. They can also walk around gated communities to determine if a pedestrian entrance may be open. Data collectors can honk a vehicle horn at a single family housing unit when an unleashed dog prevents access to the front door. If at home, the resident will likely come to the door in response.

If study protocols permit, data collectors can ask the security guard or complex manager, in lieu of granting access to the housing units, if they would distribute a study brochure or data collector name and number to the selected housing units. If asked, they may also identify which, if any, of the selected housing units are currently vacant.

As society becomes increasingly security-minded in this age of identity theft, terrorism, and crime, the presence of gatekeepers will be encountered more and more frequently. It is critical, therefore, that researchers recognize this trend, as well as the potential effect on nonresponse that gatekeepers represent. In doing so, researchers should include in their procedural manuals and interviewer training programs material on how to deal effectively with gatekeepers. Specific instructions should be included regarding what information may be shared with gatekeepers about the study and what cannot be shared in order to protect respondent confidentiality. Strategies and tools for dealing with gatekeepers should be developed, such as informational brochures suitable for gatekeepers, main office/research director contact information, letters from the research director to the gatekeeper, and so on.

General Social Survey (GSS)

The National Data Program for the Social Sciences of the National Opinion Research Center (NORC), University of Chicago, is a social indicators and data diffusion program. Its basic purposes are (1) to gather and disseminate data on American society in order to (a) monitor and explain societal trends and constants in attitudes, behaviors, and attributes, and (b) examine the structure and functioning of society in general and the role of various subgroups; (2) to compare the United States to other societies in order to place American society in comparative perspective and to develop cross-national models of human society; and (3) to make high-quality data easily and quickly available to scholars, students, and others. These goals are accomplished by the regular collection and distribution of the NORC General Social Survey (GSS) and its allied surveys in the International Social Survey Programme (ISSP).

Origins

Two social science movements in the 1960s spawned the GSS. First, the social indicators movement stressed the importance of measuring trends and of adding noneconomic measures to the large repertoire of national accounts indices. Second, scholarly egalitarianism was advocating that data be made available to scientists at all universities and not restricted to elite senior investigators at large research centers. In 1971, these ideas were presented together in a modest proposal to the National Science Foundation (NSF) for "twenty-some questions" that called for the periodic asking of items on national samples with these data immediately distributed to the social science community for analysis and teaching. Approval from NSF plus supplemental funding from the Russell Sage Foundation spawned the first GSS in 1972.

Growth

From 1972 to 2004, the GSS conducted 25 independent, cross-sectional, in-person surveys of adults living in households in the United States, and in 1982 and 1987, it carried out oversamples of African Americans. There are a total of 46,510 respondents. During most years until 1994 there were annual surveys of about 1,500 respondents. Currently about 3,000 cases are collected in a biennial GSS.

Additionally, since 1982 the GSS has expanded internationally. The cross-national research started as a bilateral collaboration between the GSS and the Allgemeine Bevölkerungsumfrage der Sozialwissenschaften (ALLBUS) of the Zentrum für Umfragen, Methoden, und Analysen in Germany in 1982 and 1984. In 1984, they joined with the British Social Attitudes Survey of the National Centre for Social Research and the National Social Science Survey at Australian National University to form the ISSP. Along with institutes in Italy and Austria, the founding four fielded the first ISSP in 1985. ISSP surveys have been collected annually since that time, and there are now 41 member countries (the founding four plus Austria, Belgium, Brazil, Bulgaria, Canada, Chile, the Czech Republic, Cyprus, Denmark, Dominican Republic, Finland, France, Hungary, Ireland, Israel, Italy, Japan, Korea (South), Latvia, Mexico, the Netherlands, New Zealand, Norway, the Philippines, Poland, Portugal, Russia, Slovakia, Slovenia, South Africa, Spain, Sweden, Switzerland, Taiwan, Turkey, Uruguay, and Venezuela).

Content

The GSS lives up to its title as "General." The 4,624 variables in the 1972–2004 cumulative data set run from ABANY (legal abortion if a woman wants one for any reason) to ZOMBIES (behavioral medication for children) and have core batteries on such topics as civil liberties, confidence in institutions, crime/violence, gender roles, government spending, intergroup relations, psychological well-being, religion, and work.

The balance of components has changed over time, but currently half of the GSS is replicating core topics, one sixth deals with cross-national topics, and one third consists of in-depth, topical modules. Recent ISSP modules include the environment, gender and work, national identity, and the role of government. Recent topical modules include work organizations, multiculturalism, emotions, gender, mental health, giving/volunteering, altruism, Internet, and genetics. The data sets are available on the GSS Web site.

Research Opportunities

Several important types of research are facilitated by the GSS design. First, the replication of items allows the study of societal change. Moreover, because all surveys and all variables are organized in one cumulative file, researchers do not have to patch together time series from different and often incompatible data sets. By just running the data by YEAR, more than 1,600 trends can be tracked.

Second, replication also means that subgroups can be pooled across surveys to aggregate an adequate sample for analysis. For example, Blacks at about 12% of the population account for about 175 respondents in a 1,500 case sample—too few for detailed analysis. But in the 1972–2004 GSSs there are 6,399 Blacks—more than enough for analysis.

Third, researchers can both track trends and pool cases. For example, Blacks from the 1970s, 1980s, 1990s, and 2000s can be combined to have four time points and still have between 1,216 and 2,208 Blacks in each subsample.

Fourth, the 18 ISSP studies (1985–2005) offer the largest and most accessible body of cross-national social science data available. Moreover, reflecting the GSS's core interest in societal trends, the ISSPs have an across-time component. For example, the role-of-government topic in 1985 was repeated in 1990, 1996, and 2006. Thus, the GSS/ISSP has both a cross-national and across-time perspective.

Finally, the GSS's detailed and extensive set of demographics allows in-depth analysis of background influences. For example, the GSS does not have merely a single measure of education, but eight standard measures: the exact number of years of schooling completed and the highest degree obtained for respondents, mothers, fathers, and spouses. For occupation, the GSS has three-digit census codes, International Standard of Occupation Codes, NORC-GSS prestige scores, and Duncan Socioeconomic Index values for respondents, parents, and spouses.

Impact of the GSS

As the largest and longest-running project of NSF's Sociology Program, the GSS has had a tremendous impact on social science research. The GSS has been used in approximately 14,000 publications, and new usages accumulate at more than 700 per year. Among top sociology journals (*American Journal of Sociology*, *American Sociological Review*, and *Social Forces*), GSS use is second only to the U.S. Census.

The GSS has also had a large influence on college teaching. Millions of students have learned about society and research methodology in courses using the GSS. More than 400 textbooks in sociology, political science, statistics, and other fields utilize the GSS.

The GSS has aptly been described as a "national resource" by the National Academy of Science and as a "public utility for the community at large" (NSF).

The GSS is grounded in the past but growing into the future. It combines replication and innovation, incorporates both the societal change and comparative perspectives, and joins patrician quality standards with plebeian dissemination. Through these synergies it serves the social science communities and others.

GEOGRAPHIC SCREENING

Most surveys target a specific geopolitical area, so that estimates produced from their data can be representative of that area. For some surveys, the area consists of an entire nation, but other surveys aim to produce regional estimates (such as those for states, counties, or zip codes). Thus, such surveys require some sort of geographic screening, or determination that a sampled case falls within the target geography, to establish study eligibility. If the screening is inherent in the sampling design itself, no further information is required. Other studies require additional screening steps, either prior to sample release or during the field period. Decisions about the level of geographic screening for a study arise from the sampling frame to be used.

When the sampling frame for a desired geographic area can be tied clearly to that area, no screening is needed beyond the design of the sample itself. For example, the sampling frame for a mail-based survey is composed of addresses that are known to be within a specific geographic area. Thus, geographic screening is part of the sampling design itself. Similarly, the sampling frame for an area probability sample is, by definition, geopolitically based, and therefore, no additional geographic screening is needed.

Telephone surveys typically use sampling frames that are defined by areas such as the nation as a whole, states, counties, cities, Census tracts, or zip codes. Samples of telephone numbers are generated by linking telephone exchanges to the desired target geography. In random-digit dialing (RDD) surveys of relatively small areas, it is impossible to match exactly telephone numbers with the boundaries of the target area. Researchers must determine whether the level of agreement between sampled telephone exchanges and the geography of interest is sufficient for their purposes or whether further questioning of the respondents to establish their location is warranted. This questioning can be complex and difficult to operationalize, thus leading to errors of omission and commission in which some eligible people are incorrectly screened out and some ineligible people are incorrectly screened in.

Implementation of additional screening steps increases the likelihood that all sample units are within the target geography, though it is likely to increase study costs as well—both of these are factors that influence a researcher's decision on the need for further screening. Decisions on additional screening are also influenced by considerations of incidence and coverage. Incidence is the degree to which the geography is represented in the sampled telephone exchanges, whereas coverage is the proportion of sampled telephone exchanges that are represented within the target geography. RDD sampling frames are often used to maximize coverage—ideally, all telephone numbers in an area are included in the frame for the RDD sample, including unlisted numbers, which would be missed if the sample were selected from telephone listings. However, RDD samples usually do not enjoy a perfect match between telephone exchanges and the target geography, so some sampled cases may lie outside the study boundaries. In such situations, the screening interview must ask respondents whether they reside in the target area. For example, respondents may be asked whether they live in a given county, zip code, or an area bounded by selected roads or other geographic markers.

If incidence is of greater concern than coverage, a list sample can be used. A list sample is based on residential, directory-listed telephone numbers that fall within a specified geographic area, thus ensuring the location of sampled cases prior to sample release, although such lists may contain inaccuracies due to people moving while keeping their same telephone number. (This issue is becoming more problematic in the United States since the inception of number portability in 2004.) List samples increase incidence but lower coverage, because unlisted telephone numbers are excluded. A similar method of geographic screening uses geo-coding to match addresses to all possible telephone numbers in an RDD sample and thus determine which sampled numbers are within the target geography. Then, only those cases that fall within the geography are retained in the sample. Geo-coding can improve the efficiency of an RDD sample, but it decreases coverage in the same way as a traditional list sample. Neither list samples nor geo-coded samples require respondents to answer geographic screening questions, because the sampling design ensures that cases are within the target boundaries. Though both have imperfect coverage, they can increase the cost-effectiveness and efficiency of data collection, particularly for studies targeting rare subgroups or small areas.

Web-based surveys have the same geographic screening limitations as telephone surveys. If the sampling frame for a Web-based survey can be tied to a geographic area during the design phase, it is not necessary to further screen respondents upon contact. However, if estimates by geography are desired and there is doubt about the respondent's residence, as often happens in Web-based studies, then geographic screening should be included in the questionnaire.

The increased use of cellular telephones (accompanied by portable telephone numbers) and Voice over Internet Protocol (VoIP) technology poses a geographic screening challenge. The likelihood that pre-screening procedures can adequately determine the geographic location of a sampled telephone number is substantially lower for cell phones and VoIP, because the usual telephone exchange identifiers are not necessarily tied to a specific geography in the way that they are for landline telephones. Thus, it is likely that all surveys with sampling frames that include cell phones or VoIP will require additional screening of respondents to ensure that they reside within the target geography.

Gestalt Psychology

Often summarized by the phrase "The whole is greater than the sum of its parts," Gestalt psychology refers to an approach to understanding everyday human experiences as a whole rather than breaking them down into a collection of individual stimuli, behaviors, or both. This approach recognizes the ability of the human brain to piece together separate stimuli in context to one another and their surroundings so that the overall impression of an object, event, or other stimulus provides more information to the individual making the observation than was provided by the individual component stimuli. In other words, the individual may actually experience something that is not present in the stimuli themselves. A common example of this is watching a motion picture at a theater. Motion pictures (on film) actually consist of a series of still shots presented in rapid succession to give the impression of movement. Any one frame of the movie alone is simply a still photograph. When presented in rapid succession, however, the brain is able to fill in the gaps so that the individual has the experience of fluid motion.

This ability of the human brain, referred to as the *phi phenomena*, was used by Max Wertheimer to demonstrate the value of a holistic approach to studying psychology. Since that time, many other principles of Gestalt psychology have been identified. These include emergence, reification, multi-stability, and invariance. *Emergence* occurs whenever there is confusion between figure and ground in an image. The figure of an image refers to the subject or object, whereas the ground refers to the setting or background. The classic example of emergence in psychology texts is a black and white picture that initially appears to be random splotches of black ink (figure) on a white paper (ground). When the individual trains his or her eye on the white portion of the picture as the figure instead of the ground, a picture of a spotted Dalmatian dog appears.

Reification is similar to emergence in that the phenomenon is based on the visual relationship between figure and ground. Reification, however, is more often associated with the arrangement of geometric shapes, whereby the relationship of the shapes (figures) on the ground begin to form a shape of the ground. Hence, the ground becomes the figure. *Multi-stability* refers to the tendency for an ambiguous figure to be interpreted as two or more different figures such that the brain cannot decide which figure is correct. This phenomenon can be isolated to the figure itself (e.g., Necker's cube), as well as a product of figure/ground confusion (e.g., Rubin's Figure/Vase Illusion). Finally, the principle of *invariance* refers to the brain's ability to recognize simple objects, regardless of distortion (e.g., size, position/rotation).

More important to survey research are the laws of prägnanz, similarity, proximity, and closure. Each of these is critical to the design and layout of self-administered questionnaires, whether on paper or online. The *law of prägnanz* ("good form") is defined by the observation that individuals tend to group stimuli in a way that is most easily understood. In other words, the human brain attempts to interpret stimuli in the simplest and most orderly way possible. Thus highly complex graphics and symbols, or unnecessary variations in the layout of questions may increase cognitive burden on the respondent and reduce the quality and quantity of survey responses. The tendency to group similar items is another way the brain attempts to simplify visual elements. This tendency is known as the *law of similarity*. This again emphasizes the importance of consistent labeling of sections of a questionnaire. Good labels provide structure for the respondent to aide them in completing the questionnaire.

The *law of proximity* states that elements that are closer together, either physically or temporally, are more likely to be cognitively grouped than those farther apart. Thus response options should be evenly spaced so that they are mentally grouped and attention is not drawn to any one response or set of responses unless that is desired explicitly. Finally, the brain may add elements to a figure to more easily understand it as a whole. For example, a dotted line is perceived as a line rather than a series of dots. This is referred to as the *law of closure*, as the brain attempts to close the gaps in the image.

In conclusion, it is important to be aware of figure/ground relationships when laying out a questionnaire. In fine art this is commonly referred to as being aware of the "negative space" on a page. It is possible to communicate unintended messages to a respondent by focusing solely on the figure and ignoring the ground when creating an image. Likewise, in designing a survey instrument, researchers must be aware of the spacing of graphics and symbols so that unintended connections of closures are minimized.

Graphical Language

Respondents interpret the meaning of survey questions from both the verbal and graphical language used in the questionnaire. Graphical language includes various elements such as contours and lines, images, numbers, and symbols and their attributes such as movement, spatial location, color or contrast, and size. These graphical elements influence how respondents perceive survey information and therefore significantly impact the survey response process. Graphical language can convey meaning independently, or it can influence or modify how written text is perceived. Thus, it can be compared to paralanguage that is conveyed aurally through a speaker's voice (e.g., inflection, tone) and to nonverbal communication in face-to-face interactions (e.g., gaze, facial expressions, body language, and gestures). Because paper and Web surveys transmit information visually, survey designers can strategically use graphical language to convey information and meaning to respondents. However, graphical language may also confuse survey respondents when used in competing ways, carelessly, or inconsistently.

Graphical language acts like a visual paralanguage to emphasize or draw attention to information in a survey, create groupings and subgroupings of information, and improve navigation through the survey. Graphical attributes such as size, contrast, color, layout, and position can influence the meaning assigned to written text in many ways. For example, in Figure 1, the larger size and use of reverse print for the question number and the "Next Page" button and the underlining of the word *satisfaction* in the question stem help draw respondents' attention to this information. In addition, locating the question number "1" in the upper left of the screen helps convey to respondents that the number, one, means this is where they should begin.

Furthermore, graphical language can encourage respondents to perceive information as belonging together in a group and therefore as related conceptually. The Gestalt principles of proximity, similarity, connectedness, and common region indicate that information is grouped visually when items are located near each other, share similar graphical attributes (shape, size, color/contrast, etc.), and are connected or enclosed within a common region such as a square. For example, in Figure 1, using similar size, font, and reverse print for the question number and "Next Page" button encourages respondents to group them visually and then conceptually as tools to aid in navigating through the survey. In addition, using a larger size for the question stem but similar font size for each item helps respondents perceive the subgroups within the question group (i.e., response items separate from question stem). Grouping is also established by the gray lines in Figure 1 that connect the text of each item to the appropriate answer spaces and by positioning the radio buttons in closer proximity horizontally than vertically.

In addition to acting like a visual paralanguage, graphical elements such as symbols, logos, pictures, and other images can independently influence the tone of printed survey contacts (letters or emails), instructions to respondents, individual questions, and response categories. Appropriate logos and images on contact letters and survey instruments can increase respondent motivation and commitment to completing the survey. Moreover, pictures and other images can be used to convey information or enhance the meaning of written text in much the same way that facial expressions, body language, and gestures do in face-to-face communication. For example, in Figure 1 the combination of facial expression images and numbers are used to convey the meaning of each scale point.

Since research on Web surveys has shown that pictures and other graphical images can modify the meaning respondents assign to particular questions and concepts, images must be chosen carefully to avoid negative impacts on measurement, such as when the inclusion of pictures of an endangered species artificially increased respondent support for that species. Moreover, research has shown that including sizable graphical elements in Web surveys can slow page download times, thus increasing respondent burden and sometimes nonresponse. The increased use of Web surveys has heightened the attention given to graphical language in survey questionnaire design because graphical language is easy and inexpensive to include and modify in Web surveys (i.e., no printing costs). In addition to increasing the need for research into the effects of

Figure 1 Examples of the use of graphical language in a Web survey

specific graphical language elements on survey response, the greater use of graphical language has also created the need for enhanced Web programming to maintain visual consistency and standardize the survey stimulus across different configurations of respondent hardware, software, and preferences.

Guttman Scale

Given a data set of a sample of N persons and of a selection of n survey questions (variables) designed for measuring a particular trait—such as people's position on a political issue or their ability in a specific field of human activity—a Guttman Scale is the *hypothesis* that the data set would have a cumulative structure, in the following sense: For *any* two persons in the observed sample, one of them would exhibit all the manifestations of the trait that the other person would, and possibly additional ones. That is, there would be no two persons in the sample with the one person higher than the other in one variable but lower than the other in another variable.

To the extent a Guttman Scale hypothesis is supported in a data set, it can be said that all observed persons (and all their observed profiles) are comparable with respect to the selection of observed variables. And—if the data set is sufficiently rich—it can be inferred that members in the population represented by the sample can be meaningfully measured with respect to the trait (represented by the selection of variables) using a single (i.e., one-dimensional) scale.

Example

Consider, for example, public attitudes toward intervention in foreign countries as a trait in question. Presenting an appropriate sample of the adult population with the following questions can serve in measuring this attitude:

> *In the interest of our national security, do you favor spending money for encouraging a change in the policies of foreign country (C)? 1. No; 2. Yes, but only through nongovernmental organization (tax-deductible) funds; 3. Yes, any money, including nationally budgeted (taxpayers') money.*
>
> *In the interest of our national security, do you favor sending special civilian advisors in order to encourage a change in the policies of country (C)? 1. No; 2. Yes, but only as part of the normal diplomatic mission; 3. Yes, any size of special civilian mission, as necessary.*
>
> *In the interest of our national security, do you favor sending military advisers abroad in order to encourage a change in the policies of country (C)? 1. No; 2. Yes.*
>
> *In the interest of national security, do you favor sending our military troops abroad in order to encourage a change in the policies of country (C)? 1. No; 2. Yes.*

A respondent who, for the said purpose, favors spending national funds (score 3), sending any size of civilian mission (3) as well as military advisors (2) but objects to sending troops (1), would have the profile 3321, which is comparable to, and represents a more positive intervention attitude than, profile 3221, because the former is equal to or greater than the latter on every variable. But 2111 would be said to be *incomparable* to 1232, because at least on one variable the former is higher than the latter, and at least on one variable the former is lower than the latter. If, in a particular survey, all profiles are comparable—that is, no incomparable pair of profiles is observed to occur—the result is a Guttman Scale. In the previously mentioned example, if out of the $\times 3 \times 2 \times 2 = 36$ technically possible profiles, only the 7 profiles shown in the first column of Table 1 are actually observed, the data would constitute a Guttman Scale (or a *cumulative scale*).

Table 1 Example of a Guttman Scale with a single score assigned to observed profiles

Profile Based on Observed Responses	*Score* x *Assigned to the Profile*
1111	1
2111	2
3111	3
3211	4
3221	5
3321	6
3322	7

In this list of profiles each profile represents, in a strict sense, a more positive attitude toward intervention than its predecessor. Hence a single score x, from any set of ordered numbers, can be assigned to every observed profile such that (a) the higher x is, the more positive is the attitude toward intervention; and (b) given this assignment, a respondent's answers to all questions can be reproduced from his or her single score, x. Thus, if a Guttman Scale holds, the original four dimensions suggested by the four variables (and, in general, any number of variables, n) are reduced to a one-dimensional measurement scale.

Note that the order in which the variables are considered (and hence the order of their respective scores within the profiles) is immaterial for the definition and analysis of a Guttman Scale and so may be chosen as convenient. Also note that no weights are assumed to be associated with the variables.

When Data Do Not (Guttman) Scale

While pure Guttman Scales are rarely found in social research, approximate Guttman Scales have been found, for example, in studies of people's knowledge in specific areas, of the possession of household appliances, and more. Different versions of a *coefficient of reproducibility* have been proposed for assessing the degree of fit of data to a Guttman Scale. It is important to realize that deviations from a Guttman Scale can be of two kinds: (1) random deviations, suggesting the existence of a Guttman Scale with "noise," and (2) structured deviations, suggesting that two or more scales are needed to measure the studied trait meaningfully. Developing the procedures of multiple scaling, using partial order scalogram analysis by base coordinates (POSAC), Samuel Shye has generalized Guttman Scale to dimensionalities higher than one.

Misconceptions

Several misconceptions have accompanied the notion of the Guttman Scale throughout the years:

1. Some have sought to "construct" a Guttman Scale by eliminating variables (or respondents) from their data. Assuming one has had a rationale for selecting variables as representing a concept (and for defining the sampled population), such eliminations in a particular application may be questionable and should be avoided, except possibly in the context of the larger cycle of scientific investigation where concepts are reshaped and redefined. As noted, a Guttman Scale is essentially a hypothesis, which may or may not be supported by data.

2. Many believe that a Guttman Scale necessarily involves only dichotomous variables. Indeed, most illustrations and many applications in the literature are with such variables. As the example presented earlier shows, this need not be the case. However, when a Guttman Scale is found in dichotomous variables, the variables are naturally ordered according to their sensitivity in detecting the presence of the measured trait.

3. Confusion often arises between the Guttman Scale, which completely orders respondents on a one-dimensional scale, and the *simplex*, which, in Guttman's work, means a simple ordering of the variables on a one-dimensional line by an aspect of their contents. Such ordering of the variables is tested for by Faceted Smallest Space Analysis, a multidimensional scaling procedure that maps variables according to a similarity measure (typically correlation coefficient) between them. The mathematical relationship between the two kinds of spaces—that is, the measurement space into which respondents are mapped and the trait concept-space into which variables are mapped—has been studied within the theory of multiple scaling by POSAC.

As a procedure that ties substantive contents with logical aspects of data, the Guttman Scale heralded the development of Facet Theory by Louis Guttman and his associates.

H

Hagan and Collier Selection Method

The ideal method of selecting respondents within households is a probability method, but researchers seldom work under ideal conditions. They usually seek to improve within-unit coverage without adding to nonresponse. Probability selection methods, such as the Kish method, may enhance within-unit coverage but also may increase nonresponse because of the need for longer introductions, which are potentially intrusive and may alienate respondents. Longer surveys add to interviewer costs. Hagan and Collier developed a nonprobability quota technique that they believed would secure respondent cooperation more readily because it asked no household composition questions. Their procedure was based on the Troldahl-Carter-Bryant (T-C-B) respondent selection method, which in turn was based on the Kish technique.

Interviewers are given four forms, which are randomly distributed. The result is an oversampling of male respondents (desirable because of higher noncontact-related nonresponse among men). Within the eligible age range for a given survey, Form A requests the youngest male in the household; Form B asks for the oldest male; Form C, the youngest female; and Form D, the oldest female. If no such person resides there, the interviewer is instructed to ask for the person in the household of the opposite sex and same age grouping. Forms A, B, and C are each used two times in seven, and Form D is used one time in seven. Hagan and Collier reported favorable results in a sample compared with one that selected respondents by the T-C-B procedure. Demographic characteristics were similar, and the refusal rate at respondent selection was almost 5% less than the T-C-B method. Both methods have a small within-unit coverage bias because adults in households of more than two adults of the same sex whose ages are between the oldest and youngest adults have no chance of selection. Also, in three-adult households, one of the three adults would have the chance of being designated the respondent twice. Troldahl and Carter considered these violations of random sampling to be very small. Research using census data has shown that the bias caused by the Hagan-Collier method is very slight.

An example of Hagan-Collier question wording is *May I please speak to the "youngest man"?* Another example is *For this survey, I need to speak with the youngest adult male in your household over the age of 17, if there is one*. If there is none, the following question is asked: *Then may I please speak with the youngest adult female?* Wording should include the fact that the designated respondent is not the one who happens to be at home at the time but, instead, is the one who lives in the household. Interviewers need training in awareness that a woman in a one-person household fits as either the youngest woman or the oldest woman, that “youngest man” can apply to an elderly male, and that informants can be confused and think the interviewer is asking for an old man (or a young woman), among other things.

HALF-OPEN INTERVAL

The half-open interval is a linking procedure that is used in some surveys to address issues of noncoverage. Sampling frames or lists are not perfect, and survey researchers often use frames with problems such as missing elementary units, blanks for relevant information, clusters of elementary units, and duplicate listings. Of these problems, sample frames that are missing elementary units—known as *noncoverage*—frequently present important practical problems. For example, housing lists incorporating addresses are often used in household surveys. The housing list is often out of date, and when an interviewer visits the housing unit selected from the list, there can be newly constructed housing units that were not on the original list used for sampling. When there is noncoverage of the target population due to an imperfect sample frame, specific remedies are required to improve the frame coverage.

To account for the units missing from a frame, researchers may use a linking procedure. This is a useful device in many situations where the missing units are scattered individually or in small clusters. The linking procedure is often called the *half-open interval*, which indicates the interval by the boundary between the selected unit and the next unit in the list.

For example, suppose that 100 Kish Street has been selected from the housing list. From an area frame perspective, the address of 100 Kish Street has a boundary defined by its property lines up to the property of the next address on the housing list, 102 Kish Street. This boundary denotes the half-open interval, which does not include the next address on the list. If there is a new or missed housing unit within the interval (e.g., at 100 1/2 Kish Street), an interviewer treats it as a sampled unit and conducts an interview with all the units in the interval, including the pre-specified unit (i.e., 100 Kish Street). Thus, the missed units have the same probability of selection as the pre-specified unit.

Occasionally, ordinary linking procedures cannot deal with the missed units adequately. For example, in the case of an address where a single household is expected, finding a newly built apartment house with 20 dwellings presents a real dilemma, since the interviewer technically would need to conduct 21 interviews instead of 1 interview. In such cases, the additional dwellings may be subsampled to reduce the interviewer workload, and weighting must be implemented to compensate for any unequal probabilities of selection. Instead of linking procedures, a large number of newly constructed units can be put into a supplementary stratum from which they are selected with varying probabilities, although it is better if a check of the frame is available to avoid such unpleasant occurrences.

These linking procedures can also be applied to the instances where ordered lists serve as frames. For example, on a payroll listing, a new employee in a department can be missed if the frame is slightly out of date. If a unique employment position on the list, such as the employee listed last in each department, is selected as a sample unit, then the new employee is also added to the frame and selected with the same probability as the one listed last by the linking rule. Another example is the list a public school has of its pupils' households. When the household of a selected child is visited, recently born or missed children can be discovered. The linking procedure must fit the missed children into the half-open interval, thereby reducing the noncoverage of the original list.

Hang-Up During Introduction (HUDI)

A telephone interview that is terminated by the respondent during the introduction of the interview shortly after an interviewer has made contact is called a *hang-up during introduction* (HUDI). HUDI is a form of refusal to the survey request that is growing in occurrence and provides little or no opportunity for the interviewer to overcome the respondent objection.

The most difficult time to assure success in a telephone interview is during the first few seconds of the call. During this time, the interviewer has to identify the purpose and legitimacy of the call. In the past two decades, there has been an increasing tendency for respondents to hang up on the interviewer during this time without completing a full interaction with the interviewer. In contrast, in the 1970s and 1980s when telephone surveys were first gaining their legitimacy as a valid survey method of the public, there was a social norm that held most people to not hang up on a stranger (the interviewer who called them) abruptly. However, with the problems causes by excessive telemarketing in the 1990s and busy lifestyles, people are far less reluctant to just hang up.

Early work in the late 1980s found that 40% of refusals occur in the first two sentences of the introduction. Similarly, more recent research has found that HUDIs last an average of 15 seconds. A study in 2003 found that one in four HUDIs occur without the respondent saying anything at all to the interviewer, and a 2005 study found two fifths of respondents hanging up on the interviewer without speaking. Respondents may give brief and abrupt objections, which are most frequently an indication of "not interested" or "don't have time" and then abruptly hang up.

Urbanicity has been found to be negatively associated with response rate. This finding is reflected in the incidence of HUDIs by metropolitan area size. A 2005 study found a 6 percentage point gap in the occurrence of HUDIs in the 10 largest metropolitan areas compared to cities and towns of less than 200,000 population. The Northeast and West regions of the United States show the highest rates of HUDIs while the Midwest rate was found to be 5 points lower. The study also showed that households that had been sent a pre-notification mailer (advance letter or postcard) were less likely to hang up during the introduction.

The interviewer is challenged with trying to establish rapport and engage the respondent while introducing the purpose of the call. In the 1970s and 1980s, interviewer research focused on identifying the words to use in a scripted introduction to improve respondent cooperation rates. The result was the identification of preferred words but no clear agreement on the benefit of scripted introductions. During the 1990s, attention shifted to techniques of allowing interviewers to tailor introductions to engage the respondent. The goal is to maintain interaction with the respondent. Studies have found that the longer interaction is maintained, the more likely it will result in a completed interview.

The success of maintaining interaction is dependent on the interviewer skill as well as the words of the introduction and the respondent behavior. More recent research has shifted from identifying the specific words to say to identifying the interviewer characteristics that best predict a successful interview. However, with HUDIs, the interviewer has no time to respond to an objection, if one is voiced. There have been renewed efforts to develop interviewer refusal aversion training to prepare interviewers to quickly identify the most important concern of the respondent and how to overcome the objection. In addition, research is exploring characteristics of successful interviewers, including voice characteristics, which result in higher respondent cooperation rates.

There is much work to be done to better understand the characteristics of HUDIs, the correlates of incidence, and how to combat this increasing challenge to successful telephone survey interviewing.

Hansen, Morris (1910–1990)

Morris Hansen was one of the most innovative and influential statisticians of the 20th century. He helped pioneer the work of sampling techniques and the use of the total survey error perspective in designing surveys. He also developed quality control procedures for surveys that helped legitimize the accuracy of survey research. He attended the University of Wyoming (B.S.) and American University (M.S.) and had a long career at the U.S. Census Bureau and Westat, until his death in 1990.

Morris Hansen was born in Thermopolis, Wyoming, in 1910 and spent his formative years in Worland, Wyoming. He earned a B.S. in accounting from the University of Wyoming in 1934. After graduation he started his career at the U.S. Census Bureau in Washington, D.C. Fascinated by statistics in college, Morris started his formal training as a statistician when he arrived in Washington, taking evening courses at the Graduate School of the U.S. Department of Agriculture and eventually earning a master's degree in statistics from American University in 1940.

During his first years at the U.S. Census Bureau, Morris started to establish himself as a highly skilled statistician. At age 26, Morris worked on the sample design for an unemployment survey (which would later evolve into the Current Population Survey) for the federal government, an innovative project because, at the time, the government preferred using census data for their studies. Hansen convinced them that data from a survey could be as reliable, or even more so, as data collected from a census. To accomplish this, Morris introduced the concept of total survey error, which takes into account all of the sources of error in a survey, for example, interviewer effects, questionnaire design, and so forth. The cost savings that result from collecting data from a sample of the population, instead of the entire population, can then be spent on reducing the error from other sources. Although sampling introduces some error into the data, the total survey error is reduced because of a reduction of error from a multitude of sources. Hansen, along with William Hurwitz, would further develop the mathematical theory that underlies sampling methodology.

Hansen retired from the U.S. Census Bureau in 1968. Shortly thereafter he was invited to join Westat, which was, at the time, a small research organization. Morris accepted the invitation and joined Westat as a senior vice president. He would later serve as chairman of the board, after Ed Bryant, a founder of Westat and the preceding chairman, retired. While at Westat, Morris led many important government projects, such as the Consumer Price Index and the National Assessment of Educational Progress. He also developed new techniques for quality control in survey research. Morris did not retire from Westat and continued to work vigorously on statistical and survey methods until his death in 1990. Morris is remembered as an inspiration, a great collaborator, and a passionate teacher by those who worked with and learned from him.

Hit Rate

In general, *hit rate* is a ratio or a proportion, and the term is used in many environments and disciplines with specific definitions for both the denominator and numerator. In the online world, it usually means the number of "hits" a Web page receives during some period of time. In marketing, it can mean the number of sales achieved as a percentage of the number of sales calls made. In survey research, hit rate is most commonly used to refer to the proportion of telephone numbers in a sample that are working residential numbers. However, hit rate is sometimes used to mean incidence. Both meanings of hit rate are essential components of sample size calculations.

In its common usage, hit rate is synonymous with the terms *working residential rate* and *working phone rate*. For a residential telephone sample, eligible units would be those numbers that connect to a household, while ineligible numbers would include nonworking or disconnected numbers, data/fax lines or numbers that connect to an ineligible unit such as a business. For an in-person survey it might mean the proportion of occupied housing units in the frame, and for a mail survey it could mean the proportion of deliverable mail pieces in the list.

Hit rate is also sometimes used as a surrogate for incidence or the proportion of qualified contacts to all contacts. For example, a survey might require screening households for further eligibility, such as living within a particular geography, having a certain income, or belonging to a specific racial or ethnic group. In these cases the hit rate would be the probability of finding members of that target population among all contacts.

Understanding and being able to estimate these two hit rates is integral to sample design. Most formulas for calculating the number of sample units needed to complete a set number of interviews include both of these definitions of hit rate (working phone rate and incidence) in conjunction with estimates of contact rate and completion rate for the survey.

Horse Race Journalism

Contemporary political reporting, especially news that has a focus on elections and policy debates, is often covered as though these matters are a game among competing candidates and elites. Thus, this dominant approach to covering elections has come to be referred to by academics and others as *horse race journalism*, the *game schema*, or the *strategy frame*. Rather than foregrounding issue positions, candidate qualifications, or policy proposals, journalists instead tend to cast these features of the political terrain as secondary to a focus on who's ahead and who's behind in winning the campaign or a policy battle, the principal players (i.e., the generals and lieutenants) involved, and the shifting gamesmanship strategies and tactics employed.

Horse race journalism focuses almost exclusively on which candidates or players are most adept at gaining power while also undermining the political chances of opponents. A horse race is an apt metaphor, as this style of reporting translates easily into the conventions of sports coverage, with a focus on competing political gladiators who survive to campaign another day or who are the first to cross the finish line. Polling and public opinion surveys are a central feature of this political spectacle. In fact, it is polls and other surveys that supply most of the objective data for reporters to define who is winning while also providing news pegs for transitioning into attributions about the reasons for political successes and political failures.

The Dominance of Horse Race Journalism

Over the past 40 years, the rise in horse race journalism has been called by Thomas Patterson the "quiet revolution" in U.S. election reporting. Patterson's now classic analysis finds that coverage focusing on the game schema that frames elections in terms of strategy and political success rose from 45% of news stories sampled in 1960 to more than 80% of stories in 1982. In comparison, coverage focusing on policy schema, which frame elections in terms of policy and leadership, dropped from 50% of coverage in 1960 to just 10% of coverage analyzed in 1992.

Other analyses confirm the contemporary dominance of the horse race interpretation in election coverage. In one study of the 2000 U.S. presidential campaign, strategy coverage accounted for more than 70% of the TV stories at the major news networks. The most recent available analysis conducted by the Pew Center—tracking the first 5 months of 2008 presidential primary coverage—found that horse race reporting accounted for 63% of print and TV stories analyzed compared to just 15% of coverage that focused on ideas and policy proposals and just 1% of stories that focused on the track records or past public performance of candidates.

In the United States, not only has horse race strategy come to define elections, but the approach also increasingly characterizes more simplified coverage of what were originally considered complex and technical policy debates. First observed by Joseph Capella and Kathleen Jamieson in their analysis of the early 1990s debate over health care reform, when coverage of policy debates shifted from specialty news beats to the political pages, the strategy frame has been tracked as the dominant narrative in reporting of issues as diverse as stem cell research, climate change, food biotechnology, the Human Genome Project, and the teaching of evolution in schools.

Forces Behind the Quiet Revolution

Horse race journalism is fueled partly by industry trends and organizational imperatives, but also by journalistic need for narrative. In a nonstop and highly competitive news environment with a 24-hour news cycle and tight budgets, reporting the complexity of elections and policy debates in terms of the strategic game is simply easier, more efficient, and considered better business practice.

Public opinion surveys are a competitive advantage in the news marketplace; they are even an important part of media organization branding and marketing. Perhaps more important, polls help fill the demand for anything new in a day-long coverage cycle while also fitting with trends toward secondhand rather than primary reporting. The growth in the survey industry, and the almost constant release of new polling data, has helped fuel the rise in horse race coverage. For example, in analyzing trial heat polls tracking the presidential nominees, Michael Traugott reported a 900% increase in such polls from 1984 to 2000. In 2004, the total number of trial heat polls remained equivalent to that of the 2000 presidential campaign, but there was more of a mix of different types of polls, as several organizations focused specifically on anticipated battleground states. And, the increased use of tracking polls likely magnifies horse race coverage. In combination with economic imperatives and the increased availability of polling, horse race coverage also resonates strongly with the informal rules of political reporting. American journalists pay heavy attention to scandals, corruption, or false and deceptive claims, but because of their preferred objectivity norm, they typically shy away in their news stories from actively assessing whether one side in an election or policy debate has the better set of candidates, ideas, or proposed solutions. With a preference for partisan neutrality, it is much easier for journalists to default to the strategic game interpretation. Issue positions and policy debates are part of this coverage but very much secondary to a dominant narrative of politics that turns on conflict, advancement, and personal ambition.

Tom Rosenstiel has connected the objectivity norm to the new *synthetic journalism*, a trend that further favors poll-driven horse race coverage. In a hypercompetitive 24-hour news cycle, there is increasing demand for journalists to try to synthesize into their own coverage what already has been reported by other news organizations. This new information might include newly revealed insider strategy, the latest negative attack, or a perceived embarrassing gaffe or mistake. Such details, however, are problematic because the need to synthesize critical or damaging information runs up against the preferred norm of objectivity while also providing fodder for claims of liberal bias.

Yet, as news pegs, polls serve an important insulating function, providing journalists the “objective” organizing device by which to comment on and analyze news that previously has been reported by other outlets. For example, if a new survey indicates that a candidate is slipping in public popularity, the reporting of the poll’s results provides the subsequent opening for journalists to then attribute the opinion shift to a recent negative ad, character flaw, allegation, or political slipup. Kathleen Frankovic has noted a dramatic rise not only in the reporting of specific poll results but also in rhetorical references to “polls say” or “polls show,” with close to 9,000 such general mentions in her sample of newspapers in 2004 compared to roughly 3,000 such mentions in 1992. This reliance on “the authority of polls” adds perceived precision and objectivity to journalists’ coverage. According to Frankovic, this rhetorical innovation allows journalists to make independent attributions about candidate success or failure without relying on the consensus of experts. Moreover, she argues that the heightened emphasis on the polls alters the criteria by which audiences think about the candidates, shifting from a focus on issue positions and qualifications to that of electability.

Of course, an accent on strategy, ambition, poll position, and insider intrigue is not the only way that political reporters can translate an election campaign or policy debate for audiences. Journalists, for example, could alternatively emphasize issue positions; the choice between distinct sets of ideas and ideologies; the context for policy proposals; or the credentials and governing record of candidates and parties. Yet, in comparison to the horse race, the storytelling potential of each of these alternative ways of defining what is newsworthy in politics is perceived as more limited. In fact, according to the norms that dominate most political news beats, once the issue positions, credentials, background, or track record of a candidate is first covered, they are quickly considered old news.

Reasons for Concern About Horse Race Journalism

Scholars have raised multiple concerns about the impacts of horse race journalism. Patterson and others fear that the focus on the game over substance undermines the ability of citizens to learn from coverage and to reach informed decisions in elections or about policy debates. Capella and Jamieson argue that the strategy frame portrays candidates and elected officials as self-interested and poll-driven opportunists, a portrayal that they show promotes cynicism and distrust among audiences. Stephen Farnsworth and Robert Lichter go so far as to suggest that horse race coverage in the primary elections results in a self-reinforcing bandwagon effect, with positive horse race coverage improving a candidate's standing in subsequent polls and negative horse race coverage hurting a candidate's poll standings. Their observation fits with what many political commentators and candidates complain about: that overreliance on polling narrows news attention and emphasis to just the two to three leading candidates while overemphasizing perceived electability as a criterion for voters to consider. In this sense, horse race coverage can be perceived as unduly promoting the media as a central institution in deciding electoral outcomes. In terms of horse race coverage of policy debates, other than failing to provide context and background for audiences, Matthew Nisbet and Michael Huge argue that the strategy frame's preferred "he said, she said" style leads to a false balance in the treatment of technical issues where there is clear expert consensus. Polling experts offer other reservations. For example, Frankovic and others warn that overreliance on horse race journalism and polling potentially undermines public trust in the accuracy and validity of polling.

Hot-Deck Imputation

Hot-deck imputation is a popular and widely used imputation method to handle missing data. The method involves filling in missing data on variables of interest from nonrespondents (or recipients) using observed values from respondents (i.e., donors) within the same survey data set. Hot-deck imputation can be applied to missing data caused by either failure to participate in a survey (i.e., unit nonresponse) or failure to respond to certain survey questions (i.e., item nonresponse). The term *hot deck*, in contrast with *cold deck*, dates back to the storage of data on punch cards. It indicates that the donors and the recipients are from the same data set; the stack of cards was "hot" because it was currently being processed (i.e., run through the card reader quickly, which heated the punch cards). Cold-deck imputation, by contrast, selects donors from external data sets.

This entry describes the various types of hot-deck imputation: sequential, hierarchical, and nearest neighbor. This entry then discusses the assumptions underlying these methods and reviews the advantages and disadvantages of hot-deck imputation.

Sequential Hot-Deck Imputation

The basic idea behind hot-deck imputation is to match a recipient to a donor with similar characteristics and then transfer the donor's value to the recipient. There are various methods to match a recipient to a donor. The traditional hot-deck procedures begin with the specification of imputation classes constructed with auxiliary variables that are observed or known for both respondents and nonrespondents. Within each imputation class, the first nonmissing value (or record) is assigned as the potential donor. Each subsequent record is then compared to that potential donor; if the record has a nonmissing value, it replaces the potential donor. But if the record has a missing value, the most recent donor value is filled in. This is also called *sequential hot-deck imputation*.

A simple example explains this procedure. Given a sample of respondents and nonrespondents, the values on variable y are either observed or missing. If gender is known for all respondents and nonrespondents, two imputation classes can be constructed. The sequential hot-deck imputation procedure continually stores and replaces potential donor values from each nonmissing record. If a missing value on the y variable is found, the most recent donor value is then transferred to that nonrespondent.

The sequential hot-deck imputation is similar to the random imputation within-class method when donors are randomly selected with replacement. If the data set to be imputed has no inherent order (i.e., the records in the data file are random), the two procedures are essentially equivalent except for the start-up process. If the data set does have an inherent order, the sequential hot-deck imputation benefits from the positive correlation between donors and recipients. This benefit, however, is unlikely to be substantial.

The advantage of the sequential hot-deck imputation is that all imputations are made from a single pass of the data. However, a problem occurs when the imputation class does not contain an adequate number of donors. An imputation class with too few donors will cause the same donor values to be used repeatedly, creating spikes in univariate distribution of the variables of interest and resulting in a loss of precision in the survey estimates.

Hierarchical Hot-Deck Imputation

Hierarchical hot-deck imputation avoids the disadvantage of sequential hot-deck imputation. This method sorts respondents and nonrespondents into a large number of imputation classes based on a detailed categorization of a large set of auxiliary variables. Nonrespondents are first matched with respondents in the smallest class. If no match is found within that imputation class, classes are then collapsed until a donor is found.

Nearest Neighbor Imputation

Besides sequential and hierarchical hot-deck imputation methods, there are other ways to match a nonrespondent with a donor. For instance, a nonrespondent can be matched to a "nearest" donor, where "nearest" is defined in terms of a statistical distance function based on auxiliary variables. This method is also called *distance function matching* or *nearest neighbor imputation*. The distance function can take many forms. With one auxiliary variable, the distance function can be defined as the minimum absolute differences between the nonrespondent's and donor's values on the auxiliary variable. When multiple auxiliary variables are used, the distance function can be defined as the weighted absolute difference in ranks on auxiliary variables, where the weights represent the importance of the auxiliary variables. A variant of nearest neighbor imputation assigns to the nonrespondent the average value of the neighboring donors.

Assumptions

Hot-deck imputation methods assume that the missing data pattern is missing at random (MAR) within each imputation class; that is, conditional on the auxiliary variables that make up the imputation classes, nonrespondents are no different than respondents. Given this MAR assumption, the selection of auxiliary variables should satisfy two conditions in order for the imputation to reduce nonresponse bias: They have to be correlated with the *y* variable to be imputed, and they have to be correlated with the missing mechanism (i.e., why these values are missing).

Advantages and Disadvantages

Regardless of the specific matching methods, all hot-deck procedures take imputed values from real respondents in the same data file. These procedures have advantages over other imputation methods. For instance, the imputed values are plausible and are within the same range as in the observed data. Hot-deck procedures can reduce bias in univariate statistics such as the mean, and they also have the advantage that they can be carried out as the data are being collected, using everything that is in the data set so far.

There are disadvantages as well. The imputed values, though within the right range, are not necessarily internally consistent for the nonrespondents. Similar to other imputation methods, hot-deck procedures increase the variance of the estimates and may attenuate multivariate relationships. Thus, one must evaluate the hot-deck imputation for any specific data analysis purpose.

Household Refusal

The household refusal disposition is used in telephone, in-person, and mail surveys to categorize a case in which contact has been made with a household, but someone in the household has refused either a request by an interviewer to complete an interview (telephone or in-person survey) or a mailed request to complete and return a questionnaire (mail survey). The household refusal typically occurs before a designated respondent is selected. Household refusals are considered eligible cases in calculating response and cooperation rates.

In a telephone survey, a case is coded with the household refusal disposition when an interviewer dials a telephone number, reaches a person, and begins the introductory script, and the person who answers the telephone declines to complete the interview. In calls ending in a household refusal, the person the interviewer spoke with may provide an explanation for the refusal, such as “We don’t do surveys,” “I don’t have time,” “We’re not interested,” or “Please take us off your list.” In other instances, the person contacted may simply hang up. It is important to note that for a case to be coded as a household refusal, the refusal either must occur before the interviewer selects the designated respondent or must be generated by a household member other than the designated respondent. If a refusal was generated by the person known to be the designated respondent, the case should be coded with the respondent refusal disposition, not the household refusal disposition. Past research has shown that the majority of refusals in a telephone survey come from household refusals.

Household refusals in an in-person survey occur when an interviewer contacts a household, a household member answers the door, the interviewer begins the introductory script, and the person declines to proceed with the survey request. As in a telephone survey, cases should be considered household refusals when the refusal occurs before the interviewer selects a designated respondent or when the refusal is provided by a household member other than the designated respondent. A case in an in-person survey should be coded with the respondent refusal disposition—not the household refusal disposition—if a refusal was generated by the person known to be the designated respondent. Common reasons in in-person surveys for household refusals parallel those listed earlier in this entry for telephone surveys.

Cases in a mail survey of specifically named persons are coded with the household refusal disposition when contact has been made with the housing unit in which the sampled person lives and another member of the household declines to have the sampled person complete and return the questionnaire. Because little may be known in a mail survey about who in the household generated the refusal, it can be very difficult, if not impossible, to determine whether a household refusal or respondent refusal disposition is most appropriate, but when in doubt a household refusal should be coded.

Household refusals are considered final dispositions, unless a refusal conversion process is used in the survey. Because refusal rates for all types of surveys have increased significantly in the past decade, many survey organizations review cases ending in household refusals and choose such cases in which the refusal is not extremely strong in nature to be contacted again in order to try to convert the case's disposition to a completed interview.

HTML Boxes

Hypertext markup language (HTML) boxes are used in Web-based survey applications and come in all shapes and sizes, but they all allow respondents to Internet surveys to directly input text into an HTML application, for example, an answer to an open-ended survey question. This is extremely useful in survey research for gathering information, such as a respondent's name, email address, and password, but just like other HTML applications, text boxes can be modified to fit one's needs. Fortunately, they all require the same basic parameters, an *input type* and a *form action*. The input type parameter allows one to specify the HTML box one would like to use, whereas the form action defines what will eventually be done with respondent's information.

A one-line box is the most basic HTML box that can be created, as it constrains respondents to using just one input line. These boxes are useful for information responses that are made up of a word or a few words, but they become more cumbersome when used for longer text entries. If one needed to have a larger input space, then a *text area box* would be most appropriate, as the size and shape of this box can be customized allowing it to be used for all sorts of things, ranging from a sentence to much longer, open-ended answers.

In addition to these basic text boxes one could use a *selection box*, which gives the respondent a series of options from which he or she can choose. For online surveys these types of boxes are most commonly used and come in many varieties. For instance, radio buttons allow the users to select only one answer from a provided list; this is useful for survey research, because it prevents respondents from making multiple selections when only one answer is desired by the researcher. *Drop-down selection boxes* can do the same thing, but they look a little different. With drop-down selection boxes, respondents are allowed to select from a dynamic list of items instead of just clicking on the radio button that stands next to the appropriate response. These types of boxes are particularly useful for variables such as income and education, which require a single choice from a list of many options. If one wanted to allow respondents to be able to select multiple items, a *check box* is the easiest way to achieve this end, as they allow users to check as many boxes as they wish. This makes check boxes suitable for measuring constructs such as medical illness histories, which require users to provide several pieces of information for the same question.

Once the preferred input type is chosen, one must then define the form action, which is typically initiated by a "Submit" button that appears at the bottom of the form. Once someone selects the Submit button, a number of things can be done with the form's input, for example, writing the information into a text file and saving it for later use. In addition to a Submit button, often a "Reset" button is added, which allows the user to clear the form's input fields. Even though a Submit button is required to complete the HTML box and a Reset button can be omitted, the Reset button is usually added for user convenience.

Although HTML is a programming language, there are many software editors that are relatively easy to use and achieve the same end. For example, both Microsoft's FrontPage and Mozilla's SeaMonkey provide programmers with a point-and-click interface that allows one to easily create basic and more advanced forms. Additionally, numerous online tutorials are available that provide examples and other resources. Ultimately, HTML boxes are useful for a variety of purposes and always follow the same basic programming model, making them easy to learn and create.

I

IGNORABLE NONRESPONSE

Researchers who use survey data often assume that nonresponse (either unit or item nonresponse) in the survey is ignorable. That is, data that are gathered from responders to the survey are often used to make inferences about a more general population. This implies that the units with missing or incomplete data are a random subsample of the original sample and do not differ from the population at large in any appreciable (i.e., meaningful and nonignorable) way. By definition, if nonresponse is ignorable for certain variables, then it does not contribute to bias in the estimates of those variables.

Because nonresponse error (bias) is a function of both the nonresponse rate and the difference between respondents and nonrespondents on the statistic of interest, it is possible for high nonresponse rates to yield low nonresponse errors (if the difference between respondents and nonrespondents is quite small). The important question, however, is whether there truly are no meaningful differences between respondents and nonrespondents for the variables of interest. In a major article on this topic, reported in 2006 by Robert M. Groves, no consistent patterns were found between the amount of nonresponse and the amount of nonresponse bias across the myriad surveys that were investigated. That is, in many cases the nonresponse was ignorable and in others it surely was not, and this happened regardless of whether there was a great deal of nonresponse or very little.

The survey response rate is an often-used criterion for evaluating survey data quality. The general and conservative underlying assumption of this is that nonresponse is *not* ignorable. To achieve high response rates, survey organizations must devote a great deal of resources to minimize nonresponse. They might lengthen the field period for data collection, use expensive locating sources to find sample members, use multiple and more expensive modes of contact, and devote additional resources (e.g., through incentives) to convince sample members to cooperate with the survey request. Complex statistical techniques may also be used after data collection to compensate for nonresponse bias. All of these techniques dramatically increase the cost of conducting surveys. In light of this, recent trends of increasing survey nonresponse make the questions of if and when nonresponse is ignorable especially important. If nonresponse does not yield biased estimates, then by implication, it is not advantageous to spend additional resources on minimizing it.

It is difficult to conduct research that evaluates nonresponse error because data for nonresponders to the survey have to be available from some other source. When available, administrative records can be used to evaluate assumptions about nonresponders. However, such studies are rare and expensive to conduct. Other methods used to evaluate nonresponse error include comparing hard-to-reach respondents with easy-to-reach and cooperative respondents or comparing estimates in surveys with identical questionnaires but different response rates.

Though there is relatively sparse evidence that measures nonresponse error in large surveys, nonresponse error in public opinion polls has received some attention in recent years due to the political and media attention focused on such surveys. Public opinion research (especially pre-election polling) usually has a condensed field period that makes a high response rate unattainable. Key variables in these studies include commonly used measures of political and social attitudes and electoral behavior (e.g., party affiliation, ideology, media use, knowledge, engagement in politics, social integration). Most research has found few, or at most minimal (ignorable), differences in the measurement of these variables between surveys conducted in short time spans (approximately 1 week or less) with low response rates (approximately 20% to 30%) and surveys conducted with longer field periods (several months) and higher response rates (approximately 60% to 70%). With respect to sample composition, comparisons between low- and high-response rate surveys often show that both types yield similar estimates on most sociodemographic variables to data from the U.S. Census and other large government surveys. If judged by their accuracy in forecasting elections, many public opinion polls with short field periods and low response appear to be accurate and unbiased. This evidence leaves many researchers fairly confident that nonresponse often may be ignorable for public opinion surveys and that it is unnecessary and inefficient to increase the response rate.

However, these findings are not always consistent. Occasionally, a single but important variable such as party affiliation or political engagement will vary among surveys with different response rates. Also, studies aimed at measuring nonresponse error are still plagued by nonresponse. For example, comparing hard-to-reach respondents with easy-to-reach and cooperative respondents still begs the question of how different the nonrespondents that remain completely unobserved are from the hard-to-reach respondents. Also, analyses that compare low-response rate studies with high-response rate studies implicitly assume that the high-response rate studies do not suffer from nonresponse error. However, even a survey response rate of 70% still leaves 30% of the sample unmeasured.

If characteristics that affect the survey participation decision (e.g., locatability, survey topic, burden, sponsorship, and interviewer behavior, among others) are correlated with variables being measured in the survey, then the survey statistics will change as the response rate increases. For example, evidence from the American Time Use Survey (a large U.S. government survey) finds that busy sample members are no less likely to participate in the survey than others, but people who are weakly integrated into their communities are less likely to respond, primarily because they are less likely to be contacted. If social engagement is an important analytical variable, then nonresponse is not ignorable. Although the evidence from public opinion surveys on ignorable nonresponse may be reassuring, it should not be generalized to surveys focusing on other, nonpolitical topics.

Thus, the issue of when nonresponse is ignorable and when it is not remains a key concern in the field of survey research.

IMPUTATION

Imputation, also called ascription, is a statistical process that statisticians, survey researchers, and other scientists use to replace data that are missing from a data set due to item nonresponse. Researchers do imputation to improve the accuracy of their data sets.

Missing data are a common problem with most databases, and there are several approaches for handling this problem. Imputation fills in missing values, and the resultant completed data set is then analyzed as if it were complete. Multiple imputation is a method for reflecting the added uncertainty due to the fact that imputed values are not actual values, and yet still allow the idea of complete-data methods to analyze each data set completed by imputation. In general, multiple imputation can lead to valid inferences from imputed data. Valid inferences are those that satisfy three frequentist criteria:

1. Approximately unbiased estimates of population estimands (e.g., means, correlation coefficients)
2. Interval estimates with at least their nominal coverage (e.g., 95% intervals for a population mean should cover the true population mean at least 95% of the time)
3. Tests of significance that should reject at their nominal level or less frequently when the null hypothesis is true (e.g., a 5% test of a zero population correlation that should reject at most 5% of the time when the population correlation is zero)

Among valid procedures, those that give the shortest intervals or most powerful tests are preferable.

Missing-Data Mechanisms and Ignorability

Missing-data mechanisms were formalized by Donald B. Rubin in the mid-1970s, and subsequent statistical literature distinguishes three cases: (1) missing completely at random (MCAR), (2) missing at random (MAR), and (3) not missing at random (NMAR). This terminology is consistent with much older terminology in classical experimental design for completely randomized, randomized, and not randomized studies. Letting Y be the N (units) by P (variables) matrix of complete data and R be the N by P matrix of indicator variables for observed and missing values in Y, the missing data mechanism gives the probability of R given Y and possible parameters governing this process, $\xi : p(R|Y, \xi)$.

MCAR

Here, "missingness" does not depend on any data values, missing or observed: $p(R|Y, \xi) = p(R|\xi)$. MCAR can be unrealistically restrictive and can be contradicted by the observed data, for example, when men are observed to have a higher rate of missing data on post-operative blood pressure than are women.

MAR

Missingness, in this case, depends only on observed values, not on any missing values: $p(R|Y, \xi) = p(R|Y_{obs}, \xi)$, where Y_{obs} are observed values in Y, $Y = (Y_{obs}, Y_{mis})$, with Y_{mis} the missing values in Y. Thus, if the value of blood pressure at the end of a clinical trial is more likely to be missing when some previously observed values of blood pressure are high, and given these, the probability of missingness is independent of the missing value of blood pressure at the end of the trial, the missingness mechanism is MAR.

NMAR

If, even given the observed values, missingness still depends on data values that are missing, the missing data are NMAR: $p(R|Y, \xi) \neq p(R|Y_{obs}, \xi)$. This could be the case, for example, if people with higher final blood pressure tend to be more likely to be missing this value than people with lower final blood pressure, even though they have the exact same observed values of race, education, and all previous blood pressure measurements. The richer the data set is in terms of observed variables, the more plausible the MAR assumption becomes.

Ignorability

In addition to defining formally the concepts underlying MCAR, MAR, and NMAR, Rubin defined the concept of *ignorability*. Let the distribution of the complete data, Y, governed by parameter ψ be $p(Y|\psi)$. If (a) the missing data are MAR and (b) ψ and ξ are distinct (which means, in disjoint parameter spaces and, if Bayesian models are used, a priori independent), then valid inferences about ψ can be obtained using a likelihood function that is proportional to $p(Y_{obs}|\psi) = \int p(Y|\psi) dY_{mis}$, and thus, the missing-data mechanism may be "ignored" in likelihood or Bayesian inferences. In many cases, it is reasonable to assume that ψ and ξ are distinct, so that the practical question of whether the missing-data mechanism is ignorable often reduces to a question of whether the missing data are MAR. This argument requires some care, however, when using random parameter models, where ambiguity can exist between parameters and missing data. Also, even when the parameters are not distinct, if the missing data are MAR, then inferences based on the likelihood ignoring the missing-data mechanism are still potentially valid in the sense of satisfying the three frequentist criteria mentioned earlier, but may not be fully efficient. Thus, the MAR condition is typically regarded as more important when considering ignorability.

Single Imputation

Single imputation refers to imputing one value for each missing datum, where the resulting completed data set is analyzed using standard complete-data methods. R. J. A. Little and Rubin offer the following guidelines for creating imputations. They should be

1. Conditional on observed variables
2. Multivariate, to reflect associations among missing variables
3. Randomly drawn from their joint predictive distribution rather than set equal to expectations to ensure that correct variability is reflected

Methods for single imputation typically assume ignorability, and for descriptive simplicity, discussion here is focused on this case.

Unconditional mean imputation, which replaces each missing value with the mean of the observed values of that variable, meets none of the three guidelines for imputation. *Regression imputation* can satisfy the first two guidelines by replacing the missing values for each variable with the values predicted from a regression (e.g., least squares, logistic) of that variable on other variables, but not the third. *Stochastic regression imputation* adds random noise to the value predicted by the regression model and, when done properly, can meet all three guidelines for single imputation.

Hot-deck imputation replaces each missing value with a random draw from a "donor pool" consisting of values of that variable observed on units similar to the unit with the missing value. Donor pools are selected, for example, by choosing units with complete data that have similar observed values to the unit with missing data, for example, by exact matching on their observed values or using a distance measure (metric) on observed variables to define "similar." When the distance is defined as the difference between units on the predicted value of the variable to be imputed, the imputation procedure is termed *predictive mean matching imputation*. Hot-deck imputation, when done properly, can also satisfy all three of the guidelines listed earlier for single imputation.

When single imputations have been created following the three guidelines mentioned earlier, a complete-data analysis of the resulting completed data set can satisfy the first frequentist criterion for valid inferences, but any resulting analyses will nearly always result in estimated standard errors that are too small, confidence intervals that are too narrow, and *p*-values that are too significant, regardless of how the imputations were created, thus failing to satisfy the other two frequentist criteria. Special methods for sampling variance estimation following single imputation have been developed for specific imputation procedures and estimation problems, as described by J. L. Schafer and N. Schenker. However, such techniques need to be customized to the imputation method used and to the analysis methods at hand, and they require the user to have information not typically available in shared data sets. A more broadly applicable, but computationally intensive, approach for sampling variance estimation with singly imputed data is to use a replication technique, such as balanced repeated replication, the jackknife method, or the bootstrap method, with the imputation procedure repeated separately for each replicate. However, such methods assume the first frequentist criterion has been satisfied by the single imputation method, and that the user can conduct all of the repeated imputations.

Multiple imputation, which is discussed in more detail in the next section, is a generally valid approach (i.e., it satisfies the three frequentist criteria) and is broadly applicable and much less computationally intensive for the user than the replication approach. Multiple imputation involves repeating the drawing of single imputation several times, but for its exact validity it requires that the imputations are "proper" or, more generally, "confidence proper." For notational simplicity, ignorability of the missing data mechanism is assumed, even though the ignorability assumption is not necessary for multiple imputation to be appropriate.

A proper imputation is often most easily obtained as a random draw from the "posterior predictive distribution" of the missing data given the observed data, which formally can be written as $p(Y_{mis}|Y_{obs}) = \int p(Y_{mis}, \psi|Y_{obs})d\psi = \int p(Y_{mis}|Y_{obs}, \psi)p(\psi|Y_{obs})d\psi$. This expression effectively gives the distribution of the missing values, Y_{mis}, given the observed values, Y_{obs}, under a model for Y governed by ψ, $p(Y|\psi)$ $p(\psi)$, where $p(\psi)$ is the prior distribution on ψ. The distribution $p(Y_{mis}|Y_{obs})$ is called "posterior" because it is conditional on the observed Y_{obs}, and it is called "predictive" because it predicts the missing Y_{mis}. It is "proper" because it reflects all uncertainty, including in parameter estimation, by taking draws of ψ from its posterior distribution, $p(\psi|Y_{obs})$, before using ψ to impute the missing data, Y_{mis}, from $p(Y_{mis}|Y_{obs}, \psi)$. Rubin has labeled imputation methods that do not account for all sources of variability as "improper." Thus, for example, fixing ψ at a point estimate $\hat{\psi}$, and then drawing an imputation for Y_{mis} from density $p(Y_{mis}|Y_{obs}, \psi = \hat{\psi})$, would constitute an improper imputation procedure.

For simple patterns of missing data, such as with only one variable subject to missingness, the two-step paradigm of drawing ψ from $p(\psi|Y_{obs})$ and then drawing Y_{mis} from $p(Y_{mis}|Y_{obs}, \psi)$ is straightforward to implement. For a simple example, Rubin and Schenker described its use in the context of fully parametric imputation involving logistic regression models. These steps can also incorporate more nonparametric analogues. The simple hot-deck procedure that randomly draws imputations for incomplete cases from matching complete cases is not proper because it ignores the sampling variability due to the fact that the population distribution of complete cases is not known but rather estimated from the complete cases in the sample. Rubin and Schenker described a two-step procedure, termed *approximate Bayesian bootstrap imputation*, which draws a bootstrap sample from the complete cases and then draws imputations randomly from the bootstrap sample.

If the missing data follow a monotone pattern, it is straightforward to draw random samples from $p(Y_{mis}|Y_{obs})$; a pattern is monotone if the rows and columns of the data matrix can be sorted so that an irregular staircase separates Y_{obs} and Y_{mis}. Missing data in clinical trials are often monotone or nearly monotone when data are missing as a result of patient dropout; that is, once a patient drops out, the patient never returns and all data thereafter are missing. Similarly, some longitudinal surveys have monotone or nearly monotone missingness patterns when people who drop out never return. Let Y_0 represent fully observed variables, Y_1 the incompletely observed variable with the fewest missing values, Y_2 the variable with the second fewest missing values, and so on, and assume a monotone pattern of missingness. Proper imputation with a monotone missing data pattern begins by fitting an appropriate model to predict Y_1 from Y_0 and then using this model to impute the missing values in Y_1. For example, first fit a least squares regression of Y_1 on Y_0 using the units with Y_1 observed, then draw the regression parameters of this model from their posterior distribution, and then draw the missing values of Y_1 given these drawn parameters and the observed values of Y_0. Next impute the missing values for Y_2 using Y_0 and the observed and imputed values of Y_1; if Y_2 is dichotomous, use a logistic regression model for Y_2 given (Y_0, Y_1). Continue to impute the next most complete variable until all missing values have been imputed. The collection of imputed values is a proper imputation of the missing data, Y_{mis}, under this model, and the collection of univariate prediction models defines the implied full imputation model, $p(Y_{mis}|Y_{obs})$.

Creating imputations when the missing data pattern is nonmonotone generally involves iteration because the distribution $p(Y_{mis}|Y_{obs})$ is often difficult to draw from directly. However, the *data augmentation* (DA) algorithm, a stochastic version of the expectation-maximization algorithm, is often straightforward to implement. Briefly, DA involves iterating between randomly sampling missing data, given a current draw of the model parameters, and randomly sampling model parameters, given a current draw of the missing data. The draws of Y_{mis} form a Markov chain whose stationary distribution is $p(Y_{mis}|Y_{obs})$. Thus, once the Markov chain has reached effective convergence, a draw of Y_{mis} obtained by DA is effectively a single proper imputation of the missing data from the correct target distribution $p(Y_{mis}|Y_{obs})$, the posterior predictive distribution of Y_{mis}. Many software programs use DA or variants to impute missing values.

An alternative to doing imputation under one specified model is to do imputation under potentially incompatible models, for example, a potentially incompatible Gibbs sampler. These iterative simulation methods run a regression (e.g., least squares, logistic) on each variable having some missing data on all other variables with previously imputed values for these other variables, and then the methods cycle through each variable. Such regression imputation methods have been more extensively developed recently, and they provide very flexible tools for creating imputations and have a relatively long history of application.

Multiple Imputation

Multiple imputation (MI) was introduced by Rubin in 1978. It is an approach that retains the advantages of single imputation while allowing the uncertainty due to the process of imputation to be directly assessed by the analyst using only complete-data software, thereby leading to valid inferences in many situations. MI is a simulation technique that replaces the missing values Y_{mis} with $m > 1$ plausible values, where each single imputation Y_{mis} creates a completed data set, and thus MI creates m "completed" data sets: $Y^{(1)}, \ldots, Y^{(l)}, \ldots, Y^{(m)}$, where $Y^{(l)} = (Y_{obs}, Y_{mis}^{(l)})$. Typically m is fairly small; $m = 5$ is a standard number of imputations to use. Each of the m completed data sets is then analyzed as if there were no missing data, just as with single imputation, and the results of the m analyses are combined using simple rules described shortly. Obtaining proper MIs is no more difficult than obtaining a single proper imputation because the process for obtaining a proper single imputation is simply repeated independently m times. MIs can be created under both ignorable and nonignorable models for missingness, although the use of ignorable models has been the norm.

We now address how to analyze a multiple-imputed data set. Let θ represent the scalar estimand of interest (e.g., the mean of a variable, a relative risk, the intention-to-treat effect), let $\hat{\theta}$ represent the standard complete-data estimator of θ (i.e., the quantity calculated treating all imputed values of Y_{mis} as observed data), and let $\hat{V}(\hat{\theta})$ represent the standard complete-data estimated sampling variance of $\hat{\theta}$. Suppose MI has been used to create m completed data sets. A standard complete-data analysis of $Y^{(l)}$ will create the completed-data statistics, $\hat{\theta}_l$ and $\hat{V}_l = \hat{V}(\hat{\theta})_l$, $l = 1, \ldots, m$, which are combined to produce the final point estimate $\hat{\theta}_{MI} = m^{-1} \sum_{l=1}^{m} \hat{\theta}_l$ and its estimated sampling variance $T = W + (1 + m^{-1})B$, where $W = m^{-1} \sum_{l=1}^{m} \hat{V}_l$ is the "within-imputation" variance, $B = (m-1)^{-1} \sum_{l=1}^{m} (\hat{\theta}_l - \hat{\theta}_{MI})^2$ is the "between-imputation" variance; the factor $(1 + m^{-1})$ reflects the fact that only a finite number of completed-data estimates $\hat{\theta}_l$, $l = 1, \ldots, m$ are averaged together to obtain the final point estimate, and the quantity $\hat{\gamma} = (1 + m^{-1})B/T$ estimates the fraction of information about θ that is missing due to missing data.

Inferences from multiply imputed data are based on $\hat{\theta}_{MI}$, T, and a student's t reference distribution. Thus, for example, interval estimates for θ have the form $\hat{\theta}_{MI} \pm t(1-\alpha/2)\sqrt{T}$, where $t(1-\alpha/2)$ is the $(1-\alpha/2)$ quantile of the t-distribution. Rubin and Schenker provided the approximate value $v_{RS} = (m-1)\hat{\gamma}^{-2}$ for the degrees of freedom of the t-distribution, under the assumption that with complete data, a normal reference distribution would have been appropriate. J. Barnard and Rubin relaxed the assumption of Rubin and Schenker to allow for a t reference distribution with complete data, and proposed the value $v_{BR} = (v_{RS}^{-1} + \hat{v}_{obs}^{-1})^{-1}$ for the degrees of freedom in the multiple-imputation analysis, where $\hat{v}_{obs} = (1-\hat{\gamma})(v_{com})(v_{com}+1)(v_{com}+3)$, and v_{com} denotes the complete-data degrees of freedom. Rubin and Schenker summarize additional methods for combining vector-valued estimates, significance levels, and likelihood ratio statistics.

A feature of MI that is especially attractive, in the context of data sets that are shared by many users, is that the implicit or explicit model used for imputation, that is, that leads to $p(Y_{mis}|Y_{obs})$, need not be the same as the explicit or implicit model used in subsequent analyses of the completed data. Thus, for example, an organization distributing public-use data can do its best job at imputing for missing data, and then secondary analysts are free to apply a variety of analyses to the multiply imputed data. The formal derivation of procedures for analyzing multiply imputed data, however, is based on the assumption that the imputer's and analyst's models are compatible, in the sense that the imputation model is proper or confidence proper for the analyst's statistics. Formally, as X. L. Meng noted, the imputer's and analyst's models must be "congenial" for the resulting analyses to be fully valid. In order to promote near-congeniality of the imputer's and a variety of user's implicit models, the imputer should include as rich a set of variables in the imputation model as possible. For example, with data from a complex sample survey, variables reflecting features of the sample design, such as sampling weights, or reflecting important domains such as male/female, should be included as well.

It is common to make the ignorability assumption, even when it is not known to be correct, when using MI because (1) it can simplify analyses greatly; (2) the MAR assumption often seems reasonable, especially when there are fully observed covariates available in the analysis to "explain" the reasons for the missingness; (3) MAR cannot be contradicted by the observed data without the incorporation of external assumptions such as exact normality of variables; (4) even when the missing data are NMAR, an analysis based on the assumption of MAR can be helpful in reducing bias by effectively imputing missing data using relationships that are observed; and (5) it is usually not at all easy to specify a correct nonignorable model, and answers can be quite sensitive to its exact form. Therefore, a sensible approach is to use ignorability as a "baseline" assumption and to conduct additional sensitivity analyses using nonignorable models. Rubin has recommended the creation of imputations under multiple models for purposes of sensitivity analysis, in addition to the creation of repeated imputations under a single model for assessments of variability due to missing data under that model.

Many standard statistical software packages now have built-in or add-on functions for creating and analyzing multiply imputed data sets. Routines for creating such data sets include, for example, the S-plus libraries NORM, CAT, MIX, and PAN, for multiply imputing normal, categorical, mixed, and panel data, respectively, which are freely available (see http://www.stat.psu.edu/~jls/misoftwa.html). NORM is also available as a stand-alone version, as is MICE—MI by chained equations (see http://web.inter.nl.net/users/S.van.Buuren/mi/hmtl/mice.htm). In addition, IVEware is very flexible and freely available; it can be called using SAS or can be run as a stand-alone version (http://www.isr.umich.edu/src/smp/ive/). SAS now has procedures PROC MI and PROC MIANALYZE making the analysis of multiply imputed data sets easy. Other software packages have been developed specifically for creating multiply imputed data sets; for example, the commercially available SOLAS (http://www.statsol.ie/solas/solas.htm) is most appropriate for data sets with a monotone or nearly monotone pattern of missing data. Additionally, STATA provides MI routines based on the chained equation approach and supports analyses of multiply imputed data sets. For more information, see www.multiple-imputation.com.

Inbound Calling

Telephone survey calls involving call centers are classified as *inbound* or *outbound*, depending on whether the call is being received by the call center (inbound) or initiated in the call center (outbound).

Inbound calling in the survey research context usually arises from one of the following situations:

- As support for an existing mail, Web, computer-assisted telephone interview (CATI), or in-person survey. In a pre-survey letter or email to the respondent, or on the actual instrument in the case of a self-completion survey, a phone number is provided for respondents to call if they have any questions about the survey or if they want to schedule a particular time for an interviewer to call. Depending on the survey design, respondents might also be given the option to complete the survey via interview during the inbound call.
- As an additional data collection mode in a multi-mode survey. Longitudinal surveys, where a reliable mail or email address exists for communication, often offer respondents an incentive to phone in and complete the interview at their own convenience before the main field phase. Web and mail surveys often contain a phone number for respondents to call if they would prefer an interview to a self-completion mode.
- As the only data collection option, as might be appropriate for surveys of

- People who visit a particular location or use a particular service, when information is sought about their experience or transaction
- Rare populations for which no sampling frame exists and screening is not feasible
- Surveys on a particularly sensitive topic for which respondents are more likely to give accurate information only if they can do so anonymously (i.e., without the interviewer knowing who is calling). Because in these types of situations the probability of inclusion is rarely calculable, minimum incidence rates, as opposed to population estimates, are usually sought. Distributing the phone number for respondents to call in such cases is typically done by pamphlet, advertising in the press, or via related-interest Web sites and chat rooms.

The technology used for inbound calls can be as simple as a single phone on a single interviewer's desk or something as complex as that used in the large commercial call centers that support commercial banks and credit card companies, with queuing, interactive voice response (IVR), and automatic call distribution systems. Some of this advanced functionality, however, is of limited use in the survey context, because survey respondents have little motivation to wait in queues, and many surveys are longer than is practical for data collection to be done entirely via IVR.

The telephone number provided is usually toll-free (where the receiver pays for the call) to encourage more respondents to phone in. Usually different toll-free numbers are used for different surveys, to allow for more customization in the greeting. Support for multiple languages is done by publishing a different toll-free number for each language or else using a simple IVR system (such as "press 1 for English, 2 for Spanish").

Staffing is determined by both technology and service expectations. For example, more staff are needed if the phone needs to be answered by a live operator within 60 seconds during the advertised hours, and fewer staff are needed for a survey where it is acceptable for the majority of inbound calls to be routed to a voicemail system. Getting the right balance of staff is critical, as too many will result in unproductive use of interviewer time, but too few will lead to unanswered or queued calls, which is likely to irritate the respondent, create more refusals, and thereby reduce response rates.

Blended environments—where interviewers making outbound calls can also receive inbound calls—can assist staffing adequately for inbound callers, but the technology required to make blended environments effective can be complicated.

Record-keeping practices depend on the survey design and the technology available. It is advantageous if the telephony system used can capture caller-ID information, so that even if the call goes to voicemail and the respondent declines to leave a message, some record is still available that will allow, at the very least, for the inbound call to be added to the contact history for that case.

Ideally the inbound system will also be tied to the outbound survey's sample management system, so that when a respondent calls in, the relevant sample case will be accessed and thus prevent some other interviewer from making an outbound call to the same number. In addition, the history of the case can be updated to assist any interviewer who might make a subsequent call to that number.

INCENTIVES

Providing incentives, such as cash, to potential survey respondents is an effective way to increase response rates and thereby possibly reduce the potential for nonresponse bias. Incentives work best when combined with a multiple contact recruitment approach, but incentives demonstrate their effectiveness in improving response rate even at the time of first contact. For interviewer-mediated surveys, the judicious use of incentives can reduce the number of contacts required to complete an interview. Because incentives increase early responses, incentives have demonstrated their time-efficiency and cost-effectiveness by reducing the labor and postage costs of additional contacts.

Theories of Incentives

Several theories are used to explain why incentives work. The most common explanations rely on social exchange theory, but other theories include economic exchange, cognitive dissonance, and leverage-saliency theory.

Social Exchange Theory

Social exchange theory proposes that when people consider participating in a survey, they evaluate a variety of nonmonetary costs and rewards, such as the desire to help or social validation. A pre-paid incentive, whether cash or noncash, is thought to be a goodwill gesture that puts the survey, the researcher, and the sponsor in a positive light, encouraging compliance with a request to complete a survey. In addition, this gesture may establish trust between the researcher and the respondent, further encouraging compliance. This theory assumes the creation of a sense of obligation or an expectation of reciprocity, which may be facilitated by the trust established between the researcher and respondent. The incentive produces a sense of obligation that a favor needs to be exchanged, regardless of the magnitude of the favor.

This theory encourages the presentation of an incentive as a token of appreciation. Don Dillman, an early proponent of this theory, has cautioned against matching the monetary incentives to the level of effort required to complete and return the survey. This matching could trigger thinking about the relationship as an economic exchange, making it easier for people to refuse. Instead, social exchange theory depends on the perception of the incentive as a token of appreciation or symbol of trust.

Economic Exchange Theory

Economic exchange theory proposes that incentives be used to compensate people for the costs (burden) associated with survey participation, that is, pay respondents for their time and effort. This theory depends on people exercising rational choice in deciding whether to participate in a survey. People weigh the costs of participating (time and effort) against the benefits of participating, such as receiving an incentive. From this perspective, the greater the burden is—that is, the longer and more demanding the survey—the greater the incentive should be.

Cognitive Dissonance

Cognitive dissonance, as explained by social psychologist Leon Festinger and his colleagues in the 1950s, proposes that if people are given a noncontingent (pre-paid) incentive with a survey request, they will be motivated to comply with the request to avoid or to reduce an uneasy feeling that arises from accepting a reward without having done anything to deserve it. When presented with a pre-paid incentive to complete a survey, respondents are faced with several choices. They could keep the incentive and return the completed survey (as requested), or they could return the incentive with the uncompleted survey. Both choices avoid a state of dissonance. On the other hand, if the respondent accepts the incentive but does not return the survey, in theory, they experience dissonance because they did not comply with a request but accepted the reward of the request. This experience of dissonance will be unsettling and may lead to several courses of action at a later date, including returning the incentive or returning the completed survey. Survey researchers hope that most respondents will be inclined to complete and return the survey, because the other courses of action produce unsettled feelings or require as much effort as compliance with little reward—that is, returning the uncompleted survey and incentive.

Leverage-Saliency Theory

Leverage-saliency theory, first advanced in 2000 by Robert Groves and his colleagues, presumes that people are influenced by a variety of factors, which differ in importance (salience), in deciding whether to participate in a survey. Some people are motivated, for example, by survey topic or sponsor, while others are motivated by civic duty or cash incentives. These different factors, if they are known before survey recruitment, could be emphasized during survey recruitment to improve response rates. Groves and colleagues use the analogy of a scale to illustrate leverage-saliency theory. The scale can be tipped in favor of survey participation, if the survey request is tailored to the respondent's key decision-making factors. For some respondents, an incentive will be highly salient and thus serve as an important leveraging factor in determining whether or not they will participate with a survey request.

Noncontingent Incentives Versus Contingent Incentives

Research has found consistently that incentives are most effective when provided prior to the completion of the survey task, that is, when given as pre-paid or noncontingent incentives. Noncontingent incentives are much more effective than incentives of the same size that are provided upon completion of the survey (promised or contingent incentives). In addition, some studies have found that noncontingent incentives produce higher response rates than promised incentives that are of much greater value.

The greater effectiveness of noncontingent incentives, over contingent incentives, offers support for both social exchange theory and cognitive dissonance theory of incentives. The pre-paid incentive may produce a sense of trust or invoke a sense of reciprocity, which explains survey participation. Alternatively (or in addition), potential respondents may be motivated by a desire to avoid a state of dissonance that may arise from keeping an incentive without completing the request.

A meta-analysis conducted by Allan Church suggested that promised incentives do not have any significant effect on response rates. However, the mode of the survey may interact with the effectiveness of contingent versus noncontingent incentives. Another meta-analysis of interviewer-mediated surveys by Eleanor Singer suggested that promised incentives produce a statistically significant increase in response rates and, in some cases, may be as effective as pre-paid incentives in recruiting respondents.

Contingent incentives include those incentives that are awarded as part of a prize drawing or lottery. Like other contingent incentives, prize draw awards generally are less effective than pre-paid incentives, even in conditions where the prize draw has a considerably greater potential payoff value. Research on the effectiveness of prize draws is split into two camps: that they produce slightly higher response rates or they have no effects on improved response rates. Prize draws are attractive, because they are much less costly to administer, although they have other administrative headaches.

Cash Incentives Versus Noncash Incentives

Cash awards are generally more effective than noncash awards (e.g., checks, gift cards, gift certificates, or small tokens such as pens), even if the value of the noncash award is greater than the cash award. Some studies find the greater the cash incentive is, the higher the response rate will be, but other studies find that the relationship is not strictly linear. These conflicting findings suggest that there are linear effects with lower amounts of incentives (where each additional dollar produces a higher response rate) and a flattening effect with higher amounts of incentives (additional dollars produce little change in response rate, e.g., going from $20 to $25). The diminishing return between the size of the incentive and response rate casts doubt on economic exchange theory of incentives as the sole or primary explanation of how incentives work.

While noncash incentives are less effective than monetary awards, some noncontingent, noncash awards produce significant increases in response rates. Pens and charity donations appear to be the favored options for noncash incentives among those that have been reported in the research literature. Pens vary in effectiveness in increasing response rate, but the research on the role of charity contributions is more conclusive. Charity donations on behalf of the respondents do not produce a significant increase in response rates.

Data Quality

Initially, survey researchers worried that incentives would reduce data quality by reducing intrinsic motivation to complete a survey, leading to less thoughtful or less complete responses. Subsequent research has largely appeased this concern. Studies find that incentives improve or have no effect on data quality. When comparing item nonresponse to closed-ended questions, research tends to be equally split between finding no differences and finding fewer item nonresponses in the incentive groups, compared to no-incentive groups. For example, the Singer meta-analysis of interviewer-mediated studies found that about half of the studies had no differences in data quality and half of the studies found improved data quality, when respondents received an incentive. When examining item nonresponse and length of response to open-ended questions, research suggests that incentives lead to higher-quality responses, as indicated by more distinct ideas and longer responses.

Response Bias

Survey researchers worry that incentives might alter survey responses, producing response bias. The possibility of response bias has been evaluated by comparing responses from those respondents who receive an incentive to those respondents who do not receive an incentive. (These investigations do not rule out the nonresponse bias that may exist between respondents and nonrespondents.) In general, differences in responses between incentive groups and no-incentive groups are not statistically significant. However, a few studies have found that incentives may produce slightly more favorable evaluations or positive ratings from incentive groups compared to no-incentive groups, but the small differences may not be substantively meaningful.

Sample Bias

In general, studies have found few differences in the demographic composition of their samples, when comparing no-incentive groups and those groups who received incentives of various types and sizes. Thus, incentives appear to be effective in recruiting respondents from a broad range of demographic groups. Unfortunately, these findings also suggest that incentives may not be effective in recruiting respondents who are especially hard to reach or otherwise unlikely to participate in surveys (e.g., young adults), unless differential amounts of incentives are given to such subgroups. For example, Singer and colleagues reported that only one third of the studies in their meta-analysis provided support for the role of incentives in improving the representation of groups that typically are underrepresented (low-income and nonwhite) in surveys, but these studies did not provide differential incentives to these groups. Most of the interviewer-mediated studies affirm that incentives do not change the demographic composition between incentive and no-incentive groups, unless differential incentives are used. Nor is there reliable and consistent evidence that incentives reduce nonresponse bias.

Interaction Effects of Incentives in Panel Data and Mixed-Mode Studies

The role of incentives in panel or multi-wave studies has increasingly become the subject of investigation. The effectiveness of incentives may differ by the outcome of prior contact with the respondent. While Singer and her colleagues found that incentives work for panel respondents, fresh respondents, and prior refusing respondents, Norm Trussell and Paul Lavrakas found that the improvement in response rate is proportionally much greater for people who refused during a prior contact and later received a larger incentive, than for those with whom the researchers had no contact in the prior stage of the research or those who readily agreed to cooperate in the subsequent research without receiving an incentive. John Brehm found that incentives work better when a respondent refuses because of the survey characteristics (e.g., survey is too long), but incentives may be counterproductive if the respondent refuses because they doubt their ability to do the survey (they are illiterate, deaf, or ill). Using the findings from previous interactions with a respondent to tailor the recruitment strategy, including the targeted use of incentives, is the basic tenet of leverage-saliency theory.

Independent Variable

In survey research, an independent variable is thought to influence, or at least be correlated with, another variable: the dependent variable. For example, researchers hypothesize that childhood exposure to violent television can lead to violent behavior in adulthood. In such a study, exposure to violent television programming as a child is an independent variable and violent behavior in adulthood is the dependent variable.

An independent variable is commonly denoted by an x and a dependent variable by y, with the implication that "x causes y" or, in the case of noncausal covariation, "x is related to y."

Determining whether one variable influences another is of central importance in many surveys and studies, as making this determination helps researchers accept or reject hypotheses and thereby build social science knowledge. Relationships between variables help researchers to describe social phenomena.

In experimental studies, with random assignment of respondents to experimental conditions, a researcher can choose which variables are independent, because these are the variables controlled by the researcher. In population studies, patterns in data help researchers determine which variables are independent.

More than one independent variable may influence a dependent variable. Quantitative tools and approaches can assist researchers in accepting or rejecting their hypotheses about the relationships among independent variables and a dependent variable. In some analyses, researchers will "control for" the influence of certain independent variables in order to determine the strength of the relationship for other independent variables.

Using the example of childhood exposure to television violence again, another independent variable in the study could be parental control over television viewing. Yet another independent variable could be level of physical violence in the home. The complexity of a hypothesized causal model such as this increases with the number of independent variables and interaction effects among independent variables.

Ineligible

The ineligible disposition is used in all surveys, regardless of the mode (telephone, in-person, mail, or Internet). Ineligible cases are cases that were included in the sampling frame but fail to meet one or more of the criteria for being included in the survey. Cases coded as ineligible do not count in computing survey response rates.

One of the most common reasons a case would be coded as ineligible is when a survey uses screening criteria to determine whether the respondent, household, or organization contacted as part of a survey is eligible to complete the survey. For example, a survey may require respondents or households to be located within a specific geographic area, such as a specific county, town or village, or neighborhood. A case would be considered ineligible if it were discovered that the respondent or household was located outside of the geographic boundaries of the survey population. In most instances, if it were discovered during the screening process that the sampled respondent had moved out of the geographic boundaries of the survey during the field period, that case also would be considered ineligible.

An additional example of how screening criteria may result in a case being considered ineligible occurs in surveys of the general population. These surveys use residential status as screening criteria, and as a result, all cases that result in contact with a nonresidential unit, such as businesses, schools, or governmental organizations, would be considered ineligible. In in-person surveys, this often is discovered when an interviewer visits a sampled address and discovers that it is not a residence. In telephone surveys, this would be discovered when interviewers make telephone calls to businesses; fax or data lines; nonworking, changed, and disconnected telephone numbers and numbers that reach pagers. In landline telephone surveys, numbers that reach cell phones would be treated as ineligible. Also, in a telephone survey an answering machine message might allow an interviewer to determine if the number is ineligible.

Some surveys use screening at the respondent level to determine eligibility. For example, a survey may seek to collect data from respondents with a specific set of characteristics (demographics, occupation, tenure in job, etc.). Cases in which the individual respondent discloses during the screening process that he or she does not have the characteristics sought by the survey would be considered ineligible. Finally, if a telephone, in-person, mail, or Internet survey uses quotas, cases contacted for which quotas have already been filled are considered ineligible.

A number of other reasons that a case may be categorized with the ineligible disposition are specific to each survey mode. In telephone surveys, the ineligible disposition may be used when the number has technical difficulties and no one can be reached on it or when a business number is forwarded to a residence. In an in-person survey, the ineligible disposition may be used for cases in which interviewers discover that the sampled address is a housing unit that is vacant during the entire field period of a survey, and rarely, for a housing unit that has no eligible respondent (such as cases in which all residents are under 18 years of age). In mail and Internet surveys, the ineligible disposition may be used if the same respondent or addressee is sampled more than once. These duplicate mailings usually are treated as ineligible if the error is not caught until after the questionnaires have been mailed out (in mail surveys) or until after the email invitation is sent out (in Internet surveys).

INFERENCE

Inference is a process whereby a conclusion is drawn without complete certainty, but with some degree of probability relative to the evidence on which it is based.

Survey data may be used for description or for analysis. Descriptive uses include making estimates of population totals, averages, and proportions. Analytical uses include testing hypotheses about the population. The analytical uses involve making *statistical inferences*. For example, a descriptive use of survey data would be to supply an estimate of the number of male and female engineers. An analytical use would be to infer (based on valid statistical procedures) that there are significantly fewer female engineers than male engineers. Another descriptive use of survey data would be to supply the average salary of teachers. An inferential use would be to conclude that, even after controlling for education and experience, teachers of one racial-ethnic category tend to have a higher average salary than those in another racial-ethnic category.

Design-Based and Model-Based Inferences

There are two approaches to making inferences from survey data. First, in the *design-based approach*, inferences are made by looking at how statistics vary as samples are repeatedly drawn using the same sampling procedures as were employed in the actual sampling.

Second, in the *model-based approach*, inferences are made by looking at how statistics vary as the population, as described by a probability model, is allowed to vary without changing the sample. The model-based approach is also called the *prediction approach* because the model is used to predict the population units not in the sample. It is called the *superpopulation approach* as well because the population can be regarded as selected from a still larger population according to the probability model.

Inference procedures (e.g., hypothesis testing or estimating confidence intervals) can be carried out under either the design-based or the model-based approach. The design-based approach is more traditional in survey sampling. The model-based approach, on the other hand, is more consistent with statistical approaches used outside of survey sampling.

Confidence Intervals

Confidence intervals allow one to infer with a high degree of confidence that a quantity being estimated lies within an interval computed by a specified procedure.

The precise meaning of "confidence" depends on whether one is adopting the design-based or model-based approach. Clearly a confidence interval is more informative than a numerical estimate of a population quantity (called a *point estimate*) in that the confidence interval conveys information about how precise the point estimate is.

Hypothesis Testing

The purpose of hypothesis testing is to ascertain whether an observed difference in the sample is statistically significant or whether it can instead be adequately explained by chance alone. Hypothesis tests are designed so that, if there is in fact no difference, the probability of (erroneously) rejecting the hypothesis that there is no difference (i.e., the null hypothesis) is kept to a specified low level; often this probability, called the Type I error, is set to .05. A well-designed hypothesis test will also minimize the other potential error on inference, namely, not rejecting the hypothesis of no difference when a difference actually exists (i.e., Type II error). In survey sampling, it is often the case that two sample averages are independent and approximately normally distributed so the hypothesis that their difference is zero can be tested using properties of the normal distribution (this is called a *t-test*).

There is a close relationship between confidence intervals and hypothesis testing in that a hypothesis of no difference is rejected if and only if the confidence interval *for the difference* does not include zero. If one has confidence intervals for each of two independent averages and the confidence intervals do not overlap, one may reject the hypothesis of no difference between the two averages. But if the two confidence intervals do overlap, it is still possible that the hypothesis of no difference in the sample averages can be rejected.

INFORMANT

An informant in a survey is someone asked to provide information about another person, persons, or an organization, for example, when a parent is interviewed about a young child who could not answer the survey questions. Informants (also known as *proxies*) tend to be used in surveys when the target respondent is unable to respond or when it is not feasible to collect responses from all members of a group under study. As the use of informants to collect quantitative data has become integral to survey research, due to the cost-effectiveness of the approach, so has the study of the effects of using informants on the data that are collected. The substitution of informants limits the types of data that can be collected with accuracy, and proper selection methods should be used to minimize the resulting response bias that has been noted to occur occasionally when data collected from informants are compared to self-reported data.

There are several types of surveys in which the use of informants is the most efficient means of collecting responses. Informants are frequently used in surveys when members of the population under study are unable to provide responses because a physical or cognitive impairment prevents them from responding. Because informants are the only way to collect information about these target populations, informants are used despite the fact that several methodological experiments have shown that using informants produces response bias. Specifically, in surveys asking about disability, informants tend to overreport more obvious types of disability (such as difficulty with activities of daily living) and to underreport less obvious types (such as mental health problems).

Another survey situation in which the informant method of data collection has been used is when it is not economically feasible to interview all individual respondents, such as all members of a household or an organization. Studies using this method generally develop selection rules that ensure that the selected informant is likely to be able to provide accurate responses about others in the household or organization. The selection rules used by the survey are applied (e.g., randomly selecting one of the adults in the household), and the selected informant reports on the behaviors of other members of the household or organization. Further, surveys asking questions on sensitive topics have used informants to reduce bias from self-reported responses due to social desirability. These include surveys collecting information about sensitive behaviors such as alcohol, tobacco, and drug use, which tend to be underreported by respondents. For example, the results of some experiments suggest that the informant method yields estimates of alcohol use that are closer to actual alcohol sales figures than self-reported data.

The ability of selected informants to respond accurately to surveys depends on how observable the survey subjects are by the informant and on the informant's ability to recall events. The survey topics asked of informants must take these issues into account, as informants are best able to provide accurate information about others when the informant has a high degree of knowledge about those he or she is answering questions about. For this reason, topic areas in surveys using informants that include factual or "hard" measures are preferable to "soft" measures requiring subjective evaluation by those providing responses. For example, in a survey administered to principals of an organization, demographic questions answered by an informant on "hard" topics such as age, prior experience, or race will likely produce lower item nonresponse and be more reliable than topics less likely to be observable to informants, such as net worth or total household income.

Informed Consent

As outlined in the *Belmont Report* of 1979, the core elements underlying the ethical treatment of research participants are autonomy (respect for persons), beneficence, and justice. Providing adequate information and obtaining active consent for research participation are central to autonomy and respect for persons. Acknowledging the importance of autonomy requires that every potential research participant must be afforded adequate time and opportunity to make his or her own informed and voluntary decision about whether or not he or she wishes to participate in a research study. This requires the provision of adequate information about the study and, in theory, also requires that no pressure be exerted to participate. The principle of autonomy also requires that special protections be given to potentially vulnerable populations such as minors, the mentally ill, or prisoners. Individuals in these groups may be in a position of increased potential for coercion (e.g., prisoners) or may be less capable of understanding information that would enable them to make an informed decision about study participation.

Informed consent includes the process by which research participants gain an understanding of the procedures, risks, and benefits that may be associated with their taking part in a study. In virtually all surveys, the key elements of "voluntary" and "informed" consent can be provided in a concise way at the beginning of a telephone or face-to-face interview, in a cover letter for a self-administered survey, or in the introductory screen of a Web or other electronic survey. This is true regardless of level of risk and is consistent with the contemporary view of consent as an ongoing process rather than a paper document. The main elements of consent include the following:

- An explanation of the purpose(s) of the study
- An indication of the approximate amount of time it will take to complete the study
- A description of what the respondents will be asked to do
- A description of any foreseeable risks or discomforts, if any
- A description of any direct benefits to the respondents or others
- A statement describing the extent to which responses will be confidential
- A statement of the voluntary nature of participation

Contact information should also be available for questions about the research and about respondent rights. This information can be provided upon request for telephone surveys and should be included in the written introductory information in face-to-face, self-administered, and electronic modes.

Consent can be obtained from adult respondents who can understand the benefits and risks of the survey. Except in the special cases where parental permission itself could pose risks (e.g., studies of child abuse), parental permission must be obtained prior to administration of a survey to a minor, and assent (agreement to participate) should be obtained from the child or other nonadult. The age of majority is typically 18 but varies slightly in the United States from state to state.

Special challenges exist for studies being conducted by or for someone with authority or special power over potential respondents (e.g., teachers, supervisors, employers, physicians). In these cases, it is particularly important that the respondent recruitment procedures evidence no coercion, either explicit or implicit. Researchers must make a clear distinction between research questions and issues arising out of the authority relationship. To avoid the perception of undue influence or coercion, persons with authority over potential respondents should not recruit participants themselves if they will have knowledge about who did and did not participate or will have access to individual responses.

In most surveys, respondents indicate their consent by providing oral agreement at the beginning of the interview, by answering questions as they are asked or that appear on a paper or electronic questionnaire, or both. Thus, people may consent to all of an interview, to part of it, or to none of it, depending on how they respond to requests from the interviewer.

Federal regulations (C.F.R. 46.117c) on human subjects protections in the United States recognize that written or signed consent forms are not necessary or desirable in every research setting. The regulations provide that, while written consent is the norm in much research involving humans, institutional review boards may waive requirements for signed consent if they find that the research presents no more than minimal risk of harm to subjects and involves no procedures for which written consent is normally required outside of the research context. Most surveys pose risks no greater than those experienced in everyday life. Further, in many contexts, written consent forms may increase risk (e.g., research on illegal behavior, health, illegal immigrants) and may reduce cooperation unnecessarily. Telephone surveys utilizing random-digit dialing and Web survey invitations sent via email cannot incorporate signed consent in the protocol prior to the initial contact because respondents' names and street addresses are unknown to the researcher. Thus, a waiver of documentation of consent is typically the most desirable approach for most survey protocols—especially those utilizing telephone and electronic modes.

In the typical survey that presents minimal risk, lengthy and detailed information about the objectives of the survey and the questions to be asked may increase respondent burden and bias responses without safeguarding respondent rights. In these surveys, the usual practice of a short introduction—including the purpose of the study; the approximate amount of time it will take; the sponsor, responsible survey organization, or both; and the general topics to be covered—is typically deemed sufficient. This statement should also include information about the confidentiality of the responses.

More detailed information is required when survey participation may pose substantial risk. In general, respondents should be informed that the content includes sensitive topics or questions about any illegal behaviors, but they should not be told so much as to bias their answers (e.g., they should not be informed of the study hypothesis). This is consistent with much other social science research performed in laboratory settings where explanations of the hypotheses at the outset would render the study invalid, although such studies may require special debriefing of the respondents after the survey is completed. It is also important to include a statement indicating that respondents can skip questions that cause them discomfort and questions they do not want to answer.

The introductory statement and the reminders about the voluntary nature of response help ensure respondent autonomy (respect for persons) without affecting substantive responses. If appropriate, at the end of the interview, respondents can be debriefed to see if any of the matters covered were upsetting, to give further information on study purposes, or to answer respondent questions.

Institute for Social Research (ISR)

The Institute for Social Research (ISR), originally established in 1949 at the University of Michigan as the Survey Research Center under the direction of Rensis Likert, is the nation's longest standing interdisciplinary research laboratory in the social sciences. Support from the sociology and psychology departments was an important factor in the decision to establish the ISR at the University of Michigan. The center was kept administratively separate from other schools and colleges, and its executive committee was made up of members from a variety of relevant disciplines; this separation was designed to promote its interdisciplinary nature. By the early 1950s the staff had grown from 12 to nearly 200. Tenure privileges were not granted to the senior staff members by the University of Michigan Regents until 1968. Its research staff exceeds 225, representing the disciplines of psychology, sociology, economics, political science, and others. Nearly 500 permanent staff and additional contingent interviewers numbering 1,300 support the research scientists. The ISR is primarily self-supporting through grants and external contracts, largely from the federal government. ISR study findings have been used to develop policy and practice on various social issues ranging from health and drug use to racial prejudice, welfare, and retirement. The ISR is best understood through its research centers, each autonomous in its research and administration.

The Survey Research Center is the largest of the ISR centers and is a national and international leader in social science research. The four initial programs—economic behavior, political behavior, organizational behavior, and survey methodology—have grown to include active research programs such as family and demography, life course development, quantitative methodology, social environment and health issues, socioenvironmental studies, social indicators, urban and environmental studies, and youth and social issues.

The Center for Political Studies research themes are political values and participation, media and politics, race and politics, and international peace and security. Designated as a national resource by the National Science Foundation, the Center for Political Studies was originated by the development of the National Election Studies, first conducted in 1948.

The Inter-University Consortium for Political and Social Research, created in 1962, has over 600 member institutions worldwide and is the largest archive of quantitative social science data in the United States. The archive includes some 500,000 files for research and instruction. These files span political science, history, public health, sociology, demography, criminal justice, international relations, economics, gerontology, and education.

The Research Center for Group Dynamics focuses on the individual and has particular interest in social cognition and group processes. The center was founded in 1945 at the Massachusetts Institute of Technology and moved under the ISR umbrella in 1948. Studies in natural settings probe decision making, prejudice, emotion, and judgment processes, and research has practical applications to understanding group behavior and social influence that affect social concerns such as racism, crime, and delinquency.

The Population Studies Center was established in 1961 within the Department of Sociology at the University of Michigan and has been closely related to the Department of Economics since 1966. Drawing faculty from the departments of anthropology, biostatistics, economics, geography, history, natural resources, political science, psychology, public health public policy, social work, sociology, and statistics has allowed the Population Studies Center to become increasingly interdisciplinary. The center's strengths in demographic research include aging; family formation, fertility, and children; health, disability, and mortality; human capital, labor, and wealth; methodology; population dynamics; and regional studies. In 1998, the center made an institutional move from the College of Literature, Science, and Arts to ISR, becoming the institute's fourth center.

Training future generations of empirical social scientists is the long-term commitment of the ISR. The ISR has offered the Summer Institute in Survey Research Techniques for more than 60 years; designed to meet the needs of professionals, the Summer Institute teaches practice, theory, implementation, and analysis of surveys. For more than 45 years, the Inter-University Consortium for Political and Social Research (ICPSR) Summer Program has provided studies in basic methodological and technical training, data analysis, research design, social methodology, and statistics, in addition to advanced work in specialized areas. A graduate-level Program in Survey Methodology was established in 2001, seeking to train future survey methodologists in communication studies, economics, educations, political science, psychology, sociology, and statistics. The program offers a certificate, master of science, and doctorate degrees through the University of Michigan.

Institutional Review Board (IRB)

Institutional review boards (IRBs) are committees charged with the review and monitoring of research (including surveys) involving human participants. The basic principles of human research protection used today in the United States were outlined in the *Nuremberg Code* and were developed in response to the Nazi atrocities. Voluntary informed consent to research participation is at the core of that code. In response to research participant abuse in the first half of the 20th century, IRBs were mandated in the United States by the Research Act of 1974. In 1978, the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research submitted the *Belmont Report*, which recommended the basic ethical principles underlying the acceptable conduct of research involving human participants. Those principles are (a) respect for persons (autonomy), (b) beneficence, and (c) justice. These basic principles continue to form the foundation for ethical conduct of research involving human participants.

Since 1974, all research funded by the Department of Health and Human Services has been required to undergo review to ensure ethical treatment of research participants. Most organizations receiving federal funding have assurance agreements that extend this ethical review to all research conducted by the institution. Although not yet enacted, in recent years, several federal legislators have expressed interest in expanding these protections to all public and private research—irrespective of funding source.

The constitution and utilization of IRBs were included in the regulations that were codified in Title 45 (Public Welfare—Department of Health and Human Services) *Code of Federal Regulations* (C.F.R.) Part 46 (Protection of Human Subjects). The regulations require that IRBs have a minimum of five members of varying experience and expertise as well as broad demographic representation. At least one member must have scientific expertise and at least one member must be from a nonscientific area. One member of the IRB must be from outside the institution. IRBs are also allowed to invite individuals with special expertise or knowledge to provide consultation and information on individual protocols, where needed.

Review of research activities typically involves the submission of a detailed overview of the research protocol utilizing a submission form. The form asks specific questions regarding how participants will be recruited, what they will be asked to do, details of the research design, and how the data will be transmitted, stored, and disseminated. The IRB reviews this information and performs a risk–benefit analysis to assure that any risks to the participants are offset by benefits to the participants or society. The review includes the following seven components: (1) identification of risks associated with the research participation; (2) identification of probable benefits of the research; (3) to the extent possible, assurance that risks are minimized; (4) determination of whether risks are proportionate to benefits; (5) assurance that participants are given accurate and complete information about the potential risks and potential benefits; (6) determination of the adequacy of privacy and confidentiality protections; and (7) determination of the best review intervals and any necessary monitoring of data collection.

The IRB has the authority to approve a protocol, to disapprove a protocol, or to ask for revisions or modifications of a protocol before approving the protocol. The IRB's decision and any required modifications are made in writing to the investigator. If a project is disapproved, the investigator is notified of the rationale and is provided with an opportunity to respond to the IRB regarding the disapproval.

Many protocols require review by the fully convened IRB; however, most minimal risk research receives an expedited review (conducted by the IRB chair or his or her designee) if it falls into one of seven categories defined by the regulations. Other minimal risk research may be reviewed initially and then granted an exemption from review if it meets specific criteria defined by the regulations and the local IRB. The determination of whether or not a research project meets the definition for exempt or expedited review is discretionary on the part of the IRB. The application of the various types of review is determined by the local IRB. At most academic institutions, for example, all research is reviewed by the IRB to assure that basic ethical standards are met. Minimal risk surveys are typically reviewed under an exempt or expedited category.

The IRB typically requires documentation of informed consent (e.g., a form signed by the participant that outlines the project, the risks, and benefits). However, the IRB may also approve a waiver of documentation of consent. This often is done for survey projects where obtaining a signature would not be possible or feasible or necessary in light of the minimal risks involved. For example, in a random-digit dialing telephone interview, consent is obtained (typically in oral mode), but no signature is required.

The IRB must review projects at least annually (for those lasting more than 1 year) but may require a shorter interval for projects that are more than minimal risk. The IRB is also authorized to have one or more members observe the recruiting, consent, and research process or may enlist a third party to observe to ensure that the process meets the desired ethical standards and desired levels of risk and confidential treatment of data. A protocol approved by an IRB may still be disapproved by the institution for some other reason. However, if a protocol is disapproved by the IRB, it may not be approved by the institution.

Interaction Effect

An interaction effect is the simultaneous effect of two or more independent variables on at least one dependent variable in which their joint effect is significantly greater (or significantly less) than the sum of the parts. The presence of interaction effects in any kind of survey research is important because it tells researchers how two or more independent variables work together to impact the dependent variable. Including an interaction term effect in an analytic model provides the researcher with a better representation and understanding of the relationship between the dependent and independent variables. Further, it helps explain more of the variability in the dependent variable. An omitted interaction effect from a model where a nonnegligible interaction does in fact exist may result in a misrepresentation of the relationship between the independents and dependent variables. It could also lead to a bias in estimating model parameters.

As a goal of research, examination of the interaction between independent variables contributes substantially to the generalization of the results. Often a second independent variable is included in a research design, not because an interaction is expected, but because the absence of interaction provides an empirical basis for generalizing the effect of one independent variable to all levels of the second independent variable.

A two-way interaction represents a simultaneous effect of two independent variables on the dependent variable. It signifies the change in the effect of one of the two independent variables on the dependent variable across all the levels of the second independent variable. Higher-order interactions represent a simultaneous effect of more than two independent variables on the dependent variable. Interaction effects may occur between two or more categorical independent variables as in factorial analysis of variance designs. It may also occur between two or more continuous independent variables or between a combination of continuous and categorical independent variables as in multiple regression analysis. To illustrate these effects, the following sections start with the interpretation of an interaction effect between two categorical independent variables as in ANOVA, followed by the interpretation of an interaction effect between one categorical independent variable and one continuous independent variable, and finally the interpretation of an interaction effect between two continuous independent variables. Interpretation of three or more higher-order interaction terms effects follow the same logic of interpreting the two-way interaction effect.

Interaction Between Two Categorical Independent Variables

Consider a survey research study investigating the effectiveness of incentives and postal mailers on response rates in a mail survey. Incentive amount is the first categorical independent variable (A) with three groups; A_1 is a control group who receives no incentive, A_2 is a \$1 incentive group, and A_3 is a \$5 incentive group. The second categorical independent variable (B) is type of mailer with B_1 for First-Class Mail and B_2 for Federal Express. Response rates to the mail survey in percentages (Y) are the dependent variable for the study. In this typical (3×2) ANOVA there is (a) a possible main effect for incentive amount on response rates, (b) mailer type as a possible main effect on response rates, plus (c) a possible interaction effect between incentive amount and mailer type on response rates. A significant interaction effect suggests that the differences in the effects of incentive amount on response rates depend on mailer type (and vice versa). That is, in this example, the average differences in incentive amount effect on response rates are different in magnitude and possibly in direction for First Class versus what they are for Federal Express. Conversely, one can say that the average difference (in magnitude and direction) for response rates between a First-Class envelope and a Federal Express envelope depends on the incentive amount a household receives. An insignificant (negligible) interaction effect between incentive amount and mailer type on response rates suggests that the differences in response rates across incentive amounts are essentially the same for First Class and Federal Express. One can also interpret an insignificant interaction effect between mailer type and incentive amounts by recognizing that the difference between First Class and Federal Express is basically the same (in magnitude and direction) across the three incentive amounts.

Graphing interaction effects often simplifies their interpretation. It also helps analysts identify the two types, ordinal and disordinal interaction effects (as shown in Figures 1 and 2).

Ordinal Interaction

Ordinal interaction occurs when the magnitude of the differences between the levels of one independent variable on the dependent variable varies across the levels of the other independent variable, yet the direction (order) of these differences stays the same. In the response rate example, a case of an ordinal interaction might occur when, for example, the difference in response rates between First Class and Federal Express varies for each incentive amount, yet Federal

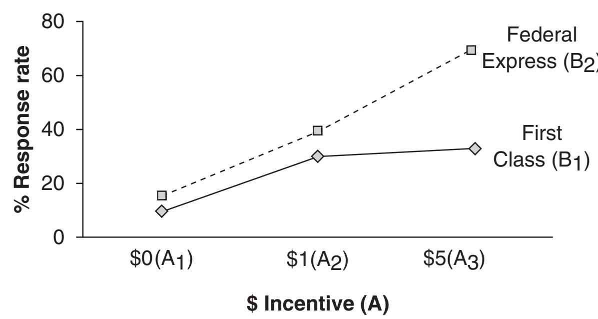

Figure 1 Ordinal interaction

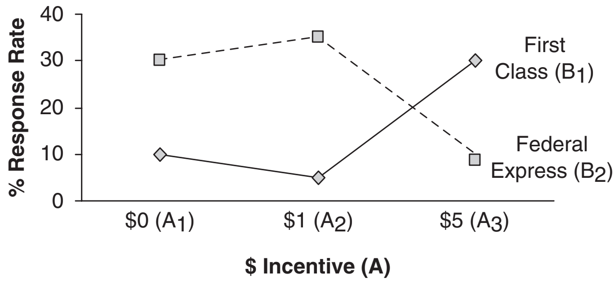

Figure 2 Disordinal interaction

Express always leads to a higher response rate than First Class, across all incentive amounts that are tested in the experimental design. Figure 2 illustrates the constant (consistent) order in the difference between Federal Express and First Class, where Federal Express (B_2) always has a higher response rate than First Class (B_1) for every incentive amount tested.

Disordinal Interaction

A disordinal interaction (as shown in Figure 2) occurs when the difference between the levels of one independent variable on the dependent variable varies in magnitude and direction across the levels of the other independent variable. An example of a disordinal interaction would occur if Federal Express leads to higher response rate when \$0 and \$1 are sent as incentives, but First Class leads to higher response rates when \$5 is sent. This type of inconsistent interaction is depicted in Figure 2.

No Interaction

No interaction effect exists when the differences in response rates between types of mailers are of the same magnitude and same order across all three incentive amounts. This case results in having parallel lines for First Class and Federal Express, as depicted in Figure 3.

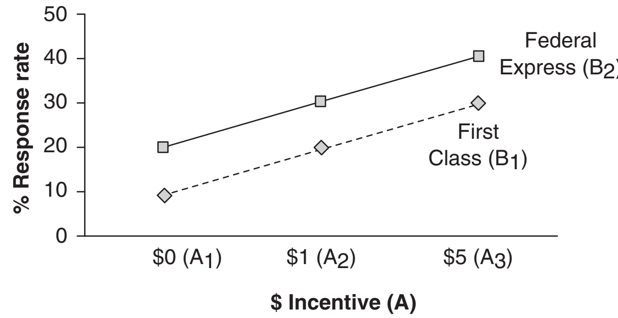

Figure 3 No interaction

Interaction Between One Categorical Variable and One Continuous Variable

Studying the interaction effect of continuous and categorical independent variables on a dependent variable is usually done through a regression analysis. A categorical independent variable usually is created using one of several coding methods when it is used in a regression analysis. One commonly used coding method is a *dummy coding*, where $C - 1$ dummy variables (taking on the values of 0 or 1) are created to represent the C categories of the variable with one reference category (e.g., a categorical variable such as race might be coded so that reference category is White and three dummy variables are created: Asian, Black, and Other race). The estimated regression coefficient for a dummy variable represents the average difference in the dependent variable between the category of the dummy variable and the reference category. The coefficient associated with the continuous independent variable represents the effect of the independent variable on the dependent variable.

Consider a study surveying people's attitudes toward government war policy and how it might be influenced by their political party affiliation (Republican versus Democrat) and the time they spend watching the Fox News TV channel. Party affiliation constitutes the categorical independent variable in this example. Time (T) in minutes spent watching the Fox News TV channel is the continuous independent variable.

To model the effect of party affiliation on attitude through a regression analysis we create a dummy variable (D) with Democrats coded "1" and Republicans coded "0."

Equation 1 provides the coefficients (b's) for a full estimated regression model that predicts people's attitude (Y) from their party affiliation (D), the time they spend watching Fox News (T), and a product term between party affiliation and time ($T \times D$). These coefficients represent the main effect of party type, main effect of time spent watching the Fox News TV channel, and an effect for the interaction on people's attitudes toward government war policies.

$$\hat{Y} = b_o + b_1\text{D} + b_2\text{T} + b_3(\text{D x T}) \quad (1)$$

Substituting the values of the variable D in Equation 1 generates two regression equations with different watching time effect on people's attitudes on war policy, one for the Republicans and the other for the Democrats. The two main effects are reflected in the coefficients b_2 and b_3 representing the interaction effect between time and party affiliation on people's attitude.

$$\hat{Y} = b_o + b_2\text{T} \quad (2)$$

$$\hat{Y} = b_o + b_1 + (b_2 + b_3)\ \text{T} \quad (3)$$

The value of b_2 in Equation 2 reflects the effect of time Republicans spend watching Fox News TV channel on their attitude. The sum of b_2 and b_3 in Equation 3 is the effect of time Democrats spend watching Fox News TV channel on their attitude. A significant test of b_3 would signify a nonnegligible interaction effect of party affiliation with the time spent watching the Fox News TV channel on people's attitude toward war policy.

Interaction Between Two Continuous Independent Variables

An interaction effect between two continuous independent variables on a dependent variable is expressed as a multiplicative term in a multiple regression analysis. A full regression model that predicts, say, parents' attitude toward schools (Y) from schools' involvement in the community (SIC) and parents' social economic status (SES) as two continuous independent variables and their interaction (SIC × SES) is presented in Equation 4.

$$\hat{Y} = b_o + b_1\text{SIC} + b_2\text{SES} + b_3(\text{SIC x SES}) \quad (4)$$

The value of b_3 represents the interaction effect between SIC and SES on parents' attitude, Y. It reflects SIC effect on parents' attitude, Y, conditioned on the levels of SES. To understand the interpretation of the interaction effect between SIC and SES, it is better to reorganize Equation 4 into

$$\hat{Y} = b_o + b_2\text{SES} + (b_1 + b_3\ \text{SES})\text{SIC}. \quad (5)$$

Equation 5 reveals that the effect of SIC, $(b_1 + b_3\text{SES})$, on parents' attitude (Y) depends on the levels of SES. One must also realize that Equation 4 can also be rearranged to express the same interaction between SES and SIC as the conditional effect of the SES variable on the dependent variable Y, conditioned on the values of the SIC variable. A close look at Equation 5 reveals its similarity to Equation 3. In fact, if SES is categorized into two categories such as high SES and low SES, Equation 5 becomes equivalent to Equation 3.

A nonsignificant value of b_3 implies a negligible or no interaction effect between the two variables SES and SIC. For a nonsignificant interaction, the regression model simplifies to

$$\hat{Y} = b_o + b_1\text{SIC} + b_2\text{SES}. \quad (6)$$

The coefficient b_1 represents the same effect of school involvement in the community on parents' attitude across all levels of parents' social economic status. Similarly b_2 represents the same effect of parents' social economic status on their attitude across all the levels of school involvement in the community.

Interactive Voice Response (IVR)

Interactive voice response (IVR) is a data collection technology that uses a recorded voice to ask survey questions by telephone, in place of live interviewers. Respondents enter their answers by pressing the buttons on the keypad of their touchtone telephone. An IVR system controls the presentation of the survey questions, captures the responses entered via touchtone, prompts respondents to answer questions, and offers automated help to respondents. IVR is also known as telephone audio computer-assisted self-interviewing (T-ACASI) and touchtone data entry. These terms all refer to computerized telephone data collection systems where respondents answer survey items via automated self-administered procedures, as opposed to giving verbal answers to live interviewers.

IVR has two primary uses in survey research. First, IVR can be used to replace interviewer-administered telephone data collection. Potential respondents may be contacted first by telephone interviewers and then switched to IVR, or they can be contacted by another mode (e.g., mail or Internet) and provided a call-in number to use for completing an IVR interview. Another use of IVR is to provide telephone survey respondents greater privacy in responding to questions of a potentially sensitive nature. When used for this second purpose, IVR interviews are typically conducted through initial contact from telephone interviewers who then switch respondents to IVR for the sensitive items. The respondent is then switched back to the interviewer after answering the sensitive questions. Regardless of the specific purpose, IVR data collection typically involves a relatively short, simple interview or a brief module that is part of a longer interview.

IVR offers a number of potential advantages over interviewer-administered modes of telephone data collection. First, because a pre-recorded voice is employed to administer all survey items, IVR respondents are all read questions, response options, and instructions in the exact same way. This provides a higher degree of interview standardization than interviewer-administered telephone data collection, where interviewers' vocal qualities, reading skills, and presentation skills vary.

A second advantage of IVR is providing greater privacy for answering questions, especially survey items of a potentially sensitive nature that could be affected by socially desirable reporting. Because IVR respondents enter their answers by pressing touchtone buttons, they do not have to be concerned about giving their responses to a live interviewer or about others (e.g., family members) hearing their responses. Research indicates respondents in IVR mode give more nonnormative answers to questions of a sensitive nature compared to respondents in computer-assisted telephone interviewing (CATI) mode. Examples include greater reports of illicit substance use, certain sexual behaviors, and negative satisfaction ratings.

Third, when IVR surveys are conducted with no interviewer involvement, this mode can be a much more cost-effective method than CATI. This version of IVR data collection saves on both the costs of recruiting, training, and supervising interviewers as well as telecommunication costs. Because telephone charges are incurred only when potential respondents call in to complete IVR interviews, these costs are lower than costs in the interviewer-administered mode where multiple outbound calls are typically made to contact each sampled unit.

IVR does have some potential limitations compared to interviewer-administered modes of telephone data collection. First, IVR mode provides unique opportunities for unit nonresponse or incomplete interviews. When respondents are left to complete an IVR interview on their own time, they are less likely to participate without the motivation provided by interviewers. Similarly, in surveys where interviewers first recruit respondents and then switch them to IVR mode, respondents have an opportunity to terminate the interview at that point, without being exposed to the persuasive efforts of an interviewer.

Second, concerns about respondent patience and terminations limit the length and complexity of IVR surveys. More lengthy IVR surveys introduce considerable risk that respondents will terminate interviews prior to completion, because no interviewer is present to encourage continued participation. Complicated surveys may also increase the risk of respondents either terminating the interview or providing inaccurate responses or no responses to some items to reduce the survey burden.

Third, the lack of an interviewer creates a potential risk of measurement error in IVR interviews, as in other self-administered modes of data collection. Without an interviewer to clarify response tasks, probe inadequate responses, and record answers accurately, IVR data can introduce other sources of respondent-related measurement error that are not as likely to occur in interviewer-administered surveys. Although IVR systems can provide a help button for respondents to use when they are having difficulty completing a question, respondents may be hesitant to use this option when they need it or they may not receive sufficient help to accurately answer an item.

Finally, when IVR data collection is used as part of an interviewer-administered survey where interviewers recruit and screen eligible subjects, cost savings compared to CATI data collection mode may not be realized. Adding an IVR module to a CATI survey would actually add costs related to the additional programming and management required for using these two modes. Costs for recruiting, training, and supervising interviewers would be similar to those costs in CATI-only mode.

Intercoder Reliability

Intercoder reliability refers to the extent to which two or more independent coders agree on the coding of the content of interest with an application of the same coding scheme. In surveys, such coding is most often applied to respondents' answers to open-ended questions, but in other types of research, coding can also be used to analyze other types of written or visual content (e.g., newspaper stories, people's facial expressions, or television commercials). Intercoder reliability is often referred to as *interrater* or *interjudge reliability*. Intercoder reliability is a critical component in the content analysis of open-ended survey responses, without which the interpretation of the content cannot be considered objective and valid, although high intercoder reliability is not the only criteria necessary to argue that coding is valid. Intercoder reliability is a standard measure of research quality, and a low level of intercoder reliability may suggest weakness in coding methods, including poor operational definitions with unclear coding categories and poor coder training.

Although there are more than 30 different statistical measures or indices of intercoder reliability, only a handful of measures are widely used and there is no consensus on the single best measure. Among all, for its simplicity and ease of use, *percent agreement* is the single most widely used index. It is measured by the proportion of coding decisions that reached agreement out of all coding decisions made by a pair of coders. However, it does not account for agreement that could occur by chance. The proportion of agreement by chance alone is higher when fewer coding categories are given and lower when more coding categories are given. As the number of coding categories increase, however, high percent agreement becomes more difficult to achieve. Percent agreement is also limited to nominal coding with only two coders with the same number of coded units. Holsti's *CR*, a variation of percent agreement index, accounts for different numbers of coded units each coder produces. Scott's pi (π), on the other hand, takes into account the agreement that can occur by chance. It also accounts for the number of coding categories and distribution of coded categories. Scott's pi (π), however, is appropriate only for nominal level coding. Cohen's kappa (κ) is another widely used index that also accounts for chance agreement. Kappa is commonly used for the nominal level coding of behaviors. Although this index has been adapted to situations where multiple coders evaluate a different set of units, it is known to be most appropriate when one pair of coders judges the same set of units without violating the assumptions of independent coders and random coder errors. A more flexible measure, although more demanding mathematically, is Krippendorff's alpha (α). This index can account for chance agreement, different levels of coding (i.e., nominal, ordinal, interval, and ratio), multiple coding categories, different sample sizes, and missing data. Generally, the selection of proper index will depend on the levels of coding, number of coded categories if coded nominal, number of coders, and number of coded units. Indices that measure association (i.e., chi-square), internal consistency (i.e., Cronbach's alpha), or correlation (i.e., Pearson's r) should not be used for the purpose of measuring intercoder agreement simply because they do not measure the level of agreement between coders. For example, if one coder consistently codes 1 point higher on a 5-point scale than the other coder, they are completely correlated (Pearson's $r = 1$) or consistent (Cronbach's alpha $= 1$), but the agreement (Krippendorff's alpha) is about half of that when treated as interval level coding with a pair of 10 coded units.

Intercoder reliability coefficients range from 0 (complete disagreement) to 1 (complete agreement), with the exception of Cohen's kappa, which does not reach unity even when there is a complete agreement. In general, coefficients .90 or greater are considered highly reliable, and .80 or greater may be acceptable in most studies. When coder agreement is poor, it can be improved by training coders with coding schemes that define coding categories as clearly as possible before the actually coding and with a couple of practice runs with small subsamples of cases to refine the coding scheme.

INTERNAL VALIDITY

As explained in the 1960s by Donald Campbell and Julian Stanley in their seminal book *Experimental and Quasi-Experimental Designs for Research*, internal validity refers to the extent to which the methodological research design used by a researcher can provide empirical evidence to test the possible cause-and-effect relationship between an independent variable (the antecedent), X, and a dependent variable (the consequence), Y. Without adequate internal validity, researchers may offer logical, reasoned arguments to speculate about the possible causal nature of any correlational relationship they observe between X and Y in their data, but they cannot use the internal strength of their research design to bolster such reasoning. Thus, although researchers can (and routinely do) draw casual inferences about "X causing Y" based on speculation from the results of many types of nonexperimental research designs, it is only with carefully planned experiments and quasi-experiments that researchers can draw internally valid conclusions about cause-and-effect relationships with a high degree of confidence.

Unfortunately, many survey researchers have not received training in experimental design and do not appear to appreciate the importance of planning research that can yield internally valid findings. As such, they often fail to take full advantage of deploying controlled experimentation with random assignment in their surveys. The following example, which occurred in 2000, helps illustrate this point.

Example of a Survey Lacking Internal Validity

The results of a nonexperimental pre-election study on the effects of political advertising were posted on the American Association Public Opinion Research listserve (AAPORnet) in 2000. This survey-based research was conducted via the Internet and found that a certain type of advertising was more persuasive to potential voters than another type. By using the Internet as the data collection mode, this survey was able to display the ads—which were presented as digitized video segments—in real time to respondents/subjects as part of the data collection process and, thereby, simulate the televised messages to which voters routinely are exposed in an election campaign. Respondents were shown all of the ads and then asked to provide answers to various questions concerning their reactions to each type of ad and its influence on their voting intentions. This was done in the individual respondent's own home in a room where the respondent normally would be watching television. Here, the Internet was used very effectively to provide mundane realism to the research study by having survey respondents react to the ads in a context quite similar to one in which they would be exposed to real political ads while they were enjoying a typical evening at home viewing television. Unlike the majority of social science research studies that are conducted under conditions far removed from real life, this study went a long way toward eliminating the potential artificiality of the research environment as a serious threat to its overall validity.

Another laudable design feature of this study was that the Internet sample of respondents was chosen with a rigorous scientific sampling scheme so that it could reasonably be said to represent the population of potential American voters. The sample came from a large, randomly selected panel of households that had received Internet technology (*WebTV*) from the survey organization in their homes. Unlike most social science research studies that have studied the effects of political advertising by showing the ads in a research laboratory setting (e.g., a centralized research facility on a university campus), the overall validity of this study was not threatened by the typical convenience sample (e.g., undergraduates "volunteering" to earn course credit) that researchers often rely upon to gather data. Thus, the results of this Internet research were based on a probability sample of U.S. households and, thereby, could reasonably be generalized to the potential U.S. electorate.

As impressive as these features of this research design were, the design had a serious, yet unnecessary, methodological flaw—one that led the researchers to miss a golden opportunity to add considerably to the overall validity of the conclusions that could have been drawn. The research design that was used displayed all the political ads to each respondent, one ad at a time. There were no features built into the design that controlled either for the possible effects of the order in which the respondent saw the ads or for having each respondent react to more than one ad within the same data collection session. As such, the cause-and-effect conclusions that could be drawn from this nonexperimental study design about which ads "caused" stronger respondent reactions rested on very weak methodological footing. Since no design feature was used to control for the fact that respondents viewed multiple ads within the same data collection session, the conclusions drawn about the causality underlying the results remained little more than speculations on the part of the researchers, because such factors as the order of the ads and the number of ads were not varied in a controlled manner by the researchers. Unfortunately this missed opportunity to use an experimental design is all too common in many survey-based research studies in the social sciences.

This study perfectly lent itself to the use of various experimental designs whereby a different political ad (i.e., the experimental stimuli), or different subsets of ads, could have been randomly assigned to different subsamples of respondents. Or, the order of the presentation of the entire set of political ads could have been randomly assigned across respondents. In either case, an experimental design with random assignment would have provided the researchers a far stronger basis (one with greater internal validity) from which to draw their causal inferences. Furthermore, such an experimental approach would have had little or no cost implications on the research budget, and a design where one and only one ad was shown to any one respondent would likely have saved data collection costs and yet would have been more powerful in supporting causal interpretations.

Conducting Internally Valid Survey Research

Cook and Campbell define internal validity as the approximate validity with which one infers that a relationship between two variables is causal or that the absence of a relationship implies the absence of cause. There are three conditions for establishing that a relationship between two variables (X and Y) is a causal one, as in "X causes Y." The researcher must demonstrate

1. Covariation, that there is a reliable statistical relationship between X and Y.
2. Temporal order, that X occurs before Y occurs.
3. An attempt to eliminate other plausible explanations than changes in X for any observed changes in the dependent variable (Y). The use of a true experimental design with random assignment of respondents to different levels of X is of special value for this last condition to be met.

The simple formula, $Y = f(X)$, often is used to depict covariation between two variables, X and Y, and is read, "Y is a function of X." The concept of internal validity essentially addresses the nature of the equal sign (=) in the equation; that is, is the relationship between X and Y a causal one? For internal validity to exist in a research study there must be covariation demonstrated between X and Y, and, therefore, X must predict Y to some statistically reliable extent. But the equal sign (and the covariation it implies) in itself does not provide internally valid evidence that a cause-and-effect relationship between X and Y has been demonstrated.

If the relationship in the formula, $Y = f(X)$, is causal, then it presupposes that X precedes Y in a temporal sense. This is what distinguishes this specification from one that says Y is the cause of X, or that each causes the other, or that each is caused by some other unspecified variable (Z)—any of which could be the interpretation of the observed correlation between two variables. Only by the use of a controlled experiment or series of experiments can the nature and direction of these interrelationships be parceled out through the implementation of the independent variable (under the control of the researcher) followed by the measurement of the dependent variable. Only in this way can evidence be gathered to demonstrate with confidence that the relationship is a causal one and not merely one of noncausal covariation.

The essential design feature of an experiment is the use of random assignment of respondents to different experimental conditions. The logic here is that with random assignment of different respondents to different conditions (i.e., the different levels of the independent variable, X), all other factors will be equivalent except for the differences that the researcher directly controls in implementing the independent variable of interest. If, for example, statistically significant differences in the mean of the dependent variable (Y) then are found between the randomly assigned groups, these differences then can be attributed to the levels of the independent variable that the researcher has controlled. Then the researcher usually will have a solid basis to conclude that it was the controlled differences in the independent variable (X) that *caused* the observed differences in Y between the groups.

A simple survey-based example of this occurs when a group of respondents are randomly assigned to two conditions: often called a *control* condition and a *treatment* condition. For this example, assume a questionnaire employs a so-called split-half experiment, whereby one random half of respondents are exposed to the standard wording of a question (e.g., the wording used in the 2000 Census to measure whether someone is Hispanic: "Are you Spanish, Hispanic, or Latino?"). The group receiving this standard wording is the control group. The other random half of respondents would be asked the question with some altered version of the wording (e.g., "Are you of Spanish, Hispanic, or Latino origin?"). In this example, the group of respondents seeing or hearing the word *origin* in their questionnaire is the treatment group (sometimes called the experimental group), as they are receiving a different wording of the question to investigate what effect adding the word *origin* will have on the proportion in the treatment group that answers "Yes." The researcher has controlled the administration of the question wording or X, the independent variable, in order to learn whether the change in wording causes a change in Y, the dependent variable, that is, the proportion of people who say "Yes" (i.e., they are Hispanic). This control over administration of the independent variable (X) is exercised via random assignment so that, in theory, nothing else is dissimilar between the two groups except for the slight change of wording between the control question and the treatment question. Thus, random assignment is the equivalent to holding "all other things equal." Because of the strong internal validity of the experimental design in this example, the researcher can conclude with great confidence that any statistically significant difference between the two groups in the proportion that answered, "Yes" to being Hispanic is associated with (i.e., caused by) the presence or absence of the word *origin* (the independent variable).

Threats to Internal Validity

To better appreciate the power of an experimental design and random assignment, it is worth a brief review of some of the major reasons that cause-and-effect inferences drawn from *nonexperimental* research lack internal validity and therefore are subject to many threats to their overall validity.

Selection

Too often the selection of the respondents that constitute different comparison groups turns out to be the main threat to a study's internal validity. For example, if a survey researcher sampled two different municipalities and measured the health of residents in each community, the researcher would have no statistical or methodological grounds on which to base any attributions about whether living in one community or the other *caused* any observed differences between the average health within the respective communities. In this example, no controlled effort was built into the study to make the two groups equivalent through random assignment, and of course, in this example that would not be possible. As such, any observed differences between the health in one community versus another could be due to countless other reasons than place of residence, including a host of demographic and behavioral differences between the residential populations of each community.

Thus, any time two (or more) groups have been selected for comparison via a process other than random assignment, the researchers most often will have no solid grounds on which to draw valid inferences about what may have caused any observed difference between the two groups. (An exception is the possibility that a researcher deployed a quasi-experimental design, one without true random assignment, but one that may have had other rigorous design features that avoided some of the potential threats to internal validity).

Unfortunately, not using an experimental design does not stop many researchers from making unfounded causal attributions. This is especially the case in the field of medical research when the health of large samples of volunteer patients is tracked over time. Such a panel survey may find many significant correlations between behavior and health (e.g., eating a lot of carrots is associated with better eyesight), but this is mere covariation, and the study design, with its lack of random assignment to comparison groups, provides no internally valid basis to support causal inferences between the measured behaviors and health.

Furthermore, any study that allows respondents to self-select themselves into different comparison groups will suffer from selection as a threat to its internal validity. However, this point is different from the common way that self-selection into a sample is thought of. So-called convenience samples suffer from a self-selection sampling bias, as the researcher has no means of knowing whether a larger population is represented by a self-selected sample (this is an issue that affects external validity, i.e., its generalizability). However, the researcher could legitimately build a valid experiment into a survey that uses a convenience sample, simply by randomly assigning the self-selected respondents to different comparison groups. Thus, as long as the respondents do not self-select themselves into the treatment and control groups, the internal validity of the study is not threatened, even if they have self-selected themselves into the larger sample.

History

This potential threat to internal validity refers to the possibility that something other than the independent variable may have taken place between the time respondents were first exposed to the independent variable and time of the measurement of the dependent variable. If so, then a differential history effect may have caused any observed differences among respondent groups in the dependent variable.

To illustrate this, consider a survey of attitudes toward local police being administered in two different, yet socioeconomically similar, communities to establish a baseline. Imagine that the survey found that these two communities held essentially similar pretest attitudes. Then imagine that in one of the two communities, local police implemented a foot patrol program putting many more police officers on neighborhood streets. After this program has been implemented for several months, both communities are then resurveyed and the community with the new foot patrol program is now found to hold significantly more positive attitudes than the other community.

Could the researchers conclude with confidence (i.e., with strong internal validity) that the foot patrol program caused the improvement in attitudes? The answer is “No” for many reasons, including that there was no way for the researcher to control for whatever else may have occurred locally between the time that the two pretest surveys were conducted that may have led to the attitudes in one community to change compared to the other. For example, a major crime may have been solved in one community in the intervening period. Was this the cause of more positive attitudes toward the police, or was it the foot patrols? This is how the differential history of two groups can confound any interpretation of cause when a true experiment is not used.

Furthermore, even if a research study starts out as a true experiment, subsequent uncontrolled history between randomly assigned groups can undermine the experiment and, thereby, undermine its internal validity. For example, imagine a study in which the interviewers at a survey organization were randomly assigned into two groups to be trained, separately, to administer one of two different introductory spiels to randomly selected households in order to determine the differential effects on response rates of the two introductions. If something eventful happened at one of the training sessions other than the difference in the content related to the respective introductory spiels—for example, an interviewer and the trainer got into a heated argument about the wording of the introductory spiel, thereby lowering the confidence of the rest of the interviewers in that group regarding the effectiveness of that introductory spiel—then this differential history could pose a serious threat to the internal validity of this research study, despite it being originally designed as a true experiment. If this were to happen, then the researchers would have a weakened basis on which to conclude that it was the content of the different introductions *and only that content* that caused any observable differences in response rates between the two groups of interviewer and their respondents.

All this notwithstanding, in many survey-based experiments, history is not a likely threat to internal validity because the dependent variable often is gathered immediately after the administration of the independent variable (e.g., most wording experiments built into a questionnaire require that the respondent answer the question immediately after being exposed to the wording), but in other instances the researcher must be very conscious of the possibility that history may have undermined the integrity of the experimental design.

Instrumentation

Anytime a measurement instrument, for example, a survey question, is changed between a pre- and post-period, any observed changes in the dependent variable of interest may be due solely to the change in instrumentation as opposed to real changes between the two groups due to a treatment or stimulus. For example, take a panel survey with two waves of data collection in which all respondents were asked, *Do you support or oppose the President's new plan to reduce taxes?* in Wave 1 data collection. Suppose after Wave 1, a random half of the respondents were exposed to a direct mail campaign touting the popularity of the new tax-relief plan. Suppose also that after Wave 1, the President began actively campaigning on behalf of the new tax-relief plan and received consistently positive press coverage. After some passage of months, another wave of data is gathered from the same respondents, but using the following question: *Do you support or oppose the President's popular plan to reduce taxes?* Imagine that at Wave 2, a sizably larger proportion of respondents who were exposed to the direct mail campaign said they supported the plan than had supported it at Wave 1 and that this increase was larger than the increase in support among the nontreatment group. Would this mean that the direct mail campaign exposure caused the apparent growth within that portion of the sample exposed to it?

The answer is "No, not necessarily," because although the small change in the wording of the measure at Wave 2 may appear innocuous—and, given the positive press coverage, might appear to be an appropriate wording change—the use of the word *popular* in the Wave 2 version of the questions could by itself have prompted (i.e., caused) more people to "conform" with majority public opinion and say "Yes" to the question than otherwise would have happened had the exact Wave 1 wording been used. This could especially be true for the respondents exposed to the direct mail campaign. In particular, the treatment (the direct mail campaign) may have interacted with the wording change in the post-test question to cause the disproportionate shift in expressed support of the new tax plan among the group exposed to the mail campaign. Thus, it is possible that the change in support among the treatment group would have been no different in size than the change among the group that did not receive the direct mail campaign had the question wording not been altered.

Mortality

Imagine that an experimental test of a new remedial science curriculum is implemented so that a large random sample of inner-city high school students is randomly assigned to a treatment group or a control group. The control group does not receive the remedial curriculum. The treatment group receives the remedial instruction during a special 30-minute class held only for them at the end of the regular school day. After 6 months of being exposed daily to the remedial curriculum, the treatment group actually scores lower in science knowledge than does the control group. Does this mean that the curriculum actually caused the treatment group to do more poorly on their science knowledge test?

Although that is possible, imagine instead that receiving the remedial education curriculum caused more students in the treatment group to remain in school after 6 months because they were receiving the special attention. However, in the control group, more students dropped out of school during the ensuing 6 months, with students having the lowest knowledge of science being the ones most likely to drop out. In this case, differential mortality (or differential attrition) would render the two groups no longer equivalent when the comparison was made between each group's average science knowledge score after 6 months. As such, researchers must guard against respondent/subject mortality threatening the internal validity of their experiments. And, even if the researchers cannot foresee or control against differential mortality, the possibility that this might occur must be measured and its possible effects taken into account before one can interpret experimental results with confidence. In particular, any survey-based experiment in which the experimental treatment causes differential response rates, but the dependent variable is something other than the response rate, is subject to the effects of differential mortality.

There are other threats to the internal validity that may undermine a research design's ability to support cause-and-effect reasoning. However, by using a true experiment with random assignment, the researcher is on much firmer ground in making valid causal attributions than without an experimental design.

Internal Validity/Random Assignment Versus External Validity/Random Sampling

Now that it has been explained that random assignment is the cornerstone of experimentation and the establishment of internal validity of a research design, it is worth observing that many survey researchers and students new to the field appear to confuse random assignment with random sampling, or at least seem not to appreciate the distinction. Random sampling is very much a cornerstone of external validity, especially when it is done within the context of a probability sampling design. The beauty and strength of high-quality survey research is that a researcher often can meld *both* random assignment and random sampling, thereby having strong internal validity *and* strong external validity.

Researchers who use the survey mode of data collection typically are much more familiar with the science of sampling than they are with the science of experimentation. Although many of them may not have prior familiarity with the term *external validity*, they are very familiar with the principles underlying the concerns of external validity: If one wants to represent some known target population of interest accurately, then one best utilize a sampling design that (a) well represents that population via a properly constructed sampling frame and (b) uses a random probability sampling scheme to select respondents from it, thereby allowing one to generalize research findings from the sample to the population with confidence and within a known degree of sampling error. Within a total survey error framework, the avoidance of coverage error and nonresponse error are each a necessary condition for achieving strong external validity, and together they comprise the sufficient condition. Thus, survey researchers need to use sampling frames that fully cover the target population they purport to represent and need to achieve an adequate response rate that avoids meaningful nonresponse bias.

The linkage between internal validity and external validity concerns whether any cause-and-effect relationship that has been observed in a survey research experiment can be generalized beyond the confines of the particular sample (subjects/respondents) on which the test was conducted. For example, the field of psychology has a long and honored history of using experimentation with strong internal validity. However, it also has the well-known (and not so honorable) history of questionable external validity for too often using unrepresentative convenience samples of college undergraduates.

Conclusion

One cannot understate the importance of the research "power" that is afforded by an experimental design in allowing a researcher to test the causal nature of the relationship between variables with confidence (i.e., with strong internal validity). As noted earlier, this often can be done at little or no additional cost in the data collection process, and sometimes it can even save costs as it may reduce the amount of data that must be gathered from any one respondent.

International Field Directors and Technologies Conference (IFD&TC)

The International Field Directors and Technologies Conference (IFD&TC) is a voluntary organization of practitioners of survey data collection for nonprofit organizations. Its 1993 charter describes the IFD&TC as providing "an opportunity for survey research personnel who are involved in the direction of survey field operations, the technological aspects of survey data collection, and their management to meet and exchange ideas and information at an annual conference." This entry describes the current focus and somewhat unusual characteristics of the IFD&TC as a professional organization, its membership and governance, and its origins and development from predecessor organizations.

The Conference

The intent of the IFD&TC (according to its charter) "is to provide ***informal*** [emphasis added] interaction between field director, field technology, and survey management personnel of a type not usually available in professional conventions or through professional journals. The sessions [are] informal and focus on work in progress or recently completed, and on exchanges of information, practices, and opinions on relevant subjects of common interest. Finished papers ready for publication, public distribution, or production in official formal proceedings are not required [and not encouraged]." Extensive time is provided for discussion during sessions and for casual interchange during lengthy breaks between sessions. Because the attendees generally do not represent organizations in competition with each other, the discussions also are unusually frank, open, and mutually sharing. These characteristics have fostered strong personal loyalty by regular attendees and a welcoming attitude toward those new to the field.

Presentations frequently focus on the practical aspects of survey data collection by personal interviews, telephone interviews, mail questionnaires, email, the Web, and by fax. Topics often include the following: (a) the hiring, training, and supervision of interviewers; (b) methods of improving response rates; and (c) the technical issues of designing and managing computer-assisted personal, telephone, Web, and multi-mode surveys.

The annual conference is typically held in May, immediately following the annual conference of the American Association for Public Opinion Research (AAPOR). The IFD&TC is typically held in the same city (or a nearby city) as AAPOR, starting with an informal party on a Sunday evening and continuing through Wednesday morning. For details about the conference, see the IFD&TC Web site. To limit conference size and to maintain the tradition of openness, candor, sharing, and informality, attendance restrictions are part of the charter. Attendance is limited to "persons involved in survey research who have responsibility for field direction, technological aspects, or management of survey data collection, and who are associated with academic institutions, government agencies, or other nonprofit organizations."

Speakers from profit-making organizations have been invited to attend sessions on topics of common interest. No organization may send more than 16 attendees, and these must be divided between field director and field technology interest areas. All attendees are encouraged to participate in the program as presenters, panelists, facilitators, or chairs, and so forth.

The 2007 conference had approximately 250 attendees—a conference size the organizers and members have found appropriate for a good mix of topics and informal interaction. While the bulk of the attendees are from the United States, major contingents generally attend from organizations in Canada, Great Britain, and the Netherlands, with less frequent attendance from other countries.

Membership and Governance

There are no dues or membership fees beyond conference registration. The active members consist of persons in attendance at each annual conference. The IFD&TC mailing list consists of those who have attended any of the past 10 conferences. Each year nearly half of the participants are first-time attendees, often people who are relatively new to survey data collection. They regard the conference as a learning experience and an opportunity to establish a network with more experienced members of the field.

The conference includes an open meeting at which the officers of the organization are elected and the sites and dates of future meetings are chosen. Those in attendance at that conference are the voting membership. The only officers are the two program chairs, one each for field directors and field technologies for the following 2 years, plus a treasurer. The organization is incorporated in the Commonwealth of Virginia.

History

In 1968, John Scott of the University of Wisconsin wrote a memo "A Suggestion for a Conference on Field Problems in Survey Research," which became the basis for the first Field Directors Conference (FDC), the first predecessor of the current IFD&TC. The FDC was held annually through 1988, with attendance growing from the low 20s to the mid 60s. It is significant in the history of professional organizations that FDC had 26 successful annual meetings with no written charter. At that time, each participating organization was allowed only two attendees plus two more on the program. In 1988, computer-assisted telephone interviewing had become a more frequent topic, and the conference length was extended to include a focus for those interested in the technical side of survey data collection. William Nicholls of the U.S. Bureau of the Census convened a meeting with seven other FDC regulars, and they wrote a charter for a Field Technologies Conference.

From 1989 through 1993, the FDC and FTC had separate programs and registrations and met for one and a half days each, consecutively, in the same locale. In 1993 a joint meeting of the attendees adopted a common charter, based on the FTC charter, and the IFD&TC as it presently exists was formed.

International Journal of Public Opinion Research (IJPOR)

The *International Journal of Public Opinion Research* (IJPOR) is an academic quarterly founded and owned by the World Association of Public Opinion Research (WAPOR) and published by Oxford University Press. Its first issue appeared in 1989. Seymour Martin Lipset (United States), Elisabeth Noelle-Neumann (Germany), and Robert M. Worcester (United Kingdom)—all former presidents of WAPOR—were the founding editors. The journal continued an earlier WAPOR project, the *International Journal of Opinion and Attitude Research*, published between 1947 and 1951. The current editors of IJPOR are Wolfgang Donsbach (Germany) and Michael W. Traugott (United States). The editors are appointed by the WAPOR Council for a 3-year term, which can be extended. One of the editors acts as managing editor and runs the editorial office.

The geographical composition of the team of editors reflects the intention of the journal's owner to represent public opinion research in an international scope. The leadership of WAPOR started IJPOR as an international alternative to *Public Opinion Quarterly*, which at the time was essentially the only academic journal in the field. IJPOR operates in support of the basic purposes of WAPOR while reserving editorial independence. As outlined in the Constitution of WAPOR, the association is committed to "(a) promote in each country of the world the right to conduct and publish scientific research on what the people and its groups think and how this thinking is influenced by various factors, (b) promote the knowledge and application of scientific methods in this objective, (c) assist and promote the development and publication of public opinion research worldwide, (d) promote international cooperation and exchange among academic and commercial researchers, journalists and political actors, as well as between the representatives of the different scientific disciplines." IJPOR is charged to serve these aims through the publication of scientifically sound and practically relevant research in the field of public opinion research and by promoting research from a wide range of countries and research that is based on comparative studies.

IJPOR operates on a blind peer review system. The journal has an editorial board with some 30 scholars and practitioners from a variety of countries, but the number of referees—representing more than 30 different countries—goes much beyond that list. Due to an increasing number of submissions, the rejection rate has risen to 70%. Because of the more specialized nature of its content (compared to the more general social science journals), IJPOR is found only in the second half of the impact factor rankings of relevant social science journals. It has, however, improved its position in recent years. Circulation stands at about 2,000 subscribers, a number that includes consortia subscribers.

Each issue today contains five sections: regular research articles, shorter research notes, "World Opinion" (with topical comparative public opinion data), book and journal article reviews, and news on WAPOR. When IJPOR was founded, the WAPOR Council and the founding editors wanted to establish a truly international journal that would give a forum to social scientists and polling practitioners from around the world. Like its owner association, WAPOR, the journal was meant to bridges gaps between different professional fields (academia, business, administration), different disciplines (political science, sociology, communications, psychology, to name but the most important ones), and between theory building and empirical findings. Thus, the journal's content usually offers articles and research notes on five areas: (1) theories about the dynamics of public opinion, (2) methodological problems and developments, (3) the role of the news media in public communication, (4) public opinion research as a social and political problem, and (5) public opinion data on topical issues. Much of the research published in IJPOR is of comparative nature. IJPOR is a truly international journal. After conducting a quantitative content analysis of 43 leading journals in the wider field of communication studies that claim to be international, a scholar recently concluded that, based on content and authors, the IJPOR is the only journal that can be classified as international.

However, there is still room for improvement. A content analysis of the first 11 volumes (1989–1999) conducted by the editors revealed that about half the authors work in the United States, and that many other regions, particularly Africa, Latin America, and Eastern Europe, are underrepresented. IJPOR is a journal mainly for the intersubjective evidence produced by social scientists. This is reflected in the proportions between empirical tests of public opinion theories (e.g., the spiral of silence) and purely theoretical, nonempirical deliberations. While 17% of the IJPOR articles were dedicated to the former, only 3% dealt with theory only. This focus shows also in the total number of empirical studies on the pages of IJPOR: Overall, three in four articles presented some kind of empirical research.

Most of the studies using empirical methods are based on surveys. Among these studies is a high proportion of trend or panel surveys. In addition, and given the emphasis on the news media's role for public opinion, many IJPOR articles are based on quantitative content analyses or on a combination of both surveys and content analyses. About one in ten articles are purely theoretical, conceptual, or normative, that is, without any references to empirical results.

International Social Survey Programme (ISSP)

The International Social Survey Programme (ISSP) is a continuing, annual program of cross-national collaboration. It brings together pre-existing social science projects and coordinates research goals, thereby adding a cross-national perspective to the individual, national studies.

ISSP evolved from a bilateral collaboration between the Allgemeine Bevölkerungsumfrage der Sozialwissenschaften (ALLBUS) of the Zentrum für Umfragen, Methoden, und Analysen (ZUMA) in West Germany and the General Social Survey (GSS) of the National Opinion Research Center (NORC), University of Chicago. Both the ALLBUS and the GSS are replicating, time-series studies. The ALLBUS has been conducted biennially since 1980 and the GSS annually since 1972. In 1982 and 1984 the ALLBUS and GSS devoted a segment to a common set of questions.

Meanwhile, in late 1983 the National Centre for Social Research (NCSR; then known as Social and Community Planning Research), London, which was starting a social indicators series called the British Social Attitudes Survey, secured funds to further international collaboration. Representatives from ZUMA, NORC, NCSR, and the Research School of Social Sciences, Australian National University, organized ISSP in 1984 and agreed to (a) jointly develop topical modules dealing with important areas of social science, (b) field the modules as a 15-minute supplement to the regular national surveys (or a special survey if necessary), (c) include an extensive common core of background variables, and (d) make the data available to the social-science community as soon as possible.

Each research organization funds all of its own costs. There are no central funds. The merging of the data into a cross-national data set is performed by the Zentralarchiv für Empirische Sozialforschung, University of Cologne, in collaboration with the Análisis Sociológicos, Económicos y Polïticos in Spain.

Since 1984, ISSP has grown to 41 nations, the founding four—Germany, the United States, Great Britain, and Australia—plus Austria, Ireland, Hungary, the Netherlands, Israel, Norway, the Philippines, New Zealand, Russia, Japan, Bulgaria, Canada, the Czech Republic, Slovenia, Poland, Sweden, Spain, Cyprus, France, Portugal, Slovakia, Latvia, Chile, Denmark, South Africa, Switzerland, Venezuela, Brazil, Flanders, Finland, Mexico, Taiwan, Korea, Uruguay, the Dominican Republic, Croatia, and Turkey. In addition, East Germany was added to the German sample upon reunification. Past participants not currently active include Bangladesh and Italy.

ISSP Themes

Since 1985, ISSP research has covered many key topics across a variety of disciplines.

The first theme in 1985 was on the role of government and covered (a) civil liberties, (b) education, (c) welfare and social equality, and (d) the economy.

The second theme in 1986 was on social networks and support system. It contained detailed behavioral reports on contacts with various friends and relatives and then a series of questions about where one would turn for help when faced with various problems.

The third module in 1987, on social equality, concerned beliefs about what factors affect one's chances for social mobility (e.g., parental status, education, race, etc.), explanations for inequality, assessments of social conflicts, and related questions.

The fourth module in 1988 covered the impact on the family of the changing labor force participation of women. It included attitudes on marriage and cohabitation, divorce, children, and child care and special demographics on labor-force status, child care, and earnings of husband and wife.

The fifth module in 1989 on work orientations dealt with motivations to work, desired job characteristics, unemployment, job satisfaction, and working conditions.

The sixth module in 1990 repeated the role of government theme. By replicating substantial parts of earlier modules (approximately two-thirds), ISSP not only has a cross-national perspective but also a longitudinal perspective. One is able not only to compare nations and test whether similar social science models operate across societies but also to learn if there are similar international trends and whether parallel models of social change operate across nations.

The seventh module in 1991 covered the impact of religious beliefs and behaviors on social, political, and moral attitudes.

The eighth module in 1992 replicated and extended the 1987 social equality module.

The ninth module in 1993 was on the environment. It included an environmental knowledge scale plus attitudinal and behavioral measures.

The 10th module in 1994 repeated the 1988 module on gender, family, and work.

The 11th module in 1995 was on national identity. It assessed nationalism and patriotism, localism and globalism, and diversity and immigration.

The 12th module in 1996 was the second replication of the role of government.

The 13th module in 1997 was the first replication of the 1989 module on work orientations.

The 14th module in 1998 was the first replication of the 1991 religion module.

The 15th module in 1999 was the second replication of the social inequality module fielded in 1987 and 1992.

The 16th module in 2000 was the first replication of the 1993 environment module.

The 17th module in 2001 was related to, but not a strict replication of, the 1986 social relations and social support module.

In 2002 the 18th module was the third replication of the gender, family, and work module.

In 2003 the 19th module was the first replication of the 1995 national identity module.

In 2004 the 20th module was a new module on citizenship.

In 2005 the 21st module was the second replication of the work orientation module,

In 2006 the 22nd module was the 3rd replication of the role of government module.

In 2007 the 23rd module was a new module on leisure activities.

In 2008 the 24th module was the second replication of the religion module.

ISSP marks several new departures in the area of cross-national research. First, the collaboration between organizations is not special or intermittent, but routine and continual. Second, while necessarily more circumscribed than collaboration dedicated solely to cross-national research on a single topic, ISSP makes cross-national research a basic part of the national research agenda of each participating country. Third, by combining a cross-time with a cross-national perspective, two powerful research designs are being used to study societal processes.

More than 2,300 publications based on the ISSP are listed in a bibliography available at http://www.issp.org/public.shtml.

Internet Pop-Up Polls

Internet pop-up polls receive their name from their inherent function. These polls appear on the user's screen in a new browser window, which is triggered by accessing the content of a designated Web page. Like all Internet surveys, these surveys can reduce the time and cost of conducting research by streamlining the data collection process. Utilizing a dynamic programming language such as PHP (Hypertext Preprocessor) or PERL, the researcher can create a Common Gateway Interface (CGI) script that either emails the survey responses back to the administrator or automatically drops the entries into a pre-scripted database.

Pop-up polls can improve response rates by creating more attractive and easy-to-use forms. Specifically, they allow participants to view the base Web page while simultaneously taking an associated survey. However, studies have shown that people tend to respond more to relatively plain Internet surveys that load quickly rather than more elaborate surveys that necessitate longer load times.

Some researchers directly code their surveys in HTML (Hypertextual Markup Language). HTML editors often are easier to use and achieve the same effect. Microsoft's FrontPage or Mozilla's SeaMonkey both provide a point-and-click interface that allows researchers to easily develop questionnaires and the necessary CGI scripts. Various online tutorials are available to develop either independent or dependent HTML coding abilities (see Further Readings at the end of this entry). However, in practice, simple trial and error is usually the best training method. This training is especially useful when dealing with the many technical hurdles one encounters with Internet pop-up polls.

If the HTML pop-up poll is viewed as a protagonist, the antagonist would be the pop-up blocker. This is a formidable adversary that prevents most pop-up surveys from being viewed. To achieve this, the pop-up blocker does one of two things: Either it embeds code into the HTML script preventing additional windows from opening, or it alters the action code, which in HTML is the *window.open()* command, thus preventing the survey from ever popping up. Developers avoid this problem by either using DHTML or JavaScript to create floating banners that avoid most pop-up blockers by adding additional layers rather than windows to the base Web page. This reclassification can work in tandem with proper user warnings to ensure that most pop-up surveys are properly viewed. Once this technical obstacle is overcome, one must then address the inherent social obstacles to meaningful Internet survey research.

A major problem with Internet pop-up polls is that Internet users are not representative of the broader population, and heavy Internet users are not representative of lighter Internet users. Thus, coverage bias is a concern with Internet research, in general, and specifically with HTML pop-up polls because they require a certain level of familiarity with the Web interface to successfully interact with the survey instrument. Additionally, the lack of direct oversight means that potential abuse by respondents (e.g., responding multiple times to the same survey) is more likely in a Web-based environment.

Even given these limitations, HTML pop-up polls do have valid and legitimate uses. For example, pop-up polls can be an effective way to survey traffic to a given Web site. Even though the technology sometimes appears to be overwhelming, it can be harnessed to create unique survey instruments that can achieve ends that are beyond traditional means. The Internet is here to stay and the HTML pop-up poll is a likely bridge between what Internet research was and what it will become.

INTERNET SURVEYS

Internet surveys refer to surveys that sample respondents via the Internet, gather data from respondents via the Internet, or both. Using the Internet to conduct survey research provides a great many opportunities and a great many challenges to researchers.

Background and Overview

Sample surveys have developed considerably over the past 70 years and have become the major source for the vast majority of empirical data, available today, on society, opinions, economics, and consumer preferences. Until the 1970s almost all survey work was carried out by pencil-and-paper questionnaires. Most of the collection was by means of face-to-face personal interview visits at the respondents' home or business. A small part of survey collection was by self-administered questionnaires, sometimes delivered and collected by interviewers and sometimes collected via mail. In recent times electronic telecommunications have become a predominant factor in practically all aspects of modern life, especially since the beginning of the 21st century. Sample surveys are no exception, and the widespread use of the telephone as a prime mode of communication, for at least the past 40 years, has had an important influence on survey practice. In fact, the telephone survey has become the major mode of collection in the sample survey field, especially in North America and Western Europe, both for surveys of households and individuals and for surveys of establishments. Other modes of advanced telecommunication, such as Internet, email, videophone, fax, and mobile phones, are fast becoming important supplements and even competitors to the fixed line telephone.

Internet surveys, sometimes termed *Web surveys* or *WWW surveys*, have fast become an important component of the trend to replace face-to-face interviewing, as the main mode of collection in survey work, with *telesurveys*—surveys carried out by modern telecommunication methods. The growing widespread access to the Internet and its extended use for a variety of purposes, particularly in Western Europe and North America, together with the rapid technological development of advanced browsers, XML, ADSL, and Java technology have brought about the continually increasing massive use of the Internet for survey work. The Internet survey can be viewed as a considerably enhanced replacement of the email survey, where text questionnaires are emailed to respondents, who are then asked to return the completed questionnaire by email. However, the Internet survey overcomes many of the inherent limitations of email surveys. The possibilities of visual and audio stimulation, the online interactive capabilities, and the potential of enhanced skip patterns available in the design of an Internet survey make it an extremely powerful survey data collection tool, far superior to the email survey. On the other hand the Internet survey may often suffer from serious problems of coverage, representativeness, and nonresponse bias.

Advantages

The major advantage of the use of the Internet in data collection is the very low cost per respondent, as compared to other modes of data collection. This has made the Internet survey an extremely attractive option to a wide range of survey researchers, primarily in the areas of opinion polling and market research, where the principles of probability sampling are not always considered as being of prime importance and large numbers of respondents are judged as valuable. The initial set-up costs entailed in the design of high-quality collection instruments via the Internet may be somewhat higher than those required for the design of paper questionnaires or computer-assisted telephone interviewing (CATI) instruments. However, this is more than offset by the current operational savings, due to self-administration of the survey instrument. The savings in the direct costs of interviewers, their training and control, are substantial. While other self-administered instruments, such as mail questionnaires and simple email collection, share with Internet surveys the advantage of not requiring the intermediary function of interviewers, for Internet surveys the costs involved in the control of unit and item nonresponse, callbacks, and editing are minimal and lower, in general, than those for other self-administered modes.

An important advantage of the use of the Internet for data collection lies in the advanced enhancements of the visual and aural aspects of the collection instrument. The use of color, animation, and even video and audio effects can, if used with care, facilitate the completion of the questionnaire for the respondent. The real-time interaction between the collection instrument and the respondent is a definite improvement over the fixed form of questionnaire required by other modes of data collection. Thus the use of drop-down menus, the possibilities to refer easily by hyperlinks and radio boxes or buttons to instructions and classifications, the possibilities to display photos of products or magazine covers, and other features all make the task of completing an Internet questionnaire much easier than for conventional instruments. Online editing, logical checks, and complex skip patterns can be employed in ways that are virtually invisible to the respondent.

However, some words of warning are in order with respect to the possibility of overkill in the use of these enhancements. The design of a good Internet questionnaire is a difficult and complex task, requiring a combination of survey research experience and advanced technical knowledge, far beyond that required for the design of conventional survey instruments. Also it is important to recognize that there are important differences in the design principles of the visual outlay for traditional questionnaires and the features of screen design. It is all too easy to cram bewildering amounts of information, complex instructions, and too many response alternatives within a single overcrowded screen, resulting in frustration for the respondents and high rates of break-offs (partial completions), missing data (item-nonresponse), or both. Finally it should be noted that variations in users' screen size and resolution, in operating systems, and in browsers may complicate the design and require simpler options.

Other advantages of Internet surveys are in the direct processing of the collected data in electronic form, bypassing the tedious and error-prone processes of data-capture, editing, coding, and logical checks required in traditional data collection methods. Some of these advantages are obtained to a certain degree by other modern computer-assisted collection methods (e.g., CATI and computer-assisted personal interviewing [CAPI]), though the Internet is usually associated with a more efficient method of data processing.

Finally, although not always perceived as such by the respondents, the Internet does provide for advanced methods of ensuring confidentiality, far beyond those afforded by conventional collection methods. The use of personal identification numbers or passwords provided to pre-designated respondents, secured access, and other technical enhancements can ensure that the individual data collected are not accessible to anyone except to the data collector. The widespread use of the Internet in nonsurvey contexts, for e-commerce purchases, registration, and other commercial activities, in which often full credit card details are required, with only a relatively minor extent of electronic fraud, should convince even the most skeptical that the data they provide for Internet surveys can be very secure.

Problems and Challenges

The main drawbacks in the use of the Internet for survey work are problems of coverage, lack of suitable sample frameworks, and nonresponse. The problems of coverage and coverage error are definitely the most serious of these problems for the vast majority of Internet surveys. While there has been a spectacular increase in the use of the Internet in the past decade, access and use of the Internet is still far from universal among households, even in well-developed countries. Accurate and up-to-date estimates of Internet use are hard to come by, but even the highest current estimates of Internet use (at least once a month) by households in North America in 2007 do not exceed 70% and fall below 60% for most countries in Western Europe. Numerous empirical studies have shown that, besides the fact that Internet coverage is relatively low, it is highly differential with respect to many socioeconomic variables and also with respect to attitudes and opinions. Thus, Internet users differ considerably from nonusers, in many important ways. This implies that the extent and nature of Internet undercoverage makes the use of the Internet completely inadequate as a tool for obtaining data on which valid inferences can be made, in a large number of cases, especially for opinion polling and attitude surveys, and in any survey that is measuring a construct related to education and income. Even in the cases mentioned next, when coverage is not an issue, it will often be difficult to select a probability sample, because of the lack of a complete adequate sampling frame.

It should be noted that the term *Internet survey* covers a wide range of different possibilities to use the Internet as a data collection tool in sample surveys, which may differ with respect to the potential impact of coverage and frame problems. Thus in many cases, the Internet may be used as an alternative mode of collection, within a mixed-mode collection process. Respondents may be given the option of responding via the Internet, at the time of their choice, rather than by CATI, by touchtone data entry or by a self-administered mail questionnaire. Although the mixed-mode survey may combine some of the advantages of the Internet mode of collection, such as easing the respondent's task, with the advantages of non-Internet surveys, such as enhanced representativeness and availability of a good sampling frame, it will, in general, be more expensive and entail a complex design.

When the Internet is used as the unique mode of collection, there may be significant differences in the way the target population is defined, with implications for the problem of undercoverage. In some cases the survey relates to a well-defined population, such as employees of a business, members of an organization, or students of an educational establishment. In many of these cases adequate sampling frames will be available, such as institutional listings of email addresses of employees or students. In this case, probability sampling can be used, and providing nonresponse is well controlled, scientifically valid inferences can be obtained from an Internet survey. Another type of survey in which the Internet can be used efficiently with few problems of coverage is that of surveys of businesses, establishments, or organizations. The Internet coverage of institutions, businesses, and organizations is virtually complete, with the possible exception of very small businesses. While frames of businesses and institutions are generally available, they will often not include email addresses, so an initial approach by mail or telephone may be required.

Another case in which coverage problems are nonexistent is that of surveys in which the population is defined a priori as that of Internet users, such as surveys of customer satisfaction or Internet site evaluation. Here the problem of the sampling frame may be severe if the survey is of all users of the Internet, since there are no general lists of Internet users. Internet service providers will obviously provide lists of their customers only for surveys commissioned by them. If the population survey is defined as those accessing a specific site or using a specified Internet service, the frame problem can be solved by sampling systematically from the users at the time of entry, with multiple selections avoided by the use of cookies. For these types of surveys the problems of nonresponse are paramount, and typically very low levels of response are obtained.

However, in many cases the Internet is used for survey work in a relatively uncontrolled way, without rigorous definitions of a survey population and therefore without a scientifically designed sample method. This has serious implications for the possibility to make valid well-based inferences about the subjects studied. At the extreme, the ubiquitous Internet versions of entertainment polls, customer preference and feedback surveys, and unrestricted self-selection and volunteer opt-in opinion polls are set up with appeals to anyone who is willing to do so to respond. No valid inference can be obtained from such attempts, which do not bear an association with scientific surveys. Unfortunately, a large number of well-publicized appeals to respondents to respond to these so-called Internet surveys have produced very high numbers of respondents, who cannot, however, be considered as representative of any well-defined population. The fact that the number of respondents thus obtained is very large (sometimes in the hundreds of thousands) is represented as sufficient to ensure reliability of the results, whereas, in fact there is not even a possibility to evaluate the biases inherent in such efforts. The attempts to overcome the lack of any scientific sampling design by post-stratification or other methods of weighting or imputation are not effective to ensure the correction of these biases.

Future Developments

The Internet is a powerful and inexpensive method of data collection, with many advantages and enormous potential in cases where it can be used in the context of probability sampling. However, in many current applications, coverage and frame problems prevent its being used for probability sampling–based surveys to ensure valid inferences. Future developments may change the situation. Thus the proposed introduction of a unique universal personal communications number for use with all modes of telecommunication (fixed-line and mobile phones, fax, and email) may solve many of the problems associated with coverage and absence of frameworks, at least for multi-mode surveys.

Interpenetrated Design

An interpenetrated survey design is one that randomly assigns respondent cases to interviewers. This is done to lower the possibility that interviewer-related measurement error is of a nature and size that would bias the survey's findings. This type of design addresses survey errors associated with the survey instrument and the recording of responses by the interviewer. One way to reduce *subjective* interviewer error is to develop a survey using an interpenetrated design—that is, by ensuring a random assignment of respondents to interviewers. Surveys employing an interpenetrated design, when such is warranted, will tend to reduce the severity of interpretation errors resulting from the conflation of interviewer bias with some other statistically relevant variable that might serve as a basis for assigning respondents. It will also typically reduce the overall standard error of response variance, especially for types of questions that inherently require some judgment or interpretation in recording by the interviewer.

Example of an Interpenetrated Survey Design

Assume a survey of 100 women from known high-risk populations (e.g., low income, substandard education, history of domestic violence), who are being queried about their tobacco use. The survey will be administered face-to-face by five interviewers and will feature a mix of demographic and binary-response questions, as well as several open-ended questions about the respondents' psychosocial triggers for smoking that the interviewer will interpret and assign a clinical risk index score.

In an interpenetrated design, the 100 women will be randomly assigned to each of the five interviewers. This means that any potential skewing of recorded results arising from bias or judgment by any single interviewer will be relatively equally shared by all of the respondents assigned to that interviewer and could therefore be considered "background noise" in terms of finding correlations within and among classes in the data. By contrast, in a noninterpenetrated design, it is possible that a correlating variable or class could be overemphasized or underemphasized by the relative weight of interviewer bias across a nonrandom assignment of respondents to interviewers.

For example, if all pregnant women queried about their tobacco use were assigned to a single female nurse interviewer who believes smoking is a social vice and not a chemical addiction, the nurse-interviewer's own subjective bias might contribute to Type I or Type II error for the class of pregnant women, relative to the survey's working hypothesis, or the bias might introduce systemic error into the response-variation rate for the class of pregnant women assigned to that interviewer. An interpenetrated design, in this example, would decrease the likelihood that one interviewer's behavior will contribute in a statistically significant way to analytic error.

Challenges in Implementing an Interpenetrated Design

The use of an interpenetrated design can mitigate the inflation of *statistical* error engendered from *systematic* error in survey design, for surveys with measurement tools or questions that fail to adequately control for interviewer bias, in cases where such bias could affect findings.

It can be difficult to engineer an effective interpenetrated design, however. There may be situations, particularly with large-scale face-to-face surveys, when geography or interviewer expertise with a particular class of respondent reduces the design's capacity to fully randomize the assignment of interviewer to respondent. There may be some benefit to determining whether a mixed strategy might be appropriate, with a partial randomization along respondent demographic, location, or cohort lines that are not believed to be relevant to the hypothesis of the survey or in its final analysis. As with any survey design, the question of which variables should be considered relevant must be approached with great caution.

Colm O'Muircheartaigh and Pamela Campanelli, in their targeted meta-analysis of the British Household Surveys of the 1990s, concluded that there was a significant increase in the inflation of variance rooted in measurable interviewer effects that were comparable in scope to the variance attributed to survey-design effects. Their findings, and the work of other statisticians, suggest that a clear understanding of the interviewer effect on the intraclass correlation (rho) is necessary for effective survey designs, and the use of an interpenetrated design can be quite effective in mitigating this interviewer effect at a statistical level.

However, depending on the nature of the survey, it can become prohibitively expensive or complex to employ an interpenetrated design. Surveys requiring face-to-face interviewing, for example, might generate substantial interviewer travel costs if the respondents are located across a broad geographic territory. Even in telephone interviews, the additional resources needed to ensure appropriate randomization with small groups of interviewers—perhaps through a stratified sampling model—can increase the burden of developing the survey and may generate additional analysis to ensure that the interpenetrated design contributed in a statistically significant way to an improvement in precision for the survey's final analysis. With a telephone survey, it is hardly ever feasible to control the sample so that each interviewer works only a randomly assigned subset of cases.

Given the increase in costs and complexity that can occur when implementing an interpenetrated design, researchers should determine carefully—using appropriate statistical tools—whether the very real benefits of an interpenetrated design outweigh the added costs and complexities of developing and implementing one.

INTERRATER RELIABILITY

The concept of interrater reliability essentially refers to the relative consistency of the judgments that are made of the same stimulus by two or more raters. In survey research, interrater reliability relates to observations that in-person interviewers may make when they gather observational data about a respondent, a household, or a neighborhood in order to supplement the data gathered via a questionnaire. Interrater reliability also applies to judgments an interviewer may make about the respondent after the interview is completed, such as recording on a 0 to 10 scale how interested the respondent appeared to be in the survey. Another example of where interrater reliability applies to survey research occurs whenever a researcher has interviewers complete a refusal report form immediately after a refusal takes place and how reliable are the data that the interviewer records on the refusal report form. The concept also applies to the reliability of the coding decisions that are made by coders when they are turning open-ended responses into quantitative scores during open-ended coding.

Interrater reliability is rarely quantified in these survey examples because of the time and cost it would take to generate the necessary data, but if it were measured, it would require that a group of interviewers or coders all rate the same stimulus or set of stimuli. Instead, interrater reliability in applied survey research is more like an ideal that prudent researchers strive to achieve whenever data are being generated by interviewers or coders.

An important factor that affects the reliability of ratings made by a group of raters is the quantity and the quality of the training they receive. Their reliability can also be impacted by the extent to which they are monitored by supervisory personnel and the quality of such monitoring.

A common method for statistically quantifying the extent of agreement between raters is the intraclass correlation coefficient, also known as Rho. In all of the examples mentioned above, if rating data are not reliable, that is, if the raters are not consistent in the ratings they assign, then the value of the data to researchers may well be nil.

INTERVAL ESTIMATE

Interval estimates aim at estimating a parameter using a range of values rather than a single number. For example, the proportion of people who voted for a particular candidate is estimated to be 43% with a margin of error of three (3.0) percentage points based on a political poll. From this information, an interval estimate for the true proportion of voters who favored the candidate would then consist of all the values ranging from a low of 40% to a high of 46%—which is usually presented as (0.40, 0.46). If the interval estimate is derived using the probability distribution of the point estimate, then the interval estimate is often referred to as a "confidence interval" where the "confidence coefficient" quantifies the probability that the process and subsequent derivation will produce an interval estimate that correctly contains the true value of the parameter.

While point estimates use information contained in a sample to compute a single numeric quantity to estimate a population parameter, they do not incorporate the variation in the population. Interval estimates, on the other hand, make use of the point estimate along with estimates of the variability in the population to derive a range of plausible values for the population parameter. The width of such intervals is often a function of the "margin of error," which is itself a function of the degree of confidence, the overall sample size, and sampling design as well as the variability within the population. In practice, intervals that are narrower usually provide more specific and useful information about the location of the population parameter as compared to wider intervals that are often less informative or more generic (e.g., the population proportion of voters in favor of a candidate is between 0 and 1 would be an interval estimate that is not informative).

Interval estimates can be derived for any population parameter, including proportions, means, totals, quantiles, variances, regression parameters, and so on. The generic format of an interval estimate for the population parameter θ can be written as $\hat{\theta} \pm DV \times SE(\hat{\theta})$ where DV represents a distribution value determined by the sampling distribution of the estimator $\hat{\theta}$, and *SE* refers to the standard error of the estimator. Many interval estimates are in fact symmetric around the corresponding point estimate (i.e., as is generally true for means, totals, and proportions based on simple or stratified random sampling designs), but this property is not universal. For example, if interest is given to estimating the variability in birth weights in a population using a simple random sample of hospital birth records, then estimates of σ^2 will be based on a chi-squared distribution and thus will generally be asymmetric about the point estimate.

As example, suppose that interest is given in estimating the average household 6-month out-of-pocket dental expenses within a midwestern U.S. state. An interval estimate is to be derived using a sample of 10 households that are randomly selected from each of eight geographically defined strata. Sample means, variances, and stratum sizes (i.e., numbers of households) are provided in Table 1.

A $(1-\alpha) * 100\%$ confidence interval estimate for the mean household dental expenses is given by $\bar{y} \pm t_d (1-\alpha/2) \times [v\hat{a}r(\bar{y})]^{1/2}$ where the degrees of freedom d are computed as the number of sampled units (i.e., 80) minus the number of Strata (i.e., 8). From the information in Table 1, a 90% confidence interval estimate of the mean 6-month household out-of-pocket dental expenses based on this stratified sample of 80 homes from 8 strata is $\$109.83 \pm 1.667 * (13.26)^{1/2}$ or equivalently, (\$103.76, \$115.90), implying that one can be 90% confident that the true mean 6-month household out-of-pocket dental expenses is between approximately \$104 and \$116.

Table 1 Data from a stratified random sample of 10 households in each of 8 geographic strata to be used to estimate the mean household 6-month out-of-pocket dental expenses

Stratum	Stratum Size (Households)	Sample Size	Sample Mean	Sample Variance
1	150,000	10	\$88.50	660.49
2	100,000	10	\$108.90	900.00
3	50,000	10	\$110.25	576.00
4	50,000	10	\$100.00	784.00
5	50,000	10	\$106.75	729.00
6	75,000	10	\$176.40	1,296.00
7	25,000	10	\$200.20	1,444.00
8	300,000	10	\$98.70	529.00
	Sample variance of the sample mean:			**13.26**
	Stratified sample mean estimate:			**\$109.83**

Interval Measure

An interval measure is one where the distance between the attributes, or response options, has an actual meaning and is of an equal interval. Differences in the values represent differences in the attribute. For example, the difference between 3 and 4 is the same as the difference between 234 and 235. Interval measures have fixed measurement units, but they do not have a fixed, or absolute, zero point. Because of this, it is technically not correct to declare that something is so many times larger or smaller than something else, although this often is done nonetheless.

Unlike other less sophisticated levels of measurement (e.g., nominal and ordinal measures), interval measures have real meaning. The relationship between the value and attribute is meaningful. For instance, temperature (Fahrenheit or Celsius) can be divided into groups of one degree and assigned a different value for each of the intervals such that anything from 50 degrees to 50.99 degrees has a value of 50. The distance between 50 and 51 degrees has an actual value, one degree. On the other hand, one cannot say that 90 degrees is twice as hot as 45 degrees because there is not an absolute zero.

Within social science research, interval measures are not particularly common because there are only a limited number of attributes that can take on an interval form. When used, they tend to be based on constructed measures like intelligence tests or standardized tests. Another common interval measure is a year. Some within the behavioral sciences use the Rasch model to create interval measures from count data.

It is often common in the research literature to see ordinal measures treated like interval measures. Many ordinal measures have characteristics that suggest that they could be thought of as interval measures. Many subjective rating scales are treated as interval measures. For instance, it is common to see measures using a 7- or 5-point scale, like the "strongly agree," "agree," "disagree" Likert scale battery interpreted as interval. It is easy to see why the interpretation exists, but it is not possible to conclusively state that the different values are exactly equally spaced. That said, many argue that with sufficient testing, it is possible to gain a sense of confidence that the intervals on an ordinal scale are close enough to be treated as though they are equivalent.

Interval measures allow more transformations than nominal and ordinal measures and are generally considered stronger measures, thereby supporting the use of parametric statistical procedures. This means that interval measures must also satisfy the assumptions of nominal and ordinal measures. Therefore, the interval measures 3 and 4 can be thought of in terms of these other measures, such that 4 is considered to have more of the attribute being measured than 3 as is found in ordinal measures. At the same time, a nominal interpretation would suggest that all things assigned 3 would have similar attributes to one another. Because of this, interval measures can always be transformed into ordinal or nominal measures.

Interval measures allow fewer transformations than ratio measures and are considered weaker measures. The central tendency of an interval measure can be represented by its mode, median, or mean. Usually, the mean is considered to provide the most information. Interval measures can also be added and subtracted.

INTERVIEWER

Interviewers are survey staff who contact the people from whom the study seeks to gather data (i.e., respondents) to explain the study, encourage them to participate, and attempt to obtain a completed interview. Once a sample member agrees to participate in a survey, the interviewer is then responsible for administering the survey questions (i.e., survey instrument) to the respondent. At times, the skill sets necessary to successfully complete these two tasks—sample recruitment and data collection—differ in conflicting ways. In encouraging participation, interviewers must adapt (i.e., tailor) their approach to gain cooperation based on their interaction with the respondent, whereas for administering the questionnaire in most surveys they are encouraged to use a standardized, scripted approach.

Traditionally, there have been two types of survey interviewers: telephone interviewers and field interviewers. Telephone interviewers administer survey instruments over the telephone, whereas field interviewers go to a respondent's home (or business for business surveys) to contact respondents and complete the in-person interview face-to-face. More recently and at a growing pace, interviewers are also being used to provide technical assistance (e.g., help desk) to self-administered surveys, such as mail or Web.

This entry presents the responsibilities of interviewers, along with the various skills needed and the training and supervision of interviewers. Next, this entry discusses common interview techniques and the impact of interviewers on the data collected. Lastly, this entry addresses the importance of interviewers to the data collection effort.

Responsibilities and Skill Sets

Interviewers have multiple responsibilities on any survey effort. Their initial responsibility is to contact respondents, and when necessary, screen for the eligible respondent, and also to provide detailed information to help explain the survey. During this initial exchange, interviewers attempt to gain cooperation from respondents so that they will complete the survey task.

Interviewers are also responsible for converting cases where a respondent, or gatekeeper (someone who is keeping the respondent from talking directly with the respondent), has initially refused to participate. Another key responsibility for interviewers is to administer the survey instrument and to do so in an unbiased manner while correctly recording the responses obtained from the respondent into the survey instrument. The successful execution of these responsibilities contributes heavily to the success of the overall data collection effort.

Successful interviewers, regardless of mode of interview, need to possess a set of varied skills. Interviewers must be convincing, professional, friendly, knowledgeable, and empathetic. The interviewers' attitude can also have a large impact on their overall success. They must also possess persuasion skills and use these skills to initially gain cooperation, as well as to collect complete data and encourage continued participation as the interview progresses.

Interviewer Training and Supervision

Although the location and content of training for telephone and field interviewers can vary, the overall information conveyed about the survey and the techniques used to convey information are similar across survey administration modes. Telephone interviewers are usually located in a centralized facility and are trained on-site at a call center. However, field interviewers are often decentralized and are often brought to a centralized location, such as a hotel, for training.

The length of interviewer training often differs based on the mode of survey administration. Generally, telephone interviewer training is shorter than that for field interviewers because of the nature of the work. Telephone interviewers need to know how to use a computer and telephone, whereas field interviewers also have to know how to approach and gain access to residences or businesses, complete time and expense reports, as well as how to upload (or transmit) survey data to a centralized database. These differences in job responsibilities account for the differences in training content and length and in compensation levels. Both types of interviewers, however, must also undergo general training, which introduces them to the job and the field of survey research, before undergoing project-specific training.

However, the information conveyed about the survey effort and the training techniques used is often very similar. It is understandable that regardless of survey administration mode, all interviewers need to be trained on the basic purpose and importance of the survey, as well as in administration techniques. Further, all interviewers also need to have hands-on practice with the systems used to collect the data, such as computer-assisted personal interviewing (CAPI) and computer-assisted telephone interviewing (CATI) systems. Regardless of mode, trainers often use similar techniques to convey the information that interviewers need for their job. Trainer-led lecture, small group discussion, mock interviews that all interviewers participate in (also called "round robin" interviews), paired practice, verbal and written quizzes, and hands-on practice with systems are techniques used in many training sessions. There have been several studies that have looked at the impact of interviewer training on subsequent job performance. Some of this literature focuses on the impact of using various training techniques for refusal avoidance and conversion on subsequent performance.

While the performance and monitoring of interviewers are important regardless of mode, the techniques used to supervise telephone and field interviewers differ. Telephone interviewers are often considered easier to manage because they are centrally located and supervisors can interact with them during each interviewing shift. It is also possible to silently monitor telephone interviews, using both audio and visual displays, in a way that is undetectable by the interviewer and respondent. This can result in provision of feedback to interviewers soon after they are observed, which may help improve their performance. It is also possible to meet in person with telephone interviewers to provide both individual feedback and feedback on how the entire data collection is proceeding.

However, due to the decentralization of field interviewers, many of these same techniques are not available to supervise field interviewers. While telephone meetings can be held with multiple field interviewers simultaneously, it can be difficult to get interviewers engaged during such a forum. Further, to monitor the work of field interviewers, supervisors must actually physically join a field interviewer when they are performing their duties. (Unlike with telephone interviewing, the respondent is thus aware of the presence of the supervisor.) Other monitoring can be done via computer-assisted mechanisms, for example, where the computer used for interviewing automatically makes an audio recording for a section (or multiple sections) of the interview.

For both types of interviewers, however, timely and complete feedback on their performance is critical to the maintenance and improvement of their skills. Supervisors of both telephone and field interviewers should provide this information routinely to their interviewers and provide routine coaching and mentoring in an attempt to maintain and improve interviewer skills, thereby helping the overall data collection effort.

Common Interviewing Techniques

There are multiple techniques used to conduct an interview, and the type of technique used in a particular study is dependent upon the study's purpose. Interviews that are more qualitative in nature and whose purpose is to gather information to be used in construction of a future survey instrument are often loosely structured, and the interviewer has a lot of discretion in the types of questions asked as well as the wording of particular questions. These kinds of interviews can be *unstructured* (where only general topics to cover are provided), *semi-structured* (where some questions are listed but interviewers have freedom to add, delete, or alter questions), or *structured* (where the questions need to be asked as listed).

Alternatively, for quantitative survey data collection efforts, there are *standardized* and *conversational* interviewing techniques. Each technique is appropriate for a different type of survey effort.

Standardized interviewing techniques are viewed by many survey professionals as the preferred method because they enable all respondents to receive the same stimuli (question and response wording) in the same way. In theory, this technique minimizes the impact of the interviewer such that any differences observed can be attributed to differences among respondents, and not to interviewer behavior. A benefit of standardized interviewing is that the effect of the interviewer on the data collected is decreased. Much has been written detailing the techniques used to ensure interviewers administer the survey instrument in a standardized way. These instructions focus on things such as reading all survey text verbatim, using nondirective probes to obtain complete information, recording all respondent answers exactly as provided, and administering the survey in a neutral, nonjudgmental manner.

Conversational interviewing involves following the survey text as written most of the time, but allowing for not asking or confirming the answer categories that may have been provided in an earlier part of the interview by the respondent through their comments or response to the questions. It also allows interviewers to provide unscripted explanations and definitions to clarify questions. For example, when asked if she attended college, the respondent answers, "Yes, I went to Michigan State," and three questions later the interviewer is supposed to ask what college the respondent attended, the interviewer could confirm, "So, you went to Michigan State University for college, is that correct?" instead of reading the question exactly as written. The idea is that the interview is more a conversation between interviewer and respondent, and by allowing for use of confirmatory statements it shows that the interviewer is actually listening to the respondent and not just asking questions and not paying attention to the answers, or other information, provided. A downside to conversational interviewing is that it does not control the impact of the interviewer as closely as standardized interviewing does, and this is viewed as problematic by some researchers.

Impact of the Interviewer on the Data Collected

As mentioned earlier, interviewers can have an impact on the quality, completeness, and accuracy of the data collected. That is, interviewers can contribute to survey error (the difference between the true value of what the researcher is trying to measure and the data that are obtained). Nonsampling error is difficult to measure, but there are three main ways used to detect interviewer-related error: (1) directly observing the interviewers, (2) examining the answers interviewers obtain (i.e., examining the association between the interviewer and the respondents' answers), and (3) validating the data collected with an independent (external) source.

It is important to realize that interviewers can affect both the variance and bias of the obtained estimates. The variability in interviewer administration can impact the variance of estimates, whereas demographic characteristics and other interviewer behaviors can affect bias.

The impact of interviewers on data can take several forms. Interviewers who accept a "don't know" response from respondents without probing or giving the respondent additional time to think about their answer can have more missing data. Also, interviewers who do not provide a probe, when one is called for, can impact the accuracy of the data. For example, if a respondent is asked the degree to which they agree with a statement—

strongly agree, somewhat agree, somewhat disagree, or strongly disagree—and the respondent says "agree," if the interviewer does not probe to see whether the respondent means "strongly" or "somewhat" agree and just chooses a response, then the data may not accurately reflect the respondent's view. Or if an interviewer directs a respondent toward an answer choice, that action can impact the variance of the estimate.

In many ways, the interviewer has to "teach" the respondent how to be a "good" respondent by providing verbal feedback on the respondent's actions during the interview. For example, if a respondent says "don't know" to questions and the interviewer never probes, then the respondent sees that providing more precise answers to the questions is not viewed as important. Further, if an interviewer lets respondents veer off of the interview topic repeatedly without trying to bring them back on task, then the respondents learn that this is acceptable behavior.

Interviewers can also impact the number of respondents who agree to be interviewed. Good persuasion skills are necessary for interviewers. If interviewers do not possess these skills and do not learn them during training, then the response rate can suffer as more respondents decline to participate.

Research has also investigated whether interviewer demographic characteristics, personality characteristics, or social skills can impact the survey result. In particular, interviewer race, religion and ethnicity, social status, education, and age have all been investigated. Although a significant amount of research has been conducted over multiple decades to look at the impact of interviewer demographics on survey data, few consistent significant results have been found. The only significant results that have been observed are when the interviewer characteristics are directly related to the questions being asked (e.g., gender of interviewer and questions about gender roles and equity). Research has also been conducted looking at the interaction between characteristics of the respondent and the interviewer, and in general this research finds few interactions and those that are found are of a complex nature and not easily disentangled. The general consensus seems to be that there is no demographic basis for choosing an interviewer.

Data collection costs are usually the largest piece of any survey budget. As such, the work performed by interviewers has a direct impact on the survey budget. If interviewers take more time to complete an interview than initially budgeted, then the overall project budget is likely to suffer unless other measures are taken to counter that overrun. Similarly, if interviewers complete interviews much more quickly than budgeted, this will have a positive effect on the project budget. Further, if interviewers are able to complete more interviews than initially projected, the need for additional interviewers and interviewing time may be reduced, which would also have a positive effect on the budget.

Importance of Interviewers to the Data Collection Effort

As the main visible representatives of the survey, and the people who are actually collecting the data, interviewers play a crucial part in data collection efforts. Interviewers are often the only contact that a respondent has with the survey team and as such need to provide a positive, professional image of the study. Interviewers are also a key part of obtaining an acceptable response rate by convincing respondents to participate in the survey and by conducting refusal conversions on respondents who initially refuse to participate. If an interviewer is disinterested or ineffective in obtaining cooperation from respondents, this can result in significant refusals or passive noncooperation, which can be detrimental to a study's response rate and data quality.

Interviewer Characteristics

Interviewer characteristics refer to the personal attributes of the interviewer who is conducting a survey with a respondent. These attributes may include physical attributes, such as gender, age, and voice qualities, and attitudinal or behavioral attributes, such as confidence or friendliness. Both visual and audio cues are available to respondents in face-to-face surveys, but respondents have only audio cues in telephone surveys. The characteristics of the interviewer introduce additional factors into the interaction between interviewer and respondent that may affect data collection and data quality. Research has shown that interviewer characteristics affect unit nonresponse, item nonresponse, and response quality.

Physical Characteristics

Physical characteristics of the interviewer, such as age, gender, or race, may be used by the respondent in the decision whether to agree to the survey request and to set expectations of the interview experience. Studies on the effects of these attributes on interview outcomes show mixed results. There is evidence that older interviewers are more likely to be consistent in administering surveys and introduce less response variation. No consistent effects of gender have been found on data quality although female interviewers, on average, achieve higher response rates. There has been considerable study of interviewer race effects. The matching of characteristics of the interviewer to the respondent has been shown to improve respondent cooperation and data quality. Respondents appear to be more comfortable and thus cooperative with someone similar to themselves, especially in interviews on sensitive topics such as inequality and racial discrimination.

In telephone interviews, interviewer characteristics can only be conveyed through the audio interaction with the respondent. Physical characteristics that can be perceived over the phone include gender, age, and possibly, race and ethnic origin, as well as voice characteristics such as loudness and rate of speech. These characteristics can be measured both acoustically and through subjective perception. Acoustic measures of voice properties that have been studied include fundamental frequency of the voice sound waves, the variation in fundamental frequency, and measures of rate of speech and inflection. While acoustic voice measures have been found to help explain interviewer success, the measures studied have not been found to explain outcome of a particular contact. As with face-to-face interviewing, female interviewers tend to have higher response rates, but there is limited empirical evidence of gender effects on data quality. Race and ethnic origin of the interviewer may be conveyed through accents or articulation, but there is little research on these possible effects.

Attitudinal and Behavioral Characteristics

Attitudinal and behavioral characteristics of the interviewer have also been found to be related to survey response and cooperation. These characteristics are more difficult to measure, but they have been found to be significant predictors of response, as they represent the attributes of the interviewer that lead to establishing successful interviewer–respondent rapport. Attitudinal characteristics that have been studied include interviewer confidence, optimism, and persuasiveness. Behavioral characteristics have included attention to details, social skills, and interview behaviors such as points of engagement in survey introductions. Interviewer confidence, as measured either by the interviewer or by an observer, has been found to be positively related to survey success, although evidence is not conclusive. The effects of interviewer optimism, friendliness, agreeableness suggest that being overly open with a respondent leads to greater response variation. Interviewers who are socially skilled, without being overly sociable, are more likely to be able to tailor the interaction with the respondent and maintain data quality across interviews. A study that analyzed the effects of interviewer physical attributes, interviewer attitudes, and interviewer behaviors across multiple surveys and across countries found all three categories of characteristics to significantly predict interviewer response rates, with interviewer attitudes being the best predictor.

Attitudinal and behavioral characteristics can be conveyed over the phone, but they lack visual cues such as interviewer demeanor or expression. An interviewer may be judged as being friendly, conversational, or competent. Studies to identify the voice qualities of the best interviewers have included human ratings of voices by trained raters. Ratings have included both physical properties, such as pitch, rate of speaking, and loudness, as well as perceived attitudes, including pleasant to listen to, conversational, confident, competent, friendly, and enthusiastic. Early studies found lower refusal rates for interviewers who spoke rapidly, loudly, with standard American pronunciation, and who were judged as sounding confident and competent. A more recent study of survey introductions found listener ratings of greater confidence and voice breathiness to predict lower response rates, while variation across contacts, on multiple voice measures, was characteristic of high response rate interviewers.

Many studies have included interviewer experience as a characteristic to predict survey outcomes. Rather than a monotonic relationship of experience with higher response rates and data quality, there is indication that interviewers of middle-range experience are the most successful. Experience, as an interviewer characteristic, is clearly confounded with the physical, attitudinal, and behavioral characteristics discussed. The right combination of these characteristics is more likely to lead to success and experience on the job.

Effects

Interviewer characteristics contribute to defining the social interaction of the interviewer and respondent. Interviewer variation exists and contributes to survey outcomes. The mechanisms that define the effect of the characteristics are dependent on other survey conditions, including the respondent and the survey design.

Interviewer Debriefing

Interviewer debriefing is a process used to gather feedback from telephone and field (in-person) interviewers regarding a particular survey effort. As the project staff members who most closely interact with respondents, interviewers provide a unique perspective on how questions are answered by respondents and which questions may be difficult to ask or answer. They also can provide other, general observations about the administration of the survey instrument. These debriefing sessions can be held either in-person (as is usually the case for telephone interviewer debriefing sessions) or over the phone (as is often the case for field interviewer debriefing sessions).

Prior to conducting an interviewer debriefing, a member of the project staff—either the project director or the person who has managed the data collection effort—usually creates a detailed questionnaire for interviewers to complete prior to the session. Most of the questions should be short-answer (closed-ended) but also should include space so that the interviewer can provide feedback and concrete examples from their own experience in administering the survey on specified topics. Providing an additional open-ended question at the end of the questionnaire can also encourage the interviewer to comment on any other circumstances not covered in the debriefing questionnaire.

The debriefing questionnaire is given to interviewers by their supervisor, and they are instructed to complete it prior to the debriefing session. Interviewers are usually given several days to complete the questionnaire and are encouraged to initially spend a concentrated amount of time filling out the questionnaire and then continue adding to it in subsequent days as additional examples or comments occur to them. This process allows interviewers to spend multiple days thinking about their comments and allows them to relate those comments that are important to them. Further, quiet interviewers may be overlooked or not speak up much during the debriefing discussion, and gathering written comments from all interviewers allows project staff to get the entire range of feedback and not just feedback from the vocal interviewers.

A few days after handing out the debriefing questionnaire, project staff members meet with the interviewers to lead a discussion about the interviewers' experiences with respondents and the questionnaire, as well as to gather their comments on the data collection effort. This discussion is often organized like a focus group where the moderator attempts to get all participants involved in the discussion and where the discussion is directed by notes the moderator has prepared ahead of time. The information gathered during the interviewer debriefing session is only as good as the questions designed to elicit the information as well as the ability of the session leader or moderator to encourage participation and keep the discussion productive throughout the session.

For interviewer debriefing sessions, the questions on the debriefing questionnaire usually should form the structure of the discussion. It is important, however, for the project staff who are moderating or leading these discussions to be able to readily identify comments that need additional detail (or probing) as well as to readily identify comments that are off track so the discussion can be kept focused on the topic at hand. The written debriefing questionnaires are then collected at the end of the session.

Interviewer debriefing sessions can be audio- or videotaped for follow-up and archive purposes; however, in practice it is more likely that one or two project staff members will be assigned to take notes during the discussion. These notes, along with the written questionnaires, form the basis for the summary of the interviewer debriefing that can then be utilized by project management and the client or survey sponsor as part of the survey evaluation process. A key skill required for the project staff members assigned to summarize the interviewer debriefing comments is the ability to evaluate the comments in terms of what reasonably can and should be changed and what cannot or should not, as well as what issues are important for the overall survey administration and which are not. This sifting and evaluating of interviewer debriefing comments must be completed by a senior project staff member who understands the entire survey process and survey objectives in a way that interviewers, with their limited role on the project, usually cannot.

Interviewer debriefing sessions can also be opened up to include supervisor and monitors (for telephone interviews) or field observers (for field interviews). Similar to interviewers, these supervisory staff members offer a unique perspective on the data collection process. By virtue of their job, they are exposed to a large number of interviewers, and because of this exposure, they can synthesize the experiences they observe across the entire staff rather than focusing on one person's view. Supervisory staff also are more likely to be familiar with the survey research process and specific survey objectives and therefore are able to sift through comments in a way that results in the identification of common problems or issues that need addressing.

Interviewer debriefing notes can provide a rich narrative on the real-world administration of the survey instrument and provide insight into the data collection process that project staff and survey designers are usually unable to directly observe. Project managers, clients, or survey sponsors can use interviewer debriefings along with other observations gathered from project staff members and respondents and the quantitative survey data collected to identify any problems with the survey effort, questions that may need revision before the next survey administration round, or procedures or processes that need adjustment to meet the goal of fielding the best survey effort possible with the resources available.

Interviewer Effects

In many surveys, interviewers play an important role in the data collection process. They can be effective in gaining cooperation of the sample persons, helping clarify survey tasks, or motivating the respondent to provide complete and accurate answers. Thus, interviewers can contribute to data quality, but they can also contribute to measurement error. Interviewers can affect respondents' answers through their mere presence as well as their behaviors when administering the survey.

There are several ways in which interviewers seem to influence respondents' answers. First, the presence of an interviewer can stimulate respondents to take social norms into account when answering a survey question. Pressure to conform to social norms can lead to the underreporting of socially undesirable behavior and the overreporting of socially desirable behavior. Second, observable interviewer characteristics, such as age, gender, or race, can affect many stages of the answer process, for example, by changing the salience of the question topic and therefore altering the retrieval process or by influencing the respondents' judgments of which answers would be socially appropriate. Third, the interviewer's verbal and nonverbal behavior can also affect respondents' answers. For example, the interviewer's feedback, facial expressions, or rate of speech can be taken by respondents as reflecting (dis)-approval of their answers or how important the interviewer thinks the question is. Finally, the interviewer can make errors when delivering and recording the answers to a question. These errors are particularly problematic if they are systematic, for example, not reading certain questions exactly as worded, delivering them incorrectly, omitting necessary probes, or neglecting some response categories.

It is important to note that the effects of interviewers on respondents' answers are not equally strong across all types of questions. Social norms apply only to certain behavioral and attitudinal questions. Interviewers' observable characteristics play a role only if they are related to the question content. Early studies on interviewer effects have shown, for example, race-of-interviewer effects for racial items and gender-of-interviewer effects in gender-related attitude questions but no effects with attitude questions related to other subjects. Similarly, the effects of interviewer behavior also vary by question type. They are more likely to occur if respondents are forced to answer questions about unfamiliar topics, questions about topics that are not salient, questions that are difficult to understand, or questions that leave room for differing interpretations to be elicited by the interviewer. Interviewer errors in question delivery are more likely to occur for longer questions or questions asked in series. Filter questions with long follow-up sequences can provide the opportunity for an interviewer to shorten the questionnaire, even when that is not what the researcher wants to happen.

Interviewer effects can have different consequences for survey estimates. Survey researchers differentiate between systematic interviewer effects that bias survey results and variable interviewer effects that increase the variability of a survey statistic while not introducing bias. Results will be biased if most respondents or certain subgroups systematically deviate in the same direction from the "true" score when interviewed by interviewers with specific characteristics or behavior. Race and gender are examples of such characteristics. But interviewer effects can also increase the variance of a survey statistic without introducing any systematic bias into the estimates. If, for example, interviewers have idiosyncratic ways of phrasing a question or conducting probing, all respondents interviewed by the same interviewer will be affected in the same way, but respondents questioned by another interviewer will be exposed to a different set of idiosyncrasies and might alter their answers in a different way. And even if all the individual biases introduced by the interviewers cancel each other out, the interviewers have the effect of increasing the variance of the respondents' answers. This is usually referred to as *interviewer variance*.

In practice, the size of interviewer effects is not only difficult to predict in advance but often even difficult to measure in retrospect. A random assignment of respondents to interviewers (an interpenetrated design) is necessary to estimate the size of such interviewer variance. To assess interviewer bias, knowledge of the respondent's true score or some similar validation measure is necessary. Past research on interviewer effects for attitudinal items has compared answers from groups of respondents randomly assigned to specific interviewers. All that can be learned from those settings is that a pairing of certain types of interviewers and respondents results in answer distortion. However, estimates of the size of this bias and the accompanying answer quality cannot be made without making additional assumptions.

Reducing Interviewer Effects

Several approaches can be taken to reduce interviewer effects.

1. Interviewer effects on variance and bias vary with survey mode. Evidence from past studies has shown larger effects in face-to-face than telephone surveys, and interviewer effects are, by definition, typically absent for self-administered modes. However, in making a decision to eliminate the interviewer, one should keep in mind that interviewers play other important and positive roles in the survey process, for example, in recruiting hard-to-convince respondents. Thus, removing the interviewer may introduce or increase other types of survey errors.

2. If the biasing effect of an interaction among observable interviewer characteristics, question content, and respondent characteristics is well understood, interviewers and respondents could be deliberately matched in ways known to reduce bias. However, even if it were known that certain interviewer–respondent pairings provided more accurate answers, deliberate matching would not be feasible for most surveys because respondent characteristics may not be known in advance or due to legal restrictions prevent the hiring of interviewers based exclusively on observable characteristics. Random assignment of respondents to interviewers is therefore often recommended.

3. Interviewer training can help reduce the variability in interviewer behavior. The data collection process can become more standardized if interviewers learn to do several things more systematically:

- Explain the question-and-answer process to the respondent.
- Motivate the respondent to provide high-quality answers.
- Read questions exactly as worded.
- Probe nondirectively.
- Record answers without interpretation, paraphrasing, or additional inference about the respondent's opinion or behavior.

Interviewers also need to learn to interact with the respondent in a way that minimizes the potential for the respondent to infer a preference for any response. Careful and adequate probing can in some instances lead to higher-quality answers, but in general it appears that interviewers exert more effects on self-reports when the structure of the question–answer interaction is not fully scripted by a protocol. Overall, the risk of interviewer effects can be reduced with well-written questions; for example, questions that are easily understood by the respondent do not carry much cognitive or emotional burden and do not leave room for interpretation.

4. Finally, organizational parameters can be set in such a way that they reduce the likelihood of interviewer effects. Supervising interviewers and monitoring their behavior will help ensure that the questionnaire is implemented as intended. The interviewer reward system can be altered so that interviewers are motivated to focus on achieving not only a high number of completed cases but also high-quality data. A reduction in interviewer workload for a particular survey will further reduce the effects of each individual interviewer on the survey results.

However, it is likely that weaknesses in the interviewer–respondent interchange are inherent to human communication. Thus, reduction of interviewer effects through training or changes in organizational parameters may not be completely successful. Current research is therefore focusing on the possibility of including indicators of the mechanisms that produce interviewer effects in statistical analysis of survey results. This approach requires interviewer information to be part of the dataset.

Interviewer Monitoring

Interviewer monitoring is a process of observing and evaluating the performance of an individual who is conducting an interview to gather survey data. Interviewer monitoring is typically conducted in an effort to reduce interviewer-related measurement error by allowing the researcher to understand where in the interview mistakes are being made, with whom are they being made, and under what circumstances. Interviewer monitoring is also necessary as a deterrent to interviewer falsification. If the interviewer is made aware that he or she will be monitored and is kept blind as to when the monitoring will occur, the temptation to falsify data can be greatly reduced. This entry contains an overview of the role of interviewer monitoring, followed by a summary of the types of data collected while monitoring, the ways monitoring data can be used to improve the quality of surveys, and finally a summary of the monitoring techniques employed in telephone and face-to-face interviews.

Monitoring Different Aspects of Interviewer Behavior

When interviewers are employed to collect data, they play a central role in the success or failure of a survey. The first responsibility of the interviewer is to persuade the respondent to take part in the survey (for face-to-face interviews, this may be preceded by the need to locate the respondent). Persuading the respondent to participate is not a simple task. It requires a unique set of skills to tailor the conversation to the respondent and win his or her trust while maintaining a professional and courteous presence. More often than not, the interviewer will have only a few seconds before the reluctant respondent will break off from the interview. By monitoring the interaction between the interviewer and respondent, information can be gathered to reduce the frequency with which these break-offs occur.

Once the interviewer gains the trust of the respondent and begins to conduct the interview, a different set of skills is required to ensure the respondent answers every question and does so accurately. If the interviewer is not efficient in administering the questionnaire, break-offs may occur before the interview is completed. There also may be questions that a respondent is not comfortable answering. The interviewer must be able to persuade the respondent to answer these questions without offending him or her or biasing the response. Unless the interviewers are being monitored, those managing the survey have no way of maximizing the frequency and quality of the response the interviewers attain.

Interviewer monitoring also may provide study managers with information that allows them to identify potential problem questions, scripts (verbatim), and nonverbatim delivery. While cognitive testing is typically used to revise survey questions before they are put into the field, there is always a nonzero probability that interviewers still will have difficulty administering a question or that a question still may be misinterpreted by respondents. Interviewer monitoring provides an additional mechanism by which to evaluate the effectiveness of the questionnaire in producing the data desired. If the script or question is verbatim, the wording can be modified based on the information gathered while monitoring. If there is a problem with the way a script or question is being delivered, this information can be used to help the interviewer find a more effective delivery.

Types of Data That Interviewer Monitoring Can Generate

The information gathered while monitoring interviewers can be grouped into four basic categories: (1) operational execution, (2) falsification evidence, (3) interview quality, and (4) questionnaire design. Operational execution includes observations of how accurately the interviewer performs tasks that are unrelated to the actual administration of the questionnaire, but may have an impact on the results of a survey. Examples of these types of tasks include accurately recording the interview outcome or setting up a time to conduct the interview when the respondent is not available on first contact. These types of observations are often based on simple counts and are the source for cooperation, refusal, and completion rates among other commonly reported statistics. Falsification evidence includes any attempt on the part of the interviewer to fabricate or omit data. This could be as minor as purposely skipping a question that should be asked or as major as outright making up data for entire questionnaires. The latter is unlikely to occur when the interview is conducted by telephone in a centralized facility because of the increased likelihood of being caught. It is more likely to occur in face-to-face interviews where the interviewer is either unable to locate the respondent or does not feel safe in the area where the respondent lives.

Interview quality contains observations as to how well the interviewer performs while conducting the interview. These types of observations may include assessments of the interviewer's voice quality (e.g., enunciation, pace, volume), how well the interviewer follows the interview protocol (e.g., coding answers correctly, reading verbatim scripts as written, probing when necessary to clarify answers, maintaining neutrality), and how effectively the interviewer interacts with the respondent (e.g., persuades the respondent to participate, addresses concerns, answers questions). Questionnaire design refers to observations about the flow and delivery of the interview that are a function of the way the script was designed. Poor question wording and incomplete logic skips may be uncovered while monitoring.

How Interviewer Monitoring Can Improve Survey Quality

The data gathered while monitoring interviewers can be used to (a) coach interviewers to improve their performance, (b) inform managers of production issues to be corrected while the study is in the field, (c) develop individual performance assessments that can be used for merit review, (d) make refinements to the script or questionnaire, and (e) assess the amount of interviewer error associated with the given study. Data used for coaching is typically information related to interview quality. These data usually are based on observable behavior that can be objectively assessed. The data should include specific examples of what the interviewer is doing or not doing well and give the interviewer concrete examples of how to improve their performance. Interview quality and operational execution and data falsification are considered core observations that should be monitored throughout the course of a study. Monitoring allows production managers the ability to identify problems when they occur and correct them while the study is under way. These types of observations also make up the core of many performance evaluations. Therefore it is critical that the observations be accurate and reliable.

While some types of errors observed while monitoring interviewers are directly linked to data quality (e.g., failing to complete the interview, miscoding the respondent's answers, and failing to probe and/or clarify ambiguous answers), it is not always clear how other types of errors may impact data quality (e.g., breaking neutrality, failing to read scripts or questions verbatim). Thus the link between interviewer monitoring and the measurement of interviewer-related error in a given survey can often be quite complex. Many measures of interviewer-related error in surveys come from statistical analyses of the survey data themselves rather than the data gathered while monitoring interviewers. These are often reported in conjunction with the production-based observations mentioned earlier.

Interviewer Monitoring Techniques

The ways in which interviewer monitoring takes place vary greatly depending on the type of interview being conducted. For telephone interviews it is common for the person monitoring to listen in unobtrusively from a remote location. This has the advantage of allowing the interview to be monitored in real time, thus reducing the lag between the interview and feedback to the interviewer. It does, however, place limits as to the depth of observations that can be made. In contrast it is very uncommon for a face-to-face interview to be monitored in real time. There are some computer-assisted personal interviewing applications that allow face-to-face interviews to be recorded so they can be reviewed after the interview is complete. This creates a longer duration between the time of the interview and when the interviewer can be given feedback on his or her performance. The advantage of monitoring recorded interviews after the fact lies in the depth at which they can be evaluated. In the end, the nature and extent of interviewer monitoring on a survey is often dictated by the way the survey is being conducted, the type of information needed, and the resources available to devote to monitoring.

Interviewer Monitoring Form (IMF)

An interviewer monitoring form (IMF) is a framework or set of guidelines used to facilitate interviewer monitoring. A carefully developed IMF is central to the development of standardized processes for measuring interviewer-related error and conducting interviewer training and debriefing. The primary purpose for developing an IMF is to minimize interviewer effects and increase interviewer productivity. This entry contains a brief summary of what is known about interviewer monitoring forms, why they are used, and what they should include.

It is widely accepted that interviewer behavior can be a significant source of measurement error in surveys and that effort to observe and reduce this error is a necessary element of conducting survey research whenever interviewers are used to collect data. Interviewer monitoring forms are typically used to monitor the performance and behavior of telephone interviewers. This is due to the fact that telephone interviewers are centrally located and can be observed from a remote location while the interview is taking place. Traditionally it has been up to the individual organization conducting the research to develop its own IMF. Over the past 40 years or more, a wide variety of methods have been developed.

Although many different approaches to monitoring the performance of telephone interviewers have been proposed, there currently exists no standard, widely accepted IMF through which interviewer performance can be assessed and compared across interviewers, studies, or research organizations. This is due in large part to the complexity of the interview process and the wide variety of purposes for conducting telephone interviews. It also, in part, reflects the diversity of "real-world" motivators that influence the nature of the IMF that an individual organization might develop. Still, there exists a growing body of research into understanding what an IMF should contain and how it should be used.

Early interviewer monitoring forms were designed with the sole objective of identifying interviewer errors. This focus stemmed from the desire to quantify the amount of interviewer error a given study might contain. As the industry's understanding of interviewer behavior has become more refined and computer resources have increased, interviewer monitoring forms have become more sophisticated. More and more is being done to better understand the verbal behaviors that contribute to a successful interview, to quantify the behaviors that are observed, and to use these observations to influence future interviewer behavior through feedback and training. Many current IMFs are designed to accomplish multiple objectives. These may include the facilitation of coaching and training, the generation of data for interviewer performance reviews and methodological investigation, and the provision of a framework for interview process auditing.

The content of the IMF depends not only on these objectives but also on the purpose of the interview or the study as a whole. Every study that uses interviewers to gather data should have policies and procedures that the interviewer is expected to follow (e.g., reading certain questions verbatim, coding answers accurately, and maintaining neutrality). These behaviors do not typically produce a great degree of variability because they are baseline expectations. In other words, they are minimum standards that every interviewer should meet as they are central to the effort of reducing interviewer-related measurement error. As such, they commonly serve as the backbone for the auditing process. An IMF may also contain speech-related behaviors that reflect the way the interviewer uses her or his voice or interviewer–respondent interaction behaviors that reflect the way an interviewer deals with reluctant respondents to maintain or promote cooperation.

Examples of speech-related behaviors include enunciation (clarity), modulation (volume fluctuation), and speed (rate of speech). These behaviors are relatively easy to operationally define and observe. Although they may be more powerful predictors of a successful interview, interviewer–respondent interaction behaviors often are more difficult to operationalize. Not all respondents are the same with regard to their willingness to participate. A good IMF will recognize this by containing respondent behaviors that are good indicators of a respondent's willingness, or lack thereof, to participate. A good IMF will also contain behaviors that reflect an interviewer's ability to deal with reluctant respondents. Observing these interviewer and respondent behaviors is critical to maximizing the impact of interviewer training and feedback as they have the highest likelihood of reducing nonresponse and other nonsampling error.

Interviewer Neutrality

Interviewer neutrality occurs when an interviewer provides no indication of desired responses (remains unbiased) during the interview process. Interviewers are trained to betray no opinion about survey questions to minimize interviewer-related error that occurs when responses are influenced by respondent perception of what the interviewer indicates is an appropriate answer. The process of collecting data using interviewers is designed to obtain valid information (i.e., a respondent's accurate responses), but to be effective the information must be collected in a consistent and neutral manner that minimizes bias. Neutral administration of surveys requires the training of interviewers to not reveal their own opinions or preferences, either verbally or nonverbally, which could induce respondents to provide inaccurate answers in response to perceived interviewer preferences. Specifically, rapport-building behaviors, interviewer feedback, and respondent vulnerability to social desirability and acquiescence need to be considered.

Interviewer neutrality can be accomplished by training interviewers to gather data in a nonjudgmental manner and to use a normal tone of voice throughout the interview process. It is important that interviewers avoid using words or nonverbal cues that imply criticism, surprise, approval, or disapproval. Verbal behavior such as "Yes, I agree" or "I feel the same way," or nonverbal behavior such as smiling, frowning, giving an intense look, or an extended pause may be interpreted by the respondent as approval or disapproval of an answer. Although interviewers are encouraged to establish rapport with respondents to promote respondent motivation, the interviewer must be continually aware of the risk of expressing personal opinions or preferences. When interviewers provide verbal or nonverbal feedback throughout the interview, it is vital to avoid using any feedback techniques that may be interpreted as approval or disapproval. Interviewers should avoid expressing personal opinions on the topics covered in the survey, as well as communicating any personal information that the respondent may use to infer the interviewer's opinions. The validity of the data can be threatened if respondents are aware of interviewer opinions or preferences. Because the goal of interviews is to provide an environment in which respondents feel comfortable reporting accurate answers, it is critical that the interviewers' opinions or preferences do not influence the respondent in any way.

Finally, social desirability (wanting to provide socially acceptable answers) and acquiescence response bias (the tendency to agree with perceived interviewers' opinions) can threaten the validity of the data. Social desirability bias occurs when respondents answer questions to present themselves in a favorable light (providing answers they feel are most socially approved). Acquiescence response bias occurs when respondents agree with statements from the questions that are spoken by the interviewer regardless of content and can lead to responses that merely reflect agreement with what the interviewer is reading rather than the respondent's own opinions. Training for interviewer neutrality should seek to minimize the effects of social desirability and acquiescence. If interviewer neutrality is ensured, interviewer-related error is reduced and thus allows for a more accurate measurement of a respondent's true scores in the variables of interest.

Interviewer Productivity

Interviewer productivity refers to the ways of measuring what is achieved by telephone and in-person survey interviewers when they work to (a) gain cooperation from sampled respondents and (b) complete interviews with these respondents. Measuring interviewer productivity is a major concern for those conducting and managing surveys, for several reasons. Knowledge of productivity is essential to survey budgeting and developing realistic estimates of survey costs. Managing a survey requires an understanding about how many completed interviews, refusals, noncontacts, ineligibles, and callbacks can be expected for a given survey. Productivity information is often used to reward interviewers that are performing well or to retrain those who are not being productive (enough). Interviewer productivity information is also a necessary aspect of planning and scheduling the number of interviewers needed for fielding a survey and for monitoring survey progress. It is also important to communicate productivity expectations to interviewers in advance of the start of data collection so they know how to perform adequately.

Literature

Interviewer productivity is discussed in the literature on survey methods. Don Dillman has noted the importance of interviewer productivity by indicating that the length of time taken to complete interviews needs to be taken into account in scheduling interviewers. Paul Lavrakas has proposed that interviewer productivity be measured by the speed with which samples are worked and also by the ratio of the number of completed interviews to the number of refusals and partially completed interviews. He suggests using these kinds of productivity measures to set interviewer pay rates and manage surveys. Interviewers who are more productive also have a greater influence on the amount of survey data collected than do less productive interviewers. This is because more productive interviewers end up completing more interviews than less productive interviewers. Robert Groves describes how estimates of the standard errors in a survey are directly related to the average number of interviews completed by each interviewer. In contrast, interviewers who are less productive may well have greater influence on other aspects of survey data quality such as nonresponse and possible nonresponse error.

Influences and Uses

There are currently no agreed upon standards of interviewer productivity because productivity can be influenced by so many characteristics of an interviewer-administered survey, including the survey mode (telephone, face-to-face), the survey population, the length of the questionnaire, the experience of the interviewer, and the particular phase of survey contact (initial contacts vs. callback attempts). The most frequently used measure of interviewer productivity is the number of completed interviews obtained by an interviewer during some set period of time, such as "per hour." This is important to measure, as most surveys have a goal to achieve a specific number of completed interviews within a pre-specified field period length.

Interviewer productivity can be influenced by incentives added to their compensation. At least one study has found that the number of interviews an interviewer will complete during a shift can be affected by the offer of a monetary reward pegged to productivity. However, rewarding interviewers for productivity has potential drawbacks (e.g., interviewers may engage in cheating to earn monetary rewards), so this practice is generally frowned upon. Thus, whenever an incentive system is considered for rewarding interviewers for their productivity, it is critical that it be combined with a reliable and rigorous system of monitoring the interviewers.

Computer-assisted telephone interviewing (CATI) and computer-assisted personal interviewing (CAPI) are the two main survey modes that use interviewers and that are concerned with interviewer productivity. However, CATI surveying is the predominant survey mode for most survey organizations, and the majority of productivity measures that have been developed are those obtained with CATI systems, which facilitate the collection of many measures of interviewer productivity, including (a) number of call attempts per hour, (b) number of completed interviews per hour, (c) number of refusals per hour, (d) number of ineligibles per hour, (e) total number of minutes worked, (f) average length of completed interviews, (g) quality of interviews completed, (h) monitoring scores, and (i) attendance and tardiness. Some of these measures clearly apply to face-to-face interviewing with CAPI.

Information on interviewer productivity is generally used by survey managers to forecast progress toward survey deadlines and goals and also for communicating with interviewing staff about their performance on a survey. Interviewer productivity is often used to estimate the number of interviewers needed to meet survey goals or the number of hours or days required to reach a survey deadline. For example, if interviewer productivity for a particular survey is measured as an interviewer taking a half hour to complete one interview, and the survey goal is to have 400 completed interviews, then multiplying 400 by one half hour equals 200 interviewer hours that are required to reach the survey goals. However, since hours per complete interview tends to increase while a survey is in the field—because of an increasing proportion of unproductive calling (no answers, answering machines, refusals)—it is usually more accurate to recalibrate interviewer productivity periodically throughout the survey and re-estimate the number of interviewer hours needed to reach survey goals. This calculation can be made easier, for example, by logging daily productivity information on a spreadsheet, which can then be used to forecast the number of interviewer hours and the number of days required to meet survey goals.

Performance Evaluations

Interviewers want to know how their performance is evaluated, and productivity information is a useful way to provide this kind of performance evaluation. Survey organizations often post interviewer productivity information for every interviewer on a survey, such as the number of calls per hour, hours per completed interview, refusals per hour, and ineligibles per hour that interviewers achieve over the course of a survey project on a daily basis. Because the productivity of every survey is different, this information provides interviewers, supervisors, and managers with a way to assess their progress on a particular survey. Some organizations calculate control limits on measures of interviewer productivity and then identify which interviewers are outside the acceptable range of performance. Interviewers who are outside the range of the control limits on the high side may be promoted (e.g., to become lead interviewers, monitors, or supervisors), whereas others may be investigated to determine if there is a possibility of falsification. Those outside the range of control limits on the low side may be sent for additional training to improve their productivity. However, productivity measures are generally correlated, so they must be used carefully by survey management. For example, interviewers who achieve a high rate of completed interviews will generally see their calls per hour decrease because their time is occupied with interviewing respondents, which takes more time than making call attempts.

Future Directions

Most survey organizations are concerned about interviewer productivity, including declining response rates, lack of trained interviewers, and the problems of managing a part-time work force of interviewers. A survey of telephone survey organizations conducted in 2007 found that almost all survey call centers (84%) regularly collect productivity information on interviewers. However, only 54% reported that they actively use this information as a way to analyze and to make decisions about interviewers. Standards of interviewer productivity differ among survey research organizations and are dependent on the specific goals of each organization and of each survey. But no survey organization can survive if it does not pay attention to and regularly measure interviewer productivity. In the future, interviewer productivity measures will become even more important, as survey costs increase and organizations look for ways to increase ever-declining survey response rates.

INTERVIEWER-RELATED ERROR

Interviewer-related error is a form of measurement error and includes both the bias and the variance that interviewers can contribute to the data that are gathered in face-to-face and telephone surveys. In interviewer-administered surveys, although interviewers can contribute much to the accuracy of the data that are gathered, they also can contribute much of the nonsampling error that finds its way into those data.

The methodological literature includes startling examples of measurement error due to interviewer mistakes. In 1983, an interviewer's incorrect recording of one wealthy respondent's income resulted in the erroneous report that the richest half percent of the U.S. population held 35% of the national wealth. This finding, widely publicized, was interpreted to show that Reaganomics favored the wealthy. When the error was detected and corrected, the actual estimate was 27%—only a slight increase from the 1963 figure. Most survey designs do not feature weighting schemes that permit one interviewer's random error to have such a profound effect. Usually, random interviewer errors "cancel each other out," not threatening data validity.

It is systematic, rather than random, interviewer-related error (i.e., bias) that typically affects survey data. Systematic, or correlated, error occurs when interviewers make similar "mistakes" across many interviews. Such errors may actually reduce item variance, but they play havoc with the accuracy of resulting estimates. This entry focuses on the sources of, and treatments for, systematic interviewer error and discusses efforts to prevent, measure, manage, and correct for this type of bias.

Preventing Interviewer-Related Error

Prevention focuses on three basic strategies: (1) reducing or eliminating human intervention between respondent and data capture, (2) engineering error-proof questionnaires and associated data collection tools, and (3) standardizing interviewer behaviors to minimize error.

In their review of interviewer-related error, Robert M. Groves and his colleagues note that the very presence of an interviewer has been shown to bias responses. Employing computerized, scanned, or voice-response self-administration avoids both the costs and errors associated with employing human interviewers. Sloppy data resulting from respondent-related error, the bugaboo of self-administration, can be attacked through programming that mandates response and requires clarification of contradictory information.

This approach, however, has its own drawbacks. Notable among them are higher front-end costs and lead time, limitations on complexity, and lower response rates. Cybernetic approaches are expensive for all but the simplest of questionnaires; they require intensive programming, pretesting, and debugging to meet the requirement that they be far more error-proof than is required when a trained interviewer is involved. Even for simple questionnaires, the value added by the presence of an interviewer to motivate engagement and probe for focused and detailed answers compensates for and usually exceeds the error contributed. Complex enumerations and life history matrices are approached with trepidation in the absence of trained interviewers. Finally, it is far easier for respondents to opt out of higher-burden self-administered surveys than to avoid or disappoint a pleasant, yet determined and persistent interviewer.

Because both interviewer-administered and self-administered data collection have strengths and weaknesses, in surveys where the elimination of interviewers entirely is not prudent or possible, questions known to be affected by interviewer characteristics or limits to their capabilities can be switched to self-administration. Barbara Mensch and Denise Kandel found in their reanalysis of data from a longitudinal study that young respondents having the same interviewer over multiple data collection waves significantly underreported drug use. Their conclusion was that the development of "over-rapport" with the interviewer heightened self-censorship. Because that very rapport was responsible for the panel's extraordinary retention (ongoing response) rate, the solution was to maintain continuity of interviewer assignments but move the sensitive questions to self-administration.

A second major strategy for preventing interviewer-related error is engineering error-proof questionnaires and associated data collection tools. Sometimes interviewers slip up; it may be due to principal investigators laying out "banana peels" in the form of confusing questions, excessive burden, "overly academic" language, complex skip instructions, and crammed layouts. The burgeoning literature on designing Web surveys for clarity and ease of self-administration provides guidance for improving all surveys—these questionnaire design principles, adapted to interviewer-administered questionnaires, also increase an interviewer's ability to provide error-free data. Pretesting, focus groups, and cognitive interviews lead to questionnaires that have fewer opportunities for error.

The third prevention strategy is standardizing interviewer behavior to censor actions associated with measurement error. Two competing theories of how best to do this suggest different approaches to preventing interviewer error. The dominant paradigm seeks to severely constrain interviewer behavior as a means to *standardize the presentation of the stimulus* by the interviewer across all interviews. An alternative conversational approach to interviewing seeks to *standardize the understanding of the stimulus* by the respondent across all interviews—that is, to communicate what the investigator really wants to know, even when the question must be adapted to the particular respondent's cognitive abilities, language skills, and knowledge.

In the standardizing-the-stimulus approach, questions must be asked exactly as written in the order provided; only neutral probes can be used and only scripted answers can be offered for respondent questions; and interviewers can offer a severely restricted set of verbalizations, none of which is leading or even affirming. Ad-libbing is anathema, sometimes even on scripted introductory materials. These "unfriendly" and sometimes counterintuitive standards can contribute mightily to break-offs (partial completions), as many respondents grow weary of hearing the same answer categories repeated or are forced to listen to and answer a question they think they have already answered. But the cost is seen as a worthwhile trade-off for the benefits of keeping tightly lidded the "Pandora's box" of interviewer discretion.

Practical experience and the literature note sizable variability in interviewer compliance with these principles. For example, Peneff found widespread violation of norms in his observational study of French interviewers. For this and because of the tyranny of conversational norms, interviewers may try to smooth awkward situations in ways that cause respondents to censor their remarks.

Field studies use interviewer observations and telephone survey calling centers use random monitoring to evaluate and code interviewer behavior, but the vast majority of survey interviewing is unobserved in both telephone and face-to-face surveys and thus prone to error introduced by noncompliance with strict interviewing rules. Past research has indicated that interviewers have been found to change the wording from 20% to 95% of the time and that interviewer experience (tenure) is uncorrelated with this form of error. Training is seen as one of few available responses, but training itself has not been found to be highly correlated with subsequent reductions in error. In many cases, wording changes are minor and do not affect the answer. Failure to probe and inadequate probing have been found to be major contributors to nonnegligent interviewer error.

In the standardizing-the-meaning paradigm (also called conversational interviewing or flexible interviewing), interviewers are given discretion to vary the script if they judge it will increase response accuracy. In a telephone survey experiment conducted in the late 1990s, Fred Conrad and Michael Schober found that this approach increased valid answers on ambiguous factual questions. Standardizing-the-meaning approaches result in longer interviews and higher costs due to the extra time in training interviewers about the goals of specific questions and the subsequent extra time during negotiating question meaning with respondents. This paradigm has been in use for decades but has been mostly limited to elite interviews and in situations where a structured questionnaire is viewed as inappropriate or ineffective.

Flexible interviewing opens the door to untrammeled interviewer discretion, and once opened, it may be difficult for interviewers to identify those situations that require the standardizing-the-stimulus approach and those that do not. On the other hand, the counterintuitive restrictions on interviewer behavior in the standard model foster violation of rules, which could bleed over into other aspects of interviewing. One solution to this dilemma is to designate certain key questions whose wording is ambiguous in meaning to respondents as standardizing-the-meaning and clearly restrict interviewer discretion to these questions only. In effect, that is what likely occurs in the field in many cases, as interviewers left to their own devices try to negotiate better answers from confused or recalcitrant respondents.

Measuring Interviewer-Related Error

Although interviewer-related error cannot always be prevented, it usually can be measured. Measurement can then lead to decisions about managing away future error, correcting the tainted data, or ignoring it. The gold standard in measuring interviewer variance is the intraclass correlation, rho. Rho involves calculating an analysis of variance with the interviewer as the treatment. Rho measures how much of the variance is contributed by interviewers; even a small rho can sizably inflate the variance of a variable. Unfortunately, the practicalities of survey work do not play to the strengths of rho. Interviewers often cannot be assigned randomly to respondents, especially when face-to-face interviewing is the mode of data collection; in current survey operations, multiple interviewers handle a single case and specialists may be assigned all the cases of a particular type. Furthermore, one telephone interviewer may handle 50 cases while another completes 2 cases. These conditions either violate rho's assumptions or limit its practical applicability.

A second approach to measurement is to create an ongoing "error profile" from the collected data. Questions central to the anticipated analysis are tracked in terms of missing data, "don't know" responses, data reduction staff assessment of the quality of responses to open questions, and any other more easily quantified measure related to error. Some questions will show high error rates across all interviewers. These are the "banana peels" in the questionnaire, best addressed by redesign and retraining across-the-board. Others will show high variance in error rate by interviewer. These are the interviewer-specific correlated errors that can be addressed through targeted retraining or more draconian solutions.

The most common approach to measurement of interviewer-related error involves observing field interviewing and monitoring telephone interviews. Interviewer observation can cover only a minimum of actual interview time (even in telephone centers) and is expensive, labor intensive, and difficult to analyze in real time. Quantitative coding of interviewer behavior is used in telephone survey labs to offer corrective feedback, but, in part because of the disconnect between day-to-day managers and principal investigators, there is little evidence that these protocols protect the integrity of key research hypotheses.

Managing Interviewer-Related Error

Training, supervision and ongoing feedback, interviewer–respondent matching, and validation are four ways to manage interviewer-related error. Jack Fowler and Tom Mangione have provided most of what little empirical evidence exists in the area of training and supervision. Training and supervision are shown to be effective in reducing error; however, more experienced interviewers are sometimes more likely to make errors than those with less experience—perhaps because they feel they have earned the right to cut corners and use their discretion.

A very small number of interviewer characteristics are proven causes of bias. Herb Weisberg provides a useful review of this literature, concluding that surveys directly related to interviewer characteristics are ones to worry about, such as anti-Semitism questions asked by Jewish interviewers. Gender effects have been noted but are difficult to generalize. Unambiguous race effects on questions that deal with racial matters lead to the rule of thumb to race-match in such interviews. Managing interviewer effects usually amounts to matching interviewer and respondent characteristics as closely as possible, "just to be safe." Weisberg's counterpoint is that it is not known if matching race results in overreports of race-biased attitudes and interpretations. Much of the work done in this area is decades old.

Interviewing invalidation, that is, fabricating answers to part or all of the questions interviewers ask, is a dark cloud on the horizon of survey research. A determined interviewer who falsifies data makes detection almost impossible. Management efforts to uncover validation problems include reinterviews with respondents (often difficult to complete or sadly ambiguous), analyzing the data by interviewer to search for suspicious patterns (hobbled by small sample sizes), and careful follow-up on questionable interviewer behavior.

Correcting Interviewer-Related Error

Most interviewer-related error cannot be detected and thus cannot be corrected. The first line of defense is increasingly foolproof questionnaires, better training, and closer supervision. The second is careful analysis of missing and suspect data and, where possible, imputation of missing data. The greatest effect in reducing and correcting error would stem from increased research into the sources and solutions for interviewer-related error, a research area generally neglected in contemporary survey methods research.

Interviewer Training

Interviewer training refers to the instruction that survey research interviewers receive at various stages of their employment, and in various ways, to make it more likely that they will perform their jobs effectively. It is absolutely essential for achieving high-quality survey samples, interviews, and resulting data. Organizations that hire people to conduct standardized survey interviews understand that one of the most critical success factors is how well interviewers are trained and managed. The purpose of training interviewers is to teach the principles, skills, and basic procedures needed to conduct telephone or face-to-face interviewing in a manner that achieves high-quality, reliable, and valid information for research.

Training Elements and Expectations

Initial training for new interviewers provides the fundamentals, such as the nature of interview work, workplace ethics (e.g., attendance, professionalism), using computer-assisted interviewing (CATI or CAPI) systems, and emphasizing standardized interviewing techniques. Procedures for training interviewers should ideally focus on all the skills for basic interviewing needed across most surveys in general.

For maximum effectiveness, interviewer training must convey performance expectations for interview work and teach interviewers how to conduct a standardized interview. Interviewer training describes acceptable methods for questioning respondents and how to collect interview information with a high degree of accuracy and reliability. Because interviewers are the intermediaries of questionnaires (and questions) to respondents, they can also be an important source of error in the survey process. The crux of interviewer training then is to reduce interviewer-mediated error. This is accomplished by educating interviewers and demonstrating proper interviewing techniques, such as how to read questions as worded, neutrally probe respondents, relate to respondents so as not to introduce bias to survey answers, and record answers as accurately as possible. Overall, trainings should reinforce interviewers' interactions with respondents as interpersonally neutral while asking interview questions. Interviewer training should not only introduce and explain basic interviewing concepts but also provide time for deliberative practice of skills. Trainees gain knowledge, skill, and confidence through observation and participation in activities that mimic real interviewing.

Basic and Project-Specific Training

In a 2007 study of telephone survey research organizations, John Tarnai and Danna Moore found that almost all such organizations use trainings to increase interviewing skill and knowledge and that new interviewers are required to participate in training before they can begin calling. Most organizations have developed trainings that include written procedures for standardizing interviewing and on average spend about 6 hours per interviewer to cover basic interviewing training and practice. Table 1 displays the main topics and activities regularly covered in basic introductory trainings by telephone survey organizations (of note, these same topics and activities essentially apply to face-to-face interviewing).

Many organizations also regularly hold project-specific trainings, which detail requirements and circumstances on individual surveys. Trainings may also be expanded to cover complex survey situations; for example, questionnaires that have complex conditional skip patterns or that screen for eligible survey respondents often require additional training for interviewers. Other examples of the need for project-specific training are when the survey topic is sensitive or includes respondents classified as members of a vulnerable or protected population. Both of these situations will generally require talking about human subject research, confidentiality, the rights of respondents, and special issues raised by respondents.

Table 1 Main interviewer training topics

- Description of standardized interviewing and the rules to adhere to
- Explanation and examples of acceptable probing and feedback
- Demonstration of how to use CATI software systems
- Explanation of the various types of questions used in data collection
- Explanation of respondent reluctance and cooperation
- Proper interaction with respondents
- Addressing respondent concerns
- Explanation of survey introductions
- Practice and role play by interviewers
- Explanation of refusal behavior and interactions
- Explanation and use of case disposition codes
- Practice and role playing mock interviews
- Data entry errors and ways to make corrections
- Explanation of research ethics
- Expectations of interview performance and how performance is measured
- Explanation and practice of dialing
- Human subjects research and confidentiality
- Special emergency situations and what to do

Additional Types of Training

There are other types of trainings for interviewers such as those that specifically address performance improvement or advanced interviewing tasks, such as refusal conversions or addressing and diagnosing survey problems. These trainings focus on improving individual interviewing skill for increasing survey participation and countering nonresponse at both the survey introduction and the item level. These specialized trainings are intended to increase interviewers' awareness of their own behavior during different parts of their contact with respondents, to help them be more able to recognize respondent's concerns, and to practice delivering rapid responses to concerns raised by respondents. Research on interviewer training has shown that advanced trainings such as refusal avoidance, tailoring introductions, and recognizing and addressing respondent concerns can positively change interviewer behavior and lead to greater respondent cooperation. The distinguishing characteristics of high-performing experienced interviewers are that they (a) engage respondents with more confidence, (b) have a larger combination of behaviors, (c) prolong interactions, and (d) actively communicate to persuade respondents.

Interviewers are often required to conduct practice interviews by pairing-off to role play with one another while supervisors monitor their performance, offer a critique, and provide feedback. In real life, difficulties will be encountered during interviews, and supervisors can prepare interviewers by acting the part of a recalcitrant respondent during trainings. Supervisors may role play the part of a particularly recalcitrant respondent and make suggestions to interviewers about "what to say" and "how to say it" in the most persuasive manner, thus affording interviewers with the tools needed to effectively address the noncompliant respondents they are likely to encounter.

Trainings are useful for observing how interviewers interpret survey and training materials, how they translate knowledge into practice, and for confirming interviewer understanding of what constitutes a standardized interview. Some larger survey organizations have moved toward using computer-based training, interviewer certification, or other testing systems to assess whether new interviewers have sufficient knowledge and training to move to production interviewing.

Interviewer training is significantly related to improved interviewer performance, which most survey organizations regularly measure. Assessment of interviewer performance through monitoring on a regular basis and the use of interviewer-based metrics across surveys provides documentation of whether trainings have a measurable impact collectively on interviewer skills and the accuracy of data collected. Past research has shown that individual interviewer effects (survey errors) in a survey are greater when the number of interviewers working on a survey is small or when any one interviewer's workload (number of completed interviews) is significantly greater than that of other interviewers. It is important to know whether interviewer effects are occurring in a survey and when to adjust for this. The main way to correct interviewer behavior is to provide specialized training for addressing problems or increasing certain skills. Interviewer training and productivity management go hand in hand to influence and direct interviewer skill development and behaviors.

Communicating productivity expectations to telephone interviewers during training provides interviewers with benchmark information on job tasks and provides measures against which they can compare their own level of performance and so they know how to perform adequately or what they need to do to improve. Supervisor interactions with interviewers should reinforce expectations stated during trainings. Productivity plays an important part in interviewer training, as increasing productivity through more completions, fewer refusals, fewer missing items, and more call attempts are generally the goals of interviewer training.

Training interviewers, regularly monitoring their performance, and providing direct and timely feedback to interviewers about their performance is the most consistent way to establish and ensure that interviewing as a process is done to a set standard and according to best practices. Training of interviewers is essential for producing high-quality survey data. Interviewer training introduces and emphasizes quality aspects of interviewing work. For instance, achieving acceptable response rates is important for the reliability and validity of a study and is directly linked to interviewers being able to get respondents to cooperate with the interview. To gain high rates of respondent participation, interviewers need to be taught basic persuasion techniques. Confidentiality is another area of concern to many respondents, and interviewer trainings should emphasize assuring respondents that their identifying information is kept private and that their individual survey responses will not be reported. Effective trainings incorporate a thorough description of what it means to keep data confidential, how data can be compromised, and what its importance is to respondents. At issue is interviewers' ability to alleviate respondent fears that confidentiality cannot or will not be ensured.

Refusal conversion training is another type of interviewer training that is important to survey organizations. Converting respondents who have initially refused interviews has become an increasingly important strategy for achieving acceptable response rates and for bringing in respondents to a study that are inherently different from the early, more easily obtained respondents on measures important to the study results. More formally, this is referred to as trying to reduce nonresponse and possible nonresponse error. Training interviewers to effectively convert refusals requires increasing their knowledge of the reasons respondents refuse and providing interviewers with specific statements and appeals that can be used to counter respondents' refusal language.

Training Standards

Interviewer training is an important way to convey to interviewers what is expected of them and how to adequately perform the job of interviewing in a standardized way. Survey training activities are very important to survey quality and are considered a best practice for survey organizations. The International Standards Organization has established a set of standards for market, opinion, and social research that includes a requirement for at least 6 hours of training for new telephone interviewers. The goal of this requirement is to ensure that all interviewers receive a minimum amount of training in standardized survey interviewing, thereby ensuring better quality survey results.

Interviewer Variance

Interviewer variance describes the part of the overall variability in a survey statistic that is associated with the interviewer. Clusters of respondents interviewed by the same person tend to have more similar responses than do clusters of respondents interviewed by different interviewers. This cluster effect can appear, for example, if an interviewer uses inappropriate or inconsistent probing techniques, has idiosyncratic interpretations of questions and rewords them accordingly, or differs in the way he or she reads answer categories. In addition, interviewer-specific interactions between the interviewer and respondent can lead to an intra-interviewer covariance term that contributes to the variance of the estimate.

The effect of interviewers on responses can increase the variability of survey estimates in a way parallel to the effect of clustered samples. The standard errors of such survey estimates are inflated compared to those computed for a simple random sample. Thus, ignoring the clustering of respondents within interviewers can yield misleading results in significance tests or in the coverage rates of confidence intervals. Most statistical packages use linearization or replication methods to correct the variance estimation for different kinds of sampling designs. To account for an interviewer clustering effect, those procedures require either an interviewer identification variable or appropriate replicate weights created by the data collector as part of the data set.

The overall variance of the respondent mean is inflated by interviewer variance according to the function $deff = 1 + \rho(w - 1)$, where w is the average number of interviews conducted by individual interviewers, and ρ is the intraclass correlation coefficient among responses produced by a common interviewer. If all respondents interviewed by the same interviewer answered in exactly the same way, ρ would be equal to 1. The size of ρ reported by various researchers has shown substantial variation among surveys and survey variables. The average value for ρ in many (mostly telephone) studies is 0.01, but values of about 0.05 are not uncommon, while for some surveys and items a ρ as high as 0.2 has been observed. These seemingly small values can have a large impact. If the average workload for an interviewer in a survey is 100, a ρ of

0.01 can produce a design effect of 1.99. Both a high workload and a high value of ρ contribute to a problematic design effect. A value of $deff = 2$ would be equivalent to cutting the sample size in half.

Telephone surveys often have high interviewer workloads. Thus, even with low values for ρ, interviewer variance may be a problem and should be accounted for in the data analysis. In face-to-face surveys, not only interviewer variance but a second source of variance contributes to the size of the design effect. Interviewers often work in small geographical clusters to reduce the cost of data collection. The attributes of respondents interviewed by the same interviewer can therefore be correlated simply because people who live in close proximity are likely to be similar to each other in some way. To determine whether it is the interviewer or the geographical proximity that is responsible for the cluster effect, an interpenetrated sample design is required, one in which a random subsample of the full sample is assigned to each interviewer. In practice, there often are considerable limitations to implementing interpenetrated assignments. They are usually too expensive for area probability samples. And randomizing telephone cases among interviewers can usually be done only within the shifts that interviewers work.

Instead, interviewer variance can be reduced if fewer cases are assigned to an individual interviewer. (Although if too few cases are assigned on average, other sources of interviewer error may be inflated; e.g., interviewers may not become as proficient in administering the question.) Other strategies include measures to enhance the standardization of the interview procedure through training and monitoring of the interviewer. Improved questionnaire design can also help reduce interviewer variance. To correct standard errors for clustering effects due to interviewers, data sets must provide interviewer identification variables, a practice that is still rather uncommon.

INTERVIEWING

Survey interviewing is typically a formal, standardized conversation between a person asking questions (the interviewer) and a person giving answers to those questions (the respondent). The respondents are selected because they belong to a population of interest. The population can be very broad (e.g., residents of a city or state, registered voters) or very narrow (e.g., people who have been diagnosed with a particular disease; females who smoke cigarettes, have less than a high school education, and watch the local news on a specified television station). In addition to asking questions, the interviewers may also play other roles, such as gaining initial cooperation from the respondents or showing respondents how to answer self-administered questionnaires on paper or by computer. While some survey data may be collected by self-administration (e.g., mail or Internet-based surveys), many surveys, particularly long, complicated ones, require the use of an interviewer. Thus interviewing is an important aspect of survey research. This entry provides an overview of factors relevant to interviewing, many of which are discussed in greater detail in other entries in this volume.

A Short History of Interviewing

Survey interviewing, or its equivalent, has been conducted for thousands of years, from ancient times when rulers sent out census takers to gather information about the people they found (in households or elsewhere), including the gender and age of each person. Businesses have long queried their customers and clients about products and services. In the 1930s and 1940s, U.S. government agencies began conducting many more surveys than before. As before, the interviews were conducted using paper questionnaires. This was called PAPI, for paper-and-pencil interviewing. At that time almost all interviewing was conducted face-to-face.

In the United States, telephone interviewing became popular in the 1960s, because by that time most households in the country had telephones. (This was not the case in Europe and other developed countries, where private telephones were very expensive and could take months to get installed.) However, face-to-face interviewing was still used for long, complicated surveys and those that required visual aids or physical tasks such as card sorting.

While large main-frame computers had been used for decades for survey data processing, it was not until the widespread availability of minicomputers—later called personal computers (PCs)—in the late 1970s and early 1980s that interviewing became computerized. Thus computer-assisted telephone interviewing (CATI) was born. Later, when laptop computers were created and became affordable, computer-assisted personal interviewing (CAPI) became common. (At this point, European surveyors took the lead with this technology, having skipped over CATI because of lower residential telephone coverage.)

As more respondents became familiar with them, computers were used for computer-assisted self-interviewing (CASI). Respondents often need assistance with how to answer computerized questionnaires, so typically an interviewer plays the role of instructor. With the introduction of a sound component, audio computer-assisted self-interviewing (ACASI) became possible. It is primarily used to (a) ask sensitive questions that a respondent might not want to answer to an interviewer, (b) ask questions in languages other than the one or two used on the written questionnaire, or (c) offer an oral version of a questionnaire to a respondent who cannot read well.

Interviewer Effects

Interviewing can cause *interviewer effects*, a subset of a larger problem called *measurement error*. The primary causes of interviewer effects are improper administration of the questionnaire and the effects of interviewer characteristics themselves. Interviewers can negatively affect the administration of a questionnaire in many ways, such as by misreading questions and deviating from a standardized script. Improper questionnaire administration can be held to a minimum through the use of professional, well-trained interviewers. The way to minimize interviewer-related error is to standardize the interviewing as much as possible.

Interviewer Characteristics

Interviewer characteristics are those things about a particular interviewer that may, in some circumstances, affect how a respondent will answer survey questions. They include gender, age, race, ethnicity, and in some countries, perceived or actual class, caste, or clan. Interviewer characteristics can affect respondent–interviewer rapport and respondent answers, positively or negatively. In some cases, if there is a major concern that an interviewer characteristic may affect the respondent, interviewers may be matched with respondents on that characteristic. For example, only female interviewers would interview female respondents or only older male interviewers would interview older male respondents.

Interviewer Training

The quality of survey interviewing is dependent on good interviewer training. Surveys conducted by professional survey organizations use professional interviewers who have been trained extensively. At the other extreme, some surveys are conducted by volunteers who have been given little or no instruction. Regardless of whether or not interviewers are paid, it is essential that they are trained to do the job expected of them. While a large part of interviewer training relates to the administration of the questionnaire (e.g., asking the questions as worded; reading or not reading answer categories, as directed; knowing when and how to probe), there are many other important aspects to this training. They include (a) identifying the appropriate sample unit (e.g., a household, a telephone number, an individual), (b) obtaining and maintaining respondent cooperation, and (c) following prescribed rules regarding contacts (number of attempts, days and times of attempts, etc.). In addition to the information in the questionnaire's introduction, interviewers should be given backup information, including "fallback statements," about the study so that they can answer potential respondent questions. Such questions may include which firm is conducting the survey, who is sponsoring or funding the survey, why the household or respondent has been selected, approximately how long the interview will take, whether or not the information will be confidential, and who to contact if they want further information.

Regardless of the length of the questionnaire and the experience of the interviewers, the person conducting the survey or supervising the data collection should prepare a written interviewer training manual. The manual should be used for initial training and also be available for review throughout the data collection period. In fact, if certain instructions, probes, lists, and so forth, are important and may need to be referred to during an interview, they should be either printed out separately or available on the computer screen, so that an interviewer can refer to them instantly.

Most important is to make clear to the interviewers what the "conventions" are on the questionnaire, for the interview. In other words, (a) when do they read a question and stop to hear the respondent answer, and (b) when do they read a question and continue reading predetermined answer categories? This is a very important part of standardization for any survey administration, for it is known that respondents will answer differently if they are given answer choices or categories to select from (closed-ended question) or not (open-ended question). It is important that these conventions be consistent throughout the questionnaire. For example, a question mark after a statement might indicate to stop reading the question and wait for the respondent to answer, while a series of three dots might indicate to continue reading answer categories:

(a) *Do you agree or disagree?*

(b) *Would you say . . . strongly agree, somewhat agree, somewhat disagree, or strongly disagree?*

The instructions must also make clear when it is acceptable for an interviewer to expand on a question, including paraphrasing the question or supplying a definition. Typically this is not allowed, but there are exceptions, especially in so-called conversational interviewing. For example, if a respondent does not understand a factual question but explains an answer to the interviewer, the interviewer can "work with" the respondent to come up with the correct answer. If, for example, the question is *How many brothers and sisters do you have?* and the interviewer has been supplied with guidelines (such as how to count stepbrothers and stepsisters and half brothers and half sisters), then a conversation between the two is appropriate.

Two important aspects of interviewer training, particularly for volunteer interviewers, relate to confidentiality and neutrality. Confidentiality means that everything that occurs in the interview is confidential. The interviewer should never discuss a respondent's answers with others except project personnel. In addition, the interviewer should never reveal who has been interviewed. This is particularly an issue for community or school surveys where volunteer interviewers may personally know some of the respondents. Indeed, if an interviewer is given a name, address, or telephone number that is familiar, he or she should return that information to a supervisor and not attempt an interview.

The interviewer must also maintain a position of neutrality. That is, respondents should not be able to tell where interviewers stand on issues they are asking about. This can be a problem particularly for volunteer or untrained interviewers. Interviewers should be neutral, not only in their words, but also in their nonverbal behavior and dress. An interviewer who personally disapproves of a respondent's answers may communicate that feeling through raised eyebrows, a frown, or tone of voice. Such nonneutral behaviors can significantly bias subsequent responses.

While neutrality is a must, interviewers should be supplied with information to assist respondents after the interview if circumstances warrant that. For example, if a survey of smokers is about smoking cessation, interviewers should have a telephone number available for quit smoking help. The survey sponsor may decide to offer the information only to respondents who ask for it or to all respondents at the end of the interview. Information on help with domestic violence should be available if relevant to the topic of the questionnaire and if the respondent has mentioned such violence. In cases like these, the assistance should be offered to all respondents who mention the problem, whether they request it or not, but the offer should come only after the interview has been completed, so as not to bias subsequent questions.

Interviewer Monitoring, Supervision, and Validation

Interviewer training and supervision do not end with the training held prior to the start of data collection. It is important to continue to supervise, including monitoring and validating their work and re-training when necessary. Interviewing that is conducted from a centralized facility offers the ability for greater supervision and monitoring. Telephone calls may be monitored and, with CATI surveys, monitoring can include following along with the questionnaire as viewed on another computer screen as the interview is conducted. With the appropriate computer connections, it is possible for a sponsor or client to monitor interviews from another site. Interviews conducted at other sites (e.g., interviewers calling from their home phones, face-to-face interviews conducted in homes, malls, or clinics) offer fewer opportunities to monitor and supervise, making training and validation even more important.

Validation is the term survey researchers use for checking interviews that have been conducted—to verify to the extent possible that they have actually been conducted, conducted correctly, and with the appropriate respondents. The major way to validate an interview is to recontact the respondent (usually by telephone, regardless of mode of interview), explain the contact as checking the quality of the interview, and ask a few of the questions from the original interview, to verify the integrity of the data. It is standard practice to validate a percentage of each interviewer's work. Sometimes this percentage is greater for less experienced interviewers or for all interviewers at the beginning of a survey. However, it is recommended that validation continue for all interviewers and throughout the entire data collection period. If falsification of data is likely, it may be necessary to validate 100% of that interviewer's cases, both interviews and noninterviews. For CATI interviews, supervisors can also check the computerized time clock, to verify that the interview took as long as it should have (e.g., not 3 minutes for a standard 20-minute questionnaire). If the validity of the data is in doubt, the case(s) should be deleted from the final data set.

Calling Rules

Calling rules (or contact rules) refer to the rules of data collection set up by the survey administrator. They include the dates to begin and end the data collection, the days of the week and times of day that calling will be allowed, how many contacts each potential case should be tried (typically a maximum number), and how to code the outcome of each contact attempt. Except in telephone surveys where a predictive dialer is used to assign an already connected call to an interviewer, interviewers can play an integral part in the success of the study by reviewing the history of each case and deciding the best way to proceed before the next contact is attempted. An important part of this process is to gather information from a prospective respondent or household about the best day of the week and time of day to attempt another contact. The more contact attempts made, the more likely a potential respondent will turn into an actual respondent.

Intracluster Homogeneity

Intracluster (or intraclass) homogeneity is a concept related to the degree of similarity between elements in the same cluster. The intracluster (or intraclass) correlation coefficient, ρ, measures the degree of homogeneity among population elements within the sampling clusters. Intracluster homogeneity is computed as the Pearson correlation coefficient between pairs of elements that are in the same cluster.

In terms of the variance components in an analysis of variance (ANOVA), intracluster homogeneity measures the extent to which the total element variance in the population is due to the *between-cluster variance*. In other words, ρ measures intracluster homogeneity in terms of the portion of the total variance that is attributable to cluster membership. When there is complete homogeneity within clusters, the between-cluster variance accounts for all the variance in the population and ρ is equal to 1.0. When there is complete heterogeneity within clusters, the within-cluster variance accounts for all the variance in the population and ρ is a negative number equal to the inverse of the size of the cluster minus 1.0. Finally, when the clusters are comprised on random elements from the population with no relationship to each other, ρ is zero.

In practice, the intracluster correlation coefficient typically is positive, but usually not very close to 1.0. This implies that there is some homogeneity within clusters, with elements from the same cluster being more similar to each other than elements selected at random from the population. In these cases, cluster sampling is less efficient than simple random sampling, necessitating some other gain to cluster sampling, like cost savings, to justify the efficiency loss for a cluster sample.

Cluster sampling is frequently used in practice because often it is not feasible or possible to compile sampling frames that consist of all population elements, especially when sampling large human populations. In addition, many times the costs of face-to-face interview data collection are prohibitive when sampling large human populations that are geographically dispersed.

For example, a complete sampling frame of all K–12 public school students in the United States does not exist, and it would be prohibitively expensive for any survey organization to construct such a sample frame. On the other hand, a complete frame of all K–12 public schools in the United States may be available from various sources, and a complete frame of students within each school is usually available. Therefore, a sample of students may be selected in two stages. In the first stage, a sample of schools is selected from the frame of all schools. In the second stage, a sample of students is selected from the frame of all students within each selected school.

Under this sample design, each school constitutes a sampling cluster, and the final sample consists of all sampled students from all sampled schools. This two-stage cluster sample design may be expanded to incorporate additional sampling stages. For example, one possible four-stage design is to select school districts in the first stage, schools in the second stage, classrooms in the third stage, and students in the fourth and final stage. Thus, cluster sampling allows the sample to be selected in successive stages. The sampling frame at each stage is either readily available or can be conveniently constructed.

Although cluster sampling can lead to considerable cost savings, it also is known to significantly increase the variance of many survey estimates as a result of intracluster homogeneity. Sampling clusters are usually defined by geographic or spatial proximity; that is, population elements within the same clusters are close to each other physically. Examples of clusters that are often used in sample surveys include counties, city blocks, census tracts, schools, hospitals, households, and so on. With respect to many population characteristics (demographic, socioeconomic, political, behavioral, epidemiological, health care, and the like), elements in the same clusters tend to be more similar than those in different clusters, resulting in a positive correlation among elements in the same clusters. By confining the sample to a subset of clusters, cluster sampling tends to reduce the spread and representativeness of the sample. Compared to a simple random sample of the same size (in terms of the number of elements), a cluster sample is more likely to lead to extreme estimates and hence increased sampling variance.

Intracluster homogeneity is an important tool for measuring sample efficiency and for survey planning. The efficiency of a complex sample design may be measured by the *design effect* (*deff*), defined as the ratio of the variance under the complex design to the variance of a simple random sample of the same size. For a complex design that involves unequal selection probabilities, stratification, and clustering, the design effect may be decomposed into three multiplicative components: (a) weighting effect, (b) stratification effect, and (c) clustering effect. The clustering effect of a two-stage cluster sample may be expressed as

$$deff = 1 + (m - 1)\rho,$$

where m is the size of the subsample selected from each cluster. When the subsample size differs across clusters, the average subsample size may be used as an approximation. The clustering effect of a three-stage cluster sample may be approximated by

$$deff = 1 + (m_1 - 1)m_2\rho_1 + (m_2 - 1)\rho_2,$$

where m_1 is the average number of secondary sampling units (SSUs) selected within each primary sampling unit (PSU), m_2 is the average number of ultimate sampling units selected from each SSU, ρ_1 is the intracluster homogeneity between SSUs within the same PSU, and ρ_2 is the intracluster homogeneity between the population units within the same SSU. An estimated design effect can then be used to determine the sample size, effective sample size, and other relevant design parameters given the variance requirements and/or cost constraints of the survey.

INTRODUCTION

The survey introduction is a key step that affects the survey's response rate; therefore, interviewers need special training in it. A key part of an interviewer's role is to gain cooperation from the respondent. This opportunity for enlisting cooperation occurs within a time period of variable length, which starts with the interviewer's initial contact with the sampled unit and continues until the selected respondent agrees to participate in the survey or provides a definitive "no." Depending on the survey design, this conversation is often conducted over multiple callbacks. This time period has traditionally been called the *doorstep introduction*. In this entry, it is referred to as the *survey introduction*.

Interviewers' abilities to gain cooperation during the introduction to a survey vary greatly. For example, in exploring interviewers' survey introduction skill versus respondents' reluctance, Pamela Campanelli and her colleagues found that interviewers' skill could affect response rates by 13 to 20 percentage points for in-person surveys.

This entry details the five parts of the survey introduction and discusses the differences and similarities of introductions for surveys of establishments and surveys of households.

Parts of Introduction

The survey introduction can be thought as being made up of five parts, which generally occur in the following order.

1. Interviewers Introduce Themselves

In this first step the interviewers are typically trained to introduce themselves by saying their name; the name of the survey organization, sponsor, or both; and the topic of the survey. For example,

> Hello, I'm Pamela Jones calling from Research Inc. We are doing a study about health care and doctors for the ABC Institute of Health.

Although this sounds simple, this is a very critical step. As suggested by the University of Michigan's *Interviewer's Manual*, interviewers must convince the respondent that he or she is a professional interviewer from a reputable organization, who is collecting valuable and important data and that the respondent is key to the success of the research.

Interviewers' voice, manner, and beliefs about themselves make as much of a difference as what they say. Interviewers should show a warm, friendly, confident manner and speak slowly. If interviewers believe they will have difficulty and are not confident, this will show.

For in-person surveys, the interviewer's appearance can also be a factor in providing credibility. At the U.K. National Centre for Social Research, interviewers are not told specifically what to wear, but they are told to be "neat and neutral." For in-person surveys, interviewers have the advantage of being able to show their identification card, and it is generally suggested that interviewers smile and make eye contact.

2. Advanced Letters

Use of an advance letter is common for in-person surveys and also can be used in many telephone surveys. An advance letter gives interviewers a psychological advantage. They are not making a cold call but one that has been warmed by the legitimacy of the advance letter. Even if the person who answers the door (or answers the phone) has not received or read the letter, interviewers can still use the letter to their advantage. Well-trained interviewers have copies of the letter with them (or at least know the content) and use this as a peg to start a conversation:

> Have you read our letter? . . . No? . . . This is what it looks like. As you can see, it shows you that . . .

Well-trained in-person interviewers also carry other relevant materials that will help demonstrate the credibility and usefulness of the survey, such as newspaper clippings showing the informative results of past surveys.

3. Finding the Right Person

This step is about within-household selection and screening. If the goal of the survey is to interview one person per household, this needs to be done systematically (ideally randomly) to avoid the bias connected with simply interviewing the most cooperative or available person who answers the door or the phone.

Random procedures differ for in-person and telephone surveys. For an in-person survey, the interviewer may be trained to use an adaptation of the classic procedure designed by Leslie Kish. As outlined in the University of Michigan's *Interviewer's Manual*, this procedure is as follows:

> In order to determine whom I need to interview, I need to know who lives at this address. *[Each household member's name and age are obtained and their relationship to the informant.]*
>
> You have said the household members are *(REPEAT NAME LISTING)*; does that include everyone living here at the present time?
>
> Now I will use a selection procedure—I am going to number the persons in this household to determine whom we need to interview—it will take a second . . .

This list of numbered household members is then compared to a random selection table that can either be pre-printed on a paper questionnaire (or attached via a label) or computer-determined for a computer-assisted questionnaire.

In the case of a telephone survey, many organizations feel this is much too cumbersome, especially because the initial few minutes of contact are even more critical as it is much easier for the respondent to break off contact with the interviewer. Popular quasi-random alternatives are the use of the last or next birthday method. The last birthday method would proceed as follows:

> To get a random sample, I need to speak with the adult in the household who had the most recent birthday.

Although early studies suggested the birthday methods produced equivalent data to the Kish approach, more recent studies, such as one by Cecilie Gaziano, point out that the birthday procedures do not necessarily work as accurately as desired.

Other within-household selection issues occur when the survey is designed for a special subgroup of the population and there is no list of the members of this subgroup. In this case, households are contacted as per Step 1, and then a short, screening questionnaire is administered by the interviewer to determine if any one in the household is a member of the special subgroup. For example, a sample of elderly can be selected from a sample of households. This is more problematic in a telephone survey, as screening questionnaires can contain sensitive and intrusive questions and this can interfere with initial rapport being achieved by the interviewer.

In the case where selection or screening is needed, it is likely that the person who answers the door or phone will not be the person who is finally selected. Nonetheless, it is extremely important for interviewers to build good rapport with this household informant so that the needed information can be obtained. Also, if the informant becomes convinced of the benefits of the survey, he or she can be a good influence on the household member who has been chosen as the respondent. It should be noted that in some cases, the informant might say that the selected respondent will definitely refuse. In such cases, interviewers need to be diplomatic and make it clear that although the informant may be right, their job requires that they talk with the selected person. In some cases, the informant (serving as a "gatekeeper") may deny access to the selected respondent. Gaining access may require sensitivity and perhaps use of a different interviewer.

Not all surveys require selection or screening. It could be that all the members of a household are to be interviewed. Or in some cases, only a knowledgeable adult is sought to provide household level information. In rarer cases, proxy response is allowed with a knowledgeable adult answering for themselves as well as other household members. But although such a design saves time and money, there is a trade-off with quality. Proxy reporting can lead to poorer-quality data.

4. Handling Respondent Questions and Concerns

At any point in Steps 1, 2, and 3, the respondent may interrupt with questions, such as "How long will it take?" "How did you choose me?" "What's it all about?" Or negative statements, such as "I'm too busy" or "I'm not interested."

This is the time in the introduction that the interviewer's skill is most needed. To be successful, interviewers need to be adept in the following ways.

Be Prepared

Interviewers who are prepared will increase credibility and those who are not prepared will lose credibility. Take the following survey introduction excerpt recorded by Campanelli and her colleagues from an actual interview.

Respondent: What's the research about?

Interviewer: It's called political tracking. If you come to any question you're not sure of or don't know how to answer you just leave it, put don't know, things like that.

Respondent: Right, so it's about politics?

Interviewer: Well just how you think, what you think, that sort of thing.

In this example, it does not appear the interviewer knew anything about this survey. Instead, interviewers need to know fully about the study, they need to prepare a variety of accurate and courteous explanations in their own words. And they need to practice these outside of the interview situation. Even the best clarification can be damaged by a nervous-sounding voice.

Have the Right Mind-Set

The right mind-set makes a big difference during the introduction. Creating this is something that the interviewer can prepare in advance. For example, the University of Michigan's *Interviewer's Manual* suggests that interviewers should assume the following:

- It is the perfect time to do the interview.
- The respondent will be friendly and interested.
- If the respondent isn't interested, it is because he or she doesn't know fully about the survey yet.

Eleanor Singer and her colleagues found that interviewers' expectations about the ease of persuading respondents to be interviewed were significantly related to their response rates.

Use Active Listening/Observation

Everyone appreciates being listened to. Accurate listening to the respondent is vital during the survey introduction, but ironically it is most challenging because of the pressure to secure an interview. Good interviewers need to listen not only to the words respondents are saying but also to their tone of voice and the deeper meaning heard through their words. In-person interviewers have the added advantage of seeing respondents' facial and body language. It is also important to listen for sounds in the respondent's environment, which give clues to the respondent's situation, for example, a crying infant.

Use Tailoring

Every respondent is an individual, so general standardized replies to respondent concerns are the least effective. Robert M. Groves and Mick P. Couper have found that to be successful, interviewers need to remain flexible and be fully prepared to tailor their manner and explanation for each and every situation. It also is recommended that interviewers analyze how their reply is working and if it isn't proving successful, to try a different one.

Be Succinct

Good interviewers make their replies clear, coherent, and to the point—thus, providing long rationales should be avoided. Good interviewers should also acknowledge the respondent's viewpoint and never argue directly with the respondent during the introduction (or at any time, for that matter).

Maintain Interaction

Groves and Couper demonstrate the importance of the interviewer maintaining interaction with the respondent. The key here is that this allows rapport to develop, but more importantly it allows the interviewer to gain more information about the respondent's true concerns so that these can be addressed. Campanelli and her colleagues found that some interviewers were very good at shifting the interaction from "official" to "personal" so that the respondent is seen as an individual. But this needs to be done with sincerity and without being overly familiar.

Retreat and Reapproach

Respondent reluctance is often specific to a particular situation. Good interviewers need to watch for signs and back off before receiving a final "no." It is much better to retreat and leave the door open for another contact than to get an outright refusal.

Don't Ask Questions That Can Be Answered "No"

Good interviewers are careful not to ask questions in the introduction that can lead to the respondent's easily answering "no." For example,

> *Problematic response:* I've called at a bad time. Is it okay if I call back?
>
> *Better response:* I've called at a bad time. I'll call back another time.

5. Tactics for Subsequent Callbacks

On subsequent callbacks, interviewers ideally will reflect back to the respondent the issues that the respondent had mentioned previously. For example:

> I know that you are very busy. I was hoping that your schedule might have freed up a bit.
>
> You mentioned that you were busy getting ready for your daughter's wedding. I was hoping that now would be a better time for you.

This is to show that the interviewer has heard what the respondent said before. Then the subsequent call does not come across as bothering the respondent. Rather, it shows the respondent that he or she is very important to the success of the study.

Survey Introductions for Surveys of Establishments

When conducting surveys of establishments, there are several similarities and differences to the survey introduction. As opposed to household surveys, finding the right person to interview takes on new difficulties. Prior to the survey, one must precisely define the organizational entity that one is interested in, the location of the business unit of interest, and the name of the person within the company who will be appropriate to complete the survey. Don Dillman discusses how surveys addressed to the company can have response rates 30 percentage points lower than surveys directed to a named individual within the company. Exploratory telephone calls are often used to find out this key information. Once this is known, the respondent may be contacted by telephone with an invitation to participate, and this would follow closely the steps for household surveys (outlined earlier in this entry). In other cases, a self-administered mode may be used where the respondent is sent a postal questionnaire (and may be given a Web option) and telephone contact is limited to a follow-up method after several reminders are sent.

INVERSE SAMPLING

Inverse sampling is an adaptive sampling technique credited to J. B. S. Haldane's work in the 1940s. Under many study designs, it is desirable to estimate the frequencies of an attribute in a series of populations, each of which is much larger than the sample taken from it so that the population size is assumed to be infinite. However, the probability of the attribute occurring in some of the populations may be so small that under a fixed sample size design, not enough cases of interest are selected to estimate the attribute of interest.

Inverse sampling draws from the negative binomial distribution in that a series of Bernoulli trials are conducted until a predefined r number of successful cases occur. Usually, r is the desired number of cases from the population with the smallest probability of selecting a case with the attribute of interest. Under this design, the total sample size is a random variable. Therefore, traditional estimates, based on the binomial distribution, of an attribute's probability of occurrence are biased. However, it can be shown that if the total sample size is X, then the uniformly minimum variance unbiased estimator for the probability p is $\hat{p} = (r-1)/(X-1)$. However, D. J. Best derived the variance for this estimator and showed that it is intractable as a function of p or of r. Therefore, only an upper bound, such as the one proposed by Govind Prasad and Ashok Sahai, can be derived for the variance.

Applications

Applications for inverse sampling can have broad appeal. One such application is the ability to determine the better of two binomial populations (or the one with the highest probability of success). For example, in a drug trial, where the outcome is success or failure, inverse sampling can be used to determine the better of the two treatment options and has been shown to be as efficient, and potentially less costly, than a fixed sample size design. Milton Sobel and George Weiss present two inverse sampling techniques to conduct such an analysis: (1) *vector-at-a-time* (VT) sampling and (2) *play-the-winner* (PW) sampling. VT inverse sampling involves two observations, one from each population, that are drawn simultaneously. Sampling continues until r successful observations are drawn from one of the populations. PW inverse sampling occurs when one of the populations is randomly selected and an observation is randomly selected from that population. Observations continue to be selected from that population until a failure occurs, at which point sampling is conducted from the other population. Sampling continues to switch back and forth between populations until r successful observations are selected in one of the populations. Under both VT and PW, the population from which r successes are first observed is determined the better population. In clinical trials PW is an advantageous design because it has the same probability requirements as VT, but the expected number of trials on the poorer population is always smaller. Sobel and Weiss have also extended this methodology for $k \geq 2$ populations.

Inverse sampling is also used to estimate the number of events that occur in an area of interest based on a Poisson distribution. In these situations, one can use inverse sampling to estimate the total number of events or the number of events during a certain period by selecting a sampling unit and counting the number of events that occur in that unit. A series of independent units are sequentially selected until the total number of events across all of the selected units meets or exceeds a pre-assigned number of events. The number of trials needed to reach the pre-assigned number of events is then used to estimate the mean number of events that will occur. This design assumes a Poisson distribution but not a Poisson process. Therefore, not every sampling unit selected has to have a Poisson distribution, but all the sampling units combined do have a Poisson distribution. An example of this design would be to estimate the number of accidents on the road. Because the number of accidents depends on the day of the week, a week would be the smallest sampling unit that one could assume had a Poisson distribution. If one day were the sampling unit, then a Poisson distribution might not always hold.

Inverse Sampling Designs

For finite population sampling, two inverse sampling designs have been developed over the past several years: *multiple inverse sampling* (MIS) and *general inverse sampling* (GIS). Under an MIS design, the population is partitioned into two or more subpopulations with known sizes. MIS is effective when one of these subpopulations is rare and it would be undesirable to obtain none or very few responses from the rare subpopulation. MIS sequentially selects sampling units, without replacement, until the predetermined sample sizes are obtained for all subpopulations. Sampling from a subpopulation is ceased once its quota is met. As with inverse sampling, the total sample size under MIS is a random variable. Therefore, Horvitz-Thompson estimators for finite populations are biased. As an alternative, two unbiased means and variances have been proposed. Kuang-Chao Chang, Jeng-Fu Liu, and Chien-Pai Han have derived formulas to compute the expected mean and variance of the final random sample size as well as an unbiased estimator and its variance. Also, Mohammad Salehi and George Seber showed that Murthy's estimator can be used to construct unbiased estimators of the mean and variance in a sequential sampling design. A situation where MIS is applicable is the estimation of a species of bird's prevalence in various geographic regions where the total population in the region is known and the species is thought to be rare in at least one of the regions. Sequential sampling of all birds occurs until the predetermined number of the species is selected in each region. Once a region has reached its quota, sampling from that region is ceased.

In MIS, when an attribute is very rare, it is possible that the expected total sample size is either logistically too large to achieve or results in a census. GIS addresses this issue. Like MIS, GIS is an adaptive sampling procedure where one divides the population into predefined subpopulations. Then, a preliminary simple random sample is drawn across all subpopulations. Sampling is completed if the initial sample contains a prespecified number of units in each subpopulation cell. Otherwise, a sequential sample is drawn until either the prespecified number of units within each subpopulation cell is met or the total sample size reaches a predetermined amount. By including this second condition, GIS limits the total sample and, therefore, prevents the total sample size from being unmanageable. GIS uses Murthy's estimator and its variance to estimate population parameters. Using the MIS example, under GIS, a simple random sample of birds would be drawn from all regions. If a pre-set number of the species of interest was selected from the region where the bird is most rare then sampling would end. Otherwise, sequential sampling of birds would continue until the predetermined number of this species of bird was selected or a predetermined sample size was selected.

Issue Definition (Framing)

Issue definition, or framing, refers to the careful use of language or other symbols in public discourse. If individual frames reside in both mental structures of the mind and in political discourse, framing is a social process that links the two. As such, framing is an important construct in the measurement and understanding of public opinion. Elected officials, other key decision makers, special interest groups, journalists, scholars, lobbyists, and pollsters are among those interested in issue definition (and its measurement) because of its importance in public policy formation and acceptance in modern democracies.

Public issues are inherently matters about which people disagree. There are often powerful financial interests backing one side or another. Other times, profound moral principles may be at stake. This accounts for the importance of public issues and the difficulties in studying them. Language used to describe political issues is not static. As the major political parties and interest groups fight over issues, the key battleground is political language. Interest groups struggle to gain acceptance for their terms and ideas and to have them incorporated into political dialogue. To win the battle over the acceptance of key terms is often the key to a wider political victory.

One key aspect of issue framing is that the terms used are carefully chosen by political and other intellectual elites to convey messages that resonate in particular ways with key elements of the public. As Donald Kinder and Lynne Sanders have noted, frames lead a double life. What they mean is that issue frames are both literary devices and mental devices. Frames are powerful because they are precisely chosen terms or phrases that resonate with the ways humans are programmed to think.

The most successful frames for issues are never casually chosen. They are carefully cultivated by elite communicators—such as politicians, political pundits, and prominent media correspondents—who know exactly what they are doing. Sociologist William A. Gamson is a leading figure in studying how public issues are described in the mass media, and how people learn these ideas, use them, and reproduce them in their daily lives. Gamson's research points to a series of framing devices and reasoning devices that together make up an "issue package." Issues that are in front of the public for a long period of time will eventually have fully developed frame structures that are quite complete. Particularly complex issues will also have a variety of competing frames associated with them. One of the key framing devices is *metaphor*. When a political figure uses a metaphor such as "war" to describe the appropriate response to a social problem such as terrorism, this choice is made advisedly. The term is chosen in such a way that alternative ways of thinking about the problem do not come to mind. Effective framing often is done in a way that seems so natural and uncontroversial that other ways of conceptualizing the issue can hardly be imagined.

The effective framing of a problem is often inclusive of preferred solutions to the problem. For example, the George W. Bush administration's choice of phrases for framing the global struggle with terrorism in the wake of attack and destruction of the World Trade Center as the "War on Terrorism" emphasized the use of organized military force to maintain public order and allay the fears of the population. The war metaphor also diverted thinking away from alternative forms of force such as police or detective work, as well as various soft-power strategies of public diplomacy and cultural engagement.

Once frames are established in mainstream public discourse, they become conventional, and journalists and others start to use them in routine ways. This tends to close off alternative interpretations and gives the impression that other points of view have been discredited or no longer apply. When a particular way to frame something is ascendant, the focus tends to be diverted away from an examination of the nature of the highly charged political phrase and what political advantage it is providing.

The challenge for pollsters and other survey researchers is to regularly use the most neutral terms possible but still convey accurately what public policy issue is being studied. This can be difficult, particularly when phrases enter popular discourse in an uncritical manner. Many academic surveys contain embedded experiments to examine the effects of question wording on survey response. Simple wording variations involve the order of names or whether descriptions or additional labels are provided to respondents. These investigations can be viewed as *framing effect studies* and may have substantive interpretations in public opinion research.

Depending on the language chosen, surveys and polls can measure and analyze public opinion but also sometimes help manufacture a particular response. This is, on one hand, a problem of question wording variation and the kind of random noise that can affect survey questions. But there is also the possibility of using aspects of real public discourse in the framing of questions. If survey research were to adapt question language that mimics actual public discourse by political elites, it would open the door to substantive interpretations of question wording effects. However, an advantage of this approach would be to help understand the dynamic role of language in political discourse and in the formation of public opinion. The literature of political journalism and the framing activities of social movements provide many examples to help formulate such studies and interpret the results.

Item Order Randomization

Most social scientists are aware that responses to survey questions can be significantly affected not only by how questions are worded but also by the order in which the questions are asked. Furthermore, they are generally aware that the order in which the response alternatives within a question are presented can likewise have a significant influence on survey results. Despite this awareness of order effects in surveys, many investigators either ignore these potential sources of measurement error in designing their questionnaires or fail to systematically control for them by fully randomizing the order in which the items are presented.

Most researchers who suspect there is the potential for an order effect in the questionnaire they are designing will rotate the items, typically presenting them in order X on one form of the questionnaire and order Y on the other. A prototypical example of this practice comes from a November 1997 Gallup poll. On one form of the questionnaire, respondents were asked the following questions in this sequence:

1. *How likely is it, in your view, that a terrorist group will attack the United States using* chemical or biological weaponry *sometime within the next ten years—very likely, somewhat likely, somewhat unlikely, or very unlikely?*
2. *How likely is it, in your view, that a terrorist group will attack the United States using* nuclear weaponry *sometime within the next ten years—very likely, somewhat likely, somewhat unlikely, or very unlikely?*

On the other form of the questionnaire, respondents were asked the same questions in reverse sequence. These alternative sequences produced a significant question order effect. In this case, where there are only two questions to consider, simply reversing the sequence of the items amounts to fully randomizing them and controlling for order effects. But if there are three or more related questions to be asked in a sequence, then full randomization requires more than just asking the questions in one order and the reverse order. With three questions to be asked, for example, there are $3 \times 2 \times 1$, or six possible permutations of the order in which the items can be presented: Q1-Q2-Q3, Q1-Q3-Q2, Q2-Q1-Q3, Q2-Q3-Q1, Q3-Q1-Q2, and Q3-Q2-Q1. It is relatively rare, however, to see such a fully randomized order of item presentation in a survey questionnaire, particularly when the data must be collected using a noncomputerized, paper-and-pencil questionnaire, because of the cost and the impracticality of administering six separate versions of the questionnaire. But fully randomized designs do not appear to be that much more common in computerized telephone and personal interviewing or in Web-based surveys, in which they can be readily implemented by programmers.

Aside from the additional staff time it may take to program such designs, researchers may resist doing so because of the small subsample sizes that will be available to analyze the effects of the different orders of item presentation. For a national sample of 1,000 cases, for example, a fully randomized design of six separate conditions will result in approximately 166 respondents per subgroup, which makes it difficult to detect statistically significant effects and to automatically control for nonrandom measurement errors. These must still be analyzed systematically. Given current practices of simple question or response alternative rotation, many potential order effects in existing data sets have yet to be discovered and controlled for through item order randomization, or even properly understood.

ITEM RESPONSE THEORY

Item response theory (IRT) is an approach used for survey development, evaluation, and scoring. IRT models describe the relationship between a person's response to a survey question and his or her standing on a latent (i.e., unobservable) construct (e.g., math ability, depression severity, or fatigue level) being measured by multiple survey items. IRT modeling is used to (a) evaluate the psychometric properties of a survey, (b) test for measurement equivalence in responses to surveys administered across diverse populations, (c) link two or more surveys measuring similar domains on a common metric, and (d) develop tailored questionnaires that estimate a person's standing on a construct with the fewest number of questions. This entry discusses IRT model basics, the application of IRT to survey research, and obstacles to the widespread application of IRT.

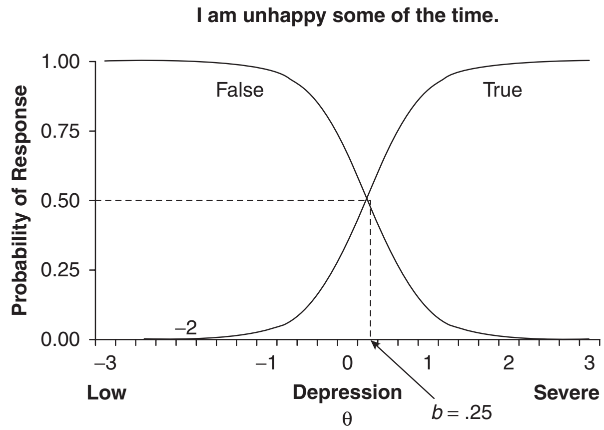

Figure 1 Item response curves representing the probability of a "false" or "true" response to the item *I am unhappy some of the time* conditional on a person's depression level. The threshold ($b = 0.25$) indicates the level of depression g(θ) needed for a person to have a 50% probability for responding "false" or "true."

Note: Numbers on the θ-axis are expressed in standardized units and, for the illustrations in this discussion, the mean depression level of the study population is set at 0 and the standard deviation is set to 1. Thus, a depression score equal to ($\hat{\theta} = 2.0$) indicates that a person is 2 standard deviations above the population mean and is highly depressed.

IRT Model Basics

Item Response Curves

IRT models describe for each item in a scale how the item performs for measuring different levels of the measured construct. For example, the item *I don't seem to care what happens to me* would have IRT properties reflecting it is informative for measuring people with severe levels of depression, and an item such as *I am happy most of the time* would have IRT properties reflecting it is informative for measuring people with low levels of depression.

The probabilistic relationship between a person's response to an item and the latent variable (θ) is expressed by item response curves (also referred to as category response curves or item trace lines). For example, Figure 1 presents the IRT response curves for the item *I am unhappy some of the time*, which has two responses, "false" and "true," and is part of a scale measuring depression.

Individuals with little depression are located on the left side of the θ continuum in Figure 1, and people with severe depression are located on the right side of the axis. The vertical axis in Figure 1 indicates the probability that a person will select one of the item's response categories. Thus, the two response curves in Figure 1 indicate that the probability of responding "false" or "true" to the item *I am unhappy some of the time* depends on the respondent's depression level.

The response curves in Figure 1 are represented by logistic curves that model the probability *P* that a person will respond "true" to this item (*i*) as a function of a

$$P(X_i = true|\theta,a_i,b_i) = \frac{1}{1 + e^{a_i(\theta - b_i)}} \qquad (1)$$

respondent's depression level (θ), the relationship (*a*) of the item to the measured construct, and the severity or threshold (*b*) of the item on the θ scale. In IRT, *a* and *b* are referred to as *item discrimination* and *threshold parameters*, respectively.

The item threshold or severity level (*b*) is the point on the latent scale θ at which a person has a 50% chance of responding "true" to the item. In Figure 1, the item's threshold value is $b = 0.25$, which indicates that people with depression levels a quarter standard deviation above the population mean have a 50% chance of indicating "false" or "true" to the question.

The discrimination or slope parameter (a) in Equation 1 describes the strength of an item's ability to differentiate among people at different levels along the trait continuum. In Figure 1, the slope at the inflection point (i.e., the point at which the slope of the curve changes from continuously increasing to continuously decreasing) is $a = 2.83$. The larger the a parameter is, the steeper the curve is at the inflection point, and steeper slopes indicate that the *item characteristic curve* increases relatively rapidly, such that small changes on the latent variable lead to large changes in item-endorsement probabilities. The a parameter also describes the relationship between the item and the trait being measured by the scale, such that items with larger slope parameters indicate stronger relationships with the latent construct.

IRT Model Information Functions

Another important feature of IRT models is the information function, which describes the extent to which an item is useful for measuring persons at different levels of the underlying latent construct, with higher information denoting more precision. Figure 2 presents the item information functions that are associated with three depression items (respondent's trait level [θ] is shown on the horizontal axis and information magnitude is shown on the vertical axis).

The shape of the item information function is determined by the item parameters. The higher the item's discrimination (a) is, the more peaked the information function will be. Thus, higher discrimination parameters provide more information about individuals whose trait levels (θ) lie near the item's threshold value. The item's threshold parameter(s) (b) determines where the item information function is located. In Figure 2, the item *I don't seem to care what happens to me* is informative for measuring high levels of depression, the item *I am unhappy some of the time* is informative for measuring moderate depression levels, and the item *I cry easily* is not informative for measuring any depression level relative to the other items.

The item information functions are a powerful tool because they allow questionnaire developers to reduce respondent burden or to create shorter questionnaires by selecting the most informative set of items that are relevant for the population under study (e.g., a researcher working with a clinically depressed population could select items best for assessing high levels of depression). Items with low information (low discrimination) function may indicate that this particular item has a problem because (a) the content of the item does not match the construct measured by the other items in the scale, (b) the item is poorly worded and needs to be rewritten, (c) the item is too complex for the educational level of the population, or (d) the placement of the item in the survey is out of context.

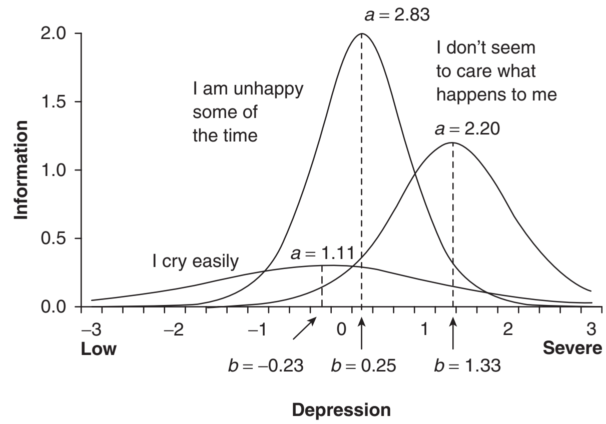

Figure 2 Item information functions for three items: *I cry easily, I am unhappy some of the time*, and *I don't seem to care what happens to me*.

The individual item information functions can be summed across all of the items in a scale to produce the scale information function as shown in Figure 3 (the associated reliability [r] is also provided on the vertical axis). Overall, the scale is highly reliable for measuring moderate to severe levels of depression (i.e., when reliability is above $r = .90$). However, scale precision worsens for measuring persons with low levels of depression.

Family of IRT Models

There are more than 100 varieties of IRT models to handle various data characteristics, such as dichotomous and polytomous response data, ordinal and nominal data, and unidimensional and multidimensional data. The common parametric unidimensional IRT models include the one-, two-, and three-parameter logistic models for dichotomous response data and the graded response model, partial credit model, rating scale model, and generalized-partial credit model for polytomous response data.

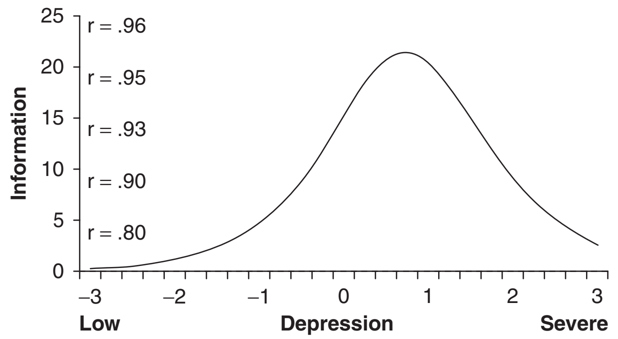

Figure 3 Scale information function for a 57-item depression questionnaire. The horizontal dashed lines indicate the level of reliability (r) associated with different levels of information.

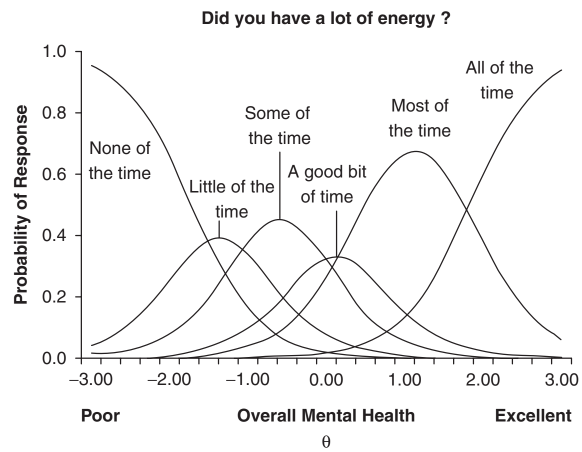

Figure 4 Category response curves representing the probability for selecting one of the six response options for the item, *Did you have a lot of energy?* conditional on a person's mental health level.

Figure 4 presents IRT category response curves (estimated from the graded response model) for a polytomous response question, *Did you have a lot of energy?* which appears in a health status questionnaire. In the figure, there is a curve associated with each of the six possible responses, which models the probability of endorsing the response conditional on a person's level of mental health.

IRT Model Assumptions

The IRT models described in the previous sections make three key assumptions about the data: (1) unidimensionality, (2) local independence, and (3) monotonicity. These assumptions should be evaluated before any IRT model results are interpreted, but IRT models are robust to minor violations of the assumptions, and no real data ever completely meet the assumptions.

The unidimensionality assumption posits that the set of items measures a single continuous latent construct. Unidimensionality can be evaluated by performing an item-level factor analysis to evaluate the factor structure that underlies the observed covariation among item responses. If multidimensionality exists, the investigator may want to consider dividing the scale into subscales, based on both theory and the factor structure provided by the factor analysis, or consider using multidimensional IRT models.

The assumption of local independence means that the only systematic relationship among the items is explained by the conditional relationship with the latent construct. In other words, if the trait level is held constant, there should be no association among the item responses. Violation of this assumption may result in erroneous decisions when selecting items for scale construction. The impact of local dependence can be evaluated by examining how the item parameters and person scores change when one or more of the locally dependent items are dropped.

The assumption of monotonicity means that the probability of endorsing or selecting an item response indicative of better health status should increase as the underlying level of health increases. Approaches for studying monotonicity include examining graphs of item mean scores conditional on *rest-scores* (i.e., total raw scale score minus the item score) or fitting a nonparametric IRT model to the data that yield initial IRT probability curve estimates.

Applications of IRT Modeling in Survey Research

Much of the development and application of IRT modeling has occurred in educational measurement, where IRT is used to help administer and score educational tests like the SAT (Scholastic Assessment Test) and the GRE (Graduate Record Examination). Other disciplines have realized the value of these applications and are learning how to adapt these methods for (a) evaluating the properties of existing scales and guiding survey revisions, (b) determining measurement equivalence across research populations, (c) linking two or more questionnaires on a common metric, and (d) developing item banks for computerized adaptive testing applications.

Evaluating Existing Scales and Guiding Survey Revisions

IRT modeling makes an excellent addition to the psychometrician's toolbox for developing and revising survey questionnaires. The IRT category response curves help questionnaire developers evaluate how well each of the response categories for each item functions for different levels of the measured construct as well as determine whether more or fewer response categories are needed.

The IRT information curves serve as a useful tool for instrument developers to evaluate how well an item or scale functions for measuring all levels of the underlying construct. Developers can use the information curves to weed out uninformative questions or to eliminate redundant items that provide duplicate levels of information across the construct continuum. Effects on precision for removing items from the scale can easily be evaluated with the scale information function. Also, information curves allow developers to tailor their instrument to provide high information (i.e., precision) for measuring their study population. For example, if a developer wants high precision to measure a person at any level of depression (i.e., high information across all levels of the construct continuum), then the information function in Figure 3 suggests adding more items to the scale (or more response options to existing items) that differentiate among people with low depression levels.

Assessing Measurement Equivalence

Items in a survey questionnaire are carefully written to ensure that they are tapping into the same construct no matter which population is responding to the questions. For example, considerable care is taken when an instrument is translated from one language to another. Despite this careful translation process, it may turn out that although the words are the same, the two populations may hold culturally different views of the question. For example, a common finding in depression questionnaires is that Hispanics are more likely to respond positively to a question such as *I feel like crying* than are non-Hispanics, despite controlling for differences between the two populations' depression levels, perhaps because Hispanics are more likely to believe that crying is an acceptable social behavior. This is known as differential item functioning (DIF).

DIF is a condition in which an item functions differently for respondents from one group than for another. In other words, respondents, with similar levels on a latent trait but who belong to different populations, may have a different probability of responding to an item. Questionnaires containing such items may have reduced validity for between-group comparisons because their scores may indicate a variety of attributes other than those the scale is intended to measure.

IRT provides an attractive framework for identifying DIF items. In IRT modeling, item parameters are assumed to be invariant to group membership. Therefore, differences between the curves, estimated separately for each group, indicate that respondents at the same level of the underlying trait, but from different groups, have different probabilities of endorsing the item. More precisely, DIF is said to occur whenever the conditional probability, $P(X)$, of a correct response or endorsement of the item for the same level on the latent variable differs for two groups.

DIF analysis has been used to detect measurement equivalence in item content across cultural groups, males and females, age groups, between two administration modes such as paper-and-pencil versus computer-based questionnaires, and from one language translation of a questionnaire to another. Also, DIF testing can be used for evaluating question ordering effects or question wording effects.

Linking Two or More Scales

It is common in many research settings for several existing instruments to measure the same construct. Combining or comparing results across studies that use different questionnaires in a meta-analytic study is difficult because the questionnaires may have different lengths, different number of response options, and different types of questions with different psychometric properties. IRT modeling provides a solution through its ability to link the item properties from different scales on to a common metric. Several methodologies exist for linking two (or more) instruments. Ideally, one would administer both instruments to a representative sample and then IRT-calibrate (obtain the properties of) the items simultaneously. Alternatively, a set of items that are common to both instruments can be selected as anchors. The anchor items are used to set the metrics to which items not common to both instruments are scaled. Therefore, instruments with a different number or difficulty of items can be linked by responses to a common set of anchor items.

These applications take advantage of a key feature of IRT models, which is the property of *invariance*. If IRT model assumptions are met, item parameters are invariant with respect to the sample of respondents, and respondent scores are invariant with respect to the set of items used in the scale. After the IRT item parameters are estimated (i.e., calibrated), researchers can choose the most salient items to target a person's level of function with the smallest number of items. This method results in different groups receiving different sets of items; however, any given set of items calibrated by the best-fitting IRT model should yield scores that are on a similar metric.

Building Item Banks and Computerized Adaptive Testing

The IRT principle of invariance is the foundation that researchers use to develop computerized adaptive tests (CATs), which yield tailored instruments that estimate a person's level on a construct (e.g., depression) with the fewest number of items. To accomplish this, a CAT has access in its data bank to a large pool of items that have been carefully selected and calibrated by IRT models (called an *item bank*).

Based on a person's response to an initial item, the CAT selects the next most informative item from the item bank to administer to the respondent. After each response, the computer selects and administers from the item bank the next most informative item until a minimal standard error or maximum number of administered items is obtained. The benefits of CAT technology include (a) decreased respondent burden, (b) reduced "floor and ceiling" effects, (c) instant scoring, and (d) widespread availability of this technology on many platforms (e.g., Internet, handheld devices, computer-assisted telephone interviewing).

Limitations

The survey research field has much to gain from IRT methods; however, there are limitations to widespread application. First, many researchers who have been trained in classical test theory statistics may not be as comfortable with the advanced knowledge of measurement theory IRT modeling requires. In addition, the supporting software and literature are not well adapted for researchers outside the field of educational measurement. Another obstacle is that the algorithms in the IRT parameter-estimation process require large sample sizes to provide stable estimates (from 100 for the simplest IRT model to 1,000 or more for more complex models). Despite the conceptual and computational challenges, the many potential practical applications of IRT modeling cannot be ignored.

JACKKNIFE VARIANCE ESTIMATION

There are two basic approaches to estimation of the variance for survey data: the Taylor linearization method and the resampling method. The resampling method includes the jackknife, balanced repeated replication (Fay's method as a variant), and bootstrap methods. The resampling method calls for creation of many replicate samples ("replicates" in short) taken from the original sample (called also the full or parent sample). Each resampling method uses a unique way of creating the replicates. Each replicate provides a point estimate of the population parameter of interest and the variability among the replicate estimates forms the basis of estimating the variance of the point estimate.

Let θ be the population parameter to be estimated from the sample and let R replicates be created, from which R replicate point estimates, $\hat{\theta}_j$, $j = 1, 2, \ldots, R$ of θ are obtained. Then the jackknife variance estimator is given by $\hat{V}_J = \sum_{j=1}^{R} c_j(\hat{\theta}_j - \hat{\theta})^2$, where c_j are scaling constants to correct the bias and $\hat{\theta}$ is the point estimate based on the full sample.

A special case of the jackknife variance estimator for the sample mean under simple random sampling is a helpful way to understand the idea behind the method. In this case the maximum number of replicates that can be created in a replicate sample is formed by deleting one sample unit at a time—the number of replicates is equal to the sample size n. Then the jackknife variance formula is given by $\hat{V}_J = \{(1-f)(n-1)/n\} \sum_{j=1}^{n} (\hat{\theta}_j - \hat{\theta})^2$ where $f = n/N$ is the finite population correction, N is the size of the finite population under study, $\hat{\theta}_j = \sum_{i \neq j, i=1}^{n} y_i/(n-1)$ is the sample mean of the j-th replicate sample, and $\hat{\theta} = \bar{y} = \sum_{i=1}^{n} y_i/n$, the sample mean for the full sample. Note that in this special case, $c_j = (1-f)(n-1)/n$ for all $j = 1, 2, 3, \ldots, n$. It is not difficult to show that the variance estimator $\hat{V}_J$ is equivalent to the usual variance estimation formula $\hat{V} = \{(1-f)/n\} \sum_{i=1}^{n} (y_i - \bar{y})^2/(n-1)$. Therefore, the jackknife variance estimator is an unbiased variance estimator for this special case.

However, even when the point estimate is a complex one, such as a ratio estimate, the jackknife variance estimator still gives approximately correct variance estimate if the sample size is large (the technical term for this property is *consistency*). The same is true for other point estimates that are defined in a smooth functional form of sample (weighted) totals or averages—survey weights should be used especially when unequal probability sampling has been used. Such point estimates for which the jackknife is consistent include the ratio, regression coefficient, and correlation coefficient, but not the median or, more generally, quantiles.

When the sample design is complex with stratification and clustering (in one or multi-stage), estimation of the variance of a survey estimate is not simple. The usual approach is to assume that the primary sampling units (PSUs) have been selected with replacement within strata, although replacement sampling is seldom used in practice. Then the variance estimator can be written in a form of PSU level aggregates of the variables involved in the definition of the point estimate. This approach easily incorporates the cluster effect on the variance estimate. So it simplifies the variance estimation substantially. However, the price of this simplification is that the variance estimate is generally overestimated as a result of the assumption of replacement sampling of the PSUs. The overestimation is not serious if the PSU level sampling fraction is small, and mild overestimation is generally accepted—this leads to mildly conservative results when the variance estimate is used in statistical inference. However, if the sampling fraction is not small, the overestimation can be substantial, and incorporation of the finite population correction (fpc) may be helpful to reduce the overestimation. (This issue applies not only to the jackknife method but also to the Taylor method.)

Under the with-replacement sampling assumption, replicates are created by deleting one PSU at a time. So if there are R sample PSUs, there will be R replicates (i.e., $R = \sum_{h=1}^{H} n_h$, where H is the number of strata and n_h is the stratum PSU sample size). The variance estimator given at the beginning is applicable in this situation. To compute $\hat{\theta}_j$, the sample weights have to be modified. If replicate j is defined by deleting a PSU in stratum h, then the sample weights of the sample units in the remaining $(n_h - 1)$ PSUs are inflated by the factor of $n_h/(n_h - 1)$, while keeping all other sample weights unchanged. The scaling constant in the variance formula is given by $c_j = (n_h - 1)/n_h$ under the replacement sampling assumption. If, however, the fpc is not negligible, then it can be incorporated through $c_j = (1 - f_h)(n_h - 1)/n_h$, where $(1 - f_h) = (1 - n_h/N_h)$ is the fpc for stratum h and n_h and N_h are stratum PSU sample and population sizes, respectively, if PSUs have been selected by simple random sampling. For the case that PSUs have been selected by unequal probability sampling such as the probability proportional to size sampling, $f_h = \bar{\pi} = \sum_{i=1}^{n_h} \pi_{hi}/n_h$, which is the average inclusion probability of PSUs selected from stratum h, may be used to avoid excessive overestimation. However, the use of the fpc in this way usually results in underestimate of the variance. (Better corrections are available, but they are beyond the scope of this entry.)

Survey weighting involves not only base sample weighting but also various adjustments, such as nonresponse adjustment, post-stratification ratio adjustment, and so on. Mimicking these adjustments on the replicates, the jackknife variance estimator reflects the effect of the weight adjustments on the variance. This is considered one of the strengths of the jackknife variance estimator.

The degrees of freedom of the jackknife variance estimator are determined by $R - H$ including the situation where $H = 1$ (i.e., no stratification). While it is advantageous to have a large number of replicates so as to have a large number of degrees of freedom, having a large number of replicates requires more effort to create replicates and to calculate the variance, as well as more computer space to store replicate weights. So it is ideal to take a good balance between the advantages and disadvantages of having a large number of replicates. If a smaller number of replicates is desired, then sampling units are randomly grouped to form artificial clusters called random groups even when clustering has not been used. Even for a cluster design, PSUs may be combined to reduce the number of replicates. However, such manipulation should be done carefully because it may introduce some bias in the variance estimate.

A special case, which is often employed in practice, is the stratified cluster design with $n_h = 2$ for all strata. In this case, instead of using all possible $2H$ replicates, one can use only H replicates, selecting one replicate from each stratum. It is equivalent algebraically with the full jackknife for a point estimate that is defined as a linear statistic of sample observations, and its degree of freedom is H, which is the same as for the full jackknife. For nonlinear statistics, the equivalence does not hold. However, the two estimators are still close to each other. For this special case, $c_j = 1$ for all H replicates if the fpc is ignored.

In the jackknife variance estimator formula, $\hat{\theta}$ may be replaced by the average of the replicate estimates, $\bar{\hat{\theta}} = \sum_{j=1}^{R} \hat{\theta}_j/R$. However, the difference is usually small, so it does not generally matter which is used. The jackknife and the Taylor linearization variance estimators are approximately the same for point estimates for which they are valid on large samples (i.e., they are asymptotically equivalent).

Joint Program in Survey Methodology (JPSM)

The Joint Program in Survey Methodology (JPSM) is the oldest and largest program in the world offering graduate degrees in survey methodology. Located at the University of Maryland, JPSM was established in 1993 following the award of a grant from the National Science Foundation. JPSM was created to strengthen the federal statistical system by providing advanced training in survey statistics and methodology. It is a partnership between the federal government—specifically, the Interagency Council on Statistical Policy (ICSP)—and a consortium of the University of Maryland, the University of Michigan, and Westat. An innovative feature of the program is its sharing of classes across universities via video systems. In a typical term, almost half of JPSM's courses are shared this way, mostly with JPSM's sister program at the University of Michigan (the Michigan Program in Survey Methodology), but also with graduate programs at the University of Nebraska in Lincoln and the University of North Carolina at Chapel Hill. JPSM has become the hub of a national system of graduate education in survey methods.

Educational Programs at JPSM

JPSM offers a variety of educational programs including master's and Ph.D. programs in survey methodology, certificates in survey methodology and survey statistics, citations in introductory survey methodology and economic measurement, short courses, and summer internships. Its students include staff from the federal statistical agencies and from the many survey firms in the Washington, D.C., area that serve the statistical agencies. In addition, JPSM attracts and trains new entrants to the field of survey research.

JPSM began accepting students into the master's degree program in 1993. Because its primary goal is training survey practitioners, the master's program remains JPSM's central educational offering. As of September 2006, more than 140 students had graduated from JPSM with master's degrees. At that time, more than two thirds of the degree-seeking students were enrolled in the master's program. The master's program consists of a set of core courses, covering data collection, basic statistical methods, applied sampling, and total survey error. In addition, students get hands-on experience with surveys. Each year, the students conduct a survey, the JPSM Practicum; the master's students also offer survey consulting and are required to complete an internship at a survey firm. The master's program offers two "tracks," or concentrations—one in statistical science, the other in social science. Students in both tracks take the core courses. Those in the statistical science track take additional classes in probability and statistics, sampling, and survey estimation. Those in the social science track take additional courses in questionnaire design, cognitive processes related to surveys, and the analysis of survey data.

The purpose of the Ph.D. program is to train the next generation of researchers and teachers. The first doctoral students were accepted in 1999; as of September 2007, 13 students were pursuing Ph.D. degrees. Six doctorates have been awarded. Like the master's program, JPSM's Ph.D. program offers concentrations in statistical science and social science. Ph.D. students must meet three major requirements. After their first year, they are required to pass a qualifying exam. The qualifying exam covers the material in the required courses for the master's students. Doctoral students in statistical science are expected to be proficient in the topics covered in the core master's courses as well as the master's-level statistical science courses; similarly, doctoral students in the social science track must demonstrate their proficiency in the material covered in the classes required for the social science master's students. At the end of their second year, doctoral students must pass a comprehensive exam, demonstrating their mastery of even more advanced material. Finally, the doctoral students must complete a dissertation describing original research in survey statistics or survey methods.

JPSM also offers programs for students who are not seeking degrees. These programs are designed mainly to upgrade the skills of people who are already working as survey researchers. The most demanding are two certificate programs tailored to students who already have an advanced degree in another field but are seeking to learn more about survey methods. Each of the certificate programs is a bundle of six semester-length courses. In addition to its semester-length classes, JPSM also offers 20 or more short courses each year. The short courses are 1- or 2-day classes taught by experts on a given topic. Approximately 700 persons attend JPSM short courses each year. The citation programs recognize persons who have completed specific combinations of short courses and a semester-length class in survey methods.

JPSM also has one program—the Junior Fellows Program—designed for undergraduates; it seeks to recruit promising undergraduates to the field of survey research. The program consists of a weekly seminar at JPSM and an internship with one of the federal statistical agencies. In a typical year, about 30 students take part in the Junior Fellows Program; more than 200 Fellows have taken part since the program began.

Future Directions

As JPSM enters its second decade, it seeks to expand its ties to other programs (especially the Michigan Program in Survey Methodology), to become a more conventional department at the University of Maryland, and to continue to provide innovative educational offerings. JPSM's graduates have already made their mark on the federal statistical system and on the field more generally; their impact on survey research is likely to grow in the years to come.

Journal of Official Statistics (JOS)

The *Journal of Official Statistics* (JOS) was launched in 1985. It is published by Statistics Sweden, the National Statistical Institute of Sweden. It replaced the then–century-old *Statistisk tidskrift* (Statistical Review). The ambition was to make JOS an internationally recognized communication medium on methodology and policy matters facing national statistical institutes and other producers of statistics. The language is English. The intended readers are working primarily at statistical agencies or in universities or private organizations and dealing with problems that concern aspects of official statistics and other production of statistics.

JOS functions as any other respected journal. All in-scope submissions are sent to referees for evaluation, and an associate editor together with the chief editor make the editorial decision for each manuscript. The number of associate editors has grown over the years from 5 in 1985 to 40 in 2007. The proportion of accepted manuscripts is approximately 22%. Examples of topics include new methods, interesting applications of known methods, comparative studies of different methods, authoritative expositions of methods in a certain field, and discussions of policy issues.

It is believed that the official statistics community has an unexploited potential for producing methodological articles. It seems that government statisticians publish less frequently than other professionals involved in statistics. Documents often remain at the draft stage without any international circulation. Sometimes these authors do not have to publish, and incentives to publish are not provided by their agencies. In consequence, many valuable contributions remain within the home-agency and do not initiate a more extensive research process involving scientists at other agencies, universities, or research organizations with an interest in these matters. JOS has been very successful as an outlet for these types of authors, and the journal's policy has been to provide them with as much guidance as possible, perhaps more than what is expected by scientific journals.

JOS is published four times a year. All issues from the start are accessible on JOS's Web site, which is searchable. All access is free of charge, all articles can be downloaded with no windows in place; that is, as soon as an issue has been printed it is available on the Internet. The Web site also contains information about subscription rates.

Key Informant

Within the context of survey research, *key informant* refers to the person with whom an interview about a particular organization, social program, problem, or interest group is conducted. In a sense, the key informant is a proxy for her or his associates at the organization or group. Key informant interviews are in-depth interviews of a select (nonrandom) group of experts who are most knowledgeable of the organization or issue. They often are used as part of program evaluations and needs assessments, though they can also be used to supplement survey findings, particularly for the interpretation of survey results. Key informants are chosen not because they are in any way representative of the general population that may be affected by whatever issue is being studied, but because they are believed to have the most knowledge of the subject matter.

Key informant interviews are especially beneficial as part of an initial assessment of an organization or community issue, allowing for a broad, informative overview of what the issues are. In survey studies, key informant interviews can be valuable in the questionnaire development process, so that all question areas and possible response options are understood. Relying on this method is also appropriate when the focus of study requires in-depth, qualitative information that cannot be collected from representative survey respondents or archival records. While the selection of key informants is not random, it is important that there be a mix of persons interviewed, reflecting all possible sides of the issue at study. Key informant interviews are most commonly conducted face-to-face and can include closed- and open-ended questions. They are often audio-taped and transcribed so that qualitative analyses of the interviews can be performed. Key informant interviews are rarely used as the sole method of data collection for a study or particular issue, as there is little generalizability that can come from them. However, they have a useful role, especially at the beginning stages of research studies when information gathering and hypothesis building are the goal.

Kish, Leslie (1910–2000)

Leslie Kish was a statistician, sociologist, and cofounder of the Institute for Social Research at the University of Michigan. His work had a profound and lasting effect on the field of survey research. His book *Survey Sampling*, published in 1965, formulated many of the principles that are today taken for granted in scientific survey research. The theory of equal probability sampling was first proposed in *Survey Sampling*, as was that of the design effect (*deff*). The Kish method of selecting respondents with equal probability is named for Leslie Kish. He was also an early proponent of counting and measuring nonresponse in survey research.

Kish emigrated to the United States from Hungary along with the rest of his family in 1925 at the age of 15. His father died shortly after the family arrived in the United States, and Leslie had to find work to help support the family. While working full-time he finished high school through an evening program in 1930. He then enrolled in the City College of New York while he continued to work full-time during the day. With less then 1 year left in his college studies, in 1937 he volunteered for the International Brigade and fought for the Spanish Loyalists in the Spanish Civil War.

In 1939 he returned to New York City and the City College, graduating with a bachelor's degree in mathematics later that year. He then took a job with the U.S. Census Bureau in Washington, D.C., and after working there a short time, he obtained a job with the U.S. Department of Agriculture (USDA). There he was the department's first sampling statistician. His boss at that time was Rensis Likert. Kish, Likert, and others at the USDA implemented the scientific survey sampling techniques that are still in use today. In 1942 Kish left the USDA to join the U.S. Army and served as a meteorologist until 1945.

In 1947 Kish and others (including Likert) went to the University of Michigan to establish the Survey Research Center, which went on to become the Institute for Social Research. At Michigan, Kish first earned a master's degree in mathematical statistics in 1948 and then a Ph.D. in sociology in 1952. He retired in 1981 and was professor emeritus at Michigan until his death in 2000. While in earlier jobs Kish was able to effect change at an organizational level, teaching at the University of Michigan provided him with a much larger stage from which he helped shape the entire field of survey research.

Kish was a devoted and enthusiastic scholar. He was a Fellow of both the American Academy of Arts and Sciences and the American Association for the Advancement of Science. In 1994 he was named Honorary Fellow of the International Statistical Institute, an honor that has been referred to as the Nobel Prize of Statistics. In 1995 Kish was named Honorary Member of the Hungarian Academy of Sciences.

He also had a passion for teaching and the dissemination of knowledge. Eager to see scientific sampling methodology spread to other countries, he started the Sampling Program for Foreign Statisticians in 1961. The program was an unqualified success. It has trained hundreds of statisticians from scores of countries. The program continues its mission today as the Sampling Program for Survey Statisticians.

Kish Selection Method

Most surveys of attitudes and opinions have two stages: The first is drawing a random sample of dwelling units, and the second is selecting one person within a dwelling unit to interview. Leslie Kish published a landmark article in the *Journal of the American Statistical Association* in 1949 that described a rigorous, almost pure probability method of sampling persons within households to be surveyed. He named two basic conditions: (1) There must be a known probability of inclusion (excluding zero) of each adult in the population, and (2) it must be a practical and efficient procedure to implement.

Although survey data collection at that time often was conducted in person, Kish's plan is suitable for telephone surveys as well. It is accomplished by the interviewer's listing the age and sex of the adult members of the household and their relationship to the head of household and then consulting a table to choose the correct respondent. The interviewer numbers all the males first from oldest to youngest and then all the females in order of decreasing age. Kish provided two different sets of tables. In his first example, the interviewer has six tables, labeled A to F, which indicate first the numbers of adults in households from 1 through 6 and then below, the number of the adult to be interviewed. Each table lists the target individual in systematic order that differs among the tables, and the first three tables are set up in such a way that males are more likely to be selected because males tend to be underrepresented in surveys. In his second example, used more frequently in research today than the first procedure, there are eight tables labeled A, B1, B2, C, D, E1, E2, and F. Tables A, C, D, and F will be used one sixth of the time, and the others will be used one twelfth of the time. These tables give equal chances of selection to individuals in households of 1, 2, 3, 4, and 6 adults. Dwelling units with 5 adults are overrepresented to "compensate" for the inability of this method to represent households of more than 6 adults, a very small proportion of the population. Kish estimated, at the time he was writing, that only 1 or 2 adults per 1,000 would not be represented, usually young females.

Here is one example of the Kish method question wording, used by Robert W. Oldendick and his colleagues:

> *In order to select the right person to interview, we need to list all the people living in your household who are 18 years of age or older. First, could you tell me the ages of all the males living in your household who are 18 years of age or older—that is, from the oldest to the youngest? Next, could you tell me the ages of all the females living in your household who are 18 years of age or older—that is again, from the oldest to the youngest?*

Some researchers have introduced other methods because they believe that Kish's procedure takes too much time to enumerate household members, respondents may perceive it as intrusive, and it may increase refusal rates. In other words, they criticize it for potentially adding to nonresponse, although it can decrease within-unit noncoverage. The method may be more of a problem in larger, as opposed to smaller, households. Age is not asked in one-person households or in one male/one female units. Another criticism is that the tables may be outdated because of changes over time in the distribution of households or that the tables are inappropriate for some countries with different population patterns. Some surveyors have found that the Kish selection method, per se, is not very intrusive but that refusal rates tend to increase with any method that requires two consents—the first from the informant who answers the phone and the second from the designated respondent. Several researchers report that the Kish method is still a reliable and noninvasive method when interviewers are skilled and well trained in it. It is important that interviewers have faith in the method because they otherwise unconsciously may communicate negative attitudes toward a method, thereby decreasing the cooperation rate. Several comparative studies have included the Kish method with other methods on coverage, response, costs, and other characteristics.

KNOWLEDGE GAP

This entry focuses on the concept of the knowledge gap, which is a specific hypothesis within the area of diffusion of knowledge, and subsequent derivations. A number of models of social change are based on the notion that change is a cumulative process. In such models, small changes result in differential rates of change for the social system—slow system change at first, followed by increasingly faster rates of change during the middle of the change process, followed by slowing rates of societal change at the end. This process is reflected in the familiar "S-curve" which shows an accumulative sum over time. Two prominent models that follow the logic and assumptions of the cumulative process perspective include models of *diffusion of technologies* and *diffusion of knowledge* in the social system. Originally proposed by Phil Tichenor and his colleagues in the early 1970s, the knowledge gap hypothesis predicts that as mass-mediated information enters a social system, certain segments of the population (such as those with higher socioeconomic status [SES]) acquire the information faster than the other population segments (those with lower SES). This process results in an increase rather than a decrease in the gap in knowledge between these two segments over time.

It is important to emphasize that the knowledge gap hypothesis is not about whether or not there is a gap between high and low SES segments of the population. Rather, the hypothesis concerns the widening of the gap over time. Actual tests of the knowledge gap hypothesis require data over time and are not prevalent in the scholarly literature. Studies of differences in knowledge levels for various segments of the population at one particular point in time might be better thought of as studies of knowledge differences or deficits (although they typically describe themselves as "knowledge gap" studies). The original knowledge gap study described the gap itself and took it as a given. The knowledge gap hypothesis is offered as an explanation as to how the gap might grow to the size it sometimes becomes when the same amount of information is available through media that penetrate most of society.

The original article by Tichenor and colleagues pointed out what researchers had known for years: that certain people expose themselves to certain kinds of information more, pay more attention, and retain more of it than do others. As a result, those who want to acquire more information will do so more quickly than those who do not. Some researchers have suggested that interest in the given topic under consideration is actually the important factor that determines the rate of information acquisition; others suggest that the important factor is motivation. Whatever the explanation for the phenomenon, empirical evidence is voluminous and can be found throughout social science research literature under such topics as "selective attention," "selective avoidance," "selective retention," and more general studies of learning from the media.

The primary contribution of the knowledge gap hypothesis is that, by describing the process as one that occurs over time, and by focusing on more macro concerns, attention was turned to the implications of this phenomenon for the social system rather than for individuals.

Knowledge gap research has been extensive and examined in a number of fields, including communications, political science, survey research, psychology, sociology, rural planning, forestry and wildlife management, health and medicine, biology, and numerous others. It is safe to say that hundreds of knowledge gap studies have been conducted in the intervening years, examining contingent or limiting conditions or aspects of the knowledge gap associated with particular media (the original article focused on newspapers), ways of limiting or countering the knowledge gap, or the implications of the knowledge gap for such behaviors as cancer prevention or political participation.

As was the case almost since the inception of the knowledge gap hypothesis, most research efforts on the hypothesis continue to be conducted at one point in time. These studies do not investigate the knowledge gap hypothesis, per se, but instead focus on one possible result of the hypothesis, a gap in knowledge levels between different segments of society at a particular time point. The most recent extensions of the knowledge gap have focused on the role of other media in supplementing knowledge or limiting the knowledge gap and have moved beyond newspapers to television and other media, spurred by the diffusion of new communication technologies such as computers and the Internet.

In addition to the examination of the knowledge gap hypothesis in relation to knowledge gain, the ideas developed in the knowledge gap hypothesis have been extended to access to traditional media and new technologies, resulting in several new research terms, such as the *digital divide*, *communication gaps*, and *communication inequities*. In studies of the digital divide, interest is often on diffusion and access to computers and the Internet and the implications of differential access for members of society.

Knowledge Question

A knowledge question is designed to capture the extent to which people have stored factual information in long-term memory and how well they can retrieve and respond with that information when asked a survey question about a given topic. Knowledge, as a concept, is distinct from attitudes and opinions. Knowledge, moreover, is not synonymous with the term *information.* Whereas information describes a wider breadth of content that may include non-neutral as well as neutral elements, knowledge is considered neutral, factual content. The term *factual* is one that has been debated. Facts refer to those content elements on which there is consensual agreement. For example, it is a fact that it takes two thirds of Congress to override a presidential veto. Whether or not a given politician was arrogant during a debate, however, is a subject that is not likely to yield consensual agreement. Many topics can be assessed with knowledge questions, including politics, health, consumer issues, popular culture, science, and education.

Knowledge questions are used for several purposes. First, knowledge questions can be used to screen people for follow-up questions about people's attitudes on a given topic. If it is determined that a person has little or no knowledge of a topic, it may not be efficient for the researcher to ask that person follow-up attitude questions on that subject. Second, knowledge questions are used to assess a person's intellectual engagement on a topic, because knowledge is often predictive of various attitudes and behaviors. For example, citizens who are knowledgeable about politics tend to be the citizens who vote in elections; in other words, political knowledge predicts voting. Third, knowledge questions may be used for evaluative purposes. A school's performance may be assessed by how well its students have mastered a given set of material.

There are two primary types of knowledge questions: *recognition* and *recall.* Awareness questions are often assessed with recognition measures. Recognition measures ask people whether or not a given person, topic, or event is familiar to them. Specific knowledge content, however, is often assessed through recall measures. Recall items come in two forms: aided and unaided. An aided recall question is a closed-ended question that presents a respondent with several response choices from which the respondent selects an answer. An unaided recall question is asked in an open-ended format; the respondent receives no hints about the answer, and the respondent's answer is often recorded verbatim. Assessing a respondent's general awareness of a person, topic, or event is often less cognitively taxing on him or her than assessing a respondent's memory of specific knowledge content.

The main concern over recognition items is social desirability bias. People may say that they recognize an object because they want to appear informed. Consequently, some researchers follow up recognition items with specific content questions or include false (bogus) names or events in their recognition items to determine the extent to which people provide false positives (errors of commission) when it comes to recognition.

A general concern over asking knowledge questions is that respondents may feel intimidated when they perceive that they are being tested; they may be afraid of giving the incorrect response and looking ignorant or foolish. Anxiety can sometimes be minimized by prefacing questions with phrases such as *Do you happen to know* . . . or *As far as you know* . . . . Prefacing knowledge questions with softening phrases, however, may make people feel too comfortable giving "don't know" responses when they do know the correct answers but are not confident they know them and thus are hesitant to take a chance answering the questions. This can be problematic for researchers who are assessing the knowledge levels among different groups, particularly if some groups have greater propensities to guess than other groups do. For example, research has long shown that women are less likely to guess at knowledge items than are males. It is difficult to sort out a group's propensity to guess from its true levels of knowledge acquisition.

Knowledge levels for populations have been assessed with both direct and indirect measures. Direct measures ask specific, factual questions. Indirect measures include interviewer impressions of respondents' knowledge levels. While interview ratings have been used as knowledge measures, the validity of interviewer assessments is questionable because interviewer ratings are inherently subjective.

Mail and Internet surveys are problematic modes for conducting studies of people's knowledge levels, because respondents have the opportunity to look the answers up before completing the survey instruments. Consequently, telephone surveys and face-to-face interviews are preferable modes for assessing knowledge levels.

L

Language Barrier

Language barrier dispositions occur in U.S. surveys when a household member or the sampled respondent does not speak or read English (or another target language) well enough to complete the interview. The language barrier disposition is used in all surveys, regardless of the mode (telephone, in-person, mail, and Internet). Language barrier dispositions in surveys in the United States are not common, but their frequency is growing. Approximately 20% of the U.S. population in 2005 spoke a language other than English in their home, according to the U.S. Census Bureau. Furthermore, the 2005 U.S. Census estimates show upwards of 5 million residents being "linguistically isolated," in that they can speak little or no English. Language barriers are more likely to occur when data collection is conducted in central city areas and in rural areas of the Southwest.

The language barrier disposition functions as both a temporary and a final disposition. Cases may be coded temporarily with a language barrier disposition and then contacted again (in the case of a telephone or in-person survey) by an interviewer who speaks the same language as the household or the sampled respondent. In a mail or Internet survey, the survey organization may re-mail or resend a translated version of the questionnaire. However, cases with a language barrier final disposition often are considered eligible cases and thus are factored into survey nonresponse rates. The exception to this would be if the target population for a survey specified that respondents must speak English (or another specific language) to be eligible to complete the questionnaire.

Survey researchers may include a variety of categories within the language barrier disposition. One category of language barrier is used in telephone or in-person surveys for those cases in which there is no one in the household present at the time of contact who can speak or understand the language in which the introduction is spoken. Other categories of language barriers include cases in which the sampled respondent does not speak the language in which the interview is conducted or does not read the language in which the questionnaire is printed (for mail surveys) or displayed (for Internet surveys). Finally, a third category of language barrier occurs in in-person and telephone surveys when an interviewer fluent in the language spoken by the household is not available to be assigned to the case at the time of contact.

Because cases with a language barrier disposition increase the nonresponse rates in a survey, researchers fielding surveys in areas known to be multi-lingual often use practical strategies to ensure that households or respondents who do not speak the language in which the interview is to be conducted can complete the survey. In telephone and in-person surveys, these strategies usually include employing multi-lingual interviewers and arranging to have the survey questionnaire and all supporting materials translated into one or more additional languages. In mail and Internet surveys, these strategies usually include having the questionnaire and supporting materials translated into one or more additional languages and then re-sending (via U.S. Postal Service or email, depending on the mode) the translated questionnaire and materials to respondents who reported that they are unable to read English.

Finally, it is worth noting that occasionally a language barrier is used by a household or a respondent as an excuse to avoid completing the interview. These cases are very rare and happen mostly in in-person and telephone surveys. If this situation occurs, it should be considered a refusal, not a language barrier. Because there is no standardized manner for interviewers to determine if this situation has occurred, these types of cases should be reviewed carefully by a supervisor or contacted again by a different interviewer.

LANGUAGE TRANSLATIONS

Many survey projects at national and cross-national levels use questionnaires developed in one language and translated into another. The quality of these translations is a crucial factor in determining the comparability of the data collected. Conversely, poor translations of survey instruments have been identified as frequent and potentially major sources of survey measurement error. This entry outlines key aspects of conducting and monitoring survey language translations.

Essentially, translation allows researchers to collect data from people who cannot be interviewed in the language(s) in which a questionnaire is already available. In countries such as the United States, long-standing linguistic minorities and newly immigrated groups make translation into multiple languages essential to ensure adequate coverage and representation of different segments of the national population. The 2000 U.S. Census was available in six languages, with language aids being provided for 49 languages. The 2010 Census is likely to accommodate even more languages. In Switzerland, different segments of the population only speak one of the three main official languages. It is thus necessary to field Swiss national surveys in Italian, French, and Swiss German. At the same time, translation is occasionally motivated by official rather than practical requirements; in Great Britain, for example, some surveys are translated into Welsh, although most of the Welsh population uses English with native language competence.

Translation is not always part of an original survey research plan; sometimes it has to be added at short notice in order to interview unanticipated linguistic groups. Questionnaires or sets of questions are also sometimes simply "borrowed" from one study for use in another. In being borrowed for a new population, they may also need to be translated. Medical, psychological, and educational diagnostic instruments, often developed at great cost, are regularly adapted for new locations on the basis of translation. The aim may simply be to use the questions, not to compare data across populations. These are usually proprietary instruments for which permission is required and a fee possibly levied. In the cross-national context, international surveys may occasionally be able to use English as a lingua franca and thus avoid translating. However, most multi-lingual and cross-national projects must rely on translation to produce questionnaires in the languages needed.

Study Design and Translation

Two basic models are used to conduct multi-lingual studies. Researchers can decide to ask the same questions or to ask questions that differ in content but are thought to be comparable across populations. Ask-the-same-question models are by far the more common. In these models, a questionnaire is developed in one language, which is then translated to produce the other language versions required. Following terminology used in the translation sciences, the language translated "out of" is known as the *source language* and the language translated "into" is known as the *target language*. Most multi-lingual surveys, whether national or international, adopt ask-the-same-question procedures. If developed and implemented properly, they permit researchers to compare data, variable by variable, across populations.

Managing Translation Efforts

How a study conducts its translation effort depends on budgets, time schedules, the languages and number of respondents involved, and locations to be covered. Equally important are the research team's views on best practice and thus on whether participants are required to adhere to specifications or guidelines. Some projects delegate responsibility for translations to their fielding organization(s) or to translation bureaus or brokers. These may take over the translation effort or collaborate with the project staff or researchers, providing translators and possibly translation software, but leaving quality assessment up to the project staff. Alternatively, project staff can hire or buy translation tool and memory software and manage their own efforts, working with in-house and contracted personnel as needed. Some organizations have in-house language units or regular contractors for target languages they frequently need. In oral translation, translation call centers may be involved.

Technical Tools for Production and Assessment

Driven by time constraints, cost-efficient production and monitoring methods, as well as project volume and complexity, technology plays an increasingly important role in survey translation. Various technical aids are available, including translation tools, vocabulary databases, and project management software to monitor delivery schedules, phase completion, and documentation. Research is under way in several organizations to develop tools tailored to the needs of survey translation and assessment in the context of computer-assisted applications.

Translation Monitoring and Documentation

Systematic monitoring of translation quality also calls for technical support. In addition, team translation efforts rely on documentation from one stage for efficient execution of the next. Numerous projects use templates aligning source and target texts to facilitate the translation and documentation processes. In some projects, final draft versions are monitored centrally; in others, this responsibility is left with the individual language teams. Those translation teams who are monitoring these processes centrally need to align and compare the matching versions of different languages and any accompanying documentation. When source questionnaires are altered over time, monitoring also involves identifying and aligning different versions of the source and translated questionnaires and any notes on harmonization made across shared languages.

No translation or monitoring procedure is an automatic guarantee of quality. Even when guidelines or protocols are appropriate, errors will occur. An optimal model of quality assurance for survey research is still being developed. Careful implementation and revision conducted by appropriate personnel is critical. After the translation team considers their work completed, an external quality assessment is recommended. Models for external assessments are currently being developed in the international context.

Harmonization

As used here, the term *harmonization* is an extension of the principle of asking the same questions. In multilingual studies, several countries or groups may use or share the same language (e.g., Spanish or French). Sometimes a study stipulates that efforts must then be undertaken to harmonize questions across those populations sharing a language. In a harmonizing procedure, countries sharing a language compare and discuss their individually translated versions with a view to removing any unnecessary differences in a final harmonized version. The degree to which harmonization is obligatory differs; many studies recognize that regional standards of a shared language result in necessary differences in translations.

Team Translation

Views on what counts as good survey translation practice have changed noticeably in the last decade. Translation guidelines produced by the European Social Survey, by the U.S. Bureau of Census, by the World Health Organization's World Mental Health Initiative, and by the International Workshop on Comparative Survey Design and Implementation, all available online, emphasize the benefits to be gained from organizing survey translations in a team effort.

These team procedures consist of (at least) five steps that may be reiterated: (1) draft *translations* by translators; (2) *review* by the entire team; (3) *adjudication* by the team or a subgroup of it; (4) *pretesting* and translation adjustment; and (5) *documentation*.

In these procedures, acronymed in the European Social Survey guidelines as TRAPD, documentation is an ongoing process, informing each stage of development and documenting final outcomes and decisions.

Team translation efforts bring together a group of people with the skills to resolve the challenges inherent in producing good survey translations. In such arrangements, several translators produce draft translations. These translators are people with the relevant language competence, training in translation, and recent practice in translation work. Their translations are revised and finalized in collaboration with substantive experts and survey research specialists. Documentation of, and commentary on, output facilitates each stage. Team approaches emphasize the need for a collaborative effort of people with different skills. Because they incorporate review into the translation process, translations are reviewed and corrected before the final version is approved.

Back Translation

A more traditional form of survey translation usually has one translator translate. Assessment of the translation is often made by having a second translator produce a *back translation* of the translated text. Thus, if an English questionnaire is translated into Czech, the back translation step translates the Czech translation into English, without the translator seeing the original English version. The assessment of the Czech text is made by comparing the two English versions (source and back translation). If these are thought to be comparable (enough), the Czech translation is considered to have passed muster.

Back translation was one of the earliest procedures to establish itself in survey research and, over time, became associated with quality assurance. In translation studies, however, translation quality is normally assessed by focusing on the target translation, not source-language texts. Back translation can be an aid to researchers who do not understand the target language and want to gain a sense of what is in a text. However, as increasingly recognized, back translation cannot function as a refined tool of quality assessment.

Translation: Difference and Sameness

All translation is expected to convey in the target language whatever meaning is considered essential in the source text. However, the purpose of a translation determines what counts as an essential, and the target audience and the mode of presentation further affect how essentials are realized in translation. The extensive debate in translation theory literature related to these issues is beyond the scope of the present entry.

Behind any decision to translate survey questions lies the assumption that the translation will result in the same question in a different language. This is not a trivial assumption. It implies that we can identify those constituents of a question that must be translated to assure that the same question results. Currently we do not have a fully fledged and robust theory or even a description of what such constituents might be. In practical terms, most survey translations concentrate on rendering the semantic content of the source questions. Thus, if a source question asks *How often do you visit your parents?* a translation would be expected to refer to the set of people normally associated with the term *parents* in English and not, for example, to *relatives* and to ask a question about *visits* rather than a question about, for example, *seeing*.

Cultural and linguistic considerations often interact to complicate translation. A literal translation of the question *How often do you visit your parents?* would puzzle populations that commonly share living arrangements with their parents. It might also be necessary to specify linguistically which *parents* are intended and who *your* should refer to.

Adaptations

Translation alone is often not sufficient to render questions appropriately and adaptations may be required. *Adaptations*, as the term is used here, are changes that are not purely driven by language. They take different forms, partly determined by the needs or context of a given target group. Some adaptations are simple, such as changing Fahrenheit measurements to Centigrade. Others are more complex, depending also on the purpose of the question. Questions on health, for instance, may need to mention different symptoms for various cultures to determine the presence of the same complaint or illness across populations. In tests of knowledge, different questions may be needed to avoid favoring one population, and in skills and competence research, target-language versions depend heavily on adaptation. Visual components may be adapted to accommodate the direction in which material is read in a given culture or language. Some populations may be unfamiliar with questionnaires and need more navigational guidance and instructions. Careful adaptation helps researchers produce target-culture questions that will collect data comparable to that collected with the source questions.

Oral Translation and Interpreting

Sometimes surveys do not produce written translations but ask bilingual interviewers to translate orally from source-language questionnaires while conducting the interview. The limited research available on oral translation points to multiple differences between orally translated and written translations, thus raising questions about quality and comparability and, in turn, the reliability of the resulting data. Interpreted interviews, in which an interpreter mediates between interviewer and respondents, are a second underresearched form of oral translation. However, if a language does not have a written form, oral translation and interpreting are the only ways to interview respondents who understand only that language. Guidelines on interpreting are currently being developed by the U.S. Bureau of Census and the International Workshop on Comparative Survey Design and Implementation.

Last-Birthday Selection

Survey researchers are usually concerned with choosing respondents within households after households are selected randomly. Within-unit coverage and nonresponse are key issues, so researchers want to select the correct respondent and gain his or her cooperation. Each of these goals has costs. One popular quasi-random compromise is the last-birthday (LB) method of selecting respondents from within a sampled household in random-digit dialing surveys. It circumvents the pitfalls of pure or nearly pure random methods by being relatively quick, easy, and likely to secure cooperation. Probability methods can involve a potentially lengthy and intrusive process of querying the informant (person who answers the phone) about all household members eligible to be interviewed before selecting the correct respondent from the resulting list.

An example of LB question wording is, *In order to determine whom to interview, could you tell me, of the people who currently live in your household who are 18 or older—including yourself—who had the most recent birthday? I don't mean who is the youngest adult, but rather, who had the most recent birthday?* If the respondent does not know all the birthdays, the following question can be asked: *Of the ones you do know, who had the most recent birthday?* Some researchers have sought to study the best wording to choose the correct respondent and secure cooperation.

The first published description of birthday methods tested a next-birthday (NB) method, assuming that the incidence of births is random and the first stage of selection in a two-step process. The researchers, Charles Salmon and John Nichols, considered this method to be the second stage of sampling, with all members of a household having an equal probability of being chosen. After implementation, however, the researchers recommended use of a last-birthday (or most recent birthday) procedure because some respondents were confused about whom to nominate. LB now is used more frequently than NB because it appears that informants understand it better or are more likely to know past birthdays than upcoming birthdays.

Several studies show that births are not necessarily distributed randomly across months in some countries and that LB also tends to produce distributions of birthdays skewed toward the months closely preceding the interviews in households of two or more adults. Skewed distributions should not result in bias, however, unless birthdays are connected to interview topics. Another drawback is that informants in large households, compared with those in small households, are less likely to know everyone's birthday. LB tends to overrepresent females but may represent blacks and younger males better than do other procedures. Females may be overrepresented because they tend to answer the phone more frequently than males, and sometimes they may be "protecting" males from coming to the phone. Other times informants want to do the interview so they inaccurately report they had the last birthday.

It is important that informants understand the question because misunderstanding can lead to within-unit coverage problems, especially among the less educated, the foreign born, and larger households. Sometimes informants erroneously think that the interviewer wants the youngest household member. Interviewers also should ascertain the respondent's day and month of birthday to be sure they are speaking with the correct person. Stressing the need for scientific accuracy can improve the response rate. Research on the LB method indicates that the respondent has been nominated incorrectly between about 10% and 25% of the time. Intensive training of interviewers regarding the question and accuracy of respondent selection, especially in households of three or more persons, is likely to decrease the incidence of coverage mistakes. Some research on the LB technique shows that the inaccurately selected respondents did not contribute to biased results, whereas other research demonstrates some contribution to bias when certain demographic variables associated with incorrect respondent selection were related to specific substantive results.

LB can be more economical than, or comparable to, the Kish respondent selection technique (which is close to being a pure probability method) in length of contact with informants, interview length, and cooperation rates. LB can be a little less economical than nonprobability methods, including those that simply select the most available or willing respondent. This is because any technique that selects one and only one respondent in a household requires many more callbacks, on average, to contact that respondent than a technique that allows essentially anyone to be the respondent.

LEANING VOTERS

Leaning voters is a term in politics and survey research methods that has several meanings. The nominative application refers to voters who are not strongly affiliated with any political party, nor are they hard-core independents. They lean toward being a partisan of one stripe or another.

Another definition refers to voters who do not indicate that they are solidly supporting one candidate or another—but they do lean toward supporting a candidate. Related to this, a third definition is a verb: Researchers *lean* voters when they allocate undecided voters to one candidate or another through use of various heuristic or empirical methods. The term derives from how the two concepts are traditionally measured.

Candidate Support Measures

When researchers measure candidate support in pre-election polls, there usually are respondents who initially support a candidate and those who say they are undecided (or refuse to tell the interviewer). Many researchers follow up with these "no opinion" respondents, probing to determine whether they lean toward supporting a candidate. Then these leaners are combined with the firmer supporters, that is, the choosers, to report total support. Experience has shown that this is the most accurate way of determining candidate support. Using this measurement method, researchers can separately analyze the truly undecided, a candidate's strong supporters, and those who are leaners.

Party Identification Measures

Because party affiliation is a psychographic attitude or orientation, rather than a hard-and-fast demographic characteristic such as gender, age, race, or educational attainment, different partisanship measures can have a real effect on the proportion of partisans in polls and other sample surveys. There are several standard measures that enable researchers to partition U.S. voters into a continuum ranging from "strong Democrat" through "independent" to "strong Republican." One standard measure of party identification was developed by researchers at the University of Michigan for the National Election Studies:

> *Generally speaking, do you consider yourself a Republican, a Democrat, an independent, or what?*
>
> If respondents choose a party, they are asked if they consider themselves *a strong [Democrat/Republican] or a weak [Democrat/Republican].*
>
> Respondents who say they are independents are asked, *Do you think of yourself as closer to the Republican or Democratic Party?*

It is these independents—the ones who choose Republicans or Democrats at this point—who are typically labeled "leaners."

The Gallup Poll uses a similar measure, but frames the initial question, *In politics today* . . . . Most researchers now agree that the Gallup measure allows for more short-term variability in party identification. Other polls use variations of these two methods. For example, the Minnesota Poll asks everyone who does not initially choose a party whether they lean toward the Democratic Party or toward the Republican Party; this is simpler and quicker and has the effect of providing a somewhat less cumbersome 5-point scale and does not partition partisans into weak and strong.

However, limiting party affiliation measures to closed-ended questions also may shunt those who consider themselves aligned with third parties into the leaner or independent categories. In some cases, especially in states where there are strong third parties (e.g., Minnesota), or in national elections when there is a strong independent party candidate (e.g., Ross Perot in 1992), these closed-ended questions may not allow researchers the analytical power they need to understand the electorate properly.

This measurement issue is key to understanding the research about the behavior, demographics, and attitudes of leaning voters compared with true partisans and independents. Earlier in the 20th century, some scholars argued that leaners were similar to independents, and a good way to analyze U.S. political data was to talk about a trichotomy—Democrats, Republicans, and everyone else. This ignored third-party candidates, such as George Wallace in the 1968 presidential election, Ross Perot in the 1992 presidential election, and others in various state elections. More recently, some scholars have made a strong empirical argument that voters who lean toward one party or another ultimately behave more like true partisans than independents, who are less likely to participate in politics and more likely to have fewer strong attitudes about public policy issues. They also argue that true independents are a small—about 1 in 10—portion of the electorate. Practically, however, many, if not most, media pollsters default to the earlier typology when they report and analyze poll results: Democrats, Republicans, and everyone else.

In election forecasting that uses pre-election polls, especially in close elections, what pollsters do with leaning voters when making their forecasts often will contribute to a correct or incorrect prediction. As such, understanding how leaning voters are measured is key to journalists, media readers and viewers, and other political analysts.

Level of Analysis

A social science study using survey data can be set at the micro level when individuals are analyzed, or it can be set at a higher, more macro level when aggregates of individuals such as households, wards, precincts, firms, neighborhoods, communities, counties, provinces, states, or nations become the unit of analysis. This structural level, spanning the range from most micro to the most macro, at which a social scientific investigation is carried out is called *level of analysis*. A particular study may also cut across several levels of aggregation. For example, a multi-level study of the educational effectiveness of a certain education program may include pupil-specific, classroom-specific, school-specific, and school-district-specific information and analyze the data at each and all of the levels.

The choice of level of analysis should be driven by researchers' theory and, subsequently, their research questions. There are two large, contrasting issues of concern over why the level of an analysis must be carefully chosen and specified. The first is the famous issue, or the infamous problem, of the *ecological fallacy*, popularized by William S. Robinson in 1950. Simply stated, the ecological fallacy is an incorrect inference about individual or micro-level effects or relationships drawn by analyzing aggregate or macro-level data. Many theories are set at the individual level. However, it is easy to overlook the possible fallacy and study social relations in the aggregate because data are more widely available at that level.

The second issue is that of *emergent property*, which may appear when a number of simple entities (or individual actors or agents) operate in an environment, social or otherwise, forming more complex behaviors as a collective. Emergent properties are not reducible to the properties of the individual agents. This idea is attributed to Émile Durkheim in *The Rules of the Sociological Method*, initially published in French in 1895. The idea of emergent property is a potent and power one, and its influence can be found outside of the social sciences today. For example, researchers of artificial intelligence study the so-called emergent functionality. Put another way, a component has a particular functionality, which is not recognizable as a subfunction of the global functionality. For survey researchers, data collected at the individual level should not be aggregate in order to draw inference for a particular behavior at a higher level, which may be emergent.

Both the ecological fallacy and emergent property are important issues for survey researchers because the (primary) sampling unit of a survey sets a limit for the level of analysis a researcher wants to use. A sampling unit is the elementary unit that is sampled or selected for detailed examination, and valid statistical sampling requires that each sampling unit have a determinable nonzero chance of selection and that each be selected randomly. Statistical properties aside, sampling unit gives the level at which detailed information is acquired. For example, the General Social Survey (GSS) in the United States samples English-speaking individuals 18 years or older living in noninstitutional arrangements in the United States. Naturally, the GSS is most appropriate for analysis at the individual level.

All surveys on which individuals are interviewed are not at the individual level. For example, the Panel Survey of Income Dynamics (PSID) has household as the sampling unit. Even though it is the individuals who are interviewed, detailed information is available at both the individual and the household level. Similar surveys include the British Household Panel Survey (BHPS) and the European Community and Household Panel (ECHP). An analysis of the BHPS, ECHP, or PSID households should be as straightforward as an analysis of individuals using the GSS. An analysis of individuals from the BHPS, ECHP, or PSID, however, becomes trickier than one may think even though there is detailed information available for these individuals who are drawn from the households sampled by certain statistical principles because these individuals in the same household are no longer independent observations; they form clusters that deserve special statistical treatment.

Another example of surveys where the level is not set at the individual is the National Organizations Study (NOS). Even though the eligible establishments (or organizations) were initially identified through the 1991 GSS, the NOS sampled work organizations, with establishment as the sampling unit. Obviously, researchers analyzing the NOS data set the level of analysis at the organizational level. Clearly, the questions that get asked on a survey like the NOS will not be the same as those directed toward individual solo entrepreneurs because of emergent property in work organizations.

Finally, it is worth reiterating that the level of one's theory and that of the analysis must be consistent with each other. The proliferation of household-level surveys, together with the frequency in which data from such surveys are analyzed to answer individual-level questions, poses an interesting challenge for the survey researcher: Can household surveys be used to answer individual questions? The answer is a qualified "yes." The qualification comes in two ways: To the extent that dependence among members of the same household is recognized and handled properly, and to the extent that individuals' representation of the population is appropriate (if necessary, weighted), household surveys can answer individual questions because individuals are the ones who are interviewed individually, not collectively as a household. The last point also raises another question for survey researchers: How well can individuals represent households of which they are a member? That is a question for survey designers, and as such, it is beyond the issue of level of analysis.

Level of Measurement

Level of measurement refers to the relationship between the numeric values of a variable and the characteristics that those numbers represent. There are five major levels of measurement: nominal, binary, ordinal, interval, and ratio. The five levels of measurement form a continuum, because as one moves from the nominal level to the ratio level, the numeric values of the variable take on an increasing number of useful mathematical properties.

Nominal

Nominal variables are variables for which there is no relationship between the numeric values of the variable and characteristics those numbers represent. For example, one might have a variable "region," which takes on the numeric values 1, 2, 3, and 4, where 1 represents "North," 2 represents "South," 3 represents "East," and 4 represents "West." Region is a nominal variable because there is no mathematical relationship between the number 1 and the region North, or the number 2 and the region South, and so forth.

For nominal variables, researchers cannot compute statistics like the mean, variance, or median because they will have no intuitive meaning; the mode of the distribution can be computed, however. Nominal variables also cannot be used in associational analyses like covariance or correlation and cannot be used in regressions. To use nominal variables in associational analyses, the nominal variable must be separated into a series of binary variables. Only nonparametric statistical tests can be used with nominal variables.

Binary

Binary or "dummy" variables are a special type of nominal variable that can take on exactly two mutually exclusive values. For instance, one might have a variable that indicates whether or not someone is registered to vote, which would take on the value 1 if the person is registered and 0 if the person is not registered. The values are mutually exclusive because someone cannot be both registered and not registered, and there are no other possibilities. Like with nominal variables, there is no mathematical relationship between the number 1 and being registered to vote, but unlike nominal variables, binary variables can be used in associational analyses. Technically, only nonparametric statistical tests should be used with nominal variables, but the social science literature is filled with examples where researchers have used parametric tests.

Ordinal

Ordinal variables are variables for which the values of the variable can be rank ordered. For instance, a researcher might ask someone their opinion about how the president is doing his job, where *1 = strongly approve, 2 = somewhat approve, 3 = somewhat disapprove*, and *4 = strongly disapprove*. In this case, the values for job approval can be ranked, and researchers can make comparisons between values, for example, saying that someone who gives a job approval value of 1 approves of the president more than someone who gives a job approval value of 3.

However, a researcher cannot make exact mathematical comparisons between values of the variable; for example, it cannot be assumed that a respondent who gives a job approval of 4 disapproves of the president twice as much as someone else who gives a job approval of 2. Researchers can, however, compare values using "greater than" or "less than" terminology and logic.

The mode and the median can be computed for an ordinal variable. The mean of an ordinal variable is less meaningful, because there is no exact numerical "distance" between the number assigned to each value and the value itself.

Ordinal variables can be used in associational analyses, but the conclusions drawn are dependent upon the way that numbers were assigned to the values of the variable. For instance, reassigning the values of job approval such that "strong approval" is now a 5, "somewhat approval" becomes a 4, and so on, would change the sign of the correlation between job approval and another variable. Thus, the associational relationship observed between two variables is a by-product of both the way the ordinal variables were coded and the underlying relationships in the data. Technically, only nonparametric statistics should be used with ordinal variables, but the social science literature is filled with examples where researchers also have used parametric statistics.

Interval

With interval variables, distances between the values of the variable are equal and mathematically meaningful, but the assignment of the value zero is arbitrary. Unlike with ordinal variables, the differences between values assigned to the variable are meaningful, and researchers use the full range of parametric statistics to analyze such variables.

As with ordinal variables, interval variables can be used in associational analyses, but the conclusions drawn are dependent upon the way that numbers were assigned to the values of the variable. Interval variables can be rescaled to have a different value arbitrarily set to zero, and this would change both the sign and numerical outcome of any associational analyses. Parametric statistics can be used with interval variables.

Ratio

With ratio variables, distances between values of the variable are mathematically meaningful, and zero is a nonarbitrarily assigned value. Anything that can be counted—votes, money, age, hours per day asleep—is a ratio variable.

Values assigned to ratio variables can be added, subtracted, multiplied, or divided. For instance, one can say that a respondent who views 6 hours of television per day views twice as many hours as another respondent who views only 3 hours, because for this variable, zero is nonarbitrary. By contrast, one cannot say that 60 degrees feels twice as warm as 30 degrees, because 0 degrees is an arbitrary construct of the temperature scale.

With ratio variables, researchers can calculate mean, median, mode, and variance and can use ratio variables in the full range of parametric associational analyses, with meaningful results.

LEVERAGE-SALIENCY THEORY

Leverage-saliency theory, as first proposed by Robert M. Groves and his colleagues in 2000, is a unifying theory to help explain survey nonresponse, with the goal of helping to identify strategies to counter nonresponse.

Nonresponse is a critical challenge to survey research. Those who do not respond to surveys (or to parts of questionnaires) may differ in important ways from those who do respond. Leverage-saliency theory attempts to describe the underpinnings of individual behavior related to the individual's choosing to cooperate or not to cooperate with a survey request. The theory posits that different people place a different level of importance to various attributes associated with a survey request. These attributes are like weights on a scale, tipping the scale to the sample person either acceding to or declining a particular survey request. An implication of the theory is that the response propensity of any one person deciding to cooperate or not with a specific survey request will vary across different survey requests and that few people will always agree or never agree to participate when they are sampled for a survey.

This entry describes several key attributes of the survey request and how these interact in terms of their leverage, value disposition, and saliency to affect survey response. The entry includes suggestions as to how interviewers can tailor their requests to make more salient those attributes with the greatest amount of positive leverage for an individual from the sample. This entry describes the leverage-saliency theory in terms of an individual sample person. In theory, the ability to alter the survey request design in ways that make salient those request attributes, to which various subgroups give positive leverage, will aid in increasing response among subgroup sample members as well. However, in practice, this often is hard to achieve at a cost-acceptable level.

Leverage-Saliency: Tipping the Scale

It can be helpful to think of survey request attributes as weights on a scale. Each attribute has three qualities: (1) the distance to the scale's fulcrum (point of balance), (2) the sample person's disposition toward the attribute (ranging from positive to negative), and (3) the saliency of the attribute. The further the attribute of the survey request is to the scale's fulcrum, the greater the amount of leverage it exerts in the sample person's decision making. A strong amount of leverage for a survey attribute (e.g., the perceived value of an incentive) is helpful only if the disposition toward this attribute is positive. If the sample person perceives the attribute as negative (e.g., being insulted by being offered too low an incentive), then the increased leverage of the attribute may decrease the likelihood of responding. The leveraged force from any single request attribute can be exerted only when that attribute is made salient in the sample person's decision-making process. Thus, the goal of the survey researcher is to make salient those attributes that have the greatest amount of positive leverage for a sample person. This also holds for any subgroup of the sample (e.g., 18- to 34-year-olds) for whom the survey researcher makes salient some request attribute believed to be positively valued by the members of that subgroup.

In theory, researchers who are able to recognize and make salient the survey request attributes that a sample person values positively increase the likelihood of the sample person cooperating with the survey request, thereby increasing the response rate. The challenge is that the level of importance (i.e., the leverage) of the different request attributes that the sample person views as positive, in most cases, is unknown to the researcher. In addition, sample members may hold several different survey request attributes with varying leverages and dispositions toward these attributes in the balance of their decision-making process. Taken together, this causes survey researchers to face a serious dilemma in trying to stem nonresponse.

Common Attributes of Survey Requests

In almost all survey requests, the researcher presents several attributes to the sample person. First, the survey researcher typically makes the topic of the survey known (i.e., makes the topic salient) to the sample person early in the survey request. If the topic of the survey holds low leverage for the sample person, this may not be enough to tip the scales in favor of the person's acceding to the request. However, other attributes of the request may contribute to the decision-making process of the sample person. These additional attributes include the nature and amount of incentive for responding and other persuasive communications, for example, being told that the survey will help one's local government decide about how to improve recreational opportunities in one's community. By making one or more of these other attributes salient, the survey researcher's efforts may produce a cooperating sample person. The saliency of these other request attributes, however, must outweigh the sample person's perceived burden of completing the survey.

Another survey request attribute is the authority and prestige of the sponsoring organization. The perception that the sample person has of the sponsoring organization can vary widely. Some subgroups of respondents may view a survey request from the government or from an academic institution as legitimate, and the survey's saliency may contribute to tilting the scale toward their responding. On the other hand, respondents who are members of subgroups that have been alienated by the sponsoring organization may perceive the authority of the request with great suspicion or hostility. In this case, researchers who emphasize the authority of the sponsoring organization inadvertently may be making salient an attribute that may tip the scale toward not responding.

Survey researchers also use incentives in survey requests to encourage a sample person to respond. If a sample person views an incentive positively and with a great amount of leverage, making an incentive salient in the survey request may be the difference between a refusal and an acceptance to respond. Past research has found that the effects of incentives on survey response vary relative to the leverage-saliency exerted by other request attributes (i.e., an interaction effect). For example, studies have found that the effects of incentives decrease when topic leverage is high and the topic is made salient. In addition, some have theorized that survey participation, particularly when the sponsoring organization is a major societal institution like the government or local schools, invokes the norms of obligation to one's civic duty. Research has also found that among sample members who have a high level of community involvement, the effectiveness of incentives on survey response is dampened.

The reason for making the previously discussed survey request attributes salient and exerting what leverage they may have on the decision-making process is to counteract the weight of the perceived burden of the survey. If there is one survey request attribute known to all survey researchers to be a burden, it is sample members' perception that completing this survey is a burden on their time. The extent to which survey researchers can reduce the saliency of this perceived burden and increase the saliency of other attributes may extract enough positive leverage to tip the scales in favor of choosing to respond.

Implications for Survey Research

Researchers have tested the theoretical positions of the leverage-saliency theory and have found it to be a useful perspective for describing the behavior of sample members. From these empirical studies of the theory, several implications for survey research can be deduced.

First, sample members have many different reasons for accepting or declining a survey request, and these reasons are often unknown to the person making the survey request. The exception is when an interviewer learns, during introductory contact with a sampled respondent, what the particular respondent is concerned about and interested in.

Second, no one scripted introduction will meet the diverse needs and concerns held by a diverse sample of respondents as it is worded by the researchers. Thus, survey researchers must devise ways of learning to make salient those request attributes that provide the most positive leverage in the decision-making process of the individuals who have been sampled. Research has suggested that expert survey interviewers who are able to engage the sample person in an extended conversation, even if the conversation is not directly related to the survey request, are better able to gauge the sample member's potential concerns and interests by carefully observing the respondent's verbal and nonverbal behavior. Interviewers can then use this information to inform possible hypotheses as to what the concerns of the sample members are and thereby better consider how to tailor their verbal behavior to address these concerns. Through the act of tailoring the survey request, interviewers can be intentional in making salient those survey attributes that may allay the concerns held by the sampled person. Past research has shown that many interviewers can be trained to engage in these behaviors more effectively than what comes naturally to them without the training. This approach to interviewing is sometimes called refusal avoidance training.

The use of tailoring a survey request to address the potential concerns of a sample person is demonstrated as follows. If a survey interviewer approaches a sampled person with a request to complete a survey focusing on illegal drug behavior, the survey interviewer may attempt to gauge how important privacy is to the sampled person and to then make salient the privacy features of the survey request (e.g., the use of computer-assisted self-interviewing equipment). An in-person survey interviewer may pick up on the sampled person's cues regarding personal privacy by noticing if the curtains to the home are open to the street, if the person checks to see who is at the door before opening it, and if the person appears guarded in the presence of the survey interviewer. These may be clues used by the survey interviewer to conclude that privacy holds great leverage by the sampled person and that making the privacy precaution attribute of the survey request more salient will increase the likelihood of the sampled person to accede to the survey request.

A final consideration for the application of leverage-saliency theory applies to panel designs, whereby the same respondents are contacted over time to participate in the survey for more than one wave of data collection. Experience with the respondent from previous waves, including both contact information gleaned from call or contact history data and answers the respondent provided to previous questionnaires, could be used to help tailor the next survey request so as to make it especially salient to the targeted respondent.

Likely Voter

A likely voter is someone who is registered to vote in an upcoming election and is deemed likely to vote in that election, for example, by pollsters trying to forecast the election outcome. Pre-election pollsters face a unique challenge. At their most germane, they seek to sample a population that is unknown and indeed technically unknowable, because it does not and will not exist until on and around Election Day; this population is the voting public. For a survey that seeks to measure the attitudes and intentions of voters in a given election, the only recourse is to estimate this population through a process known as *likely voter modeling*.

There are no fixed rules for likely voter modeling, and techniques vary. But all begin with a similar approach, using known or self-reported information, or both, about respondents—for example, actual or self-reported voter registration status, actual or self-reported voting history, self-reported interest in the campaign, and self-reported intention to vote—to determine their likelihood of actually participating in the coming election. More controversially, some also may use weighting adjustments for political party affiliation or for demographic targets drawn from exit polls or other sources.

There are three main types of likely voter modeling: (1) screening, (2) scaling, and (3) probability (propensity) modeling. In screening, respondents are identified as likely voters on the basis of their answers to a series of questions. In scaling, or cutoff modeling, qualification requires selected answers to, say, any five of eight questions. The third approach employs a probability model to build a probable electorate in which each respondent is assigned a weight (which can range from 0 to 1) reflecting her or his estimated likelihood of voting.

In the first two approaches, respondents are either classified as "likely voters" and included in the sample, or as "nonvoters" and excluded; in the third, all respondents are included, but with varying weights. Results are identified as representing the views of "likely" or "probable" voters and, in some cases, are distilled further to "certain" or "definite" voters.

Some polling organizations use a single, pre-established likely voter model; others run several models, assessing results across a range of scenarios positing differing levels of voter turnout and then investigating differences across models when they occur. To some extent, all likely voter models involve human (professional) judgment as to the elements they include, the turnout level or levels they anticipate, and the weights applied; at the same time, they are empirically based and ultimately tested (and ideally are later refined) against the actual election outcome.

Likely voter modeling is fraught with hazard. As easily as estimates are improved by good modeling, they can be worsened by poor modeling, for example, through the inadvertent inclusion of nonvoters, the exclusion of actual voters, or both. Poor likely voter modeling is the likeliest cause of inaccurate final estimates in otherwise rigorous pre-election polls.

Poor modeling can negatively impact results well before the final estimate. Ill-conceived likely voter models can introduce volatility in estimates—swings in candidate support that do not reflect actual changes in opinion but rather changes in the characteristics of respondents moving into and out of the model. The goal of good likely voter modeling is to report real changes, not changes that are an artifact of the model itself.

Likely voter modeling increases survey expense (or decreases effective sample size) because it requires discarding or weighting down interviews with nonvoters. To avoid this downside, while still claiming to produce a likely voter survey, some pollsters use weak or lightly screened models that include an unreasonable number of nonvoters. Weeks or months before Election Day, these estimates cannot be held to account by actual results, but they can produce different estimates in different surveys, making variations in models look like volatility in the electorate.

Indeed, one useful way of evaluating a likely voter model is to compare the turnout level it estimates with reasonable expectations for that election. For example, a model that includes 55% of the general population as likely voters in a primary election where anticipated actual turnout is 15% would be a poor one. However, even models that winnow down to an appropriate turnout level may miss the mark by misstating the size of key population groups within the electorate (e.g., senior citizens, African Americans, or women) or the voter preferences within these groups.

In random-digit dialing sampling, a best-practice approach is to interview unlikely voters to obtain sample-balancing demographics to use in weighting, enabling likely voters to be calculated as a subset of the full census-weighted data set. In registration-based sampling, adequate full-population weighting parameters generally are not available. Those data may be unweighted, or weighted to other data, commonly exit poll results from previous, supposedly comparable elections. Estimates from surveys weighted in this fashion can be vulnerable to differential turnout among population groups from election to election. On the other hand, adjusting likely voter data (either obtained via random-digit dialing, registration-based sampling, or a combination of the two) to an empirically based estimate of political party allegiance may compensate for sampling "noise" expressed as trendless night-to-night variability in party identification.

Polling organizations tend to switch from general population or registered voter samples to likely voter modeling over the course of the last few months before Election Day, in an effort to sharpen their estimates by limiting their samples to the most relevant population that can be identified. These polls ask respondents whom they would support "if the election were held today." The election, of course, is not held that day, and that day's likely voters may or may not participate as actual voters on the real Election Day. Nonetheless, within the confines of what these polls attempt to measure, likely voter modeling is a necessary effort—and a largely successful one, given the usual accuracy of final estimates in good-quality pre-election polls.

Likert Scale

The Likert scale, named for Rensis Likert (pronounced "lick-urt") who published a seminal report describing its use, possibly is the most widely employed form of attitude measurement in survey research. Similar to nearly all psychometric scale measures, the Likert scale consists of multiple items that typically are summed or averaged to produce a more reliable measure than could be obtained by use of a single item.

The Likert scale is a special type of the more general class of *summated rating scales* constructed from multiple *ordered-category rating items*. Its distinguishing characteristics are as follows:

- Each item uses a set of symmetrically balanced bipolar response categories indicating varying levels of agreement or disagreement with a specific stimulus statement expressing an attitude or opinion (e.g., *Ripe cherries are delicious*).
- The response category points for each item are individually labeled (e.g., *Strongly Agree, Agree, Disagree, Strongly Disagree*).
- The descriptive text of these labels is chosen so that gradations between each pair of consecutive points seem similar.

This sense of equidistance often is reinforced by a set of consecutive integers (e.g., 1, 2, 3, 4) used to label each alternative along the continuum of choices. Although in technical terms, the response format used for Likert scale items is at the ordinal level of measurement, researchers traditionally have used parametric statistics (which assume at least an interval level of data) to analyze Likert scales.

It is commonplace for researchers to use the term *Likert scale* incorrectly. The term often is used to refer to an individual item or the response choice set featured by the items. These usages are improper. Rather, a Likert scale is a multi-item measure, each item in a Likert scale is known as a *Likert item*, and the response categories of a Likert item are known as a *Likert response set*.

Likert response sets may include four or more points, though five categories are traditional. Typical wording labels for the five categories are *Strongly Agree, Agree, Neither Agree Nor Disagree, Disagree*, and *Strongly Disagree*, though certainly other descriptors indicating varying levels of agreement and disagreement are used. Though a five-category set is most frequently employed, many psychometricians advocate using response sets of seven, nine, or even eleven points. Others prefer an even number of response choices, eliminating the neutral alternative to force a positive or negative expression of attitude. Use of four or six categories is the norm when an even number is offered.

Choosing the number of points featured by Likert items should not be driven by personal preference or simply whether one judges it appropriate to prevent fence-sitting by using a forced-choice response set with an even number of response options. Rather, the reliability of Likert scales can be affected by the number of response categories. In situations where low scale score variability is expected, reliability generally can be improved by employing greater numbers of categories. In contrast, when opinion toward the topic is widely divided, scale reliability is largely independent of the number of categories.

Although true Likert items use a symmetrically balanced agree–disagree continuum for individually labeled response choices, several other types of ordered-category items are often and incorrectly referred to as Likert scales or Likert items.

In Table 1, examples A and B are true Likert items; example C is not. More accurately, example C is an ordered-category rating item with the Likert-like properties of a bipolar and balanced response set (reinforced with sequential numbers). It is not a Likert item because the respondent does not indicate degree of agreement with a stimulus attitude statement; rather, the respondent is asked to indicate a level of satisfaction or dissatisfaction with a characteristic of some object or entity. Likewise, neither example D nor example E is a Likert item. Though the descriptive labels in example D are bipolar, they are not constructed using negation to achieve balance, and they do not ask for agreement with a stimulus attitude. In example E, the response choices are neither bipolar nor balanced and do not refer to a stimulus attitude statement. Each is an example of a generic ordered-category

Table 1 Likert versus Likert-like items

A. I think the president has been doing a wonderful job while in office.

Strongly Disagree	Disagree	Neutral	Agree	Strongly Agree
☐	☐	☐	☐	☐
1	2	3	4	5

B. I feel safe walking alone in my neighborhood at night.

Completely Agree	Mostly Agree	Somewhat Agree	Somewhat Disagree	Mostly Disagree	Completely Disagree
☐	☐	☐	☐	☐	☐

C. How satisfied or dissatisfied are you with the reliability of this product?

Very Satisfied	Somewhat Satisfied	Neither Satisfied nor Dissatisfied	Somewhat Dissatisfied	Very Dissatisfied
☐	☐	☐	☐	☐
1	2	3	4	5

D. Compared with adults in general, how would you rate your own health?

Excellent	Very Good	Good	Fair	Poor	Very Poor
☐	☐	☐	☐	☐	☐
1	2	3	4	5	6

E. When you drink coffee, how frequently do you choose to drink decaf coffee?

Never	Rarely	Occasionally	Often	Nearly Always
☐	☐	☐	☐	☐
1	2	3	4	5

F. Choose the one box along the continuum between each pair of antonyms that best describes how you view the service representative who assisted you.

Rude	1	2	3	4	5	6	7	Polite
Intelligent	1	2	3	4	5	6	7	Stupid

rating item. Similarly, neither item in the set shown as example F is a Likert item. Although the response choices are bipolar, they are not individually labeled and no attitude statement is referenced for agreement or disagreement. Rather, each item is known as a *semantic differential* or, especially when the sequenced numeral reinforcement is omitted, a *discrete visual analog scale* item.

Likert items and their corresponding Likert scales are subject to response distortions. Central tendency bias may result from respondent reluctance to select extreme response categories. Acquiescence bias can result when respondents choose to agree with statements because of a desire to choose what they believe is the "correct" or otherwise most appropriate answer. Similarly, social desirability bias may result when respondents attempt to portray themselves or an organization to which they belong in a favorable light. Researchers typically try to attenuate these effects by varying attitude statements so that some are expressed in a positive form while others are expressed in the negative.

After data collection, Likert items may be analyzed individually, or the value scores observed among theoretically related items may be summed or averaged to create a Likert scale. Though it is common to treat a single Likert item's observations as interval level data, it is more conservative to view such data as ordinal; the assumption that all respondents perceive differences between adjacent levels as equidistant is a tenuous one, particularly when smaller numbers of response choices are involved. When treated as ordinal data, Likert item results can be analyzed using nonparametric tests or chi-square tests of association. Likert scale data may be treated as interval data measuring a latent variable, and if relevant assumptions are met, parametric statistical tests (e.g., analysis of variance) can be applied. Finally, data from Likert items or scales sometimes are reduced to the nominal level by combining all agree and disagree responses into one of two corresponding categories (e.g., "accept" vs. "reject"). When this transformation occurs, a chi-square or McNemar test is the statistical procedure typically applied.

List-Assisted Sampling

List-assisted sampling is a technique used in telephone surveys, which utilizes information from the Bell Core Research (BCR) telephone frame and directory listings to produce a simple random sample. This is accomplished by stratifying the BCR telephone frame into two strata. The high-density stratum consists of 100-banks that contain at least one listed number, and the low-density stratum consists of hundreds of banks without a listed number. The proportion of the sample drawn from each stratum depends on the requirements of the study. This technique started to be widely used by telephone survey researchers in the early 1990s because it increased the efficiency of traditional random-digit dialing (RDD) methods, in particular, the Mitofsky-Waksberg method. List-assisted sampling helps to provide a solid foundation, as well as lending statistical justification, for increasing the efficiency of the sample while not sacrificing coverage. As a result, this sampling technique is used widely by telephone researchers to reduce costs and shorten the data collection period. List-assisted sampling can be done in a few different ways, namely, by (a) dual frame design, (b) directory-based stratification, and (c) directory-based truncation. There are some slight biases associated with list-assisted samples in that those 100-banks without a listed number will contain some residential numbers but are not as likely to be included in the sample. However, these biases are minor when compared to other samples with a more complete sample frame, especially when the gains in efficiency are taken into account.

Impetus for a New Method

In the United States, only 20% of all possible telephone numbers are assigned to a residence. This produces problems for researchers conducting surveys with the U.S. population via telephone in that the amount of work that would be needed for interviewers to cull through all the phone numbers in the country is enormous. A telephone sample with only 20% of the numbers reaching the targeted household is extremely inefficient, and as a result, the survey costs increase as does the length of the field period. There have been various sampling methods used in the past to address this problem, but by far the best known is the Mitofsky-Waksberg method. Introduced in the late 1970s, the Mitofsky-Waksberg method of RDD takes advantage of the fact that residential numbers are often clustered together consecutively in the BCR telephone database, which contains information on telephone exchanges and their geographical mapping throughout the United States. By drawing a sample of 100-banks, which consists of the area code, the prefix, and first two digits of the four-digit suffix, and then dialing a randomly selected number within these banks to determine whether residences are contained within the bank, the Mitofsky-Waksberg method culls the nonresidential sample at a much more efficient rate. A 100-bank will only be retained if the random number that is dialed is indeed a residential number; otherwise, the 100-bank is discarded. Once the 100-banks are chosen, then the telephone numbers are generated by assigning a random two-digit number to the end of the 100-bank exchange.

The two-stage RDD sample design is not without its problems, however. First, some clusters of 100-banks may not contain the minimum number (k) of residential numbers required for that bank. Hence, this greatly slows down the efficiency of calling, as all numbers in this bank must be called in order to meet the minimum number of phone numbers. Second, determining the residential status of a number by simply dialing that number is not necessarily a foolproof method. Often the status of the number will be unknown, and the cluster may be rejected erroneously during the first stage of the sample design. Also, the person responding to the initial phone call may regard the number as a residential number, when in reality it may be something other than a residential number, which would then mistakenly make the 100-bank eligible for inclusion. Third, each cluster must be monitored throughout the field period to ensure that k numbers are sampled from the cluster. This is a great drain on resources and often results in longer field periods as cluster yields may only become apparent later on in the data collection period. Further, numbers used as replacements for nonresidential numbers within a given cluster will not receive as many chances for resolution as those numbers identified as residential numbers early on in the field period. Lastly, the most cumbersome problem with the Mitofsky-Waksberg method is the two-stage cluster design it utilizes, which increases the variance of the estimates when compared to a simple random or stratified design. As these problems made themselves more apparent over the course of experience with telephone surveying in the 1980s, a new method was sought.

Directory-Based Sampling

With the rise of national directories of the listed numbers in the United States (e.g., White Pages, MetroMail), calling efficiency was greatly increased. Sample designs could be based on a one-stage selection procedure from these national directories, and only a very small percentage of numbers would be found to be nonresidential, depending on how often the database was updated. While this provided researchers with a purely residential sample, it also excluded numbers that were unlisted residences. This increased the problem of coverage error in telephone surveys. This presented a problem to survey researchers as they realized that not only were they excluding these unlisted residential numbers from the sample frame, but households vary significantly based on their decision to list their phone number. This pressing problem gave rise to list-assisted sampling, which sought to preserve the efficiency associated with the directory-based sampling but also to increase the amount of coverage to something close to the Mitofsky-Waksberg method.

List-Assisted Sampling

To produce a sample frame that utilizes the best in coverage from the Mitofsky-Waksberg method while maintaining the efficiency seen in directory-based sampling methods, the sample frame information used in both of these methods needs to be combined. By enumerating the numbers of the BCR frame and matching these numbers to the directory of listed numbers, researchers are able to establish the listed status of each number on the BCR frame without dialing a single digit. Once the listing status of each number is known, researchers can then draw a sample of numbers directly from the BCR frame, without utilizing a two-stage design. There are three predominant ways of producing a list-assisted sample frame: (1) the dual frame design, (2) directory-based stratification, and (3) directory-based truncation.

Dual Frame Design

In the dual frame design a RDD sample is selected from the BCR frame, and a sample of telephone numbers is selected from the directory frame. These frames are then fielded independently of each other. The efficiencies gained by using a directory-based sampling frame are balanced with the coverage offered by the BCR frame. However, there are problems with this approach. First, the BCR frame still contains all of the problems that were associated with the Mitofsky-Waksberg method: unknown residential status, clustering, inclusion of empty hundreds blocks, and so on. Second, combining the two samples into one data set provides a whole new set of estimation problems. Ideally one would use a one-stage sampling procedure based on a single frame.

Directory-Based Stratification

The directory-based stratification method is a one-stage sample based on the BCR frame with the listed status of each number obtained by comparing the frame to the directory. Once the listed status of each phone number is known, the BCR frame is separated into two strata. The first stratum contains 100-banks with at least one listed number, known as the high-density stratum, and the second stratum contains 100-banks without a listed number, known as the low-density stratum (in this case *density* refers to residential status, not listed status). Phone numbers are then randomly selected from both strata; however, more numbers are usually drawn from the high-density stratum to increase the efficiency of the calling effort. Ultimately, it is up to the researcher, based on the needs of the data collection effort, which percentage of the final sample is drawn from the high-density stratum versus the low-density stratum. Again, the give-and-take between efficiency and coverage play a key role in the decision-making process.

Directory-Based Truncation

Another way to implement a list-assisted sample is to use the truncated design. After the banks are divided into high- and low-density strata, the low-density stratum is dropped entirely. This dramatically improves the efficiency of the dialing; however, the coverage error is increased as a result of the loss of some residential numbers in the low-density stratum. It has been estimated that 55% of all numbers contained in a high-density stratum are residential, given the tendency of residential numbers to be clustered together. However, only 3% to 4% of telephone numbers in the low-density stratum are residential numbers because there are far fewer 100-banks that contain residential numbers but no listed numbers. Hence the bias associated with directory-based truncated designs is only slightly higher when compared to designs that draw sample from both strata.

Bias in List-Assisted Samples

List-assisted samples overcome many of the problems they were designed to conquer. They are much more efficient than traditional RDD methods, while still maintaining the necessary coverage to produce a truly representative sample. In addition, these samples consist of one-stage sampling, which avoids the problems associated with the clustering of 100-banks and assures that all 100-banks have a chance to be selected into the sample frame, albeit some are more likely to be included than others. However, researchers have shown that some bias still is present in list-assisted samples.

By comparing a list-assisted sample using a truncated design to a pure EPSEM (equal probability of selection method) sample drawn from the BCR frame, small differences between the two samples become apparent. When these two samples are compared, no statistically significant differences in measures of sex, race, age, or geographic region emerge. There is a slight difference in education level, where those with higher education are found to more likely be contained in the high-density stratum; however, this is not significant either. Estimates of urban/rural designation are also slightly different, with households in rural areas underrepresented in the high-density stratum. It should also be noted that people who move often will likely be assigned telephone numbers in newly opened 100-banks and therefore will be more likely to be in the low-density stratum due to the lag time in updating the directory listing.

Implications

List-assisted sampling has greatly improved the efficiency of field work with regard to large, random-selection telephone surveys. By incorporating the directory listings into the BCR frame, researchers have found that the problems associated with each frame individually can be overcome when these two frames are combined. No longer beholden to the Mitofsky-Waksberg method of RDD sampling, telephone surveys have been fielded much more quickly (and at less cost), and as a result, study findings have been released to the public (or client) earlier. Increasing efficiency in telephone surveys is not just a matter of saving money but also of maintaining relevance in a fast-paced research world. Undoubtedly the next innovation in telephone sample design will prove to be even more efficient in the future.

Listed Number

A listed telephone number is one that can be retrieved from a telephone company's directory assistance service, and it also may be published in a local telephone directory. The majority of U.S. residential landline (wired) telephone numbers are listed, but a growing proportion are unlisted—more than 40% as of 2008. There is no equivalent concept of "listing" that applies to cell phone (wireless) numbers in the United States, as there are no directory assistance services or telephone directories that are publicly accessible that contain cell phone numbers.

Whether or not a landline telephone number is listed is predictive of the likelihood that a completed interview will be attained with that household in a telephone survey. A greater proportion of interviews are completed with numbers that are listed than are completed with unlisted numbers. There are two primary reasons for this. First, those people who list their telephone number, in general, are more positively disposed to cooperate when they are reached for a telephone survey, compared to those with unlisted numbers. Concern about privacy is one of the factors that explain this. The demographic correlates of whether or not someone lists their number also are related to this, as minorities (who generally have lower cooperation rates in surveys) are less likely than are whites to have a listed landline number.

Second, almost all listed numbers also have an address associated with them. As such, researchers can send advance mailings to these households when they are sampled for a telephone survey to alert them ("warm them up") to the fact that an interviewer will be calling them. Advance letters with as small an incentive as $2 have been found to raise cooperation rates by approximately 10 percentage points in general population telephone surveys in the United States.

On average, listed telephone numbers require fewer callbacks than unlisted numbers for them to reach a proper final disposition. Thus, the calling rules used by a survey center to process listed numbers should differ from the rules used to process unlisted numbers. However, unless a survey center has their telephone samples screened for listed versus unlisted status or received this information for each number in their sample from their sample vendor, it will not be possible for them to take the listed versus unlisted status into account as their computer-assisted telephone interviewing system processes the callback attempts.

List-Experiment Technique

The list-experiment technique is a survey measurement technique that uses an experimental design to measure a sensitive topic in a way that circumvents much of the questionnaire-related and respondent-related measurement errors that may result from using other methods due to the biasing effects of social desirability and privacy concerns. For example, in 2007, a study using the list-experiment technique reported that more than one fourth of Americans (26%) would be "upset or angry" if the country were to elect a female president. This percentage was much higher than what had been reported previously about the magnitude of this concern from surveys that used more standard (nonexperimental) measurement techniques.

In its simplest form, the list-experiment randomly assigns a sample of respondents to one of two groups: a control group and a treatment group. The control group is exposed to a questionnaire version in which they are asked to consider a list of statements that may or may not apply to them; then they are asked to report "how many" of the statements apply. They are not asked to indicate which of the statements in the list apply, but merely to indicate the total number of statements that apply. For example, if there are four statements, then a control group respondent merely provides an answer from "zero" to "four." In contrast, the treatment group is exposed to a different version of the questionnaire in which they are asked to consider the same statements, but the list they are given includes one more statement than the list given to the control group. Neither the control group nor the treatment group is aware that they are being exposed to a different list. The treatment group is not asked to indicate which statements apply but merely to give the total number of statements that apply. If, for example, the control group is given four statements, then the treatment group is given a list with the same four statements plus one additional (fifth) statement. This additional statement is about the sensitive issue that the researchers are trying to measure accurately.

By comparing the average answer given by the respondents in the treatment group with the average answer given by the control group respondents, the researchers have an unobtrusive way of estimating how many people in the target population the sensitive issue applies to. Because this technique is used when a controversial or otherwise sensitive issue is being measured, there are reasons for the researchers to be concerned if the issue were asked about directly. The concern is that if that were to happen, a reduced proportion of respondents (i.e., biased on the low side) would be identified as having the issue applying to them.

For illustration purposes, imagine that a researcher was interested in measuring whether or not a person had a handgun in his or her home. Asking this question directly in a survey would likely yield biased data because of social desirability and privacy effects. Using the list-experiment technique, the researcher would randomly assign respondents to one of two versions of the questionnaire. One version, the control condition, could contain the list of items shown in Table 1. The other version, the treatment condition, could contain the list of items shown in Table 2. The sensitive item added to the list in Table 2 is *I have a handgun at home*.

The ordering of these items in the two questionnaires should be randomized so that not all respondents are exposed to the same order. In this example, imagine that the researcher found that the respondents in the control group who were exposed to the four statements shown in Table 1 gave an average answer of 1.8, meaning that on average approximately two of the four items applied to them. In contrast, imagine that in this example the respondents in the treatment group who were exposed to the five items gave an average answer of 2.3. The difference between the two group means is $2.3 - 1.8 = 0.5$. Taking this difference (.5) and multiplying it by 100 indicates that 50% of the respondents in the survey have a handgun in their home. This follows from the fact that a controlled experiment was deployed in which the only difference between the two randomly assigned groups of respondents was that the treatment group was

Table 1 Items shown to control group

I went to the grocery store in the past 7 days.
I went to a movie theater in the past 30 days.
I took money out of an ATM yesterday.
I have a high-definition television at home.

Table 2 Items shown to treatment group

I went to the grocery store in the past 7 days.
I went to a movie theater in the past 30 days.
I took money out of an ATM yesterday.
I have a high-definition television at home.
I have a handgun at home.

exposed to one more item in the list than was the control group. Given that this is a design with strong internal (cause-and-effect) validity, the researchers can be confident about the findings.

As powerful as it is in improving the accuracy of measuring sensitive survey topics, the list-experiment technique has a methodological flaw of its own and also has a major analytical disadvantage associated with it. The flaw comes about because anyone in the treatment group who is shown the list with the sensitive issue and for whom all the statements apply is disclosing that fact by giving an answer that equals the total number of items in the list. In the handgun example in Table 2, anyone who says "five" is known to have a handgun. This may cause some people who should answer "five" to instead answer "four" to not allow the interviewers and researchers to know for certain that they have a handgun. Because of this flaw, the list-experiment technique likely yields an underestimate of the prevalence of the sensitive characteristic. A way to reduce the impact of this flaw is for the researchers to make certain that the list of statements shown to everyone contains at least one nonsensitive statement that has an extremely low rate of occurrence. If this is done, there will be very few respondents in the Treatment Group who are put in the position of responding with an answer that gives away that the sensitive statement applies to them.

Analytically, because respondents merely answer with the number of statements that apply, as opposed to indicating which statements apply to them, researchers cannot do analyses on the sensitive item itself at the level of the individual respondent. This is due to the fact that they cannot know whether the individual respondent possesses the sensitive characteristic, except in the case of two types of respondents. In the previously mentioned handgun example, only for people in the treatment condition who answered "five" can it be known for certain that they have a handgun at home and only for those who answered "zero" can it be known they do not have a handgun at home. All others who answered anything other than "five" or "zero" may or may not have a handgun. As such, analyses (e.g., multiple regression) about which of the respondents have handguns, and why, cannot be conducted. Group-level analyses can be conducted, for example, analyses that indicate which demographic characteristics are more likely to correlate with possessing the sensitive characteristic, but not individual-level analyses.

Despite these disadvantages, the list-experiment technique provides researchers with a powerful method to avoid most of the major biasing measurement effects that can and often do result when more direct survey questioning is used to measure sensitive issues.

List Sampling

List sampling is one of the basic ways that survey samples can be created. The basic concept of list sampling is deceptively simple. The process is to choose a subset of the elements (the sample) from a listing of all elements (the sampling frame) using a specific selection process. The selection process may have several features, for example, sampling with replacement or sampling without replacement.

In list sampling, as in other sample selection processes, issues arise about whether the sample estimate is an unbiased and reliable estimate for the characteristic or attribute in the full list of elements. Bias and reliability are measures of how well the estimator for the attribute computed using list sample data corresponds to the true value for the attribute in the full list.

Bias is the difference between the true value and the expected value of the estimator. A specific estimator can be determined to be unbiased or nearly unbiased on the basis of sampling theory for the estimator and the sampling process, but the bias cannot be estimated explicitly from a sample.

Reliability is a measure of the reproducibility of the estimate from the sample over repeated application of the sampling process with the same sample size from the same list. The sampling variance is a commonly used measure of an estimate's reliability. Unbiased estimation of the sampling variance requires that (a) every unit in the list has a known, positive chance of being selected (i.e., the unit selection probability is greater than zero) and (b) every pair of units has a positive chance of being in a sample (the joint selection probability for any pair of units is greater than zero).

List sampling can be performed incorporating a number of different sampling processes depending on the analysis objectives for the sample, the information available for each unit in the list, and data collection procedures. As examples, list sampling can be configured as either single-stage or a multi-stage sampling and with or without stratification.

Single-Stage List Sample

The most basic approach to list sampling is an unrestricted simple random sample, which uses a random, equal-probability selection to identify a subset of units on a list for the sample (for a sample size of *n*, all possible combinations of *n* units on the frame have the same chance of being selected). The advantage of this type of list sampling is the ease of use: It can be done using a random number generator on a spreadsheet. The primary disadvantage is that the distributional characteristics of some samples will differ substantially from the distributional characteristics of all the elements in the sampling frame. As an example, a researcher requires an estimate of the percentage of children in a specific State Children Health Insurance Program (SCHIP) who had immunizations in a specific year. The sampling frame is the listing of children served in a specific state by SCHIP during the year. Using an unrestricted simple random sample, a valid random sample may contain only girls or children of a specific age. Although the chances of such samples are extremely small, unrestricted sampling random sampling will allow such samples.

A stratified random sample can avoid such uncharacteristic samples by imposing some control on the sample. Using information on an attribute for each element in the list, this information can be used to define explicit or implicit strata. *Explicit stratification* partitions the full list into two or more mutually exclusive parts; for example, the list of SCHIP children can be partitioned by gender: girls and boys. The number of units selected can be proportionally allocated relative to the number of elements in each stratum, or some of the strata may be assigned a proportionately larger sample size than other strata.

Implicit stratification produces a similar result but does not specify a sample size to each stratum. It requires (a) sorting the sampling frame by the attribute for all elements in the list and (b) the use of a sequential selection process to select the sample. A sequential selection process requires that each element be considered in the order that it occurs in the list and a probabilistic decision is reached for each element concerning the element's inclusion in the sample. With equal probability sequential selection, the sample will be approximately proportionally allocated to each implicit stratum and each sample element would have the same selection probability. For example, implicit stratification with the list of SCHIP children would have the list sorted by gender and then the use of an equal probability sequential selection process to select the sample. The proportion of girls and boys in the sample would closely match the proportion of all girls and boys in the original list.

Explicit and implicit stratification can be used in tandem to control on multiple factors. For example, a list sample of SCHIP children can be explicitly stratified by gender and then implicitly stratified by a second factor (such as age) to further control the characteristics of the sample. Such a sample would contain a specific number of girls and boys. In addition, the age distribution of girls (or boys) within the sample will closely match the age distribution of girls (or boys) in the sampling frame. The advantage of explicit and implicit stratification is that the characteristics of the elements in the sample can be controlled to reflect the distribution of key characteristics of the elements in the sampling frame or, in the case of explicit stratification, to allocate more (or less) sample to individual strata. The disadvantages are that data on the characteristics need to be available for essentially all elements in the sampling frame, and, if the sample is disproportionately allocated to the strata, the sampling variance (computed using the sample weights) for the estimates based on the sample may be increased relative to the sampling variance for an unrestricted simple random sample.

Multi-Stage List Sample

In some surveys, face-to-face interviews may be required or the elements on a list may fall into natural clusters, such as boxes of papers. When face-to-face interviewing is required, it can be cost efficient to form clusters of elements in the same geographic area and assign field interviewing staff to collect the data from all or a sample of elements in the cluster. For example, clusters of SCHIP children can be formed using the zip code or county of residence. A sample of clusters and then all or a sample of the children would be selected.

Explicit and implicit stratification and equal or unequal probability of selection can be used for the selection of both the clusters and the elements within the clusters.

LITIGATION SURVEYS

Litigation surveys are surveys that are used in legal proceedings. Like surveys in nonlitigation contexts, they measure opinions, attitudes, and behavior among representative samples of the general public, consumers, employees, and other populations. They afford a useful mechanism for collecting and evaluating opinions or experiences of large groups of individuals bearing on disputed issues in civil and criminal lawsuits. When administered by independent persons who qualify as court expert witnesses in survey methodology by reason of their knowledge, experience, and education, these group assessments may provide more trustworthy information on legal questions than the testimony of a handful of witnesses chosen by an interested party.

State and federal courts throughout the United States now regularly admit survey evidence. However, before 1963, survey respondents' statements were considered *hearsay* (i.e., statements made outside of court, which are offered to establish facts), and such data were disallowed by many American courts. In 1963, the U.S. District Court in *Zippo Manufacturing Co. v. Rogers Imports, Inc*. [216 F. Supp. 670, S.D. N.Y.] recognized that survey evidence fit within certain exceptions to the hearsay rule (i.e., the "expert opinion" exception and the "state of mind" exception), essentially removing the hearsay objection as a bar to the introduction of survey evidence in U.S. courts. Today, surveys also have achieved the status of admissible evidence in legal proceedings in other countries as well, such as Canada, the United Kingdom, France, and Germany.

Litigation surveys provide evidence on a multiplicity of issues and now are used routinely in court as well as for the alternative resolution of civil disputes through mediation and arbitration. Public opinion surveys, consumer surveys, and employee surveys represent the most common forms of surveys for litigation.

Public Opinion Litigation Surveys

In the criminal law context, public opinion surveys are frequently used by defendants in highly publicized criminal cases, such as the Polly Klaas case (e.g., *People v. Richard Allen Davis*), to support motions for change-of-venue due to prejudicial pre-trial publicity. Change-of-venue surveys sample potential jurors in the jurisdiction where a criminal case is pending, measuring their exposure to pre-trial publicity (e.g., whether respondents have heard about the pending matter, and if so, what they have heard) and the potential for prejudice (i.e., whether respondents have formed opinions about the guilt or innocence of the defendant, or "pre-judgments"). To determine whether the potential for prejudice is the same elsewhere, change-of-venue surveys sample from other jurisdictions as well.

In civil litigation, defendants in class action and mass tort lawsuits often conduct public opinion surveys to evaluate their prospects for obtaining favorable jury verdicts and to support change-of-venue motions. Plaintiffs in civil litigation sometimes commission public opinion surveys to determine in which jurisdiction to file a lawsuit where they have the option to select from several jurisdictions.

Consumer Litigation Surveys

Consumer surveys (i.e., surveys of past and potential purchasers of particular products and services) represent the most common form of litigation survey. Because consumer surveys are so routinely used in trademark and advertising controversies, courts actually have commented unfavorably on the failure of a litigant to present survey evidence, and the failure of plaintiffs to provide survey evidence in such matters may give rise to the inference that results of a consumer survey would be unfavorable to their position.

Businesses commonly use trademarks to identify their products and services to consumers and to distinguish them from those of other entities. In trademark disputes, consumer surveys measure whether a name, word, phrase, symbol, design, or a combination of these elements functions as a trademark or whether it is generic (i.e., whether it indicates the source of the product or is a common name for the product itself). Surveys in trademark disputes also assess whether consumers associate a name, word, phrase, symbol, or design with a single source (i.e., whether it has acquired distinctiveness or secondary meaning) and whether consumers are likely to be confused as to the source, sponsor, or affiliation of a product or service because of the similarity of two trademarks.

In copyright disputes, consumers are surveyed to determine whether a product or service (e.g., Napster) is mainly used for infringing purposes (e.g., to obtain copyrighted music) or non-infringing purposes. Additionally, both copyright and patent infringement disputes employ surveys to evaluate whether an infringing feature of a product has influenced consumer purchases and, if so, to apportion damages (e.g., whether the infringing software motivated purchases of a suite of software products).

In advertising disputes, surveys measure consumers' perceptions of what an advertisement or commercial communicates. Consumer surveys are used to evaluate whether an advertisement or commercial has a tendency to create a false or misleading impression among its target audience and, if so, whether the false or misleading impressions are likely to influence purchase decisions.

Consumer surveys also find application to civil actions involving other issues, including rights of publicity, defamation, and product liability.

Employee Litigation Surveys

Employee surveys are becoming the norm in class action lawsuits pertaining to wage and hour issues. Many wage-and-hour class action lawsuits concern whether employees in certain jobs (e.g., assistant store managers, department managers) are properly classified as "exempt" under federal and state law. In the United States, employers classify their employees as "exempt" or "nonexempt" for purposes of complying with the federal Fair Labor Standards Act and various state laws that govern wages and hours. Nonexempt employees (e.g., hourly employees) are entitled to a minimum wage and overtime pay, but employees who are exempted from the Fair Labor Standards Act (e.g., some salaried professionals, executives, administrators, and outside salespersons) ordinarily are not entitled to these benefits or protections.

To determine whether employers have properly classified their employees as exempt (e.g., under the executive and administrative exemptions), exempt employees are surveyed about their job duties, their involvement in various types of decisions (e.g., hiring, firing), their own supervision, and their supervision of other employees. Other wage-and-hour class action lawsuits concern whether employers have complied with the Fair Labor Standards Act and other state laws governing their nonexempt employees. For these cases, nonexempt employees may be asked questions regarding off-the-clock work, time record accuracy, meal breaks, and rest breaks.

Employee surveys have shed light on alleged violations of the Equal Pay Act of 1963 and Title VII of the Civil Rights Act of 1964, which require that men and women be given equal pay for equal work and protect individuals against employment discrimination on the basis of sex. Employee surveys in gender discrimination cases collect information regarding the qualifications, experiences, and preferences of male and female employees. This information is used to assess whether pay and promotion disparities are due to impermissible corporate policies and practices or other factors.

Surveys as Scientific Evidence

In the United States, for survey evidence to be admissible, trial courts must determine whether it is relevant, as well as reliable and trustworthy. For such determinations, trial courts now employ the scientific validity test that was initially pronounced by the U.S. Supreme Court in 1993 in *Daubert v. Merrell Dow Pharmaceuticals, Inc*. [509 U.S. 579]. In nonlitigation contexts, the usefulness of a survey also is a function of its applicability, reliability, and validity. Thus, survey methodology standards and principles used for conducting and evaluating litigation surveys essentially are the same as those used in nonlitigation contexts. General survey standards can be found in codes of conduct and guidelines published by professional associations in the survey industry (e.g., American Association for Public Opinion Research, Council of American Survey Research Organizations). Because courts have recognized the probative value and trustworthiness of survey evidence, its application to legal questions will likely continue to develop and expand in the future.

Log-In Polls

A log-in poll is an unscientific poll that typically is conducted by news and entertainment media on their Web sites to engage their visitors (audiences) by providing them an opportunity to register their opinion about some topic that the media organization believes has current news or entertainment value. Typically two choices are given for someone to express her or his opinion. One choice might be for those who agree with the issue and the other might be for those who disagree. For example, a log-in poll question might be to indicate whether a Web site visitor agrees or disagrees that *Congress should impeach the President*.

These polls are not accurate measures of public opinion on the topic. The people who choose to register their opinion on the Web site represent no known target population, and as such, the media organization cannot know to whom the findings generalize. Most often, response options such as "undecided" are not given as choices. This further invalidates the data, as anyone who holds an opinion other than what the limited response choices reflect or holds no opinion on the topic (e.g., has no previous knowledge of the topic) cannot indicate that on the poll. Furthermore, oftentimes the Web site allows people to register their opinion more than once, by exiting the Web site and then returning at another time, which is a further indication of the unreliable data these pseudo-polls generate. In fact, the data these polls generate do not even necessarily represent the opinions of visitors to the Web site since the method of sampling is self-selection, which is unreliable. Although log-in polls may provide some entertainment value for the media organization and its visitors, especially those who register their opinion, they should not be considered accurate news.

A real danger these pseudo-polls can create is when their results are disseminated uncritically as though they had some degree of validity. For example, a talk-radio program host might cite the "latest results" from the station's Web site poll to stimulate conversation about the issue from call-in listeners. As the on-the-air conversation about the poll topic proceeds, new listeners who were not tuned-in when the log-in poll results were first mentioned may have no sense how the topic of discussion started. Additionally, some listeners may assume the topic is a controversial one among large portions of the public, and the topic may get further discussed and disseminated via other uncritical news outlets and by word of mouth. Thus, what started out as a pseudo-poll finding with no basis of scientific support can take on a life of its own far beyond what it should have received.

Log-in polls also are used by organizations other than the media to gather information about visitors to their Web site. But again, the participants are self-selected, and the data are unlikely to provide the organization with reliable information about their population of visitors.
