CONTENTS OF PART I.

PEARL OYSTER REPORT.

SUPPLEMENTARY REPORTS.

PREFACE.

THE plan of this work is as follows :—

AN INTRODUCTION explaining briefly the past history of the Pearl Banks in the Gulf of Manaar and the circumstances which led to my Ceylon Expedition, and the subsequent work to which it gave rise, is followed by a section, entitled NARRATIVE, which deals with the course of the investigations undertaken by Mr. HORNELL and myself, given in chronological order. The observing stations where the fauna was investigated around the Coast of Ceylon are described in detail in the Narrative ; but those other investigations—such as the anatomy of the Pearl Oyster, a description of its parasitic worms, and an account of its pearl-formation—which will be dealt with separately in special articles later on, are not treated fully in this section. After the Narrative comes a Description of the physical condition of the pearl-oyster banks or "paars" of the Gulf of Manaar, followed by their classification from the fisheries point of view, and by a short discussion as to the causes of certain paars being unreliable, and of the serious mortality of the oysters. Then comes a section dealing with the Observations and Experiments made by Mr. HORNELL and myself on the life-history and habits of the pearl oyster, which form the basis of some of our recommendations as to the cultivation of the oyster banks.

This general part is then followed by the Supplementary or Special Reports, which various scientific friends have kindly undertaken to write upon their special groups or subjects. I feel that these articles by experts add very greatly to the completeness and value of this Report, which without them could only have given a very imperfect account of the fauna and flora of the Gulf of Manaar and of the other natural conditions of existence surrounding and influencing the pearl oyster on the various "paars."

Of these special Reports, seven are published in the present Part I. The first of these is on the Geology of the Sea-bottom, by Mr. JOSEPH LOMAS, F.G.S. ; it deals with the very fundamental question of what the "paar" is, how the hard, cemented material usually known (and marked on the charts) as "rock," which by its presence enables the pearl oysters to live there, comes to be formed.

The next is by Mrs. GEPP on the Algæ collected, and this contains an account of the previously unknown fructification of a species of *Halimeda*, one of the commonest and most characteristic forms of sea-weed on the pearl banks.

The remaining Reports are Zoological. Mr. A. E. SHIPLEY's on the Gephyrea, Mr. E. R. SYKES' on the Chitons, and Mr. J. PEARSON's on the Holothurians, all contain descriptions of interesting new forms. Mr. W. M. TATTERSALL's Report on the Cephalochorda adds no new species of Amphioxus, but performs the equally useful function of showing that some of those previously described are so closely linked by variations that they may safely be regarded as the same. It is interesting to find that out of the dozen well-established species of Amphioxus, no less than seven were found in two months work round the Coast of Ceylon.

The last Report in this present Part I.—that on the Copepoda, by Mr. ISAAC THOMPSON and Mr. ANDREW SCOTT—is by far the largest, and deals with a great number of species. It is certainly surprising that we should in such a short time, without being able to pay any special attention to the group, have come across no less than 283 species of Copepoda, of which 76 were new to science. Mr. THOMPSON has acknowledged handsomely the large share which his colleague, Mr. A. SCOTT, has taken in the more laborious parts of the preparation of the Report; but I also must draw attention to the combined industry and skill which Mr. SCOTT has exhibited in the beautiful drawings for the numerous accurate plates illustrating the new species of Copepoda.

The next Part will be ready early in 1904, and will contain Reports upon the Sponges, by Professor A. DENDY; the Hydroid Zoophytes, by Miss L. R. THORNELY; the Medusæ, by Mr. E. T. BROWNE; the Turbellaria, by Mr. F. F. LAIDLAW; the Polychæta, by Mr. HORNELL; the Cephalopoda, by Dr. W. E. HOYLE; the Cumacea, by Dr. W. T. CALMAN; the Fishes, by Mr. J. JOHNSTONE; and the Entozoa of the Pearl Oyster, by Mr. A. E. SHIPLEY and MR. HORNELL.

The remaining Parts, which it is hoped will be issued during the following year, will deal with the other groups of animals. The reports on the Amphipoda by Mr. A. O. WALKER, on the Caprellida by Dr. PAUL MAYER, on the Isopoda by the Rev. T. R. R. STEBBING, on the Ostracoda by Mr. ANDREW SCOTT, on Sarcophytum and its allies by Miss E. PRATT, on the Nudibranchiata by Mr. G. P. FARRAN, on the Nullipores by Mr. J. LOMAS, the Polyzoa by Miss L. R. THORNELY, the Crinoidea by Mr. H. C. CHADWICK, and the Alcyonaria by Professor J. ARTHUR THOMSON, are in progress, and some of them are far advanced. My wife is helping me with the identification of the remaining Echinodermata, and Professor JEFFREY BELL has kindly undertaken to examine and describe those that seem new. Mr. A. LEICESTER and Mr. W. J. HALLS are engaged in examining the Molluscan shells, and will draw up a list of all the species collected. A few other groups are still unexamined. The final Part will contain in addition the remainder of Mr. HORNELL's and my own observations and conclusions, including the results of our experiments now in progress, and our final recommendations as to the future management of the pearl oyster banks.

It is pleasant to be able gratefully to acknowledge much help, both administrative and scientific. To many in Ceylon—to their Excellencies the Governor Sir West Ridgeway and the Lieutenant-Governor Mr. E. F. im Thurn and to others—I am indebted for much kindness and consideration which smoothed away difficulties, expedited my work, and rendered duty a pleasure. I desire also to record my thanks to Captain J. Donnan, then Master Attendant at Colombo and Inspector of the Pearl Banks, and to his successor, Captain J. Legge, who, during the time which I spent with them on the inspection barque "Rangasameeporawee," spared no trouble in trying to let me examine as satisfactorily as possible the various banks and the other localities and conditions which I desired to investigate. I had also the advantage of spending some days on the pearl banks with Sir William Twynam, who has had a long extended experience of the fisheries as Superintendent from 1862 to 1896, and as Government Agent of the Northern Province.

Several men of science in Ceylon were kindly in their welcome and practical in their help. I would specially mention Dr. A. J. Chalmers, through whose good offices the Medical College at Colombo placed accommodation in one of their laboratories at the disposal of Mr. Hornell and myself; Mr. J. C. Willis, Director of the Botanic Gardens at Peradeniya, and the late Mr. Oliver Collett, of Roselle, who has himself written on the pearl-oyster fisheries. I was fortunate in accidentally meeting during my first few days in Ceylon Dr. Paul and Dr. Fritz Sarasin, who had made important biological investigations at Trincomalee; and also Professor Alexander Agassiz, then returning from his expedition to the Maldives, who very kindly allowed me to ship from his steamer to mine, as they lay together in Colombo Harbour, a reel containing 600 fathoms of steel-wire dredging rope.

I desire to record my entire satisfaction with the work done by Mr. James Hornell, both while I was with him and also since. I was fortunate in having such a capable and willing assistant, and such a helpful and pleasant companion. It would have been quite impossible for me to have got through the work that had to be done in the very limited time at my disposal had it not been for Mr. Hornell's skilled assistance.

I am much indebted to the Staff of the Colonial Office, and to Sir Michael Foster, K.C.B., of the Royal Society, for their interest in this investigation, for their advice from time to time, and for the trouble they have taken in facilitating the arrangements by which this Report will be published by the Royal Society for the Government of Ceylon. And I need hardly say how gratefully I acknowledge the appreciation of my labours shown by the Royal Society in assisting, in the first instance, towards my being requested to carry out the investigation and subsequently in undertaking the publication of the Report.

W. A. HERDMAN.

The University, Liverpool,
August, 1903.

REPORT ON THE PEARL OYSTER FISHERIES OF THE GULF OF MANAAR.

INTRODUCTION.

The celebrated "Pearl oysters" of Ceylon are found mainly on certain parts of the wide shallow plateau which occupies the upper end of the Gulf of Manaar, off the North-west Coast of the Island and South of Adam's Bridge. Pearl banks also exist on the opposite Coast of India, off Tuticorin. The animal (*Margaritifera vulgaris*, Schum., = *Avicula fucata*, Gould) is not a true oyster, but belongs to the family Aviculidæ, and is therefore more nearly related to the Mussels (*Mytilus*) than to the Oysters (*Ostrea*) of our British seas. One very notable character of great practical importance, in which it differs from *Ostrea*, is that the Pearl oyster, like our common Mussels, has a "byssus" or bundle of tough threads by which it can attach itself to rocks or other foreign objects.

The Pearl Fisheries of Ceylon, India, and the Persian Gulf, yielding the highly prized "Oriental" pearl, are of very great antiquity. They are probably the most ancient fisheries still in existence, and seem to be carried on at the present day under very much the same conditions as 2000 or perhaps even 3000 years ago. These fisheries are referred to by various classical writers, and Pliny, after saying how highly valued the pearls are at Rome, refers to Taprobane [Ceylon] as "the most productive of pearls of all parts of the world."* Pliny also describes the coral that abounds in the Gulf of Manaar, and mentions pearls and precious stones as the products of Ceylon. But the Singhalese records take us to still earlier times. According to the "Mahawanso," pearls figure in the list of native products sent as a present from King Vijáya of Ceylon to his Indian father-in-law in about 540–550 B.C.; and again when, in B.C. 306, King Devanampiyatissa sent an embassy to India the presents are said to include eight kinds of Ceylon pearls. The King's Hall in the Brazen Palace at Anuradhapura (B.C. 161) is said to have been decorated with native pearls. The mortar in the ruins of Polonaruwa shows the remains of the pearl-oyster shells which were used in its manufacture—no doubt the refuse of an

* 'Plin. Nat. Hist.,' Bk. IX., chap. 54, Lemaire's Edition. I am indebted to my colleague, Professor H. A. Strong, for kindly giving me these and other references. Athenæus and Ælian make similar statements. The anonymous "Periplus" of the Erythræan Sea describes a great pearl fishery at Colchi, near Comar, in Taprobane or Ceylon, which probably refers to some part of the Gulf of Manaar.

early fishery. Many other references could be given. In the eighth to eleventh centuries, trade in the East was in the hands of the Persians and Arabs, and we find Arab writers alluding to the pearls. We know also that they enriched the kings of Ceylon in the days of MARCO POLO (1291). One record, given by Friar JORDANUS, says that in 1330 about 8000 boats were engaged in the pearl fisheries of the Gulf of Manaar.

CÆSAR FREDERICK, a Venetian merchant (1563), crossed from India to Chilaw (about the middle of the West Coast of Ceylon) to be present at a pearl fishery, the methods of which were very much as they would be at the present day. We are told that the Tamil name "Salubham" (Sea-of-Gain) given to the Gulf of Manaar because of its pearl banks, was also applied to Chilaw, which in former times was the town nearest to the fishery. The centre of the pearl fishery is now much further north, but the oyster "paars" still exist off Chilaw, and were fished at least thrice during the nineteenth century, in 1803, 1815, and 1884. And so we continue to have glimpses,* through the centuries, of this ancient and highly prized industry being carried on with little or no change, first under the Singhalese kings of Kandy and the Tamil kings of Jaffna, and subsequently under the successive European rulers. At the time when RIBEYRO† wrote (1685), Aripu was, as it has been since, the centre of the northern fisheries, and from the description given, it is evident that the method of fishing in these Portuguese times was as we see it now, even to the manning of the divers' boats and the cessation of diving at noon. As would be expected, we have much more definite records of the details of the fisheries during the Dutch and British occupations than in previous times. We have a vivid description, by MARTIN, of a fishery which took place off Tuticorin in 1700. PERCIVAL (1803) and CORDINER (1807) both give excellent accounts of the early British fisheries. The last Dutch fishery took place in 1768, and the first under English control in 1796—and for this fishery the arrangements were made before the surrender of Colombo.

* Here is another glimpse of the early native fisheries which I have just (August 18th, 1903) received from Sir WILLIAM TWYNAM of Jaffna. He says: "It is an extract from the translation of an old Tamil work called the 'Kalveddu,' given to me some time ago by a Mr. TILLEANOBELAM, employed in the Jaffna Kachcheri"—"VIDANARAYANEN CHEDDI and the Puravu men who fished pearls by paying tribute to ALLIYARASANI, daughter of PANDIYA, king of Madura, who went on a voyage, experienced bad weather in the sea, and were driven to the shores of Lanka, where they founded Karainerkai (Karativo) and Kutiraimalai (Kodramallai). VIDANARAYANEN CHEDDI had the treasures of his ship stored there by the Puravus, and established pearl fisheries at Kadalihilapam (Chilavaturai) and Kallachihilapam (Chilaw), and introduced the trees which change iron into gold," &c., &c.

Sir W. TWYNAM adds: "The Puravu divers referred to were afterwards converted to Roman Catholicism by St. FRANCIS XAVIER, and their descendants are, I believe, the Roman Catholic Puravu divers who now come to our fisheries from Tuticorin and other ports in Southern India;" and "some large mounds of old oyster shells were pointed out to me in the neighbourhood of Marichchukaddi as having been the accumulations of Queen ALLIYARASANI's fisheries."

† My copy is LE GRAND's translation, "Histoire de l'Isle de Ceylan," Amsterdam, 1701; I believe it is doubtful whether the original Portuguese of Captain RIBEYRO was ever published.

A notable feature of these fisheries, under all administrations, has been their uncertainty and intermittent character. The Dutch records show that there were no fisheries between 1732 and 1746, and again between 1768 and 1796. During our own time the supply failed—to mention only the longer intervals—in 1820 to 1828, in 1837 to 1854, in 1864 to 1873, and finally after five very successful fisheries in 1887 and the succeeding years, culminating in the record fishery of 1891 (when the Government proceeds reached close upon a million of rupees), there has been no return for the last decade. In addition to the longer intervals given above, there were many unproductive single years or groups of two and three; in fact there were, in all, only 36 fisheries during the nineteenth century. It will be of interest to give here the complete list in the following table (p. 4), compiled by Mr. HORNELL at the Government Record Office in Colombo. Besides showing the marked intervals, and the general irregularity in results, it brings out the very considerable value of the fisheries, and is a useful indication of the relative productiveness of the principal paars.

The intermittent character of the fisheries has been recognised by various writers both before and since 1740, when Baron VON IMHOFF, then Governor, wrote in a memorandum for his successor:—"It is now several years since the pearl banks have fallen into a very bad state both at Manaar and Tuticorin; this is mere chance, and experience has shown that, on former occasions, the banks have been unproductive even for a longer period than has yet occurred at present." What was formerly put down to "chance" has in most lines of inquiry proved susceptible of scientific analysis and explanation, and it is reasonable to expect that, in the case of the pearl fisheries, investigation will lead to a better understanding of the phenomena, and a rational treatment based on such knowledge to a greater regularity in the results.

Writing in 1697, for the instruction of the Political Council of Jaffnapatam, the then Commandant of that town justly remarked that "the pearl fishery is an extraordinary source of revenue on which no reliance can be placed, as it depends on various contingencies which may ruin the banks or spoil the oysters." The above is quoted by both THURSTON and COLLETT in their recent papers. Mr. THURSTON's comment is: "And this remark holds good after the lapse of two centuries." The late Mr. OLIVER COLLETT adds: "This statement holds good after a lapse of more than two centuries—indeed, the periodical disappearance of oysters from certain of the banks, sometimes for many years at a time, may be said to form one of the peculiar characteristics of the Ceylon fishery. Nevertheless, since the British occupation of the island, a sum equal to more than one million sterling has been derived from the fishery; and the matter is therefore one of immense importance to the Government of the Colony."*

* "Pearl Oysters and Pearl Fisheries," by O. COLLETT, F.R.M.S., 'Journ. R. Asiat. Soc.,' Ceylon Branch, vol. XVI., No. 51, 1900.

PARTICULARS of the Pearl Fisheries held during the Nineteenth Century.

(Compiled from the Government Records.)

Year of fishery.	Total number of oysters fished.	Gross Government proceeds in rupees.	Name and region of bank fished. [*The notes within square brackets are added by Mr. Hornell.*]
1801	[Particulars not available as to number of oysters fished.]	150,227	Kondatchi Paar.
1803		163,154	Chilaw Paar.
1804		770,202	Aripu [Cheval and Modragam paars (*fide* VANE'S "Report" to Governor, Sir H. WARD, February, 1863).]
1806		412,842	,,
1808		842,577	,,
1809		272,463	,,
1814		1,051,876	,,
1815		5,842	Chilaw Paar.

1879	7,645,901	95,694	Kottapakku Paar (3 miles West of Cheval Paar) [Periya Paar].
1880	35,238,972	200,152	North-West Cheval Paar.
1881	27,338,596	599,533	,, ,, ,,
1884	636,000	17,153	Off Chilaw.
1887	8,834,330	103,664	North Modragam Paar.
	22,513,575	292,430	North-East Cheval Paar.
1888	22,052,769	804,247	Cheval Paar (whole) and both Modragams (North and South).
1889	38,995,447	498,377	Muttuvaratu Paar. [Included in these figures are the proceeds of 1 day's fishing each year on Karativu Paar (200,243 oysters in 1891).]
1890	33,677,892	313,177	
1891	44,311,441	963,748	

* [We cannot attach much importance to the topography of the Cheval Paar in these early records. The nomenclature of the regions has varied much in the past. For example, DONNAN'S North-East Cheval is not that of STEUART.]

Many reasons, some fanciful, others with more or less basis of truth, have been given from time to time for the recurring failures of the fishery; and several investigations, such as that of Dr. KELAART (who unfortunately died before his work was completed) in 1857 to 1859, and that of Mr. HOLDSWORTH in 1865 to 1869, have been undertaken without much practical result so far.

In September, 1900, after a continued failure of the fishery for ten years, I was asked by the Colonial Office (acting on the advice of the Council of the Royal Society and of Professor RAY LANKESTER) to examine the records and report upon the matter, and in the following spring I was invited by the Government to go to Ceylon at the end of the year, with a scientific assistant, and undertake such investigation into the condition of the pearl banks as might appear necessary. I arrived at Colombo in January, 1902, and, as soon as a steamer could be obtained, proceeded to the Gulf of Manaar.

In April it was necessary to return to my University duties in Liverpool, but I was fortunate in having taken out with me as my assistant Mr. JAMES HORNELL, who, it was arranged, would remain in Ceylon for at least a year longer in order to continue the observations and experiments we had started and complete our work. This programme has been carried out, and Mr. HORNELL has kept me supplied with almost weekly reports, and with specimens requiring detailed examination.

The s.s. "Lady Havelock" was placed by the Ceylon Government at my disposal for the work of examining into the biological conditions surrounding the pearl-oyster banks; and this enabled me on two successive cruises of three or four weeks each to examine all the principal banks, and run lines of dredging and trawling and other observations across, around, and between them, in order to ascertain the conditions that determine an oyster "paar." Towards the end of my stay I took part in the annual inspection of the pearl banks, by means of divers, along with the retiring Inspector, Captain J. DONNAN, C.M.G., and his successor, Captain LEGGE. During that period we lived and worked on the native barque "Rangasameeporawee," and had daily opportunity of studying the methods of the native divers and the results they obtained.

It is evident that there are two distinct questions that may be raised—the first as to the abundance of the adult "oysters," and the second as to the number of pearls in the oysters, and it was the first of these rather than the frequency of the pearls that seemed to call for investigation, since the complaint has not been as to the number of pearls per adult oyster, but as to the complete disappearance of the shell-fish.

Most of the pearl-oyster banks or "paars" (meaning rock or any form of hard bottom, in distinction to "manul," which indicates loose or soft sand) are in depths of from 5 to 10 fathoms, and occupy the wide shallow area of nearly 50 miles in length, and extending opposite Aripu to 20 miles in breadth, which lies to the south of Adam's Bridge. On the western edge of this area there is a steep declivity, the sea deepening within a few miles from under 10 to over 100 fathoms; while out in the centre of the southern part of the Gulf of Manaar, to the west of the Chilaw pearl banks, depths of between 1000 and 2000 fathoms are reached. On our two cruises in the "Lady Havelock" we made a careful examination of the ground in several places outside the banks, to the westward, on the chance of finding beds of adult oysters from which possibly the spat deposited on the inshore banks might be derived. No such beds, outside the known "paars," were found; nor are they likely to exist. The bottom deposits in the ocean abysses to the west of Ceylon are "globigerina ooze" and "green mud," which are entirely different in nature and origin from the coarse terrigenous sand, often cemented into masses, and the various calcareous neritic deposits, such as Corals and Nullipores, found in the shallow water on the banks. The steepest part of the slope, from 10 or 20 fathoms down to about 100 fathoms or more all along the western coast, seems in most places to have a hard bottom covered with Alcyonaria, Sponges, deep-sea Corals, and other large encrusting and dendritic organisms. Neither on this slope, nor in the deep water beyond the cliff, did we find any ground suitable for the pearl oyster to live upon.

It soon became clear to us that different paars were placed under very different physical and biological conditions, and that the sudden disappearance, or the continued absence, of pearl oysters in different localities and at different times might be and probably was due to very different causes. The Periya Paar, about 20 miles from land and close to the top of the steep slope (see p. 78), is very differently situated from the East Cheval or the Modragam paars relatively near the shore, protected to some extent from the ocean and with shallow water all around. The pearl oyster is the same animal all over the district, and facts of anatomy and physiology once ascertained will hold good; but the paars are different, each presents its own problems, and all must be studied. In reading the reports of former superintendents and inspectors of the pearl banks, it is possible, after acquiring some knowledge of the physical and biological conditions of the various paars, to account for some of the apparently mysterious disappearances of oysters and catastrophic changes in the fauna. It is unnecessary to go over all the cases that have been recorded, but the recent history of the Periya Paar, and the more noteworthy disasters on the Cheval and other important paars, will be found discussed below. For a knowledge of the past history of the pearl banks we are indebted mainly to the official reports of the Ceylon Government. I would mention especially as amongst the most important contributions to our knowledge of the subject: the reports of Dr. E. F. KELAART in 1857 to 1859; the "Account of the Pearl Fisheries of Ceylon," by Captain JAMES STEUART, Ceylon, 1843; H. SULLIVAN THOMAS' "Report on the Pearl Banks and Fisheries of Tuticorin"; "The Pearl and Chank Fisheries of the Gulf of Manaar," by E. THURSTON (Bulletin of the Madras Museum, No. 1, 1894); Mr. E. W. H. HOLDSWORTH'S "Report on the Pearl Oyster Banks," 1867; Captain J. DONNAN'S successive Reports on Inspections and Fisheries; and finally the comprehensive and most interesting "Report on the Ceylon Pearl Fisheries," drawn up in 1899 by Sir WILLIAM C. TWYNAM, K.C.M.G. (Colombo, 1900).

There is much that we agree with in all of these previous reports. There are some points in each on which we differ from the author. We account for the occurrence in another way, or draw a different conclusion from the observed facts. Several of these writers, although not strictly speaking scientific men, were accurate observers and acute investigators who have left valuable records. Others better equipped in scientific training have been prevented from doing more by unfavourable circumstances. Dr. KELAART's short reports show that he was tackling the problems in a scientific manner, and his researches were incomplete at the time of his sudden death.* Mr. HOLDSWORTH's visit to Ceylon (1865–69) was apparently made at an unfortunate time. Mr. OLIVER COLLETT states ('Journ. R. Asiat. Soc.,' Ceylon, Br., 1900) that Mr. HOLDSWORTH never had an opportunity of seeing a fishery, and according to Sir W. TWYNAM, he "did not witness an inspection of a bank with a bed of oysters on it, young or old." Mr. HORNELL and I were more fortunate, as during our cruises in the Gulf of Manaar we found pearl oysters in all stages of growth, from the microscopic free-swimming larvæ and newly-deposited "spat" to the pearl-bearing adults, and we have also two consecutive inspections of banks well covered with oysters, and the successful fishery of 1903, from which to draw conclusions. Mr. THURSTON, of Madras, has also had experience of fisheries and inspections with Captain DONNAN, and has written a most interesting and valuable record containing a great deal of incidental information as to the fauna of the Gulf of Manaar, but had apparently not the opportunity and the implements for a more detailed survey, nor the time for a more thorough investigation of the oyster problems.

To all our predecessors, however, we are indebted for information and for suggestions which have been of value to us in our work. That work has led us into various different lines of inquiry. Outside the larger influences, cosmic in origin, uncontrollable, and wide-spread in effect, such as oceanic currents, monsoon storms, depth of water, configuration of bottom, and shifting sands which may devastate a bank and cause the sudden disappearance of many millions of oysters, there are, in addition, various minor causes of failure of the fisheries, some of which we were able to investigate. The pearl oyster has many enemies, such as Star-fishes, boring Sponges which destroy the shell, boring Molluscs which suck out the animal, internal Protozoan and Vermean parasites, and carnivorous Fishes, all of which cause some destruction, and may on occasions conspire to ruin a bed and change the prospects of a fishery. But, in connection with such animate foes, it is necessary to bear in mind that, from the fisheries' point of view, their influence is not wholly evil, as some of them are closely associated with pearl production in the oyster. One enemy (a Plectognathid fish), which doubtless devours many of the oysters, at the same time

* Soon after the fishery of 1859, during which Dr. KELAART worked with the Swiss Naturalist, HUMBERT, at Chilavaturai, he was sent to England in medical charge of General LOCKYER, who was very ill and died in the Red Sea. Dr. KELAART, who was in constant attendance on the General, died suddenly a day or two later.

receives and passes on the parasite which leads to the production of pearls in others. The loss of some individuals is in that case a toll that we very willingly pay, and no one would advocate the extermination of that particular enemy.

In fact, while wholly at the mercy of its inanimate surroundings, such as storms and sand, the pearl oyster can probably cope under most circumstances with its animate environment on the paars, if not too recklessly decimated at the fisheries, and if not exposed to some exceptional combination of adverse influences. Man has thus afforded to him the opportunity of intervening. Although he cannot control the monsoon or build a sea-wall around the "paar," yet without any violent attempt to disturb the balance of Nature, or remove wholly the influence of any particular enemy, he can compensate to some extent for the damage he himself does, and he can help the oyster population to withstand the attacks of normal enemies and prevent complete destruction under abnormal combinations. This he can do by giving some attention to the breeding stock, by having a more intimate knowledge of the exact distribution of the oysters at all ages on the ground, by attending to the dissemination and location of "spat," by thinning out in parts where there is overcrowding, or where young are mixed with old, and by transplanting, when required, the growing young from unsuitable ground, where from experience it is known they cannot arrive at maturity, to more sheltered and reliable "paars."

It is clear that, in considering the conditions of existence of the oyster and the vicissitudes of the pearl banks, we have to deal with great natural influences which cannot be wholly removed, though they may to some extent be avoided and compensated for; and that, consequently, it is necessary to introduce large measures of regulation and cultivation in order to increase the adult population on the ground, have the more reliable "paars" provided more fully with successive broods of young oysters by transplantation, and so give greater constancy to the supply and remove the disappointing fluctuations in the fishery.

We have shown conclusively in our work the ease with which young pearl oysters can be dredged up in quantity and transported to considerable distances, and we can also demonstrate by our figures the advantages derived by transplantation from overcrowded and unhealthy localities to better conditions. The young are present in abundance, and they are probably sacrificed in millions every year. When we examined the Periya Paar in March, 1902, we estimated the number of young pearl oysters on the ground at not less than a hundred thousand millions; when Mr. Hornell returned in November they were all gone. With such numbers the inshore paars could be kept continuously supplied with young oysters transplanted from their precarious position on the more exposed grounds out at sea.

There is no reason for any despondency in regard to the future of the pearl fisheries, if they are treated scientifically. The adult oysters are plentiful on some of the paars and seem for the most part healthy and vigorous; while young oysters in their first year, and masses of minute spat just deposited, are very abundant in many places. The material exists, ready for man's operations.

To the biologist two dangers are, however, evident, and, paradoxical as it may seem, these are *overcrowding* and *overfishing*. But the superabundance and the risk of depletion are at the opposite ends of the life-cycle, and therefore both are possible at once on the same ground—and either is sufficient to cause locally and temporarily a failure of the pearl-oyster fishery. What is required to obviate these two dangers ahead and ensure more constancy in the fisheries is careful supervision of the banks by someone who has had sufficient biological training to understand the life-problems of the animal, and who will therefore know when to carry out simple measures of farming, such as thinning and transplanting, and when to advise as to the regulation of the fisheries.

In connection with cultivation and transplantation there are various points as to structure, reproduction, life-history, growth and habits of the oyster which we had to deal with, some of which we were able to determine on the banks, while others have been the subject of Mr. Hornell's work since, in the little marine laboratory we established at Galle, in the south of Ceylon.

Although Galle is at the opposite end of the island from the pearl banks of Manaar, it is clearly the best locality in Ceylon for a marine laboratory—both for general zoology and also for working at pearl-oyster problems. Little can be done on the sandy exposed shores of Manaar Island or the bight of Kondatchi—the coasts opposite the pearl banks. The fisheries take place far out at sea, from 10 to 20 miles off shore, and it is clear that any Natural History work on the pearl banks must be done not from the shore, but, as we did, at sea from a ship during the inspections, and cannot be done at all during the monsoons because of the heavy sea and useless exposed shore. At such times, the necessary laboratory work supplementing the previous observations at sea can be carried out much more satisfactorily at Galle than anywhere in the Gulf of Manaar.

Turning now from the health of the oyster population on the "paars" to the subject of pearl-formation, which is evidently an unhealthy and abnormal process, we find that in the Ceylon oyster there are several distinct causes that lead to the production of pearls. Some pearls or pearly excrescences on the interior of the shell are due to the irritation caused by boring sponges and burrowing worms. Minute grains of sand and other foreign particles gaining access to the body inside the shell, which are popularly supposed to form the nuclei of pearls, only do so, in our experience, under exceptional circumstances. Out of the many pearls I have decalcified, only one contained in its centre what was undoubtedly a grain of sand; and from Mr. Hornell's notes taken since I left Ceylon, I quote the following passage showing that he has had a similar experience:—"February 16th, 1903. '*Ear-pearls*,' of two decalcified, one from the anterior ear (No. 148) proved to have a minute quartz grain (micro-preparation 25) as nucleus." Since then he has found one more.

It seems probable that it is only when the shell is injured, as, for example, by the breaking off or crushing of the projecting "ears," thereby enabling some fine sand to gain access to the interior, that such inorganic particles supply the irritation which gives rise to pearl formation.

Pearls of another class are found in the muscular tissue of the animal, usually in the levators of the foot, and in the palpar region, but also frequently in the pallial insertions, rarely at the insertions of the retractor and adductor muscles. These muscle-pearls have no organic nuclei. They seem to start as minute calcareous concretions ("calcospherules") in the tissue, and the centre is sometimes crystalline. They may be extraordinarily abundant. At the insertion of one levator muscle, 23 small pearls were counted with the eye, while under the microscope 170 additional tiny spherules were found to be present.

The best pearls, however, the "cyst" or "orient" pearls, lie in the thin muscular margin of the mantle, or in the thick white lateral part over the stomach and liver, or even, secondarily, free in a cavity of the body.

Consequently, as we shall show in the section of the Report dealing with pearl-formation, we can classify these pearls from the biological point of view into three sets:—(*a.*) "Ampullar-pearls" which are not formed within closed epithelial sacs like the others, but lie in pockets or ampullæ of the epidermis. The nuclei may be sand-grains or any other foreign particles introduced through breaking or perforation of the shell. (*b.*) "Muscle-pearls" formed around calcospherules at or near the insertions of the muscles. (*c.*) "Cyst-pearls" where concentric layers of nacre are deposited on cysts containing parasitic worms in the connective-tissue of the mantle.

The majority of the fine pearls found in the soft tissues of the body of the Ceylon oyster contain, in our experience, the more or less easily recognisable remains of Platyhelminthian parasites (especially the young larva of the Cestode *Tetrarhynchus*), so that the stimulation which causes eventually the formation of an "orient" pearl is, as has been suggested by various writers in the past, due to infection by a minute worm, which becomes encased and dies, thus justifying, in a sense, DUBOIS' statement that:—"La plus belle perle n'est donc, en définitive, que le brillant sarcophage d'un ver" (Comptes Rendus Acad. Sci. Paris, 14th Oct., 1901).

To Dr. KELAART (1857–59) belongs the honour of having first connected the formation of pearls in the Ceylon oyster with the presence of vermean parasites. It is true that FILIPPI, seven years before, in 1852, showed that the Trematode *Distomum duplicatum* was the cause of pearl formation in the fresh-water Mussel *Anodonta*, and KÜCHENMEISTER (1856), MÖBIUS (1857), and others extended the discovery to other pearl-producing oysters, and to other parasites; but it is possible that KELAART knew nothing of these papers, and that he made his discovery in regard to the Ceylon oyster quite independently. He (and the Swiss Zoologist, HUMBERT, who was with him at a pearl fishery) found "in addition to the Filaria and Circaria, three other parasitical worms infesting the viscera and other parts of the pearl oyster. We both agree that these worms play an important part in the formation of pearls; and it may yet be found possible to infect oysters in other beds with these worms, and thus increase the quantity of these gems." Thus we have KELAART, in 1859, definitely stating the possibility, in the case of the Ceylon pearl oyster, of infecting other beds with the larvæ of the pearl-producing Platyhelminthian parasites in order to increase the quantity of pearls.

THURSTON, in 1894, confirmed KELAART'S observation, finding in the tissues and also in the alimentary canal of the Ceylon oyster, "larvæ of some platyhelminthian (flat worm)." He figures ('Madras Mus. Bull.,' I., Plate II., fig. 1) a section showing two of the parasites encysted between the alimentary canal and generative tubes. Here the matter rested so far as the Ceylon pearl oyster was concerned.

Long before, however, GARNER, in 1871, had associated the production of pearls in our common English Mussel (*Mytilus edulis*) with the presence of Distomid parasites; GIARD (1897) and other French writers have made similar observations in the case of *Donax* and other Lamellibranchs; and DUBOIS (1901) has more recently ascribed the production of pearls in Mussels on the French coast to the presence of the larva of *Distomum margaritarum*. H. L. JAMESON (1902), then followed with a more detailed account of the relations between the pearls in *Mytilus* and the Distomid larvæ, which he identifies as belonging to *Distomum* (*Brachycælium*) *somateriæ* (LEVINSEN). JAMESON'S observations were made on Mussels obtained partly at Billiers (Morbihan), a locality at which DUBOIS had also worked, and partly at the Lancashire Sea-Fisheries Marine Laboratory at Piel, in the Barrow Channel. Finally, DUBOIS has just published a further note (Comptes Rendus Acad. Sci. Paris, 19th Jan., 1903) in which, referring to the causation of pearls in *Mytilus*, he says (p. 178):—"En somme ce que ce dernier [GARNER] avait vu en Angleterre en 1871, je l'ai retrouvé en Bretagne en 1901. Quelques jours après mon départ de Billiers, M. LYSTER JAMESON, de Londres, est venu dans la même localité et a confirmé le fait observé par GARNER et par moi." But JAMESON has done rather more than that. He has shown that it is probable (his own words are "there is hardly any doubt") that the parasite causing the pearl-formation in our common Mussel (not in the Ceylon pearl oyster) is the larva of *Distomum somateriæ*, from the eider duck and the scoter. He also believes that the larva inhabits *Tapes* or the cockle as a first host before getting into the mussel.

We have found, as KELAART did, that in the Ceylon pearl oyster there are several different kinds of worms commonly occurring as parasites, and we shall, I think, be able to show in a later section of this report that Cestodes, Trematodes, and Nematodes may all be concerned in pearl-formation. Unlike the case of the European mussels, however, we find that in Ceylon the most important cause is a larval Cestode of the Tetrarhynchus form. We first found this larva in pearl-like cysts outside the liver of pearl oysters on the Cheval Paar during the second cruise of the "Lady Havelock" in February and March, 1902. Since then Mr. HORNELL has traced a considerable part of the life-history of this parasite, from an early free-swimming stage to a late larval condition in the File-fishes (*Balistes mitis* and *B. stellatus*) which frequent the pearl banks and prey upon the oysters. We have not yet succeeded in finding the adult worm, but it will probably prove to infest the Rays or other large Elasmobranchs which may devour *Balistes*.

We have also found the pearl-provoking Cestode larva in *Pinna*—where pearls are sometimes found—but we have no reason to suppose that *Pinna* finds a place in the same life-cycle with the pearl oyster. Nor do we think that any other Mollusc or Invertebrate is implicated. The stages in the life-cycle, as regards environment, are probably as follows:—

1. Free embryos in the sea;
2. Encapsuled in the pearl oyster;
3. Later larval stage in the File-fishes;
4. Adult in large Elasmobranchs.

We suppose, then, that the adult Worm from the body of the Shark or Ray sets free its numerous young embryos into the sea; and there we pick up the history, for amongst our Vermean embryos in the tow-net we have some caught on the Muttuvaratu Paar, in November, 1902, which we consider to be the younger stage of our *Tetrarhynchus* larva. Such free-swimming embryos on an oyster bank will readily gain access to the body of the oysters. They will be carried in with the current of water, and may either pass into the alimentary canal with the microscopic food particles or get lodged in the gills. We have found these in the gills, and have also found very young stages in the mantle; while later stages of larger size are common in the liver and in the connective-tissue of the body-wall generally. In some samples of oysters examined scarcely any individuals are free from the encysted parasites, and in one 45 cysts were counted. In the case of oysters so infested which are eaten by the File-fishes—and from the frequency with which we, and others, have found the broken-up shells in the stomach there can be no doubt that these fishes do eat the oysters—the Cestode larvæ are transferred to the body of the new host; and Mr. Hornell has found them in quantity in the alimentary canal and peritoneum of specimens belonging to the two common species *Balistes mitis* and *B. stellatus*, from several localities. The Cestodes are now in a later stage, and are clearly recognisable as *Tetrarhynchus*; but are not yet adult and have no reproductive organs. Whether they become mature in time in the body of the File-fish or, as we think more probable, in a larger animal which feeds upon that fish, such as one of the large Elasmobranchs common in these seas, we cannot yet say; but possibly that point may be settled before the Report is finished.

In those oysters, on the other hand, which do not become the prey of the File-fish the larval Cestodes have no opportunity of fulfilling their destiny as parasites, but die and become encapsuled in the layers of pearly nacre deposited by the living tissues of the oyster upon the source of irritation. What proportion of the parasites become the nuclei of pearls we are not able to say, but many, we feel sure, neither complete their life-history nor yet remain long enough encapsuled in the bodies of adult oysters to become pearls of value. There are many potential and incipient pearls in young oysters which, even if transferred to the body of a fish, contain only dead larvæ, and so are lost from the parasite population; while the death of their host prevents them from causing pearl-formation. It is not sufficient for the oyster to be infected by the *Tetrarhynchus*, it must also live, retaining its parasite, until such time as it can produce sufficient deposit of the calcareous secretion to form a true pearl. In the case of the Ceylon pearl oyster very little increase in size of the shell by additions to the ventral margin takes place after an age of three and a half or at most four years has been reached. But the shell after this period thickens greatly by the deposit of nacreous material in its interior and especially in the neighbourhood of the hinge at the dorsal edge. This is the time of rapid pearl-formation. The oyster's tissues are then in the condition which leads to the secretion and deposition of limy material either externally by additions to the thickness of the shell, or internally as successive coats deposited upon any particle—such as a dead parasite or, it may be, a sand-grain, a Diatom frustule, a fragment of nacre, ova, or excreta—which has given rise to the necessary stimulation.

There is general agreement amongst those who have seen most of the Ceylon oyster on its native banks that the animal does not, as a rule, live beyond six or seven years. Captain DONNAN's opinion is that "the oysters may be profitably fished at the age of four years, and that they are in their prime at five years, and may be kept till that age if circumstances will permit of it; but if they are kept till the sixth year they are almost certain to be found dead." From the figures he gives in his reports it seems that the age of the oysters at fisheries where we have reliable data has been nearly always under five years. The pearl oyster should be fished when it measures $3\frac{1}{2}$ inches in diameter at right angles to the hinge line, has no soft growing edge to the shell, and shows a deep V-shaped groove between the valves at the hinge.

Although it is not correct to say that there are no pearls in young oysters, for we have found some of moderate size in quite small oysters, still there is no doubt that rapid and widespread pearl-formation begins only when the animal is about three and a half years old and has ceased to grow a thin spreading ventral margin to the shell. During the year or eighteen months following this is the time when it is most profitable to fish the oysters up and open them for the sake of their pearls. Although some oysters contain more pearls than others, and some paars have on occasions been characterized by richness in pearl-production, the Cestode parasites are apparently very widely spread and generally distributed. All oyster communities of the proper age contain pearls, and it would probably be impossible to transplant young oysters to any ground in the Gulf of Manaar where they would not become to some extent infected by the pearl Cestode. The frequent thinning out of young oysters, and the transporting as required from one ground to another, which we shall recommend at the conclusion of this Report, will, however, have the effect of causing a more even distribution of the parasites, since some oysters will be taken from more highly infected ground to less, carrying with them the larvæ, either free or encapsuled, and others, again, which may have escaped infection will go to areas where they run a greater chance of encountering the parasite. It is important to note also, in view of experiments in other parts of the Colony, that the *Tetrarhynchus* parasites are not only widely distributed over the banks in the Gulf of Manaar, but also at other places on the coast of Ceylon.

Mr. Hornell* has found *Balistes* with its Cestode parasite both at Trincomalee and at Galle, and the sharks and rays also occur all round the island; so that, in short, there can be no doubt as to the probable infection of pearl oysters grown at these or any other suitable localities.

The details and illustrations of the parasitic life-history outlined above, and the figures upon which our statements in regard to the oysters are based, will be given in the special articles further on in this Report. But even when we have figured all our specimens, have described all that we have seen, and have shown what conclusions may safely be drawn, we feel sure that gaps will be left, and possibly doubts remain, which can only be filled up and finally settled by patient work extending over years, carried on by a competent observer resident in Ceylon, and having at his disposal a laboratory and experimental tanks. A marine biologist working at the Galle Biological Station can scarcely fail to add further details affecting the life-history of the oyster and the prosperity of the pearl fisheries.

During the two cruises of the "Lady Havelock," in our work on the parasites, commensals, enemies, food, and other organisms associated with the pearl oyster, we were brought in contact with many forms requiring identification, and some apparently new to science. It was clearly our duty to collect all such and have them worked up with the view of elucidating the fauna of the Gulf of Manaar and also of making any necessary comparisons with other parts of the coast. Consequently, I am now able to supplement this Report by a series of papers, written by specialists upon the various groups of animals, which not only adds to the completeness of the pearl-oyster work, but will also, I hope, be recognised as a welcome contribution to the marine biology of Ceylon.

The land fauna of Ceylon is very much better known than the marine. Dr. E. F. Kelaart published in 1852 his important work, the 'Prodromus Faunæ Zeylanicæ,' dealing with the mammalia, birds and reptiles. Mr. E. L. Layard has worked at the ornithology and conchology, and we have his papers in the 'Annals and Magazine of Natural History.' Harvey visited Ceylon in 1852 to collect the Cœlenterates and Crustacea. Schmarda, a few years later, wrote on the worms. In Emerson

* It is only due to my excellent assistant, Mr. James Hornell, to state that our observations on pearl-formation are mainly due to him. During the comparatively limited time (under three months) that I had on the banks, I was mainly occupied with what seemed the more important question of the life-conditions of the oyster, in view of the frequent depletion of particular grounds.

TENNENT'S 'Ceylon' (1859) there is a good summary of the fauna as known up to that time, with lists which were supplied, or supplemented, or revised by HUXLEY, GRAY, HANLEY, KELAART, and others. Further papers on new animals in various groups (many of them collected by Dr. W. C. ONDAATJE) have been published from time to time by BOWERBANK, ALLMAN, RIDLEY, DENDY, BELL, CARTER, NEVILL, and the SARASINS. But the most notable contribution to our knowledge of the marine fauna is THURSTON'S 'Notes on the Pearl and Chank Fisheries and Marine Fauna of the Gulf of Manaar,' published from the Government Central Museum, Madras, in 1890. In this interesting little work Mr. E. THURSTON, with the help of Professor DENDY, Professor JEFFREY BELL, Professor HENDERSON, and Mr. E. A. SMITH, gives considerable lists of the Porifera, Cœlenterata, Echinodermata, Crustacea, Mollusca and Pisces which he had collected during visits to Tuticorin, Rameswaram, and some parts of the Ceylon pearl banks.

Taking a somewhat wider area—the northern part of the Indian Ocean—there are three recent series of faunistic explorations which have some bearing on our work, viz., the reports upon Dr. ANDERSON'S collections made in the Mergui Archipelago ('Journal Linnean Soc., Zool.,' vols. XXI. and XXII.), the great series of Memoirs, Reports, and 'Illustrations' issued by Major ALCOCK, of the Calcutta Museum, as a result of the explorations of the surveying vessel "Investigator," and lastly, Mr. STANLEY GARDINER'S series dealing with 'The Fauna and Geography of the Maldive and Laccadive Archipelagoes' (Cambridge Press). The Ceylon marine fauna resembles that of Mergui in some respects, but differs in detail; Dr. ALCOCK'S "Investigator" work has been mainly—though not wholly—in the abyssal waters of the Indian seas; while the Maldives are an Oceanic group, in contrast to Ceylon which is faunistically as well as geologically a part of India. Our dredgings were nearly all within the 100-fathom line, and were mainly in the zone of 5 to 20 fathoms. This account of a shallow-water Continental coast fauna may fill a gap and be of use for comparison with these other recent investigations in the Indian Ocean.

The faunistic reports which will appear along with this INTRODUCTION in Part I. will tell their own story, but it may be well to give briefly what information I can in regard to a few of the other groups, the reports upon which may not be ready for some months.

Professor DENDY has sent me a preliminary report upon the Sponges as follows:—

"This collection of sponges appears to be by far the most extensive that has ever been made in Ceylon waters, and contains many species of great interest. Amongst the siliceous sponges, the Tetractinellida are represented by at least a dozen species, including a new *Stelletta*, a new *Plakinastrella*, and a form which will be described as the type of a new genus under the name *Dercitopsis cingalensis*. There are also a massive Lithistid, a *Placospongia*, and a curious Suberites-like species which is anchored by silky tufts of spicules in soft mud. Amongst the Monaxonids, the Chalinidæ, Ectyoninæ, and Axinellidæ are the most conspicuous groups; while of special interest from the point of view of the pearl fishery is a Clionid which burrows in the shells of the pearl oyster. Many of the Monaxonids are characterised by a strong development of horny fibre, and from these we pass by a natural transition to the true horny sponges, represented by the genera *Euspongia*, *Phyllospongia*, *Hircinia*, *Dysidea*, *Spongionella* and *Aplysina*. The *Euspongia* is a fairly good, compact, resilient bath sponge . . . . . and the possibility of establishing a sponge fishery is worth consideration." Professor DENDY then gives a list of his identifications, amounting to about 60 species.

Mr. HORNELL, who is reporting upon the Polychæte worms, has sent in a preliminary list of over 60 species, at least four of which are new to science and will (Mr. HORNELL states) be described under the names—"*Hermione ridgewayi*, *Thalenassa imthurni*, *Phyllodoce foliosopapillata* and *Spiochætopterus herdmani*."

Mr. ISAAC THOMPSON and Mr. ANDREW SCOTT, who are working up the Copepoda, state that "The collection of Copepoda is the richest and most varied series of this group that has ever been brought from tropical seas by any expedition. The group is represented by over 200 known species and nearly 80 new species, now being described. Of these new species only a small number are true pelagic forms, the remainder being littoral and semi-parasitic species, mostly associated with the pearl oysters on the paars. Some of the pearl-oyster washings were extremely rich in minute Crustaceans, mainly Amphipods and Copepods. The washings from the Muttuvaratu oysters yielded 43 species belonging to the Harpacticidæ alone, besides several species of Lichomolgidæ and Ascomyzontidæ, many of which are new to science."

Mr. A. O. WALKER, who is reporting upon the Amphipoda, writes to me that it is "The most important collection of Amphipods which has yet been made known from the tropics . . . . . It contains over 70 species, and the report will describe a large number of new species, some of which will require new genera . . . . . Many of the forms are closely allied to British and Mediterranean species, while others again have been described from the Australasian seas . . . . . The size of the individuals is small; compared with those from the Arctic and Antarctic areas they are pygmies."

Mr. JAMES JOHNSTONE, who is writing on the fishes, reports:—"The collection consists of 116 species belonging to 73 genera. It is very representative and contains species belonging to 37 families. About 6 forms are still undetermined, and most of these are probably new to science. A number of the species obtained are apparently new to the fauna of India and Ceylon."

In other groups also, Hydroids, Polyzoa, Turbellaria, Alcyonaria, Cumacea and Cephalopoda novelties are turning up, but the examination of these is not yet far enough advanced to warrant more detailed announcement. In the concluding article of the Report I hope to submit such discussion as may seem necessary of the general characteristics and affinities of the marine fauna of Ceylon.

NARRATIVE,

WITH

AN OUTLINE OF THE INVESTIGATION,

AND

DETAILS OF THE STATIONS WHERE OBSERVATIONS WERE MADE.

THE greater part of our observations at sea (as distinguished from the laboratory work which came later), both on the Pearl Oysters and on the animals that are associated with them and the conditions that surround them on the banks in the Gulf of Manaar, can be given most conveniently in the form of a narrative of our cruises in the s.s. "Lady Havelock" and with Captain DONNAN in the inspection boats. This narrative is written out with as little change as possible from the diary and other note-books in which each day's work was recorded at the time. Consequently the names in the lists of species* although, with the help of my friends who are kindly working up the groups, they have been corrected up to the time of writing, will naturally in some few cases require alteration, and therefore it will be understood that, in the event of any difference in nomenclature, the "Supplementary Reports" that follow must supersede the lists in this "Narrative." On the other hand, this section contains the authoritative statement as to the dates, localities, depths, and other particulars of the observing stations, and therefore forms a necessary introduction to the Special Reports. A station, in the later sections of the work, may be referred to briefly by its roman numeral, and the details, both as to the locality and conditions and also as to the other organisms obtained, may be found here.

I may add, in conclusion, that my view in regard to these present lists is that although by no means *complete*, they are substantially *correct* as far as they go, and will serve a useful purpose in giving a general impression of the most abundant and conspicuous, or in other ways noteworthy, organisms at each observing station. They will also enable conclusions to be drawn as to the fauna of the "paars," and as to the enemies and other competing organisms which may affect the life and prosperity of the pearl oyster.

* As all these species will be treated more fully in the Special or Supplementary Reports, I have not considered it necessary to give in these provisional lists the authorities and references. To have done so would have added greatly to the length of the lists, with little or no compensating advantage.

Mr. Hornell and I arrived in Ceylon on January 20th, 1902, so as to leave some weeks free before the end of February, when we proposed to join Captain Donnan in his annual inspection of the pearl banks. This interval I had thought essential in order that we might perfect and test our apparatus, find out the necessary methods of investigation, and make ourselves acquainted with the biological conditions in the Gulf of Manaar, and with any special features in which that region differs from the other seas around Ceylon. For the purpose of this preliminary biological survey the Government of Ceylon placed the s.s. "Lady Havelock"* at my disposal, in the first instance for a period not to exceed three weeks. This first cruise lasted for twenty days (January 30th to February 19th), and was followed, for reasons given below, by a second cruise of about four weeks in the same vessel. After that we joined Captain Donnan on his inspection barque.

In the first cruise of the "Lady Havelock" my objects were :—

(1.) To investigate the general biology of the seas around Ceylon, and especially of those places where pearl oysters were said to exist.

(2.) To examine more carefully any localities that seemed to be likely spots for uncharted pearl oyster banks.

(3.) To investigate the fauna, the bottom deposits, and the characters of the water in the Gulf of Manaar for comparison with the conditions at Trincomalee, Galle, and other parts of the coast.

(4.) To make experimental hauls of the fish- and the shrimp-trawls round the coast, so as to obtain information as to the prospects of fish-trawling as an industry in Ceylon waters.

(5.) To look into any other departments of marine biology which might be prosecuted as useful industries.

We joined the s.s. "Lady Havelock" on the evening of Thursday, January 30th, 1902; and started from Colombo harbour early the following morning. The course during this cruise is shown by the strong dotted line on the map (p. 19), and the observing stations are marked by a cross within a circle (see also more detailed map on p. 82). After steaming northwards for some hours the dredge was put overboard for the first haul about 11 A.M., at 5 miles S.W. of Negombo in $12\frac{1}{2}$ fathoms of water. The rest of the day was occupied in dredging and trawling along an area about 5 miles in length extending opposite Negombo Lake from Pamunogan at the south to Negombo, keeping from $4\frac{1}{2}$ to $5\frac{1}{2}$ miles off shore, in from 12 to 20 fathoms. A little further out the sea deepens very rapidly, 50 fathoms being reached 10 miles from land, 70 fathoms a mile further out, over 700 fathoms at about 18 miles west of Colombo and 1000 fathoms at about 20 miles from land. My object in working along

* I ought to state that on the whole the "Lady Havelock" proved a very suitable vessel for the purpose, and I desire to record also my sincere thanks to Captain Campbell and the officers and others on board for the pains they took to carry out my wishes. The steamer is shown on p. 54.

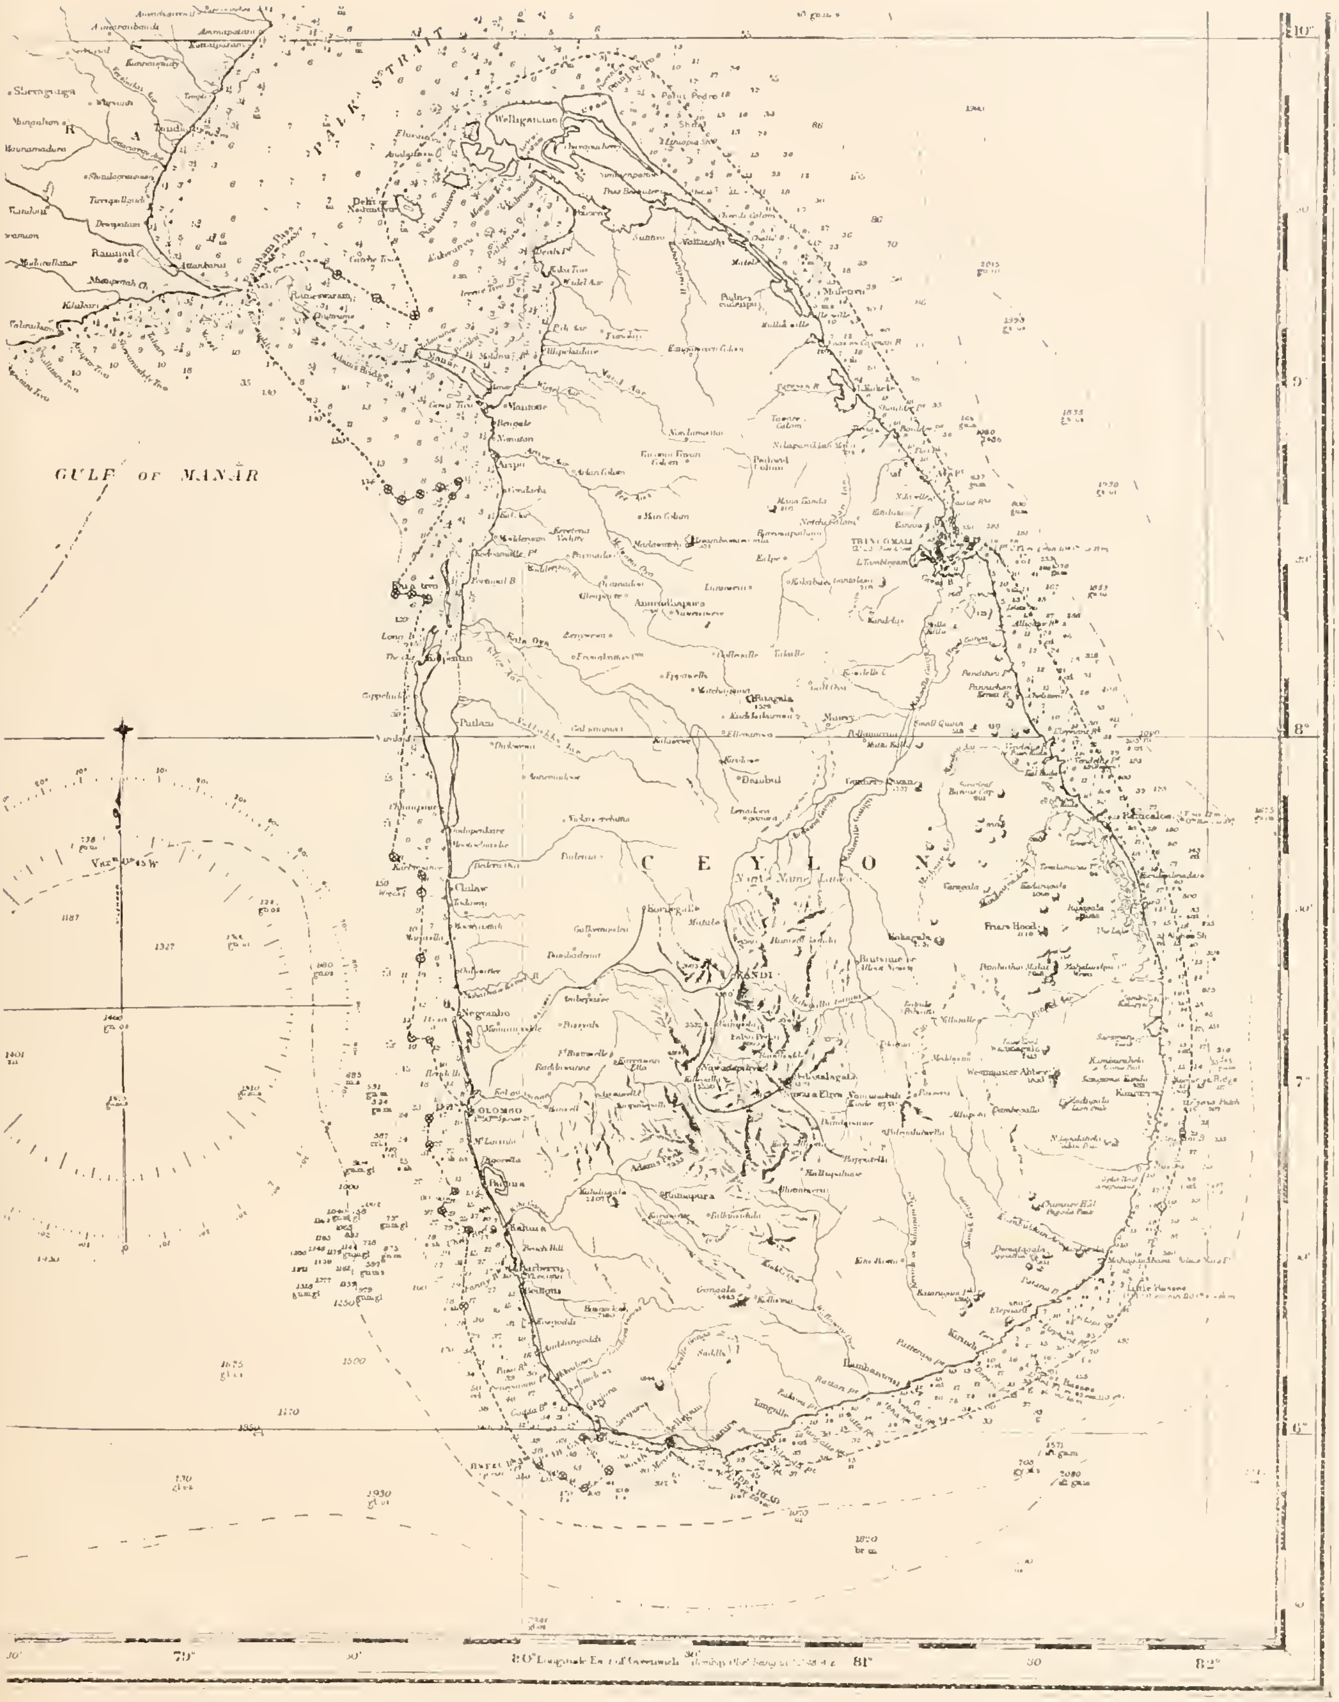

Fig. 1. Sketch-plan of route in first cruise of "Lady Havelock," January–February, 1902.

the shelf within the 20-fathom line off Negombo was (1) to get a fair sample of the conditions and the fauna for comparison with the pearl bank region off Aripu further north and (2) to explore the ground and the water, as we did wherever possible, for any stages young or old of the pearl oyster.

There is a record of an old pearl oyster bed, the "Muttu-Parawuttu Paar" lying about 4 miles W. of Negombo in 9 fathoms. No oysters have, however, been found there I believe for many years. We did not find any trace of this paar, but may have been just outside it; next day however we came upon large quantities of young pearl oysters about 7 miles further to the north. Half-a-dozen hauls of the dredge, two hauls of the 25-foot beam-trawl, with a 7-inch fish-net, and four surface gatherings with the silk tow-net were taken on this first day, off Negombo; and these, although recorded separately at the time, may now be united as one locality:—

STATION I.—Five miles west and south-west of Negombo; 12 to 20 fathoms; bottom coarse yellow sand with a few dead shells; temperature of sea, 77·5° F.; dredged and trawled. Amongst the animals were:—

Various sponges;

Diphasia mutulata, *Lytocarpus* (? n. sp.), *Campanularia juncea*, and some Plumularian Zoophytes, *Caryophyllia* sp. and *Heteropsammia michelini* (with commensal Gephyrea), Gorgonacea (*Spongodes*, &c.);

Leptoplana sp. and another Turbellarian, and *Aspidosiphon corallicola*, *Filograna* sp., *Hyalinœcia* sp., *Terebella* sp., *Acholoe* sp. (commensal with *Astropecten*), *Hesione* sp., *Ophelia* sp. and other Annelids;

Crisia sp. and other Polyzoa;

Echinus and Temnopleurids (sev. spp.), *Salmacis bicolor* and *S. sulcata*, *Lovenia elongata*, *Clypeaster humilis*, *Echinodiscus auritus*;

Thyone sacellus, *Holothuria atra*, *H. tenuissima* and allied species of "trepang" (up to 16 inches long), *Pectinura intermedia* and other Ophiuroids, *Astropecten hemprichii*, *Luidia maculata*, *Antedon* sp.;

Lepas sp., *Hippolyte* sp. (with Bopyrid) and other Macrura, *Neptunus* sp., *Calappa* sp., *Ebalia* sp., and other Brachyura;

Acanthochites penicillatus, *Styliola acicula*, *Teredo* sp. (in wood), *Arca* (sev. spp.), *Venus lamarcki*, *Cardium rugosum*, *Pinna bicolor*, *Pectunculus* sp., *Dentalium octagonum*, *Murex tenuispina* and *M. haustellum*, *Oliva candida*, *Turbo margaritaceus*, *Conus marmoratus*, *Natica* sp., *Harpa conoidalis*, *Umbrella* sp., *Pleurophyllidia* sp., *Melibe fimbriata* and *Sepia* sp.

Molgula sp., and some colonies of a snowy white *Leptoclinum* which grows over the coarse quartz sand and cements the grains together.

The Tow-net gatherings contained:—

Trichodesmium erythræum (in quantity), Diatoms, *Ceratium tripos* and some Foraminifera; *Sagitta* sp., *Salpa democratica-mucronata*, and *Oikopleura* sp.;

Copepoda—many, including a conspicuous blue form *Centropages violaceus*, and also *Oithona similis*, *Euterpe gracilis*, *Ectinosoma atlanticum*, *Temora discaudata* and *T. stylifera*, *Eucalanus subtenuis*, *Calanus vulgaris*, *Calanopia elliptica*, *Corycæus speciosus* and *C. venustus*.

[NOTE.—In coming across the Indian Ocean to Ceylon we used silk tow-nets day and night to strain the organisms from the sea-water running from the tap in one of the bath rooms. In two of these gatherings I obtained the pelagic Amphioxus (*Branchiostoma pelagicum*, Günther). One specimen was taken in a coarse net on January 16th, to the south-east of Sokotra, about halfway between Perim and the Maldives; and five others were found in a finer net on January 20th, after passing Minikoi Atoll, and therefore between the Maldives (where this species was found by Stanley Gardiner) and Ceylon.

Amongst other interesting or novel forms found on the way to Ceylon were:—a new species of *Centropages* (rather widely distributed), *Miracia minor* (taken near Sokotra, previously known from Gulf of Guinea), *Mecynocera clausi* (common), *Scolecithrix chelifer* (Red Sea, the only known locality), *Pseudodiaptomus salinus* (Suez Canal and Red Sea, males found for the first time), *Anymone spherica* (in Suez Canal), *Acartia dubia* (Suez Canal, only known previously from Gulf of Guinea), *Pseudocyclops obtusatus* and *Canuella perplexa* (both European forms, now found in Suez Canal). These will be discussed fully by Mr. Isaac Thompson and Mr. Andrew Scott in their Report on the Copepoda—see below, p. 227.]

On Saturday, February 1st, we dredged and trawled at various localities between Negombo and Chilaw, covering an extent of about 23 miles. The distance was generally from 4 to 5 miles off land, and the depth varied from 8 to 14 fathoms.

This day's hauls can be grouped into two localities; the first (Station II.) from opposite Ooluwitti to off Mararilla, half-way from Negombo to Chilaw, and the second (Station III.) off Chilaw; we dredged and trawled at both, as follows:—

STATION II.—From 7 to 14 miles north of Negombo, 5 miles off shore; 8 to 9 fathoms; bottom coarse yellow sand, shells, stones, and small coral; temperature of sea, 77·5° F., specific gravity, 1·023. Two hauls of fish-trawl and several of dredge.

Pachychalina sp., *Acanthella carteri*, *Hircinia* sp., and *Siphonochalina* sp. (pale lilac, with large oscula occupied by small colourless *Alpheus*);

Masses of living corals (up to 20 × 14 × 6 inches), many solitary corals, mainly *Stephanoseris rousseaui* and *Heteropsammia michelini*, small scarlet Actinians;

Lineus sp., *Aspidosiphon corallicola* (in the solitary corals), Lumbrinereids, *Hesione* sp., *Axiothea* tubes (in masses), *Serpula actinoceros*, *S. quadricornis*, *Sabellaria bicornis*, and many Polyzoa;

Antedon variipinna and another species (many), *Luidea maculata*, *Clypeaster humilis*, *Laganum depressum* and *Echinodiscus auritus*, *Salmacis dussumieri*, scarlet Ophiuroids, and *Phyllophorus cebuensis*;

Leucothoe spiniearpa and other small Amphipods and Isopods not yet determined, some Macrura, *Galathea* sp. (black and white), and *Pilumnus vespertilio*;

Young pearl oysters (in quantity), *Avicula vexillum*, *Conus marmoreus* and a few other common shells, *Philine* sp., *Aplysia* sp.;

Pseudorhombus arsius, and some sea-snakes (see p. 65).

On the second haul, which was 5 miles off Ooluwitti, at a depth of $8\frac{1}{2}$ fathoms, the trawl came up with the beam broken, but contained some large masses of coral and great quantities of young pearl oysters, measuring from $\frac{1}{4}$ to $1\frac{1}{2}$ (mostly 1) inch across. There is evidently at this point some hard bottom with coral growing on it, and with many broken lumps of coral and rounded masses of nullipore, from the size of a walnut to that of an orange—constituting in fact a "paar" upon which young pearl oysters are living. The oysters we got are in their first season, and probably ranged from one to three months in age. On the sand outside this hard patch we brought up quantities of the filamentous green weed (*Hypnea*, *Cladophora*, and *Gracilaria* spp.), which we found afterwards on the south part of the Cheval Paar, covered with the newly deposited "spat" of the pearl oyster.

STATION III.—Off Chilaw, $2\frac{1}{2}$ to 4 miles off shore; 9 to 14 fathoms; bottom coarse sand and small corals; temperature of sea, 77·75° F.; specific gravity, 1·023; one haul of fish-trawl and several of dredge.

Large numbers of *Heteropsammia michelini* (with Gephyreans).
Antedon sp., *Pentaceros lincki* and *P. nodosus*, *Echinanthus rosaceus*;
Aspidosiphon corallicola, Pagurids and other crabs, *Neptunus pelagicus*;
Mitra militaris, *Turbinella rapa* (the sacred chank), *Philine* sp.;
Leptoclinum (2 species).

We were now in the region of the Chilaw Paars, which consist of (1) one large bank running north and south for about 9 miles, at a distance of from 7 to 8 miles from shore, with a depth of 8 to 10 fathoms; (2) a group of two small paars lying north-east of the large Chilaw Paar, at from 5 to 6 miles off-shore; and (3) four small paars nearer the shore opposite Karkopani, about 4 miles north of Chilaw. These small paars are little hard patches, so-called "rock," on the general sandy expanse. The rough bottom varies greatly in depth, the extremes on these inner paars off Karkopani being 6 to 16 fathoms. Outside the outer large Chilaw Paar the depth increases rapidly, and at one place, in less than a mile, we pass from 10 to over 100 fathoms, at about 10 miles off shore.

On February 2nd we first had several hauls of the dredge (the trawl could not be used because of the very irregular hard bottom) amongst the inner paars off Karkopani, then trawled in the more even sandy ground (9 to 11 fathoms) between the inner and the outer paars, and finally had a couple of hauls of the dredge along the outer edge of the outer paar at depths of from 10 fathoms outwards to about 30 (the dredge dropped off the bottom finally on the steep slope about the 100-fathom line). I have placed the dredging off Karkopani as Station IV., and have united the trawling and dredging further out as Station V.; but Stations III., IV., and V., explored on the two days spent off Chilaw, do not differ much and may be regarded as one region. (Also Station LXIX., see chart of route and stations on p. 82.)

STATION IV.—Opposite Karkopani, from 1 to 3 miles off-shore; depth 6 to 9 fathoms; bottom coarse yellow sand with dead shells, nullipores and corals; temperature of sea (7 A.M.), 77·8° F.; specific gravity, 1·023. Several hauls of dredge.

Orbitolites complanata and *Heterostegina depressa* (forming a good deal of the sand);

Axinella donnani, *Acanthella carteri*, and a black leathery sponge;

Solenocaulon sp., *Sarcophytum ehrenbergi*, *Goniastræa* sp. (green), *Turbinaria cinerascens*, *Heteropsammia michelini* (with Gephyreans);

Luidea maculata, *Asterina cepheus*, *Astropecten hemprichii*, *Echinus* sp. (small, flat), *Echinolampas oviformis*, *Maretia planulata*, *Clypeaster humilis*, *Lovenia elongata*, *Thyone fusus*, var. *papuensis* (two), *Holothuria atra;*

Gephyreans (yellowish, burrowing in pearl oyster shell), Cirratulids (deep red), *Sabellaria bicornis*, Serpulids (on pearl oysters), *Trophonia* sp. (?), and Polyzoa;

Caprellids, Pagurids, Portunids, *Calappa* sp. and other crabs;

Acanthochites penicillatus, and, in addition to pearl oysters, molluscs belonging to the following genera:—*Avicula*, *Solen*, *Pecten*, *Mactra*, *Cardium*, *Arca*, *Pectunculus*, *Strombus* (*S. succinctus*), *Cypræa*, *Conus*, *Terebra;*

Branchiostoma belcheri, *Asymmetron cingalense*, and a Solenette (*Cynoglossus* sp. ?).

STATION V.—On both edges of upper end of Chilaw Paar, from 5 to 10 miles off shore; depth, 9 to 11 fathoms and upwards; bottom coarse yellow sand, with many *Orbitolites* and *Heterostegina* inside the paar, outside broken coral, *Halimeda* and Nullipores; temperature of sea (2 P.M.), 79° F.; specific gravity 1·023. One haul of trawl and several of dredge.

Tetractinellid sponges, *Siphonochalina* sp., *Acanthella carteri*, *Dictyocylindrus* (scarlet, massive), *Pachychalina multiformis* var. *manaarensis*, *Madrepora* (two species), *Pocillopora* sp., *Turbinaria cinerascens*, *Plexaura indica;*

Pentaceros lincki and a white Spatangoid;

Pectinaria sp., *Euphrosyne* sp., *Polynoe* (spiny); Polyzoa (various);

Melita obtusata, *Elasmopus subcarinatus*, *Leucothoe spinicarpa* and another (? n. sp.), some interesting new Caprellids, *Galathea elegans* and some other Decapods;

Pectunculus sp., *Pinna bicolor*, and many young pearl oysters; *Leptoclinum* sp.

The Tow-net gatherings during the day (February 2) contained *Sagitta*, *Appendicularia*, Nauplei, Plutei, Larval Polychætes, the veliger stage of Mollusca, eighteen species of Copepoda and the conspicuous blue *Centropages violaceus*.

Having now obtained what we considered fair samples of the bottom, and of the animals associated with the pearl oysters, on the paars off Chilaw, and of the ground between the paars, we steamed for some distance north along the shores of Kalpentyn Island, and anchored for the night about 1 mile off "St. Anna's Church," near the Etaly ferry across Putlam Lake (one of the succession of great inland seas, "gobbs" or lagoons, that extend up this coast of Ceylon) to Putlam Fort. The tow-net was left out all night, and on being hauled at 5 A.M. was found to contain many large Stomatopod larvæ in various Erichthus stages, and some Lucifers, various other larvæ as on the previous day and a few Copepods (*Labidocera acuta*, *L. kroyeri*, and *Calanus vulgaris*). Another haul taken at the same spot from 8 to 9.30 A.M. contained a mass of minute plant-life, *Navicula* and other diatoms, *Pediastrum*, and many small larvæ of worms and Copepod nauplei; also small adult Copepods (*Ectinosoma rosea* and *E. atlanticum* and *Oithona similis*).

A third haul at 11.30 A.M. had swarms of crab zoea and some Foraminifera (*Planorbulina*), also the blue Copepoda (*Centropages violaceus*), *Pontella securifer*, several species of *Labidocera*, including a large new species, also a greenish-blue larval Squilla. This last haul was taken further north, over Muttuvaratu Paar, but the difference in these successive gatherings is probably due to some extent to the time of day and to tidal currents carrying streams of plankton past the ship.

My intention was now to examine the neighbourhood of the celebrated Muttuvaratu Paar lying off the middle of Karativo Island, and perhaps one of the most important of the pearl oyster grounds after the Cheval and Modragam paars. It afforded profitable fisheries in 1889, 1890, and 1891.

We commenced dredging at 11.30 A.M. and spent the rest of the day in making a traverse from east to west across the paar and into the deep water lying outside it. The first five hauls were all in the neighbourhood of the paar and may be considered as one locality (Station VI.), and several hauls were then taken at two spots (Stations VII. and VIII.) further out, the first at 45 to 50 fathoms and the second at 90 to 100 fathoms. This was one of the localities where we examined the ground outside the known paars, down to the 100-fathom line, with the view of ascertaining whether there was any evidence in support of the statement which had sometimes been made in the past, that there were probably unknown beds of pearl oysters further out and in deeper water from which spat was produced for the supply of the inshore paars. No evidence was found.

STATION VI.—Across Muttuvaratu Paar, 4 to 6 miles west of the centre of Karativo Island; depth 6 to 9 fathoms; bottom sand with hard patches of "rock" at intervals; temperature of sea at noon 78° F., at 4 P.M. 79° F.; specific gravity 1·023. Five hauls of dredge.

Spongionella nigra, *Phyllospongia holdsworthi*, *Axinella donnani*;

Zoanthus sp. and lilac Actinians, *Madrepora cytharea*, *Montipora* sp., *Porites* sp., Astræids (two species), *Turbinaria cinerascens*, *Sarcophytum ehrenbergi*, *Plexaura indica* (with Cirripede galls), and other Alcyonaria;

Sabellaria bicornis and *Serpula* sp.;

Echinaster purpureus, *Ophiocnemis marmorata*, *Cucumaria turbinata*;

Pearl oysters, *Modiolaria* sp., *Modiola* sp., *Doris* sp.;

Botryllus sp. and *Leptoclinum* sp.;

Small olive-green Wrasse with white tail (*Pomacentrus bankanensis*).

STATION VII.—Further out, from 6 to 7 miles off shore; depth 45–50 fathoms; dredged.

Large masses of coral overgrown with *Chama foliata*; *Chromodoris* sp.;

Squilla (small—many—in cavities of the coral);

Sabella sp., *Eunice* sp., *Lepidonotus acantholepis* and *Harmothoe imbricata*, all evidently associated with the coral.

STATION VIII.—Still further out, $7\frac{1}{2}$ to $8\frac{1}{2}$ miles off shore; depth 90–100 fathoms; dredged.

Gorgonia miniacea, *Juncella juncea*, *Antipathes* sp. (black, fan-shaped), *Cyathohelia* (?) and another allied form;

Galathea sp. (scarlet), *Lambrus* sp., *Arcania* sp. and other crabs;

Some species of *Nassa* and *Murex* and some small Octopods.

We now steamed further north to the region of the great Cheval paars, lying off the bight of Kondatchy, and started dredging at 8 A.M. on Tuesday, February 4th, along the southern edge of the West Cheval Paar. My object was, after seeing the condition of the ground on the Cheval Paar, to make a line of dredgings across the Cheval and the region outside it to the Periya Paar.

STATION IX.—On south-west corner of West Cheval Paar, about 12 miles from land; depth 7 fathoms; bottom fine quartz gravel, nullipore concretions, and many dead young pearl oyster shells; temperature of sea, 78° F., specific gravity, 1·023; dredged.

Axinella tubulata, *Clathria indica* (on oyster shells);

Sertularia distans and other Hydroids;

Actinometra parvicirra and another species, *Pentaceros lincki*, *Clypeaster humilis*, *Holothuria tenuissima*;

Physcosoma scolops (in *Axinella tubulata*, with commensal tubicolous Oligochætes), *Serpula actinoceros*, *Armandia* sp.;

Pearl oysters, along with "Suran" and "Oorie";

Branchiostoma belcheri (several).

In this haul young pearl oysters about $\frac{1}{2}$ inch to 1 inch in size were obtained in quantity, but the majority were dead; of 200 picked up at random only 20 were living. A large number of small boring Gastropods (belonging to the genera *Purpura*, *Nassa*, *Sistrum*, &c., and known collectively to the natives as "Oorie") were present. They ranged from $\frac{5}{8}$ inch to $\frac{7}{8}$ inch long and were very active, and no doubt contribute to the mortality of the oysters. There were also present considerable numbers of the small mussel, *Modiola barbata*, known to the natives as

"Suran," which form irregular nodular masses of gravel and oysters bound together by a network of byssal threads spun by the mussel. A number of the shells of the Suran as well as of the pearl oysters were perforated by the boring Gastropods.

The next eight hauls (Stations X. to XVII., some of them really representing more than one descent of the dredge) form a series taken from east to west from inside the Cheval to outside the Periya Paar.

STATION X.—One mile to east of East Cheval Paar; depth $5\frac{3}{4}$ fathoms; bottom quartz sand and dead shells; no oysters; dredged.

Sclerophytum polydactylum, *Suberogorgia suberosa*, and other Alcyonaria;
Luidea maculata, *Astropecten hemprichii*, *Pectinura gorgonia;*
Cirratulus sp., *Acholoe* sp. (on *Astropecten*), Lumbrinereids;
Caprellids (many), *Hyastenus* sp. (covered with Hydroids);
Eburna sp., *Turritella* sp., *Philine* sp.;
Styela sp. (with red apertures), *Molgula* (many), *Leptoclinum* sp.;
Dragonet (*Platycephalus punctatus*).

STATION XI.—On East Cheval Paar; depth 6 fathoms; bottom, sand; dredged.

Hircinia clathrata (with *Acasta spongitis*);
Campanularia juncea, *Plumularia setacea* (? n. sp.), *Idia pristina* and *Monostachys dichotoma;*
Centrosiphon herdmani, n. gen. and sp. (Shipley), *Physcosoma asser;*
Clypeaster humilis and *Echinodiscus auritus*, *Lovenia elongata* and *Echinolampas oviformis*, *Synapta* sp. (?);
Lepidonotus carinulatus, *Harmothoe imbricata*, *Filograna* sp., *Retepora* sp.
Species of *Conus*, *Cypræa*, and *Oliva;*
Branchiostoma californiense, *Asymmetron* (*Heteropleuron*) *cultellum*.

STATION XII.—Between East and West Chevals; 6 fathoms; bottom fine sand and much green Algæ (*Hypnea*, *Cladophora*, *Gracilaria* spp.), no oysters; dredged.

Laganum depressum, *Clypeaster humilis*, and *Echinodiscus auritus;*
Sphæroma sp., *Mæra rubromaculata*, *Elasmopus subcarinatus*, Caprellids and other Amphipods; *Philine* sp.

STATION XIII.—On West Cheval Paar; depth 6 fathoms; bottom old worn coral fragments and dead shells.

The haul contained nothing conspicuous except a number of large pearl oysters and a few small ones. The larger ones measured $2\frac{3}{4}$ to $3\frac{1}{4}$ inches across. There were also a few dead oysters, four of which had the valves honeycombed by the boring sponge *Clione;* and some of the coral fragments contained the Gephyrean *Aspidosiphon steenstrupia*. The corals were mainly *Porites* and Astræids.

STATION XIV.—About 2 miles west of West Cheval Paar; depth 8 fathoms: bottom sand with many young and a few old pearl oysters; dredged.

Astropecten hemprichii, *Linckia lævigata*, *Echinaster purpureus*, *Clypeaster humilis*; *Chlœia ceylonica*, *Serpula actinoceros*, *S. quadricornis*, *Ophelia* sp.; *Margaritifera vulgaris* (in quantity) and *Natica* sp.

Leptoclinum sp. (green).

In this haul three dozen large and about 15,000 healthy young pearl oysters were taken. The young were placed in batches in our deck tanks and kept under observation.

STATION XV.—On Periya Paar, 18 miles off shore; depth 9 fathoms; bottom sand; many young oysters; dredged.

Petrosia testudinaria and other large sponges, *Reniera* sp. (green, with oysters attached), *Axinella tubulata* (with commensal worm) and *A. donnani*, *Phyllospongia holdsworthi*;

Favia sp. (large, green), *Adamsia* sp. (small, grey, proliferating);

Echinostrephus molare, *Ophiomaza cacaotica*, *Pectinura intermedia*;

Eunice cirrobranchiata (?), *Armandia* sp., *Sabella phæotænia*, *Serpula quadricornis*, *Leucodora* sp., Pagurids (brilliant orange);

Pearl oysters, "Suran," "Oorie," *Murex anguliferus* (the elephant chank), and species of *Conus*.

The small oysters of this haul were many of them dead. They measured from $\frac{1}{2}$ to over $\frac{5}{8}$ inch in size, and quite a number of the dead valves were perforated by boring Gastropods. Out of a small handful taken at random, 17 oysters were living and 45 were dead, 7 of which were perforated, and along with them were 3 "Suran" and 2 "Oorie" ($\frac{5}{8}$ inch long).

STATION XVI.—On Periya Paar, about a mile further north; depth 9 fathoms; bottom sand, with nullipores, dead coral and shells, with great quantities of young living pearl oysters; dredged.

Orbitolites (very large), *Heterostegina depressa*, *Amphistegina lessonii*;

Isodictya sp. (green);

Paraplanocera aurora;

Pearl oysters and *Solarium* sp., *Turbo* sp., and young Octopods (a new species with branched processes on the body);

Antennarius nummifer.

The numerous pearl oysters in this haul were nearly all young ones, from $\frac{5}{8}$ inch to $\frac{15}{16}$ inch in size, and apparently in a healthy condition.

STATION XVII.—Outside western edge of Periya Paar; 11 fathoms; bottom same as last haul; small pearl oysters very abundant; dredged.

Ciocalypta sp., and other sponges;

Holothuria atra, *Ophiocnemis marmorata*;

Phyllodoce foliosopapillata n. sp. (Hornell), *Lepidonotus trissochætus*, *L. carinulatus*, *Panthalis melanonotus* (in sandy gelatinous tubes);

"Suran," *Avicula* sp.;

Asymmetron (*Heteropleuron*) *cingalense* (12 specimens).

Of the numerous small pearl oysters in this haul rather more than half (on the average 11 to 9) were dead, many of them entangled with "Suran."

Several hauls of the tow-net were made during the day (February 4), and amongst the most abundant organisms noticed were:—

Diatoms (vast quantities), Ceratium, Peridinium, and spherical gelatinous Algæ.

Mitraria, Nauplei, and other larvæ;

Copepods (29 species), *Oithona similis*, *Calanus minor*, *Pseudodiaptomus aurivillii*, *Pontellopsis strenua* and *P. perspicax*, *Calanopia elliptica*, *Labidocera acuta*, *Tortanus forcipatus*, *Centropages* sp. (new to science);

Salpa democratica-mucronata.

The blue Copepods and Salpa were mainly in the later more westerly hauls (18 miles from shore), and the Diatoms and Algæ in the earlier hauls on the Cheval paars. A gathering taken during the night gave some large *Sagitta*, a few small Medusæ, some Amphipods and *Nebalia*.

Having now made a preliminary examination of the pearl-bank regions in the Gulf of Manaar and obtained some samples, I decided to visit various other localities round the island to which attention has been directed either by the literature of the subject or by information obtained since landing in Ceylon. We therefore made our way next through the Pamban Pass, between Rameswaram Island and the mainland of India, into Palk Bay, which lies north of Adam's Bridge (see map of route, p. 19).

On February 5th, while lying at the southern end of the passage, waiting for the pilot, the sea-temperature at 10.30 A.M. was 77·5° F., and the specific gravity was 1·0205. A tow-net gathering taken here contained a new species of *Centropages*, with a remarkable dorsal spine, and a new species of *Labidocera*.

On February 6th, at the north end of the pass, opposite the village of Pamban, at 7 A.M., the sea-temperature was 76° F. and the specific gravity only 1·019; at 7 P.M. in the middle of Palk Bay the sea-temperature was 78° F. and the specific gravity 1·021. This day was spent trawling and dredging in Palk Bay, a wide shallow area lying between Adam's Bridge and the northern end of Ceylon, and partly enclosed by the chain of islands extending southwards from Jaffna, with, for the most part, a muddy bottom at a depth of from 6 to 8 fathoms. Parts of it near the islands are much blocked, as we found later, by luxuriant coral growths, but the centre presents a large open expanse with a uniform soft bottom suitable for trawling. Pearl oysters are said to be found in a few feet of water in some places round the shore, but there are no fisheries, and our object here was not to look for "paars" but for *fish*, as I had undertaken to report upon any grounds suitable for the use of the European fish- or shrimp-trawls if occasion presented itself.

We first took a haul of the dredge to ascertain the bottom and, finding it soft and muddy, put over the large fish-trawl about 7 miles north-east of Rameswaram, at a depth of 7 fathoms, and towed for 6 or 7 miles in a south-easterly direction parallel with the length of the island. A second haul of the trawl was made from the point reached onwards in the same direction to a point due north of about the centre of Adam's Bridge and distant about 9 miles. The third haul was from that point onwards in a more easterly direction towards the Island of Manaar. The beam of the trawl came up damaged on this occasion and had to be shortened by about a foot. The fourth and last haul of the day was taken rather further out than the last and further east, off the western end of Manaar Island, and about 9 miles off shore. Here the beam again broke and required to be repaired, but the contents of the net were saved. The hauls varied from 4 to 7 miles in length and the trawl was generally down nearly two hours. The bottom remained the same and the depth was very uniform. In the middle of the stretch it deepened to 8 fathoms, but towards the end we ran into 7 again. As these hauls were practically continuous, and as the conditions and the results were so much alike in all cases, I think it best to consider the whole day's work as one locality (Station XVIII.), lying to the north of Adam's Bridge and contrasting markedly with the much more irregular bottoms and hard ground lying to the south in the Gulf of Manaar.

STATION XVIII.—South-west part of Palk Bay, off Rameswaram Island and Adam's Bridge, from 7 to 9 miles off shore; depth 7 to 8 fathoms; bottom fine soft bluish-grey mud containing casts of various Molluscan shells; four hauls of fish-trawl and one haul of dredge :—

Holothurian (white and minutely spinous, apparently a new species of *Synapta*), *Salmacis bicolor ;*

Nemertine (large red, like *Valencia splendida*, and also two slender white ones), (?) Terebella tubes, (?) Sabella tubes, *Chlœia ceylonica*, *Gastrolepidia clavigera*, other Polychætes ;

Anilocra sp., *Squilla* sp., Macrurids (sev.), Portunids and other crabs ;

Eburna sp., *Turbinella rapa*, *Fusus turricula*, *Nassaria acuminata*, *Mitra pyramidalis*, *Cerithium citrinum*, *Murex tenuispina* (many), *Natica* (with egg-coil), *Mya* sp., *Pinna fumata*, *Lithodomus* sp., *Dentalium* (up to 3½ inches long), Cephalopod eggs ;

Balanoglossus (probably *Glandiceps haekii*).

The Fish* caught on this occasion were :—

"Cat-fish" (*Arius venosus*, Cuv. and Val.) ;

"John Dory" (*Gazza equalaformis*, Rüpp., and *Equala splendens*, Cuv.). Up to

* I give the English rough equivalent as entered at the time in the diary, followed by the scientific name as determined since by Mr. J. Johnstone, who will report upon the fishes in detail.

6 inches long. Even those of 3 inches long showed the ovaries mature. Intestine dark green in colour and contents consisted entirely of a large Navicula-like Diatom;

"Arnoglossus" (*Psettodus erumei*, Bl.);

"Sand-eels" (several small *Tæniolabrus* sp. and another);

"Bass" (*Sciæna maculata*, Bl. Schn.);

"Soles" (*Cynoglossus* spp.);

"Pomfret" or "Pamplette" (*Stromateus sinensis*, Euphr.);

"Plaice" (*Pseudorhombus arsius*);

"Mackerel" (*Caranx hippos*, Linn., probably = *Scomber heberi*, Bennett).

During the day (February 6) several tow-net gatherings were taken. In the morning (8 a.m.) there was a large amount of material, chiefly Alima and other Crustacean larvæ, also some large *Sagitta*, a few Mysids and large Copepoda (*Labidocera acuta* and *Pontella tenuiremis*). In the afternoon there were fewer animals, but an enormous amount of *Trichodesmium erythræum*, which in places formed a dirty reddish scum on the surface.

This same locality (Station XVIII.) was also visited later on (March 14th) and trawled over again with much the same results. [Station XIX. is in the northern part of Palk Bay, and was worked on March 16th—see below, p. 83, and map, p. 82.]

Palk Bay measures about 34 miles from north to south (roughly from off Jaffna to the middle of Manaar Island) and 40 miles from east to west along the south (say from Manaar to Rameswaram), and is 20 miles across further up between Delft Island and Devil's Point. It is about 100 miles round the coast from Rameswaram to Punkudutiva, and another 30 across the entrance; and must contain over 900 square miles. Of this area probably two-thirds is trawlable ground, with an even muddy bottom at a depth of 7 fathoms nearly all over, while outside is the still wider area of similar character known as Palk Strait, between Ceylon and the Tanjore Coast. Our hauls in both the north and the south parts of Palk Bay showed that there are plenty of fish, and apparently this shallow area serves as a very valuable "nursery" for young fishes.

A great part of the Ceylon coast would certainly be very difficult to fish according to European methods, and in some cases it is practically impossible to trawl because of the coral reefs and other obstacles; but Palk Bay is one of a few areas where there is a considerable extent of ground suitable for trawling, and containing an abundant fish fauna.

The "Lady Havelock" now steamed round the north end of the island from Palk Bay to Trincomalee. After the Gulf of Manaar I regarded Trincomalee as the most important place I had to visit and report upon—in the first place, because of Dr. Kelaart's experiments and observations in regard to pearl oyster cultivation there some fifty years ago, and secondly, because pearl oysters are known still to live in some parts of the inner bay, where they are collected and eaten by the natives and where pearls are occasionally found. About the time we arrived in Ceylon some letters appeared in the Colombo newspapers on the matter, and a Mr. J. B. Colomb, resident in Trincomalee, sent to me one or more specimens of oysters from which pearls had been obtained.

On February 7th, at 7 A.M., we were off Muletivo Shoals, on the north-east coast, and the sea-temperature was 77° F. and the specific gravity 1·021; at 7.30 P.M. that night in Trincomalee inner bay the temperature of the sea was 78·3° F. and the specific gravity 1·022. About 2 P.M. we reached Back Bay (fig. 2), outside Trincomalee, and took a haul of the dredge (Station XX.) in order to see whether the

Fig. 2. Sketch-plan of the bays round Trincomalee, showing Stations XX. to XXXI.

ground was suitable for pearl oysters. The bottom was hard and bore a mixed fauna, but no oysters were found. The tow-net contained a number of Copepoda, including *Oithona minuta* and a new *Labidocera*, close to *L. kroyeri*.

STATION XX.—North part of Back Bay, Trincomalee; depth 11–13 fathoms; bottom hard; dredged. Amongst the animals obtained were:—

Anemones attached to *Fusus tuberculatus*, *Heterocyathus aequicostatus*, and *Heteropsammia michelini* (with Gephyreans);

Stellaster sp. (many), *Astropecten hemprichii* and *A. euryacanthus*, *Ophiocnemis marmorata* and other Ophiuroids, *Cucumaria imbricata* (several);

Aspidosiphon corallicola, &c.;

Cardium rugosum, *Fusus tuberculatus*, *Cerithium citrinum*, *Tudicla spirillus*, *Philine* sp.

We divided up the days devoted to work in the neighbourhood of Trincomalee so as to examine as much as possible of the fauna of this extensive and complicated region (see fig. 2). About twelve bays were explored either with the steamer or the small boats, and we also managed to do some collecting along the shore. The general arrangement was:—

On February 7th, Back Bay;
,, ,, 8th, Back Bay, Dutch Bay, and off Foul Point;
,, ,, 9th, at anchor, shore-collecting, and investigating the pearl oysters;
,, ,, 10th, dredging from the boats in the creeks of the inner bay;
,, ,, 11th, Tamblegam Bay.

On February 8th, at 7 A.M., the sea-temperature in the inner bay was 77·5° F., and at 8 A.M., in Back Bay, was 78° F., the specific gravity at both localities being 1·021. We started dredging at 8 A.M., in the southern part of Back Bay (Station XXI.), one of the localities where Dr. KELAART is said to have deposited pearl oysters in 1857, and where we were told the native fishermen occasionally found them.

STATION XXI.—In Back Bay, North of Fort Frederick; depth 8–12 fathoms; bottom firm sand, in places some mud; several hauls of dredge, but no traces of pearl oysters. Amongst the animals obtained were:—

Adamsia? (on Chank shell), *Virgularia juncea*, *Pteroeides esperi*;

Laganum depressum, *Thyone fusca*, n. sp. (PEARSON), *Cucumaria imbricata*, various Ophiuroids and small Asterids (mainly young *Stellasters*):

Carinella sp., *Terebella* and other worm tubes;

Portunids (small), *Ebalia* sp. and other crabs;

Turbinella rapa, *Strombus succinctus*, and species of *Conus*, *Cerithium*, *Dentalium*, and *Cardium*;

Psammaplidium sp. and *Leptoclinum* (sev. spp.).

We then tried Dutch Bay (Station XXII.), to the South of Fort Frederick, with similar results, a hard bottom with an abundant general fauna, but no pearl oysters.

STATION XXII.—Across mouth of Dutch Bay from Fort Frederick to Dutch Point; depth 13 fathoms; bottom dead coral, shells, and Nullipores; dredged.

Fungia sp., *Dendrophyllia* sp., *Heteropsammia michelini* (with Gephyrea), *Sarcophytum* sp., and other Alcyonaria;

Linckia diplax, *Astropecten zebra* (?), and various Ophiuroids;
Halsydna sp., *Serpula actinoceros;*
Pontonia sp., *Lambrus* sp., and other Decapods;
Molgula sp., and a few common Molluscs.

As we had heard that pearl oysters had been found "off the Suami Rock," Fort Frederick, between Dutch Bay and Back Bay, I considered it necessary to examine the ground further in close to the rocks where the steamer could not be taken. So we engaged a pilot's large boat with a native Tindal and crew and took with us Mr. J. B. Colomb, from Trincomalee, who professed to know where specimens had been obtained by native fishermen. We took haul after haul of the dredge close in along the northern edge of the Suami Rock (Station XXIII.), beginning abreast of the detached rock off the point of Fort Frederick peninsula and working along parallel with the shore past the old Dutch boat-jetty. We were all the time on the ground indicated by Mr. Colomb and the native pilot, and obtained good hauls, but nowhere was there any trace of pearl oysters—not even fragments of dead shells.

STATION XXIII.—Close to Suami Rock, Back Bay; depth $4\frac{1}{2}$ to 8 fathoms, mostly between 5 and 6 fathoms; bottom sand, shells, and in places stones and corals. Half-a-dozen hauls of the dredge.

Caryophyllia sp. and other small corals, *Rhipidogorgia* sp. and other Alcyonaria;
Spatangoid, *Antedon* sp., Ophiuroids, *Holothuria atra*, *Linckia multiforis;*
Melita obtusata, *Ebalia*, and other small crabs;
Malleus vulgaris, *Octopus* sp.

We then steamed across the mouth of "Great Bay," in order to try a haul of the trawl in the open off Foul Point. Unfortunately the bottom proved unsuitable, the trawl eventually caught fast, and, before the strain could be relieved, the bridle parted and the wire rope came in, bringing with it the ring of the bridle (in which was entangled a beautiful dendritic Antipatharian colony) and leaving the trawl at the bottom. We then dredged over the same ground in the hope of entangling the dredge in some part of the trawl, but in vain. We may unite these hauls as:—

STATION XXIV.—Two and a-half to three miles north of Foul Point; depth ranging from 46 to 24 fathoms; bottom hard and rough—probably rock.

Sponges (many), various corals;
Various Gorgonacea, including *Juncella juncea* and *Solenocaulon tortuosum; Antipathes* sp., and *Cirrhipathes spiralis;*
Antedon reynaudi (on Gorgonids), various Ophiurids (on Gorgonids);
Bonellia punicea (in Coral);
Melita obtusata and other Amphipods;
Ischnochiton ferreus, n. sp. (Sykes).

We landed with a party of our Maldivian lascars at Shell Bay, near Foul Point, to examine and collect on the beach. Many "calling-crabs" (*Gelasimus*) were seen, and a large quantity of molluscan shells was obtained—a species of *Bulla* was especially common. Only one specimen of pearl oyster (dead, but having the valves still attached) was found, and a closely allied species of *Avicula* with a longer wing was also taken. Amongst the other shells obtained here, and at other places round Trincomalee, were such typical Indian forms as :—

Pecten plica, *Pinna bicolor*, *P. fumata*, *P. chemnitzii*, and *P. zebuensis*, *Modiola tulipa*, *Psammobia amethystus*, *Cardium asiaticum*, *Ostrea hyotis*, *Vulsella rugosa*, *Avicula vexillum*, *Arca decussata*, *Chama foliata*, *Malleus vulgaris*, *Placuna placenta*, *Ricinula arachnoides*, *Rotella vestiaria*, *Trochus niloticus*, *Margarita acuminata*, *Phasianella lineolata*, *Fasciolaria trapezium*, *Pyrula ficus*, *Fusus tuberculatus*, *Murex haustellum*, *M. tenuispina*, *Eburna zeylanica*, *Triton lotorium*, *T. pilearis*, *T. gallinago*, *T. tripus*, *Xenophora calculifera*, *Solarium perspectivum*, *Strombus succinctus*, *S. sibbaldii* and *S. canarium*, *Cassis glauca*, *C. canaliculata*, *Dolium maculatum*, *D. olearium*, *Conus tessellatus*, *C. terminus*, *C. miles*, *C. betulinus*, *C. striatus*, *Oliva maura*, *O. gibbosa*, *O. ispidula*, *O. elegans*, *O. torsans*, *O. candida*, *Cypræa arabica*, *C. lynx*, *C. moneta*, *C. ocellata*, *C. errones*, *C. caput-serpentis*, *C. coffea*, *C. tigris*, *C. mauritiana*, *C. asellus*, *Natica mammillata*, *Pterocera scorpius*, *Harpa conoidalis*, *H. ventricosa*, *Eburna ceylonica*, *Pyrazus palustris*, *Turritella duplicata*, *T. attenuata*, *Telescopium fuscum*, *Terebra tigrina*, *Turbinella spirillus*, *Bulla ampulla* and *Spirula peronii*.

Two hauls of the dredge were now taken nearer Foul Point (Station XXV.) in much shallower water and on smoother but less interesting ground.

STATION XXV.—Three-quarters of a mile to a mile west-north-west of Foul Point; depth 8 fathoms; bottom firm, Orbitolites sand and Nullipores; dredged.

Orbitolites complanata, *Heterostegina depressa* and other Foraminifera;

Fungia dentata; *Antedon* sp.;

Hyalinœcia sp. (numerous), *Sigalion* sp.; various crabs; *Molgula* sp.;

*Amphioxus** (two, young), *Saurida nebulosa*, *Leptocephalus* and a small Sole.

Several TOW-NET gatherings had been taken during the day (February 8th), but they contained comparatively little except *Trichodesmium erythræum*, which was present in great abundance, some *Euchæta* sp., *Labidocera kroyeri*, *Euterpe acutifrons*, and many young Copepods.

The following day (Sunday) we lay at anchor in Trincomalee harbour, and employed the time in very necessary examination, preservation, and packing of specimens, and unpacking of stores, and writing up of notes. We also did some shore-collecting and obtained local evidence in regard to the occurrence of the pearl oysters at Trincomalee. Mr. COLOMB had brought on board, for our inspection, a number of the empty shells of oysters which had been picked up by the natives in shallow water between Powder

* Specimens apparently not kept, so species not certain.

Island and Victoria Wharf. They had been gathered alive in January and used for food. We measured 240 valves, which ranged in size from 2·2 to 5 centims. in diameter. The average size was 4 centims. So these, as well as all we collected ourselves, were of small size.

Trincomalee is an admirable collecting ground for molluscan shells; some of the numerous beaches in the neighbourhood have fine specimens cast up—for which natives are constantly on the look out—and there are Moormen in the town who are expert dealers, and have large stocks. I examined several of these collections, with the object of looking for large specimens of the pearl oyster; but although nearly every little box or basket of shells, made up for sale to passengers on the steamers, contains a couple of valves of pearl oysters, these are all of small size, and none were seen comparable with those from the Gulf of Manaar.

Some detached valves, about $1\frac{1}{4}$ inches long, were found on the shore close to the Cutch Company's bungalow. Near the same spot were some heaps of a large *Mytilus*, having masses of quartz gravel entangled in the byssus, and also quantities of *Pinna*—evidently all used for food. Many small rock oysters were seen adherent to boulders and masonry at various points round the bay (see fig. 3).

The sea-temperature this day (February 9th) in the harbour was 78·2° F. at 8 A.M., and 78° F. at 7 P.M. The specific gravity at both times was 1·021.

Next day (February 10th) at the same place, at 7 A.M., the temperature was 78° F., and at 7 P.M. was 78·8° F. At both times the specific gravity was 1·020. There had been some rain in the night. The temperature in our various tanks in the ship, in which we kept animals under observation, now began to vary considerably. In the ship's baths the water was 80° F., while some of our wooden tanks were only at 75·5° F. February 10th was devoted to dredging in the various smaller bays or coves which open off the so-called "harbour" (fig. 2) or inner bay of Trincomalee. We may regard each bay as one station, although several hauls of the dredge may have been taken in it.

STATION XXVI.—Outer part of Yard Cove, between Plantain Point and Middle Point and inwards to the "narrows"; depth 2 to 8 fathoms; bottom coarse sand and gravel with thin layer of mud on surface. Several hauls of dredge.

Much black branched and pale lilac Renierid sponges;
Astropecten sp.; *Synapta striata* (lilac and white, in branches of sponge masses);
Sipunculids, Lumbrinereids;
Various Ebalid, Portunid and Eurynomid crabs;
Strombus succinctus (many), *Neritina* sp. (common); *Molgula* sp.

STATION XXVII.—Entrance and middle of Cod Bay; depth 4 to $6\frac{1}{2}$ fathoms; bottom muddy sand; several hauls of dredge.

Gelliodes carnosa, *Halichondria* sp., *Clathria* sp.;
Thyone calcarea, n. sp., *Holothuria tenuissima*, *H. atra*, and *H. marmorata*;

Polynoe sp., *Glycera decipiens*;
Strombus sp. and other common Molluscs;
Amphioxus (apparently undetermined).

STATION XXVIII.—Middle of China Bay; depth 7 to 14 fathoms; bottom black sandy mud; several hauls of dredge.

Holothuria gallensis, n. sp. (PEARSON), *Astropecten hemprichii*, *A. polyacanthus*;
Glycera (small pink), and some long calcareous worm tubes, &c.

STATION XXIX.—French Pass; depth 4 to 7 fathoms; bottom mud with a few stones; several hauls of dredge.

Holothuria marmorata (the large yellow, spotted brown trepang);
Some Molluscs, Annelids and Polyzoa (including *Adeona* sp.).

STATION XXX.—Nicholson's Cove; depth $4\frac{1}{2}$–10 fathoms; bottom muddy sand; dredged.

Euspongia officinalis; and a Cubomedusa;
Holothuria atra (the large black and pink trepang);
Hyalinœcia sp.;
Strombus succinctus, *S. sibbaldii*, and a few other common Molluscs.

The shoal at the inner end of Nicholson's Cove has a hard bottom with occasional boulders, which are covered with small rock oysters up to $3\frac{1}{2}$ inches long (average size 2 inches). It is one of the few spots at Trincomalee which would probably do well for the pearl oyster.

Mr. HORNELL and I managed to land also during this day at various points to examine the shore and the shallow-water fauna—which was very important here because of the remarkable fact that the pearl oyster is found living naturally between tide-marks.

At the far end of Nicholson's Cove we found one or two dead specimens of the commercial sponge, and we also dredged a piece which proved to be *Euspongia officinalis*. This showed that it evidently grows in the neighbourhood, and we have since found it in quantity. In the mangrove swamps which fringe the ends of this and some other coves there are great numbers of small land crabs (*Ocypoda macrocera*) and also of the semi-terrestrial fish *Periophthalmus*, some of which we caught, with some difficulty. We tried to keep the *Periophthalmus* alive in our tanks on the ship, but the little fish persisted in coming out of the water and getting on deck. They scrambled up the vertical wooden sides by taking advantage of the angles at the corners of the tanks.

We waded over all the shallower parts of the harbour where Dr. KELAART had investigated the pearl oysters in 1857, and where Mr. COLOMB reported that oysters are now found by the natives. The chief place is between Powder Island and the shore near the wharf (fig. 2). Here the bottom is hard gravel with some rock *in situ* and large boulders. Rock oysters and a species of *Arca* are abundant on the rock and boulders (fig. 3) and on pieces of wreck, also quantities of

Fig. 3. Rock oysters (*Ostrea* sp.) in Trincomalee harbour at low tide.

Mytilus of good size were living on and in the gravel anchored by the byssus. Attached to these and to other objects were many pearl oysters of smallish size. Samples of these were taken alive to our laboratory on board ship. In the sand around the island *Pinna bicolor* lives in abundance, of large size, almost wholly buried, the tips of the valves just projecting beyond the level of the sand, and the byssus deep below, generally having some larger objects such as small stones and dead shells attached to it. On the shores of Powder Island we also found *Periophthalmus kohlreuteri* and thick-bodied land-crabs, and also a shore-crab with a long crenated front margin between the eyes; a *Neritina* and a *Littorina* were common, and we found a large rough Nudibranch, yellow and grey speckled, under a stone.

I obtained a native dug-out canoe and went across the bay towards Orr's Hill to see some natives diving for trepang in a few fathoms of water. The species were *Holothuria marmorata* (spotted yellow and brown forms) and *H. atra* (black, with a lighter pinkish under-surface). The divers were said to obtain 75 cents (one shilling) per 100 for these.

We next examined a reef of rock and coral lying off the Cutch Co.'s bungalow. Here by wading, or by using the water-glass in the deeper parts, we saw living coral in quantity (chiefly *Porites* and Astræids), much sponge, and many fair-sized pearl oysters attached either to mussels as before or to the rock by their byssus. They appear to extend sporadically across the sand from Powder Island to Orr's Hill. *Pinna bicolor* and *P. fumata* were present in the sand and gravel around, and an *Ostrea* on the rocks. We caught a small yellow *Ostracion* amongst the pearl oysters. Undoubtedly this spot, and the ground round Powder Island and the shoal at end of Nicholson's Cove are the best spots in Trincomalee for the cultivation of the pearl oyster. The bottom is suitable, and apparently the animals live naturally and grow fairly well there. Most of the other bays and creeks we examined are useless because of the large amount of mud present. We deposited in the harbour a number of living pearl oysters brought round from the Gulf of Manaar. They were enclosed in a wire cage anchored and buoyed at a spot duly recorded outside Little Powder Island. Mr. HORNELL will examine these on his next visit to Trincomalee.

Of the pearl oysters collected at Powder Island and on the reef off the Cutch Co.'s bungalow, 33 were at once examined as to the sexual condition—18 were males, 11 females, and 4 quite immature. The males ranged in size from $1\frac{7}{16}$ inch to $2\frac{1}{4}$ inches, and the females from $1\frac{5}{16}$ inch to $2\frac{1}{2}$ inches. Some of these were ripe, and we fertilised some ova with the spermatozoa.

On the following afternoon we examined the shore in the other direction (south), between the wharf and York Island, by means of small boat and wading. Here we came again upon rock oysters, small land crabs and a large *Ligia*, also living corals and *Pinna*. The bottom round York Island and towards the rocks near the Admiral's house is hard and seems suitable for pearl oyster cultivation ; we found several dead pearl oyster valves on the shores of the island.

On the whole Trincomalee presents several distinct advantages as a locality in which experiments in pearl oyster cultivation might be carried on ; but on the other hand it has several disadvantageous characters. As to the first, the pearl oyster already lives there in a healthy state, and sometimes, at least, produces pearls. Secondly, the locality is protected from the monsoons and sheltered in all weathers, so that work and observations could be carried on at all times of the year. Thirdly, there are several places in the bay where the bottom is hard and seems suitable for the attachment of pearl oysters. The greater part of the area is, however, very muddy ; it is said that large quantities of clay are washed down by the rains, the specific gravity of the water is rather lower than that usually found in the Gulf of Manaar, and, so far as our observations show, the plankton or microscopic life floating in the water is relatively small in amount and that will probably mean poor feeding for the larger animals. The pearl oysters we found at Trincomalee struck us as looking rather dwarfed or poorly nourished, and they were found to be sexually mature at a much smaller size than was the case with those of the Gulf of Manaar. Hence while experiments might be carried out at Trincomalee when impossible elsewhere because of weather, the conditions of water and food are probably not so favourable as in the Gulf of Manaar and would probably not lead to such active growth and shell (including pearl) formation.

The greater part of our last day (February 11th) at Trincomalee was devoted to the examination of Lake Tamblegam, an enormous shallow sea-water area opening by a narrow entrance from Great Bay. The sea-temperature at 7.20 A.M. in Great Bay, off the entrance to Tamblegam, was 78° F. and the specific gravity 1·0166 ; at 9 A.M. in Lake Tamblegam the temperature was 80° F. and the specific gravity 1·0145 ; at

7 P.M. in Trincomalee harbour the temperature was 78° F. and the specific gravity 1·0202. The entrance to Tamblegam is obstructed by a long curved sand-spit on the south and a number of scattered rocks and reefs on the north, so the steamer was unable to get within a mile or more of the channel. From there we sailed in the ship's gig with a strong easterly wind which carried us into the lake in fine style, but gave considerable trouble when we tried to return in the afternoon. The passage was found to be too narrow and too much obstructed to beat out against the wind, and when we lowered the sails and started to row out through the breakers now coming in from Great Bay, first one and then a second of the six oars broke, followed by the snapping off of one of the brass rowlocks at a critical moment. The boat then made way very slowly, dodging where possible behind the rocks at Noddi Tevu, and so eventually got through the worst of the sea and out of the narrow channels into the open bay.

Lake Tamblegam has long been known as the scene of a fishery of the flat thin "window-shell" oyster, *Placuna placenta*, a remarkable form (see fig. 4) in which

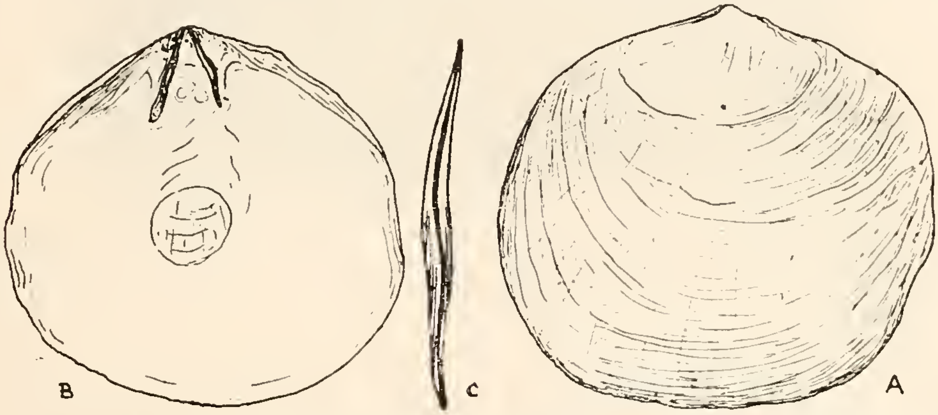

Fig. 4. *Placuna placenta*, from Lake Tamblegam; half natural size. A, outside of shell; B, inside; C, edge view.

an exceedingly thin body is contained—or compressed—between two almost flat discoidal valves of considerable size (up to 6 inches across) which can easily by scraping off the outside be rendered at least translucent to light, and are said to be used as window-panes in Chinese huts and at Goa. Pearls are not unfrequently found in these window-shell oysters and profitable fisheries have been held in the past at Tamblegam. The pearls are mostly small and these are said to be exported to India to be calcined to make chunam for betel-chewing. We did not on this visit see any living specimens of *Placuna*, although Mr. Hornell has seen them since; but the great gleaming piles of dead shells seen at various points along the shore (fig. 5) were evidence of the enormous numbers that had been taken in the former fisheries, and especially at the last fishery fifteen years ago, when the stock in the lake seems to have been nearly cleared out. There were also in places heaps of piled up rock-oysters (*Ostrea* sp.), some of very large size. These, as well as a large species of *Venus* and a mauve *Psammobia*, are used as food by the natives. The whole lake, measuring more than 20 miles round, is very shallow, most of it being under a fathom in depth. On the southern coast we found there was not enough water to row round near the shore in the ship's boat, so we crossed to near Corrinjahvat in the north

Fig. 5. Heaps of window-shell oysters (*Placuna placenta*) on the shores of Lake Tamblegam, from the last fishery.

where great piles of *Placuna* valves line the shore. We took a few hauls of the dredge here in about 1 fathom of water, and also dredged across the mouth of the inlet known as Narche Coudar (fig. 2, p. 31). In both spots (the whole of Lake Tamblegam may be regarded as Station XXXI.) the bottom was mud with a little sand, and there were few animals:—some worm tubes, a few small Medusæ, a flat Clypeastroid and some Pagurids in Gastropod shells.

The bad weather, and a knowledge that the difficulty we should have in getting out would be increased with delay, prevented our spending longer time in Tamblegam Lake, and unfortunately fully as many days as could be spared had now been given to the Trincomalee district. But I arranged with Mr. Hornell that after my departure from Ceylon he should take an early opportunity of visiting Trincomalee and Tamblegam by land, and by making use of native fishermen and divers from the shore, satisfy himself as to any of the matters which we had left undecided.

The main points on which I wished him to get further evidence were:—

(1.) Whether the water of the harbour differed much in muddiness and salinity at other seasons;

(2.) Whether the commercial sponge which we had found lived in any easily accessible spot in sufficient quantity to constitute a fishery;

(3.) Whether the window-shell oyster was still present in abundance in any part of Lake Tamblegam.

Mr. HORNELL carried out these instructions in October, 1902, when he spent a week at Trincomalee and made a thorough examination of Tamblegam Lake. He was successful in settling, I think, all the points referred to him. He found that the specific gravity of the water varied about 1·019, at a temperature of 84° F. to 90° F. But he was told this had been an unusually dry season at Trincomalee.

With the help of native divers he found the bath sponge living in quantity, of good size and suitable form, in a few feet of water along the shores of Plantain Point and in Yard Cove. I have examined the specimens he sent to Liverpool and have shown them to Professor ARTHUR DENDY, our leading specialist on the subject. Professor DENDY determines them as *Euspongia officinalis*, the common bath sponge, and describes the samples we had before us as being a fairly good, compact, resilient bath sponge, but containing a certain amount of grit in the form of broken foreign spicules in the primary fibres. He adds: "The possibility of establishing a sponge-fishery is worth consideration."

Mr. HORNELL examined a number of pearl oysters from round Powder Island and elsewhere in the harbour. They had increased in size since our visit in February but were not so numerous.

In his visit to Tamblegam (Station XXXI.) he found the temperature of the water varied from 87° F. to 90° F. and the specific gravity from 1·016 to 1·019. Amongst the animals he obtained were:—

Tetractinellid sponge (a curious Suberitid species which lives anchored in the soft mud by silky tufts of spicules, and the presence of which is regarded by the divers as an indication of *Placuna*);

Sagartia sp. (on *Cassis*) and a (?) Cerianthid (in tube);

Various crabs, including a burrowing form with scarlet antennæ;

Venus sp. (collected as food by natives near mouth of Kinnia River), *Psammobia* sp. (mauve, eaten by natives), *Placuna placenta*, Trochoid shell (abundant). *Ostrea* sp. (rock oyster).

We left Trincomalee on the night of February 11th, for Galle, and the following morning at 10 A.M., when 30 miles south of Batticalloa, found the sea-temperature to be 78° F. and the specific gravity 1·0215. We took a haul of the dredge (Station XXXII.) some distance further on, off the south-east of the island.

STATION XXXII.—Five miles East of Arugam Bay; depth 17 fathoms; bottom fine sand.

Solenocaulon tortuosum and other Alcyonaria;

Astropecten (two species);

Serpula actinoceros:

Ampelisca macrocephala, Pagurids;

Cassis glauca and a few other Molluscan shells.

A TOW-NET gathering taken at the same time yielded 26 species of Copepoda along with *Trichodesmium erythræum*.

Another haul of the dredge was taken further on at—

STATION XXXIII.—Halfway from Arugam to Little Basses, about 4 miles from land; depth 18 fathoms; bottom dead shells and Nullipore.

Axinellid sponge (large, orange, branching, gorgonid-like form, which is probably a new genus);

Solitary corals, *Plexaura indica* and some other Gorgonacea;

Rhinobrissus pyramidalis (?), various Ophiuroids;

Ampelisca macrocephala, and other Amphipoda.

We reached Welligam (or Belligama) Bay, near to Dondra Head, the most southerly point of the island, in the early morning of February 13th. One of the points I had to determine during this preliminary survey of the marine biology of the Ceylon coast was the most suitable spot for a small marine laboratory in which Mr. HORNELL could continue our work at the pearl oysters during the monsoon after I left. All naturalists know of Professor HAECKEL's visit to Ceylon in the winter of 1881–2, and of how he carried on shore and pelagic work for some months at the southern end of the island, and especially at Welligam (the "Bella-Gemma" of the enthusiastic German professor), where he found congenial quarters, ideal natives and an interesting fauna. His happiness in his general surroundings is reflected in his glowing description of the bay as a zoological paradise. Hearing that I was going to Ceylon, HAECKEL kindly wrote pressing "Bella-Gemma" upon my attention as an ideal spot for a biological station. He also very fairly mentioned Trincomalee as a place where his friends Dr. PAUL and Dr. FRITZ SARASIN had worked but which he did not himself know. Welligam looked charming on land, but seemed to us to have a poor bottom fauna compared with either Galle or Trincomalee. HAECKEL however worked mainly, if not wholly, on the surface animals collected with the tow-net; and these no doubt, so far as the oceanic forms are concerned, are much the same as at Galle.

While the "Lady Havelock" lay at anchor in Welligam, we went off in the boat and had seven hauls of the dredge scattered fairly over the bay so as to adequately sample the ground. As all parts seemed alike in character and fauna I propose to unite them as—

STATION XXXIV.—Welligam Bay, various parts; depths 2 to 7 fathoms; bottom shell-sand and a little mud; sea-temperature at 7 A.M. 77·8° F., specific gravity 1·0225; dredged.

Orbitolites complanata, *Polytrema miniaceum*, and small sponges;

Hydractinia sp., small Gorgonids;
Echinodiscus auritus, *Lovenia elongata*, *Antedon* sp.;
Glycera lancadivæ, *Serpula* sp., and some other small worms, Lepralid Polyzoa;
Ampelisca brevicornis, some Pagurids and small crabs;
Turritella duplicata, *Philine* sp. and many dead molluscan shells;
Molgula sp. (small), *Amaroucium* sp. and Amphioxus* (2).

We landed at the south-eastern corner of the bay, near the fishing village of Mirissa, which seemed the most promising part—zoologically—as it may possibly be a little sheltered from the south-west monsoon, and examined a good deal of the beach and of the shallow water near from the boat. There are red cliffs of coarse gneiss at the extremities of the bay, which no doubt give it its chart name "Red Bay." Pagurids of several species, some inhabiting the shells of Helix and other land Molluscs, were very common on the upper part of the beach and in the cocoa-nut plantations beyond. A crowd of several dozen were found congregated upon a small heap of dung evidently feeding. Others were sheltering in numbers about the roots of the trees. A *Pterocera* shell (*Pt. lambis*) was found on the beach, small Limpets were abundant on the red rocks at the point, and many long-spined purple Echinids (*Stomopneustes variolaris*) were in hollows in the rock pools, and also under the sea in cavities and crevices of the rock. Living Corals were seen from the boat in the shallow water just inside the point.

On the whole this was a disappointing bay. There is no place where experiments in the cultivation of the pearl oyster could be carried on. There is no ground where we could expect to find the animal, or where it would probably be able to live. The bay is open to the full force of the south-west monsoon, and this would introduce difficulties in collecting and other biological work during a great part of the year. It is unsuitable both for the general work of a biological station and also for the special purposes of the pearl oyster investigation.

We went on the same night to Galle—the last of the localities round the coast which I had noted for comparison with the Gulf of Manaar.

Altogether five days were spent on this occasion investigating Galle and its surroundings, and another visit of several days was paid later on, in March.

February 14th was spent in dredging in the bay, and shore-collecting;
February 15th in dredging near Watering Point, and shore-work;
February 16th in examining the Coral reef and the lagoon (see fig. 6);
February 17th in dredging off entrance to Galle Bay and neighbourhood;
February 18th in dredging and trawling in deeper water outside Galle and onwards.

On February 14th we had several hauls of the dredge in the entrance to the bay, between the points, which may be united as—

* Probably *Branchiostoma lanceolatum*, but the specimens have apparently not been preserved.

STATION XXXV.—Entrance to Galle Harbour, near the black buoys and Mata-Mada Rocks; depth $4\frac{1}{2}$ to 7 fathoms; bottom coarse sand; sea-temperature, at 6.30 A.M. 78·5° F., at 9.30 A.M. 79° F.; specific gravity 1·023; dredged.

Calcareous sponge (*Clathrina* sp.), *Hymeniacidon* sp.;

Diphasia mutulata;

Glycera sp., *Leanira* sp.;

Ampelisca brevicornis, Hippa asiatica, and several Brachyura;

Pteropods, and some shells of the genera *Cucullæa, Ostrea, Anomia, Turritella:*

Branchiostoma lanceolatum.

Fig. 6. Sketch chart of Galle Bay, showing Stations XXXV. to XLI., the Coral reef, Lagoon, position of the Biological Station (B.S.), &c.

Four hauls of the dredge taken in the afternoon and evening near Gibbet Island and the Kata Rocks may be united as—

STATION XXXVI.—Galle Harbour, off Gibbet Island and Glosenburg from Kata Rocks inwards; depth 2 to $4\frac{3}{4}$ fathoms; bottom fine sand and mud; dredged.

Some sponges, and *Hydractinia* sp.;

Nereis foliosa, *Glycera* sp., *Serpula quadricornis*;
Ebalia sp. and other small crabs;
Shells of *Dentalium octagonum*, *Eburna canaliculata*, and other Molluscs;
Leptoclinum sp., and *Branchiostoma* (*Dolichorhynchus*) *indicus*.

Halobates was seen on the surface in quantities during the afternoon, and a townet gathering taken in the evening, after dark (about 9 P.M.), contained *Corycæus obtusus*, *Labidocera pavo* and *L. kroyeri*, *Pseudodiaptomus serricaudatus*, and a new species of *Centropages*. On the following evening, after dark, we again got very much the same series of Copepoda.*

In the little bay between Gibbet Island and Glosenburg (fig. 7) the bottom is fine sand, ripple-marked, and with occasional boulders. The entrance is bounded by a chain of submerged rocks covered with Algæ and Corals. The bottom and sides are not unsuitable as a locality for biological experiments when in the condition in which we saw them, but the situation is exposed, and there is probably a heavy surf rolling into the little bay during the south-west monsoon. We examined this bay and also the creek behind Gibbet Island with some care, as the locality had occurred to us as a possible position for the biological laboratory, and moreover HAECKEL in his book on Ceylon had strongly recommended it for the purpose (see below, pp. 46, 47).

On February 15th we examined the south-eastern corner of the bay inside Watering Point, both by dredging and on shore. The hauls are united as—

STATION XXXVII.—North-west to north-east of Watering Point, about 200 yards off shore; depth 7 fathoms; bottom fine dark sand with some broken coral in places. Nearer the shore, inside Watering Point, are small coral reefs.

Various Alcyonaria and living Corals, chiefly Madrepores;
Synapta sp. (?) and *Holothuria atra*;
Filograna sp. and *Leucodore* sp.;
Calappa sp. and some Ebalid Crabs, *Hippa asiatica*, and some Pagurids;
Margaritifera vulgaris (dead shells).

We then landed at Watering Point to examine the shore, and were struck by the filthy and insanitary condition of the water which was then being pumped into water-boats to supply ships, from the old Portuguese tank. We explored the beach in both directions, and also the cliffs above, and, from the boat, the shallow water lying off the beach, with a view to reporting on this corner of the bay as a possible site for our marine laboratory. The advantages are the shelter and protection from the monsoon afforded by the headland, purity of the sea-water, and the presence of hard patches at the bottom in places where there is a fringe of living coral, and where we had found evidence of a few pearl oysters living naturally. The disadvantages are however very serious, viz., the complete isolation and the comparative inaccessibility.

* Mr. HORNELL, tow-netting at Galle since, has obtained these same Copepoda with the addition of *Calanopia elliptica*, *Acartia centrura*, *Labidocera detruncata* and a new species of *Lichomolgus*.

During the monsoon it might often be difficult to reach this spot by boat across the bay, and the distance round from the town of Galle by land is considerable (see fig. 6), and the latter part of it steep and with no proper road.

The possible sites at Galle had seemed to be :—

(1.) In the Fort, where the Government offices and European quarters are situated (fig. 6).

(2.) On Gibbet Island or Glosenburg, in or about Bayley's Villa or the neighbouring native village (fig. 7).

(3.) At Watering Point (fig. 6).

We now ruled out the last; and made a further examination of Gibbet Island. This is much nearer the town, and has a good road leading to it. Some of the

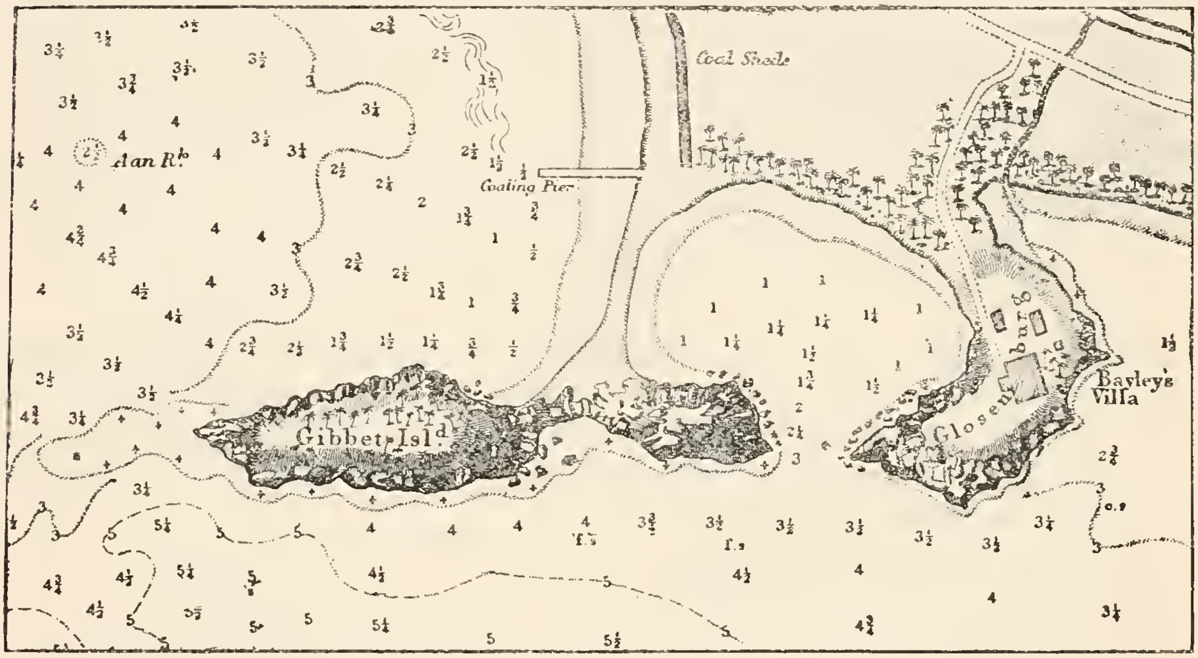

Fig. 7. Gibbet Island, Glosenburg and neighbouring creeks, in Galle Bay, showing the position of Bayley's Villa, recommended by Professor E. Haeckel, in 1881, as the site of a Biological Station.

old P. and O. Co.'s quays and walls would no doubt lend themselves well for adaptation as tanks; but, as I have shown above, it is quite a question whether work would be possible in either of the adjoining creeks during the height of the monsoon, and whether therefore this locality presents any advantage over the Fort, which would be more convenient and satisfactory in many ways for European workers.

Professor Haeckel writing, in 1881, his opinion of Galle as the site for a Marine Biological Station says*: "But more attractive to me . . . were the magnificent corals,

* English translation—'A Visit to Ceylon,' Kegan Paul, &c., London, 1883, p. 181.

which grew in extraordinary abundance on the surrounding rocks; even the little inlet used by Captain Bayley as a dock for his boat, and the stone mole where we disembarked, were closely gemmed with them, and in a few hours I had added considerably to my collection of corals. A very large proportion of the multifarious forms of animal life, which are distributed over the coral reefs near Galle, were to be seen crowded together in this narrow space—huge black sea-urchins and red starfish, numbers of crustaceans and fishes, brightly coloured mollusca, strange worms of various classes, and all the rest of the gaudy population that swarms on coral reefs and lurks between the branches. For this reason, Captain Bayley's bungalow . . . is particularly well-fitted to be a zoological station, and is only half an hour's distance from the conveniences of the town."

However, after full consideration, we differed from our German friend and decided to recommend a site in the Fort as the best position at Galle (see below, p. 92).

On two of these days we landed with a party of our Maldivians carrying ship's buckets, and, crossing the town, descended the ramparts of the Fort between "Triton" and "Neptune" Bastions (see fig. 6), in order to collect on the coral reef which fringes the shore along this side of the town, and in order to examine the possibilities of the lagoon inside the reef for purposes of pearl oyster work. The reef there runs at an average distance of about 500 feet from the shore, and the lagoon varies in depth at low tide from 1 to 6 feet. It is possible to wade over the greater part of it at a depth of 18 inches or 2 feet. The collecting is very rich, and the colouring gorgeous. Many common genera of Corals, such as *Madrepora*, *Montipora*, *Pocilopora*, and *Galaxea*, greenish-brown *Meandrina*, vivid grass-green *Astræa* or *Favia*, and others abound, but even more conspicuous in many parts of the lagoon are huge colonies of the massive leathery or slimy Alcyonaria belonging to the genus *Sarcophytum* and its allies *Sclerophytum*, *Lobophytum*, *Sinularia* and *Alcyonium*. We obtained about twelve species of the fleshy Alcyonaria in the lagoon, including *Sarcophytum ehrenbergi*, *Sclerophytum polydactylum*, *Scl. durum*, *Scl. densum*, *Lobophytum hedleyi*, *L. pauciflorum*, *L. densum*, *Alcyonium pachycladis*, and about four other species some of which are probably new to science. Amongst the other fixed forms Nullipores and incrusting Polyzoa are much in evidence forming smooth layers, filling up crevices and cementing together the separate coral colonies, branches and broken masses. STANLEY GARDINER has shown the importance of Nullipores in the formation of reefs. I am inclined to think from what I saw at Galle and also on the coral formations in the Gulf of Manaar that incrusting calcareous Polyzoa play at least as important a part in covering and consolidating the fragile, broken, or decaying coral colonies. The more abundant and characteristic Algæ (other than Nullipores) growing over the dead corals on this reef are: A small *Corallina*, three species of *Caulerpa* (probably *C. racemosa*, *C. plumaris*, and *C. sedoides*), *Halimeda tuna*, *Padina commerssonii*, *Peysonnelia rubra*, and the lace-like *Vanvoorstia spectabilis*. Bright green Zoanthids, one a long cylindrical form with two rows of tentacles, and compact masses of *Palythoa caribbæa* are also conspicuous. Even the compound Ascidians (Botryllids and Leptoclinids) are of a brilliant green colour. The Tunicate fauna of Galle includes a common *Ascidia* allied to *A. depressa* of European seas, a small red *Cynthia*, a dark brown *Ascidia* like *A. fumigata* of the Mediterranean, a dull-grey Polyclinid (? *Amaroucium*), and about half-a-dozen species of Leptoclinids, one of a lilac colour, one of a rich green, one of a very dark brown, several white and grey forms, and a large handsome new species with pinnacled upgrowths mottled black and white, which I propose to describe under the name of *Leptoclinum im-thurni*. Turning to non-colonial and more or less wandering animals, a feature of the lagoon is the huge black, brown and mottled Holothurians, which lie about on the coral sand and the commoner forms of which (*Holothuria atra*, *H. marmorata*, *H. vagabunda* and *H. tenuissima*) are fished as "trepang." Some others (*Actinopyga mauritiana*) have a flattened under-side and are coloured conspicuously black and white; and we were fortunate in finding three species which have been described as new by Mr. Pearson, viz., *Thyone hornelli*, *Actinopyga serratidens* and *Holothuria gallensis*. Long-spined purple Echinids, large Ophiuroids, star-fishes, and other Echinoderms are found. There are Turbellaria, including a beautiful white species with black mottling which, Mr. Laidlaw tells me, will require a new genus near to *Discocelis*. The Polychæte worms include spinous Polynoids, a large olive-green *Loimia*, *Eurythoe latissima*, *Onuphis maculata*, *Notocirrus trigonocephalus*, *Cirratulus* sp., a small speckled *Polymnia*, a huge *Sabellaria* (*S. bicornis*), *Spiochætopterus herdmani*, n. sp., Hornell (under stones), species of *Amphinome*, *Nereis*, *Syllis* (with buds), *Sabella fusca*, *Lepidonotus crispatus*, *Ophryotrocha*, *Amphitrite*, *Pista*, and others. We got an orange-red Nemertine, and a white species with red lines; also a pale yellow *Balanoglossus* in the calcareous sand under stones. There were many Pagurids—one a brilliant species with scarlet facings, and having the chelæ and other limbs barred with light blue and black alternately. The Amphipods we collected in the lagoon include, Mr. Walker reports, *Hyperia galba*, *Hyperoche cryptodactylus*, *Leptophoxus uncirostratus*, *Stenothoe monoculoides*, *Erichthonius abditus*, *Platophium* sp., *Mæra rubromaculata*, and a new species of *Ampelisca*. Amongst the numerous Molluscs are *Cypræa moneta*, *C. mauritiana*, a *Pleurobranchus*, an orange *Doris*. an *Aplysia*, an *Octopus*, *Harpa conoidalis*, *Pleurotoma nodifera*, *Nerita* sp., *Terebra* sp., several other Cowries and Cones, *Callochiton platessa*, and a new species of Chiton which Mr. Sykes has described as *Ischnochiton herdmani*. There were numerous brilliantly coloured fishes, including the curious little *Antennarius marmoratus*, Less.

This, of course, does not attempt to be a complete list, but merely to give some idea of the variety and abundance of the shore fauna at the spot which we eventually selected as the best in Ceylon for a Marine Biological Station.

On February 16th, at 8 A.M., in Galle harbour, the sea-temperature was 79° F., and the specific gravity 1·023. On February 17th, at 7 A.M., off Watering Point, the sea-temperature was 78·8° F., and at 6 P.M., at the same place, it was 80° F. At both times the specific gravity was 1·023. On this latter day we dredged and trawled outside Galle Bay, beginning at the south-east off Watering and Unawatti Points and working westward to the Gallehogalle Bank. The first three hauls of the dredge may be considered as Station XXXVIII., on the eastern side of the entrance to the bay, while the remaining three hauls along with three hauls of the trawl form Station XXXIX., to the westward, up to Gallehogalle Bank.

STATION XXXVIII.—Outside Watering Point and Unawatti Point, from ½ a mile to 1½ miles off land; depth 9 to 22 fathoms; bottom sand and mud with many shell fragments; dredged.

Halicornaria saccaria, *Gorgonia* sp., *Spongodes* sp.;

Spatangoid, *Clypeaster humilis*, and *Echinodiscus auritus*, *Astropecten polyacanthus* (?), *Ophidiaster cylindricus;*

Thalenessa im-thurni, n. sp., *Glycera* sp., *Hyalinœcia* sp., and Worm-tubes;

Portunids and other Crabs, some Macrura;

Strombus sibbaldii, *Eburna canaliculata*, *Oliva gibbosa*, *Philine* sp., and *Arca compacta;*

Molgula (small species);

Branchiostoma lanceolatum (at 9 fathoms, several), *B.* (*Dolichorhynchus*) *indicus* (at 9 fathoms).

STATION XXXIX.—From 2 miles south of Point de Galle westwards to Gallehogalle Bank; depths 16 to 30 fathoms; bottom fine sand; stones and Nullipore on the bank; dredged and trawled.

Polytrema miniaceum and other Foraminifera;

Stephanoseris rousseaui, *Spongodes*, *Eunephthya* and Gorgonids (sev. spp.);

Astropecten hemprichii, *Stellaster* sp., *Salmacis bicolor*, *Lovenia elongata*, *Echinodiscus auritus*, *Clypeaster* sp., and *Antedon* sp.;

Serpula actinoceras, Polyzoa (many);

Squilla, *Gonodactylus*, *Alpheus*, Amphipods and Isopods, *Pontonia*, various Pagurids and Crabs (one infested by *Sacculina*);

Philine sp., *Strombus sibbaldii*, *Sepia* sp., *Sepiola* sp.;

About 1350 Fish—of which 500 were small flat fish belonging to about 5 species and ranging from ½ inch to 4 inches in length, most being from 2 to 3 inches:—

Cynoglossus sp., *Rhomboidichthys* (2 spp.), *Arnoglossus* (?), Pleuronectidæ (very many), Gobiidæ (768, from 2 to 5 inches long), *Callionymus candicaudatus* (30, from 2 to 3½ inches long), and *C. sagitta* (50, from 1¾ to 3 inches long).

This sandy area lying to the east of Gallehogalle Bank and giving a uniform stretch for some miles at a depth of 25 to 30 fathoms is evidently a fish "nursery," or region where young fishes, both flat and round, belonging to 8 or 9 species and including such valuable forms as "Soles," "Turbot" and "Plaice," congregate in great numbers. In one haul of short duration we obtained about 1350 young fish, including 5 kinds of flat fish.

The Tow-nettings this day (February 17th) were very rich and included :—

Trichodesmium erythræum, *Ceratium*, Radiolaria ;

Various Siphonophora and Ctenophora ;

Sagitta (large), Larval Annelides, and some Syllids ;

Copepoda—Many beautiful species, including *Calocalanus pavo*, *Metacalanus aurivillii*, *Labidocera pavo* and *L. acutum*, *Centropages gracilis*, *Candacia catula*, and *C. truncata*, *Oithona plumifera* (colourless with little plumes of scarlet, and having pale lilac egg masses), and a new species of *Euchæta*—36 species of Copepoda in all ;

Also many larvæ—Nauplei, Zoea, Phyllosoma (many), Erichthus and Alima, larval molluscs and worms ;

Appendicularia, *Doliolum* and *Salpa democratica-mucronata* (large).

On February 18th we left Galle, and spent the day in dredging in the deep water further out than on the previous day, and onwards up the west coast on our way to Colombo. A considerable part of the time was spent on and off the 100-fathom line south of Galle.

At 6.30 A.M. at about 3 miles south of Point de Galle the sea-temperature was 79·5° F., and at 6.30 P.M. when we anchored for the night at $3\frac{1}{2}$ miles south of Barberyn Lighthouse it was 80° F. ; at both times the specific gravity was 1·023.

The day's dredging may be divided into 3 stations—

STATION XL.—About 10 miles off Watering Point, direction south by west ; depth 34 fathoms ; bottom coarse sand, shells, coral fragments, Nullipores and *Halimeda* ; dredged.

Polytrema miniaceum, *Alveolina boscii*, *Orbitolites complanata*, *Heterostegina depressa*, and *Amphistegina lessonii* ;

Tethya sp., some Tetractinellids, *Rhizochalina fistulosa*, and Horny sponges ;

Chironephthya variabilis, *Plexaura indica*, *Briareum* sp., *Solenocaulon* sp., Gorgonids (many), *Cavernularia obesa*, *Lituaria phalloides* and several species of Pennatulids, *Flabellum* sp., *Caryophyllia* sp., *Stephanoseris rousseaui* ;

Hydroids—*Sertularia distans*, *S.* (? n. sp.), *Antennella allmani*, *Zygophylax tizardensis*, *Idia pristina*, *Lytocarpus* (? n. sp.) ;

Clypeaster scutiformis (?) ; *Lovenia elongata*, *Phyllacanthus baculosa* and *Cidaris metularia*, *Echinothrix calamaria* ;

Species of *Protula*, *Glycera*, and *Hyalinœcia* ;

Polyzoa—a large number of species, of which Miss Thornely has already identified the following, *Cellepora cidaris*, *C. boryi*, *C. tritubereulata*, *Flustra spoliata*, *Chorizopora brongniartii*, *Cribrilina radiata*, *Micropora coriacea*, *Smittipora abyssicola*, *Membranipora cornigera*, and also species of the genera *Lepralia*, *Stomatopora*, *Idmonea*, *Cellaria*, *Schizoporella*, *Membranipora*, *Steganoporella*. *Smittia* and *Adeona*;

Galathea sp., *Dromia* sp., and several other small Crabs;

Tonicia pectinoides n. sp. (SYKES), *Turritella* sp., *Ceratosoma*, and other Molluscs;

A red species of *Cynthia* and *Ascidia* sp. (probably both new).

STATION XLI.—South of Galle, about 12 miles off land; depth, along the 100-fathom line; bottom composed of masses of calcareous branched and ramifying Foraminiferal tubes (*Ramulina* sp.); dredged.

Tetractinellid sponges;

Dendrophyllia sp., *Caryophyllia* sp., *Cirrhipathes spiralis*, *Antipathes* sp., Gorgonacea (many— half a dozen species);

Actinocucumis donnani, n. sp. (PEARSON), *Phyllacanthus baculosa*, various Ophiuroids, *Asterina cepheus*, *Stellaster* sp., *Actinometra* sp., *Echinanthus rosaceus*;

Pagurids and small Crabs;

Avicula radiata (living on Gorgonids), *Pleurotoma nodifera*, *Conus* sp., and a few other shells.

STATION XLII.—Off the Coast, about 4 miles south of Barberyn; depth 40 fathoms; bottom muddy; dredged.

Stephanoseris rousseaui (many, with Gephyrea), *Caryophyllia* sp., *Paracyathus* sp. (?);

Echinids (small), *Pentaceros nodosus*, *Astropecten hemprichii*, *Pteraster* sp.;

Aspidosiphon sp., *Pectinaria* sp., and some muddy worm tubes;

Dentalium sp.

On February 19th, at 6.30 A.M., 6 miles west of Kaltura, the sea-temperature was 79·3° F. and the specific gravity 1·023. At 1 P.M. this afternoon we lowered a white enamelled dish measuring 9 inches by 12 inches on the sounding line and found that it was distinctly visible to a depth of at least 17 fathoms—the sky being cloudy and the sea calm.

A good deal of ground was covered during the day (the last of our present cruise), and nine hauls of the dredge were taken between Kaltura and Colombo, at depths of from 20 to 30 fathoms. These may be divided into four stations:—

STATION XLIII.—Six miles due west of Kaltura (or Kalutara); depth 22 fathoms; bottom hard sand with Nullipores; dredged.

Axinella donnani;

Juncella juncea and *Scirpearella* sp., *Epizoanthus* sp. (on *Murex*), *Stephanoseris rousseaui*, and *Heteropsammia michelini* (with Gephyrea), *Flabellum* sp., *Caryophyllia* sp., and other small solitary Corals;

Cucumaria imbricata, *Clypeaster scutiformis*, *Lovenia elongata*;

Aspidosiphon corallicola, *Hyalinœcia* sp., *Pectinaria* sp.;

Melita obtusata, *Mæra rubromaculata*, and other Amphipods, some Pagurids, and some Peneids;

Murex tenuispina, *Terebra* sp., and some Lamellibranchs.

STATION XLIV.—Five miles north-west of last station; depth 30 fathoms; bottom fine sand and worn fragments of Coral; dredged.

Hydroids—*Halicornaria setosa*, and *H. saccaria*, *Lytocarpus* (? n. sp.), *Monostachys dichotoma*, *Idia pristina*, *Sertularia distans*, *Sertularella* sp., *Halecium* sp., and others;

Stellaster sp., *Linckia diplax*, small Temnopleurids, *Clypeaster humilis*;

Clœosiphon aspergillum, *Pectinaria* sp., *Sabellaria bicornis*, and some worm tubes;

Caprellids, *Calappa* sp., Portunids and other Crabs;

Philine sp., *Murex tenuispina* and many other Gastropods;

Molgula sp.

STATION XLV.—Four miles West of Pantura (or Panadure); depth 25 fathoms; bottom sand, shells and dead Corals; dredged.

Various Corals; *Gorgonia*, and *Melitodes*;

Astropecten sp., *Ophiothrix aspidota* and other Ophiuroids;

Hyalinœcia sp. (many), *Thalenessa im-thurni*, n. sp. (Hornell), *Iphione muricata*, *Lepidasthenia fulvovittata*, *Eunice* sp., *Stylarioides iris*, *Cirratulus* sp., *Serpula actinoceros*, and some worm-tubes;

Various Crabs (not yet determined);

Strombus succinctus, *Malleus vulgaris*, and a few other Molluscs;

Molgula sp.

STATION XLVI.—From off Mount Lavinia northwards to off Colombo, from 7 to 12 miles off shore; depth 25 to 30 fathoms; bottom Nullipore balls (*Lithothamnion fruticulosum*), Coral fragments, and some Orbitolites sand; five hauls of the dredge.

Orbitolites complanata, *Alveolina boscii*;

Rhizochalina fistulosa, *Tethya* sp., and other sponges;

Hydroids—*Sertularia distans*, *Sertularella* sp., *Halecium* sp., *Monostachys dichotoma*, *Idia pristina*, *Halicornaria setosa*, *Lytocarpus* (? n. sp.);

Chondractinia sp., and some sand-encrusted Anemones, *Chironephthya variabilis* (splendid arborescent colony having the axis and main branches white, and the twigs crimson lake), *Solenocaulon tortuosum*, *Juncella juncea*, *Scirpearella* sp., and other Gorgonacea (many), small species of *Fungia*, and other solitary Corals;

Actinometra sp. (dark coloured, on the dark twigs of *Chironephthya*), *Actinometra* sp. (large, orange coloured), Antedon sp. (small), *Phyllacanthus baculosa* (many large), various Ophiuroids, *Laganum depressum*, *Clypeaster humilis*;

Nemertine (red), *Trophonia* sp., Polynoids, *Serpula actinoceros*, *Eunice* sp.;

Polyzoa—(many, including *Retepora* sp., *Cellepora*, *Schizoporella*, *Adeona*, *Gemelli-*

pora, and *Cribrilina*). Most of the Polyzoa are strongly calcareous and brightly coloured (scarlet) forms;

Crabs (porcelain white, two species (?) on the white branches of *Chironephthya*), and other small Crabs;

A new species of *Chiton* (*Tonicia pectinoides*, SYKES), *Harpa conoidalis*, *Strombus succinctus*, *Murex tenuispinus*, *Murex haustellum*, *Conus betulinus*, *Natica mammilla*, *Malleus vulgaris*, *Philine aperta* (?);

Leptoclinum sp., *Rhodosoma* sp., *Styela* sp., *Molgula* sp., *Cynthia* (? n. sp.);

A small banded Sole (*Synaptura cornuta*).

TOW-NET gatherings taken during the day were notable for the abundance of Radiolaria, colonial as well as solitary—*Collozoum* and others, also *Trichodesmium erythræum*, some pelagic planarians, Syllids, Halobates, Tornaria, and the Copepoda—*Centropages furcatus*, *C. gracilis* and *C. tenuiremis*, n. sp., *Calocalanus plumosus*, *Mecynocera clausi*, *Oithona plumifera*, and about 20 others.

Although the depths were greater than that of the paars further north, it is important to note that the bottoms at several of these localities off Mount Lavinia and elsewhere south of Colombo were hard, clean, and apparently very suitable for the attachment of pearl oysters, being largely formed of the same balls of Nullipore (*Lithothamnion fruticulosum*) which characterise the paars in the Gulf of Manaar. It is very probable that this bottom extends into shallower water, and that suitable spots may be found nearer shore upon which the pearl oyster might be cultivated. It is said that a pearl oyster bank once existed off Mount Lavinia.

On the evening of February 19th we arrived at Colombo. In this first cruise in the s.s. "Lady Havelock," in addition to making a preliminary survey of the more important pearl oyster banks, we had sampled the bottom conditions and the fauna at various points round the island, and had made a special examination of the several localities (Palk Bay, Trincomalee and Galle) to which our attention had become directed. We had also considered these last and other localities very carefully with the view of choosing the best site for a small marine laboratory in which to carry on investigations and experiments with the pearl oyster. Our conclusion at the end of the cruise was that of all the places seen in coasting round the island only two would be at all suitable for this purpose, viz., Trincomalee and Galle.

Of these, Trincomalee has the distinct advantages of (1) complete shelter from the monsoons, and (2) natural beds of pearl oysters living in the harbour; but on the other hand the following may be noted as more or less serious objections:—

(1.) The specific gravity of the water is low, between 1·019 and 1·021 as compared with 1·023, the usual reading in the Gulf of Manaar;

(2.) The plankton at the time of our observations seemed sparse compared with that at Galle and in the Gulf of Manaar;

(3.) The distance, and therefore the time necessary in taking live oysters round, from the Gulf of Manaar is much greater. In the case of Trincomalee a steamer such as the "Lady Havelock" would take about 30 hours from the Cheval Paar, while Galle could be reached in about 18 hours;

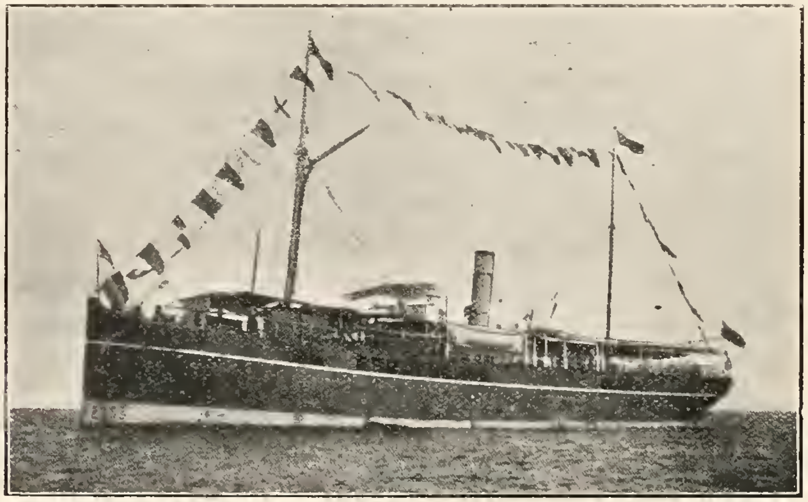
(4.) The bottom is muddy and is, in most parts, unsuitable for oyster culture, and the water is not comparable in purity with that in the Gulf of Manaar. Consequently it is probable that although some oysters may live at Trincomalee, they will not grow so rapidly and healthily as on the pearl banks;

(5.) The difficulty of access from Colombo and the distance from the scientific libraries and museum would be a real disadvantage to naturalists working continuously at Trincomalee;

(6.) Finally, for a Marine Station where ordinary biological investigations would be conducted, Galle presents a richer general fauna than Trincomalee, and has the additional special advantage of a coral reef and lagoon where collecting and observation can be easily carried on.

Galle as a locality no doubt also presents some disadvantages, the worst of which is that the bay lies open to the south-west monsoon; still there is the lagoon, parts of which could no doubt be made use of. The other advantages, the purity of the water, the richness of the plankton, the shortness of the journey from the Gulf of Manaar and the convenience of proximity to Colombo, render Galle, in my opinion, much the best site in Ceylon for a Marine Biological Station, and these eventually caused us to fix there our temporary laboratory, in which Mr. HORNELL was to carry on his work after I left the island.

I was asked, however, before deciding finally, to consider various spots in the Gulf of Manaar, such as Aripu, Chilavaturai, Kodramallai and Manaar, all on the shores of the pearl oyster region, and these I visited during our second cruise in the "Lady Havelock."



The s.s. "Lady Havelock," employed by the Ceylon Government for the pearl oyster investigation, February and March, 1902.

SECOND CRUISE.

On returning to Colombo, from this first cruise, for the purpose of joining Captain Donnan, the Master Attendant of Colombo, in his inspection of the pearl oyster banks, I saw for the first time the native barque "Rangasameeporawee" and the steam-launch "Serendib," and on examining them critically it was obvious, both to myself and to the ship's officers who were with me, that neither vessel would be able, without considerable changes, which could not be effected in time, to carry on the work which I still had to do. On pointing this out to Captain Donnan, he agreed with me, and when we waited upon the Lieutenant-Governor and represented the matter to him, he promptly authorized us to arrange for the engagement of the "Lady Havelock" for a further period of three or four weeks, as might be necessary, from 24th February. Thus it resulted that the "Lady Havelock" accompanied the two native barques "Rangasameeporawee" and "Sultan Iskander" and the s.s. "Serendib" to the Gulf of Manaar, where, in addition to carrying on my special work, she was on occasions of service in towing Captain Donnan's barque and so saving some valuable time.

This second cruise of the "Lady Havelock" lasted from 24th February to 20th March, inclusive, three weeks and four days. During the greater part of that time our steamer kept near to Captain Donnan's barque, and we accompanied him in his inspection of the banks. Not only had we thus the full advantage of the various vessels and their crews by means of which to obtain specimens and information, but Mr. Hornell and I were also able to talk over the work daily with Captain Donnan and his successor, Captain Legge. Later on we were joined by Sir William Twynam from Jaffna. That gave a unique opportunity of hearing from these two veteran inspectors and investigators about former conditions of the various banks and details of the past history of the pearl fisheries.

During this cruise the early morning and forenoon were usually occupied in following the operations of the divers, and in examining and recording the material brought up from different parts of the various "paars." About midday, when the divers ceased work, we started off in the "Lady Havelock" to dredge the neighbouring grounds between the oyster banks, or on parts of the paar in regard to which we wanted further information. In this way, beginning in the north of the district of Aripu, we examined the large and important East and West Cheval banks and the Periya Paar and several smaller banks lying some to the north and some to the south. We also, when in that neighbourhood, landed at various parts of the coast in the endeavour to find a suitable spot for a small Marine Laboratory, from which oyster culture and experiments could be conducted close to the banks. We tried Manaar, Aripu, Chilavaturai, Kodramallai, and later on the shores of Portugal and Dutch Bays, but without success. We could find no spot on the shores of the Gulf of Manaar that seemed suitable for the purpose, and none certainly with the natural advantages of Galle. On several occasions we, in the "Lady Havelock," left Captain DONNAN and the barques for a couple of days in order to run lines of dredgings across some of the deeper or more remote parts of the region, especially to the north and west.

Our journal of this cruise is as follows:—

We left Colombo on the afternoon of February 24th, having the barque "Rangasameeporawee" in tow. At 7 P.M., when off Negombo, the sea-temperature was 79·8° F. and the specific gravity 1·0235. The following morning, at 7 A.M., off Kalpentyn Island, the temperature was 79° F. and specific gravity 1·023; while at 7 P.M., when we anchored at 2¾ miles south-south-west of Chilavaturai, the temperature was 80·8° F. and the specific gravity 1·022—these temperatures being about 2° F. higher than we had found in the same sea three weeks before.

A tow-net gathering was taken at 5 miles north-north-west of Kodramallai Point. It contained a great quantity of the zoeas of Crabs, some new green Copepods (*Pontella danæ*, n. var., *Labidocera*, n. sp., and *Pontellopsis*, n. sp.), Sagitta, Lucifer, larvæ of Gastropods and Lamellibranchs. There were also many green filamentous Algæ, about 20 other Copepoda (*Eucalanus subcrassus*, *Rhincalanus cornutus*, *Ilyopsyllus affinis*, and *Centropages*, n. sp.) and many diatoms. One large bluish-green Copepod (the new *Pontellopsis*) had a plate-like radially marked mass of spermatophores on its hinder end (genital segment) which was so conspicuous as to be visible to the naked eye as a yellowish patch.

We went ashore at Chilavaturai, running in as far as we could in the "Serendib" and then in the ship's boat. Where the "Serendib" stopped, in 13 feet of water, the screw stirred up quantities of delicate red Algæ (*Hypnea musciformis* and *Polysiphonia* sp.) and very fine filamentous green stuff (*Cladophora* sp.) such as we also found growing in some parts of the Cheval Paar, and to which the minute oyster spat commonly becomes attached. These Algæ apparently grow on a coarse sandy bottom in various parts of the district.

Chilavaturai is famous in the annals of the Ceylon pearl fisheries as having always been the site of the fisheries camp during British times, except in the case of the small fishery of 1832 and the three fisheries of the Muttuvaratu Paar in 1889, 1890 and 1891. Sir W. TWYNAM and Captain DONNAN have shown however that there are reasons why Marichchukaddi, about 10 miles further down the coast, would be, in some respects, a better site for the camp in future fisheries of these northern paars.

Chilavaturai was one of the spots to which attention had been directed as a possible locality for the marine laboratory, and we consequently examined some empty rooms which adjoin the Rest-house; but found them inconvenient and in poor repair. They might no doubt be adapted to the purposes of a scientific workshop if the locality were suitable in other respects; but the shore is an impossible one.

We then steamed along the coast to Aripu, about 4 miles further north, where I had been asked to examine an empty government bungalow. This had four large, lofty rooms, a fine broad verandah and a large walled compound. Beside it were still to be seen fragments of the ruins of the old Dutch fort, to which our countryman Robert Knox made his way in 1679, when he escaped from Anuradhapura, after 20 years' captivity in the hands of the King of Kandy. This bungalow, so far as the house goes, could be made a perfectly suitable residence and workshop for the marine biologist were the locality suitable in other respects—but it is not.

At Aripu we visited the ruins of the "Doric," a classic structure often referred to in the reports of the pearl fisheries, and which we had been using as a landmark. It was built by Lord Guildford a century ago, as the official residence of the Governor when he attended a fishery, but being unused it later on fell into ruins. It has always served however as a useful and conspicuous object from which to take

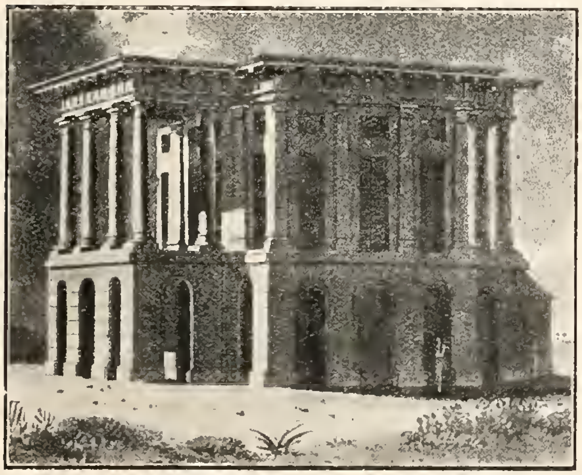


Fig. 8. The "Doric" as it was at the beginning of last century—from Cordiner's plate.

Fig. 9. The "Doric" as it now is—from a photograph taken in February, 1902.

bearings on the pearl banks. The figures given here show (fig. 8) its original appearance, from the plate in Cordiner's "Ceylon," 1807, and (fig. 9) its present condition from a photograph I took in February, 1902, with Captain J. Donnan, C.M.G., late Inspector of the Pearl Banks, in the foreground.

In the evening (February 25) we put two tow-nets out, one near the bottom and the other at the surface. The deeper net contained a large amount of the filamentous red Algæ (*Hypnea musciformis*, *Polysiphonia*, &c.), along with Molluscan and Annelid larvæ, Coscinodiscus, &c.

The surface net had Coscinodiscus and 14 species of Copepods, including *Calanopia aurivillii*, *Metacalanus aurivillii*, *Ilyopsyllus affinis*, and a new species of *Peltidium*.

On February 26th, at 7 A.M., $2\frac{3}{4}$ miles south-south-west of Chilavaturai, the sea-temperature was 78·1° F., and at 7 P.M., on the south central part of the Cheval Paar, the temperature was 79·5° F. At both times the specific gravity was 1·023.

A bottom tow-net which had been down all night was found on the morning of February 26th to contain great quantities of small Copepoda with very long caudal setæ (*Ectinosoma roseum* and *E. atlanticum*), also *Euterpe acutifrons* and a dozen other species, along with some Medusoids and Ctenophores.

About mid-day, when going under easy steam, we put out a tow-net which we had contrived with a canvas funnel in front of the mouth and having the narrow end forwards, so as to reduce the volume of water entering and so the pressure on the net. It worked well and gave us good hauls containing chiefly Nauplei, Zoeæ, 41 species of Copepoda, including the large blue *Pontella securifer* and the small long-tailed *Ectinosoma atlanticum*, *Centropages violaceus*, *Metacalanus aurivillii* (common), *Pseudodiaptomus aurivillii* (male previously unknown), and also *Ceratium* (two species), *Peridinium*, some Trochospheres, Radiolaria, many Diatoms, especially *Coscinodiscus* and long rod-like forms, *Sagitta*, *Salpa*, Appendicularians, Pteropods, and some Lamellibranch fry. It was evident from this and many other hauls that the microscopic plankton of the sea, both at surface and bottom, was very abundant in the Gulf of Manaar, and this must be of very great importance in feeding the pearl oysters.

We boarded the barque "Rangasameeporawee" later in the morning, and found that she was anchored on the position of the "shoal-buoy," a mark that Captain DONNAN has been in the habit of bringing with him on each inspection in order to indicate the north end of the long shoal which runs northwards from Karativo Island to the southern part of the Cheval Paar. The buoy (a large structure of casks and planks bearing a mast) is anchored over a sunken tank, and serves as a useful mark to take bearings from during the inspection of the banks.

We now set the divers to work to bring us up samples of the bottom, a rather coarse white quartz sand upon which great masses of fine green and red filamentous Algæ grow. These contained *Hypnea musciformis*, and undetermined species of the genera *Cladophora*, *Ceramium*, and *Chætomorpha*.

The divers brought up quantities of this weed, upon which, when put in our small glass aquaria, we soon found great numbers of very young pearl oysters—the spat being densely crowded in some places on the filaments of Algæ. The smallest size, of which there were very many, was about 0·5 millim. in diameter, but other samples measured up to 4 millims. This spat was evidently very young and the smallest had probably just become attached during the last few days. A quantity was kept alive under observation, some in wooden tanks on the barque and some in our glass aquaria on the "Lady Havelock." It was found to be restless and active, and to leave its attachment and crawl freely about on the Algæ or on the glass sides of the aquaria. For example, one specimen (*a*) crawled 5 inches up the glass within 18 minutes, the last $2\frac{3}{4}$ inches in 12 minutes; another (*b*) crawled 3 inches in

12 minutes; while a third (*c*) did $1\frac{1}{8}$ inch in the same time. Both *a* and *b* travelled at a greater rate at the beginning than towards the end of the time.

In the green weed were also large numbers of a white Leucothoid Amphipod (which Mr. WALKER considers to be a new genus), some interesting new Caprellids, and a good many Rissoa-like Gastropods about 7·5 millims. in length. Some specimens of a small white *Synapta* were also brought up in the sand.

In the afternoon we dredged and trawled from the "Lady Havelock" in the area lying south-west of the Cheval Paar. All these hauls may be united as—

STATION XLVII.—About 4 miles south of the West Cheval Paar; depth $8\frac{1}{2}$ to 9 fathoms; bottom sand overgrown with green Algæ; dredged.

Phyllospongia holdsworthi, Axinella donnani;
Astropecten hemprichii, Amphiura sp.;
Sabella phæotænia, Serpula sp.; various Crabs;
Pearl oysters (a few large and many very small), *Aplysia pulmonica* (?);
Molgula sp.;
Fish—both round and flat—including *Pegasus draconis, Upeneoides tragula, Gobius biocellatus, G. masoni, Teuthis oramin, Percis pulchella.*

On February 27th we joined Captain DONNAN in the morning on board the barque in order to see the work of the divers. During this and some following days two sets of diving operations were carried on simultaneously. Four large whale boats, each containing 10 or 12 natives under the charge of a tindal or boatswain, were engaged in making a survey by means of concentric equidistant circles—the boats circling first within a distance of $\frac{1}{4}$ mile, then between $\frac{1}{4}$ and $\frac{1}{2}$ mile, and finally between $\frac{1}{2}$ and $\frac{3}{4}$ mile from the barque, which was anchored in the centre—and keeping their distances approximately by means of radially placed buoys bearing flags. From these boats the divers went down at frequent intervals, and the result of each dive was recorded by the tindal on a plan. At the same time we had a set of two or three divers in the "Serendib" (fig. 10), and with these we took samples from between the paars or in any other localities where we wanted further information to supplement the results of the inspection boats.

The ground we worked over this morning was mostly formed of dead coral and Nullipore with some *Sargassum* and other Algæ, the depth being 6 to $6\frac{1}{2}$ fathoms. Pearl oysters of two ages were found; the larger being estimated at 3 years old and the smaller size at 6 months (see fig. 11). The oysters were accompanied by great quantities of small boring Gastropods (the "Oorie" of the divers) belonging to the genera *Purpura, Nassa, Sistrum, Pinaxia, Natica, Murex* and *Turbinella* (mostly *Sistrum spectrum* and *Pinaxia coronata*), and in places were entangled in the byssus nests of masses of "Suran" (*Modiola barbata*). A deep purple spreading sponge (? *Pachychalina multiformis*), upon which were opisthobranchs of the same colour (*Aplysia* sp.) was common.

Around such hard patches the bottom is all sand, in some parts coarse, in others finer, and varying in constitution from almost pure quartz to a neritic deposit formed mainly of the shells of Foraminifera (*Orbitolites*, *Heterostegina*, *Alveolina*, &c.). On the sand fewer oysters are found, but they cannot be said to be absent, especially in the neighbourhood of a "paar" (or hard patch). When present they are generally

Fig. 10. Our two divers on the "Serendib."

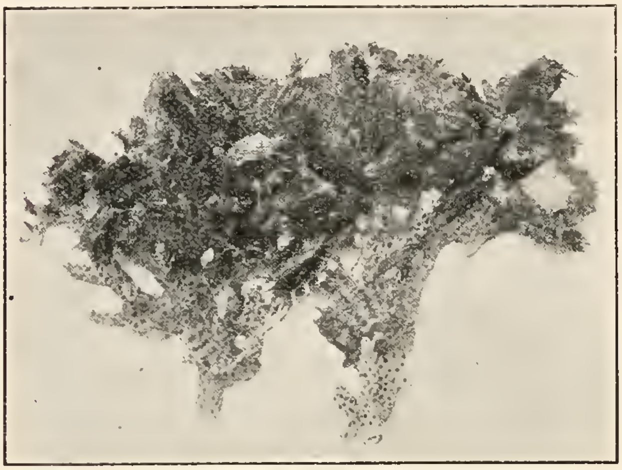

Fig. 11. Young pearl oysters, about six months old, attached to a dead Madrepore Coral.

united in clumps of several fastened together by their byssus threads or attached by some hard object such as a Nullipore nodule, a dead shell or a fragment of coral. In some cases two or three large oysters (about 3 years old) will form a centre upon which a great many young ones (about 6 months old) are fastened (fig. 12). In some places there is undoubtedly overcrowding, the larger oysters being completely surrounded with masses of young piled so closely as to smother some and probably interfere with the growth of all. This is a precisely similar case to that of the overcrowding found in European mussel beds, where the advantage of thinning out and transplanting is well known.

We got the divers to construct for us, after several dives to verify the details, a model on the deck of the "Serendib" showing the distribution of oysters on the rock and sand at the bottom. Fig. 12 is from a diagrammatic drawing (in bird's-eye-view) showing what they produced.*

Although oysters lying on the sand may manage to survive for a time, especially if

* These and our other conclusions in regard to the configuration and constitution of the paars and the distribution of the pearl oysters were verified later on by Mr. HORNELL when, at the fishery in the spring of 1903, a European diving costume being available, he was enabled to make a personal inspection of the bottom.

united in clumps, it is evident that they are in a dangerous position and are liable to be overwhelmed and smothered at any time by a shifting of the loose bottom.

There is apparently plenty of available hard ground with a dead coral, or consolidated sand, or Nullipore bottom round about the known paars to which young oysters from unsuitable sandy grounds or from overcrowded spots could be easily

Fig. 12. Diagram showing the arrangement of pearl oysters (large and small) in clumps on the sand and singly attached to flat ledges of rock.

moved. We accumulated many observations bearing on this question during the next few weeks and also during Mr. HORNELL's inspection visit to the banks in November, 1902, and during the fishery of March and April, 1903. It will be further discussed in our Recommendations at the end of this report.

In order to trace the extension of the pearl oysters beyond the limits of the recognised paars, we took a number of hauls of the dredge, in the afternoon, from south to north in the middle between the East and West Cheval paars on, in the main, a sandy bottom. These may be joined as—

STATION XLVIII.—Between East and West Cheval paars; depth $6\frac{1}{2}$ to $7\frac{1}{2}$ fathoms; bottom sand, fragments of dead Coral, shells and Nullipore; dredged.

Some solitary Corals, *Halicornaria saccaria;*

Salmacis sulcata and *S. dussumieri*, *Laganum depressum*, *Lovenia elongata*, many *Clypeaster humilis*, *Echinolampas oviformis;*

Polyzoa—13 species, amongst which are *Lepralia dorsiporosa*, *Micropora coriacea*, *Scrupocellaria scrupea*, *Schizoporella lineata*, *Cellepora avicularia*, *Idmonea serpens*, *Smittia reticulata* and *Brettia* sp.;

Stenothoe marina (variety) and other Amphipods; pearl oysters (very many, mostly young), *Turbinella rapa* and a few common Molluscs;

Asymmetron (*Heteropleuron*) *cingalense.* A new species of *Emmelichthys* was also obtained here at a later date.

A single haul (the second) in the middle of the area in question gave us nearly 2 cwt. of pearl oysters, large (3 years old) and small (6 months). Most of them were attached to fragments of worn coral or to one another.

Two hauls of the dredge upon the northern end of the Cheval region, depth $6\frac{1}{2}$ fathoms, gave much the same bottom and result, but with fewer living pearl oysters. The sea-temperature this day was, at 7 A.M., 78·3° F., and at 9 P.M., 79·5° F., and the specific gravity on both occasions 1·023, at anchor on the South Cheval. The following day (28th) the temperature, at 7 A.M., was 78° F., and at 6 P.M. it was 79·3° F. on the South-east Cheval. The specific gravity was still 1·023.

We now had various sets of pearl oysters under close observation in our wooden tanks, glass aquaria, and sea-water baths, on both the barque and the "Lady Havelock," in order to test powers of detaching and travelling and re-attaching, regeneration of the byssus when cut and when torn out, and similar matters; but the results of these experiments will be given separately further on in the report.

On the morning of February 28th we (in the "Serendib") traversed from south to north the inspection circle ($1\frac{1}{2}$ miles in diameter) which covered the southern end of the East Cheval, 18 dives being taken at about equidistant points with the following results. This will serve as an example of the many lines of dives we traversed during the next few weeks.

Dives.	Bottom.	Pearl oysters.	Any other animals.
1	Sand	Few, large and small	*Malleus vulgaris.*
2	Rock	Large oysters	*Modiola*-"suran."
3	Sand	Few large, many small	
4	Rock	Many large, few small	
5	Sand	Many small, some large	"Oorie."
6	Rock	Large and small	
7	,,	,, ,,	
8	,,	,, ,,	
9	Sand	Few clumps, large and small	
10	Rock	Clumps of large	Green corals (*Favia*), dark green *Antedon*, and *Alphæus* of same colour.
11	Sand	Few clumps, mostly small	*Pinna bicolor.*
12	Rock	Clumps of large and small	*Campanularia juncea* ("Heather").
13	Sand	None	
14	Rock	,,	,, ,,
15	,,	Small, few	,, ,, and sponges.
16	Sand	None	
17	Rock	One large	,, ,,
18	,,	None	

The large Hydroid Zoophyte *Campanularia juncea*, which grows in tufts a foot in height and looks somewhat like old withered masses of heather, is very characteristic of this East Cheval paar. The beautiful large pinnate *Halicornaria insignis* is also found here, and usually bears the protectively-striped *Avicula zebra* which is almost invisible on the Zoophyte. We also found *Meleagrina margaritifera*, the large mother-of-pearl oyster on the south part of East Cheval Paar.

In the afternoon we dredged over the ground lying between the shoal buoy and the south end of the Periya Paar.

STATION XLIX.—South-west of Cheval to off south end of Periya Paar; depth 8½ to 13 fathoms; bottom sand, Nullipores, and dead shells; 6 hauls of dredge.

Lovenia elongata, *Echinolampas oviformis*, *Maretia planulata*, *Clypeaster humilis*, *Echinodiscus auritus*, and *Echinanthus rosaceus*, *Holothuria atra*;

Worm-tubes (*Sabellaria*, *Serpula*, *Filograna*);

Tritæta tenuipes, *Leucothoe spinicarpa* and other Amphipods, *Calappa* sp., and some other Crabs, and Peneids;

Mollusca (*Turritella maculata*, *Cassis glauca*, *Strombus succinctus*, *Pinaxia coronata*, &c.), also pearl oysters, *Dolabella* sp., and a few small Octopods;

Cynthia sp.;

Branchiostoma lanceolatum, var. *belcheri* (14 specimens), *Asymmetron* (*Heteropleuron*) *cingalense* (2 specimens).

When in one of the hauls we touched the south end of the Periya Paar we obtained a great number of young pearl oysters, just as we had found before, and were to find again in our later examination of this bank.

On March 1st we moved our centre southwards on to the Modragam paars. At 7 A.M., on the south end of East Cheval, the sea-temperature was 78·7° F., and at 7 P.M., on the North Modragam, it was 79·7° F.; in both cases the specific gravity was 1·023. In the morning we made a diving traverse from south to north through the Modragams to the Cheval. The pearl oysters were not very numerous, but were exceptionally large, although probably not older than those on the Cheval Paar. Captain DONNAN, from his close observation of the oysters on these paars extending over many years, feels confident that the shells grow more rapidly, and to a larger size, on the Modragam than on the Cheval paars, and on the East Cheval than on the West. Our own measurements made later on bear this out. It is very possible that these differences may be due to feeding, and that the explanation is that the conditions become less favourable further from the shore and towards the north-west. The Modragams are also sheltered by the shoal running up from Karativo Island to the Cheval.

The details of these dives need not be given. On the whole they show much the same distribution as those given above. Between the North Modragam and the South Cheval, in 6½ fathoms, along with abundance of young pearl oysters a few months old, we found quantities of red Algæ (*Polysiphonia*, &c.) covered with minute "spat" evidently quite recently deposited.

In the afternoon we dredged again over Station XLIX., from the south-west corner of the West Cheval to the south of Periya Paar; the depths found varied from

8 to $13\frac{1}{2}$ fathoms and the bottoms and animals were much the same as before (including two species of Amphioxus). We found quantities of young oysters in our last haul, about 5 miles south of Periya Paar, 12 to $13\frac{1}{2}$ fathoms, on a firm bottom of Nullipores and Orbitolites sand, showing that there are outlying patches beyond the limits of the known paars where oysters may be found. This particular spot would, however, even if the oysters attained maturity, be too deep for most of the native divers to work. Their usual limit is about 9 fathoms. We had them a few weeks later making a few descents for us in 11 fathoms on the Periya Paar, but they had just time to get a sample of the oysters or whatever lay before them on arriving at the bottom. Captain Donnan has had exceptional divers who have made descents for him in 15 fathoms, but they had barely time to secure a single handful of the bottom before having to come up in an exhausted condition. I timed many dives and none reached two minutes, very few were over a minute and a half.

Samples from all the pearl oysters we obtained on the different paars from the divers or by dredging were examined as to their food, their reproductive condition, their general condition of body and parasites and as to any stages in pearl-formation. All these matters will however be dealt with separately further on in the report.

On March 2nd, being now in the neighbourhood of Kodramallai Point and Marichchukaddi, which was the site of the Camp during the three last pearl fisheries (1889 to 1891), and also during the recent fishery of 1903, we took the opportunity to go ashore and inspect, as Captain Donnan thought that possibly we might find a sheltered corner of the bay suitable for the marine laboratory.

We landed at Kodramallai Point, and examined the coast (fig. 13) for a little way

Fig. 13. Part of the pearl-divers' fleet at Marichchukaddi—from a photograph by J Hornell.

northwards towards the Modragam River, but found it quite hopeless for our purpose. The rock at the point forms a moderate headland and runs out seawards as a little reef. It is apparently all sandstone; there is no coral, and it gives practically no protection from the south-west monsoon. The shore of the bay is muddy and the water shallow for a long way off. There is much *Zostera*, but every living thing seems covered with a fine deposit of mud.

In the afternoon we sailed for Manaar, which I had been asked to examine and report upon. The sea-temperature at 7 A.M. on North Modragam was 79° F. and at 7 P.M. on the south bar at Manaar it was 81° F., the specific gravity as usual was 1·023 at both times.

We had caught a number of Sea-snakes (Hydrophidæ) during the last few days, and the stomachs of all these were examined to see whether any foundation in fact existed for the belief that they feed upon the pearl oysters. We found no evidence of that. Without exception the stomach contents in the snakes we caught were the more or less digested but still recognisable remains of various kinds of fish. Such examinations, and the recording of our pearl-oyster experiments and statistics, went on during the time spent in getting from one spot to another, and when lying at anchor. Dr. W. HANNA, of Liverpool, has kindly examined the Hydrophidæ I brought back and finds that three species are represented, viz., *Enhydris curtus*, *Hydrus platurus* and *Hydrophis fasciatus*.

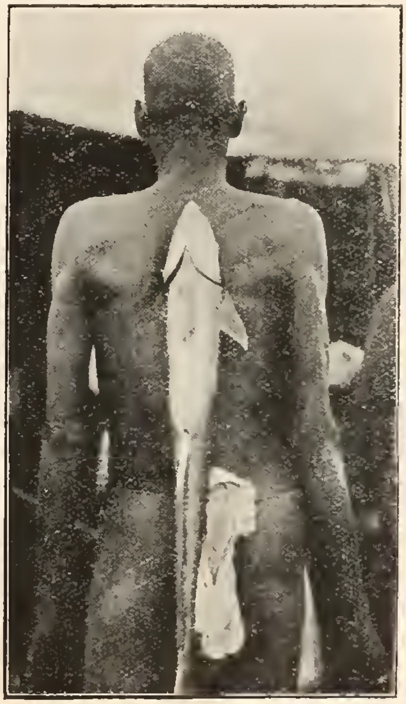

Fig. 14. Remora attached to the back of a diver.

On arriving off the south bar at Manaar we took a tow-net gathering which contained, amongst other Copepoda, *Oithona rigida*, *Euterpe acutifrons* and *Labidocera acuta*. We also caught a large Remora (*Echeneis naucrates*) measuring fully 24 inches in length and having a sucker 6 inches long. It was slate-blue dorsally and of a lighter colour ventrally. On laying it with the sucker against the upright bare back of a diver, in the air, it at once adhered so firmly that one could grasp it by the tail and pull with some force without detaching the fish (fig. 14).

March 3rd was occupied in enquiring into the marine biological possibilities of Manaar. The sea-temperature at 7 A.M. was 79°·3 F. and at 7 P.M. on the north end of the East Cheval was 80° F., the specific gravity being 1·023.

We crossed the south bar in the ship's boat with some difficulty, and went aground several times in the long shallow muddy passage leading up to the town of Manaar. The Assistant Government Agent sent for Mr. V. VRASPILLAI, the respected and experienced Adigar of Musali, who took us round to the various bays and creeks, showed us the different kinds of shore, and gave us full information as to the fishing and the shell-fish found locally, and the influence of the tides and winds. The Adigar entirely confirmed our own opinion, formed from what we saw, that there is no spot in the neighbourhood of Manaar suitable for pearl-oyster work. The North channel we found is as unsatisfactory as the South, and the great creek immediately to the north-east of the Fort is quite shallow and muddy. Not even cockle-like shell-fish can be got to live there, and in fact dead shells have to be imported from Aripu for calcining to make the "chunam" for betel-chewing. *Pyrazus palustris* is most abundant in these muddy shallows. Turtle are also plentiful round Manaar and are caught by the harpoon, which is a short four-sided iron spike sharpened at one end and having a ring on one side to which a long cord is attached. The spike is loosely fastened to the end of a pole, from which it readily becomes detached when implanted in the plates of a turtle's back, leaving the animal anchored by the long cord. Dugong are also taken here, they feed upon the Zostera which is plentiful all around.

On March 4th we were back again with Captain DONNAN and his inspection boats on the north end of the East Cheval, where at 7 A.M. the sea-temperature was 79° F. and specific gravity 1·023. The forenoon was spent examining with the divers, in the "Serendib," the middle part of the East Cheval and the area to the west of it, on which we found more oysters both large and small than within the usually recognised limits of the paar itself. In three dives on this western part the oysters came up attached to coral blocks, in the fourth they were in clumps lying on sand; they averaged 15 oysters to a dive.

In the afternoon we dredged from the "Lady Havelock" in the same region and northwards to the Periya Paar Kerrai and Vankali Paar; and obtained striking proof, as on many other occasions, of the superiority of dredging over diving as a method of obtaining the pearl oysters. The first haul, during which the dredge was only off the deck 10 minutes, brought up 65 large oysters along with other organisms. The first few hauls were practically upon Station XLVIII., dredged on February 27th, and the more abundant animals obtained* were the same as before (see p. 61); while the remaining hauls further north may be divided into two sets, those about Periya Paar Kerrai (Station L.) and those of Vankali Paar (Station LI.).

STATION L.—On Periya Paar Kerrai and to the north; depth $7\frac{1}{2}$ fathoms; bottom sand and dead shells; dredged.

Various common Corals;
Serpula actinoceros;
Mæra rubromaculata and other Amphipods;
Pearl oysters, mainly small, *Oscanius* sp.;
Branchiostoma lanceolatum and variety *belcheri* (large and plentiful).

* It will of course be recognised by naturalists that many other minute or obscure forms (Amphipods, Hydroids, Polyzoa, &c.) were obtained at nearly all these hauls; and these will be treated of in the special reports that follow.

STATION LI.—West of the last Station, on Vankali Paar and southwards; depth $7\frac{1}{2}$ to 8 fathoms; bottom sand, dead shells and Coral fragments; dredged.

Some common Corals (*Madrepora* and *Turbinaria*), and *Heterocyathus æquicostatus* (with Gephyreans), several Gorgonids (large colonies);

Clypeaster humilis and *Echinodiscus auritus;*

Aspidosiphon sp.;

Lilljeborgia pallida (a British species!);

Pearl oysters, plentiful—both large and small (60 large in a haul).

The Tow-Nets on March 4th gave us:—Medusæ, *Sagitta, Alciopa,* Appendicularians and about 35 species of Copepoda—some of them in great abundance—amongst which may be mentioned *Metacalanus aurivillii, Centropages,* n. sp., and *Calanopia minor.*

Fig. 15. Two of the divers on the "Rangasameeporawee" with the wire-net and coir cages in which our experimental pearl oysters were suspended over the ship's side for two months.

Some experiments were made during this and succeeding days in towing pearl oysters of different sizes, under various conditions, and at different rates up to 8 knots an hour, which showed us that it would be easier to transport young than old oysters in bags, nets or crates hung over the ship's side (see fig. 15), and also that old oysters are apparently less able to withstand the action of a strong current than younger forms. From the cages and baskets (generally made of the coir fibre of the cocoanut) used on these and subsequent occasions when pearl oysters were hung out over the side of the ship we obtained various small animals, especially Hydroids, amongst which were a *Clava*, two species of *Sertularia*, a scarlet *Eudendrium*, a *Bougainvillea*, and several Plumularians.

On March 5th the sea-temperature was slightly over 79° F. both morning and evening, on the north end of the Cheval, with a specific gravity of 1·023. In the morning as usual we were with the divers (who work from 6 a.m. till noon) working over the northern end of the East Cheval and outside the paar to the north and east. Practically no oysters were found. Some fine colonies of the hydroid Zoophyte *Halicornaria insignis*, with *Avicula zebra* attached, were found here (off north end of Cheval, 6 fathoms). On moving south-east along the edge of the paar to its middle portion we came upon quantities of a fine brown fucoid Alga smothered in young oyster "spat." The Alga was growing on what the divers call "flat rock"—a calcrete formed by the cementing together of the sand and shell fragments *in situ*. We also obtained at the same spot a fine tuberculated dark green Holothurian (*Stichopus chloronotus*).

In the afternoon we dredged to the north of the East Cheval Paar, running a line of hauls to the Vankali reef lying about 6 miles to the north and then north-west along the outer face of the reef and so back. Six hauls were taken which may be united as—

STATION LII.—Between north of Cheval Paar and Vankali reef; depth 3 to 6 fathoms; bottom sand; no pearl oysters; dredged.

Halicornaria setosa and *H. saccaria*, *Lytocarpus* (? n. sp.) and *Sertularia tenuis*, *Cavernularia obesa* (many), *Virgularia juncea*;

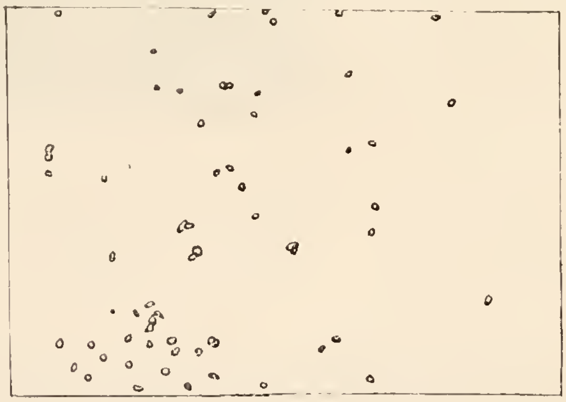
Hermadion sp., *Panthalis melanonotus*, *Psammolyce* sp., *Onuphis* sp.;

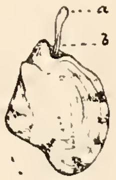
Ostracod (very large, possibly *Cypridina formosa*, or a new form); *Modiola* sp. (in gelatinous nests), and other Lamellibranchs, *Turbinella pyrum*, *Strombus succinctus*, *Pinaxia coronata*, *Pyrazus palustris*, *Persona ridens* and *Buccinum melanostoma*;

Asymmetron (*Heteropleuron*) *cultellum*.

The Tow-Nets at this locality gave us about 28 species of Copepoda, representing 12 genera. These like the other tow-net results will be given in detail in the report on the Copepoda, but Messrs. Thompson and Scott give the following as noteworthy from this haul:—*Mecynocera clausi*, *Paracalanus parvus*, *Acrocalanus longicornis*, *Centropages furcatus* and a new species, *Pseudodiaptomus aurivillii*, *Labidocera pavo*, *L. kroyeri* and a new species.

During parts of this day we had living pearl-oyster spat under observation in flat wooden tanks and in our narrow vertical "window" aquaria. In the latter, numbers





B.

Fig. 16. Arrangement of spat on glass of aquarium 7 minutes after all started from bottom. B, one individual enlarged, showing the extended foot.

of individuals placed at the bottom started at once to climb up the glass sides and travelled on the average at the rate of about an inch per minute. At the end of the first minute 65 individuals were crawling up the glass. At the end of seven minutes six had reached the surface of the water, a distance of $3\frac{1}{4}$ inches. Most of the rest had attached themselves at various points lower down. The actual disposition on the glass side of the small aquarium at the end of seven minutes, and an enlarged figure of an individual when climbing, to show the expanded foot, are given in fig. 16. The object of this record is to emphasize the great activity and the locomotory powers of the spat at this stage, when it is usually regarded as a sedentary and in fact a fixed animal. In climbing, attachment is made by the base *b* of the foot, the distal portion being elongated. Then the tip *a* fixes and *b* at the same time is freed and the animal is drawn upwards by the contraction and shortening of the muscular foot. Then *b* fixes once more, *a* is extended to a new position and the process is repeated.

Fig. 17. Sketch of young pearl-oyster spat attached to *Sargassum*.

We frequently observed that spat collected on weed (such as *Sargassum*, fig. 17, and *Hypnea* or *Cladophora*) very readily detached itself and wandered on to other objects or became transferred to the walls of the vessel, or even adhered together in balls of from 4 to 10 individuals.

We now moved to the north end of the West Cheval Paar, where on March 6th, at 7 A.M., the sea-temperature was 79·3° and at 7 P.M. 79·5° F.; the specific gravity as usual being 1·023. In the morning we ran 2 lines of dives, from the "Serendib" north-eastwards from the northern end of the West to the northern end of the East Cheval, getting a small number of large oysters (with some dead shells) and considerable quantities of young. We also brought up a very fine specimen of *Toxopneustes pileolus* with very beautiful and conspicuous pedicellariæ, in which the 3 valves are united by a discoid reddish membrane bordered by a conspicuous white line.

The rest of the day was spent in dredging at a point about 10 miles north of the morning position. Here 5 hauls were taken which may be regarded as—

STATION LIII.—Ten to twelve miles north of Cheval Paar and about 12 miles west of Vankali (or Bangalli) Church; depth $7\frac{1}{2}$ to 9 fathoms; bottom muddy sand with some dead shells; no large pearl oysters, only a few small; dredged.

Halimeda and some Nullipores, green Algæ and *Halophila ovata*;

Axinella donnani, and other sponges;

Lytocarpus spectabilis, *Campanularia juncea*, and species (which may be new) of *Halecium*, *Obelia*, *and Campanularia*; Pennatulids and various living Corals;

Clypeaster humilis, *Laganum depressum*, *Antedon* sp. (sev.), and *Actinometra* sp.;
Psammolyce sp. and other worms;
Polyzoa belonging to the genera *Lepralia*, *Adeona*, *Crisia*, and *Scrupocellaria*;
Melita obtusata, *Erichthonius* sp., *Siphonœcetes* sp. and other Amphipods, *Elsia indica* and *Lysianassa* (? n. sp.), *Lambrus*, *Pleurophyllidia* sp., and *Kalinga ornata*;
Branchiostoma lanceolatum, and variety *belcheri*.

The bottom Tow-net at 7 P.M. contained, amongst other Copepoda, *Pontella securifer*, *Ectinosoma atlanticum* and *E. roseum*, *Metacalanus aurivillii* and *Pseudodiaptomus aurivillii*—22 species in all.

At the end of the day's work we anchored about 15 miles to the north of our morning position on the Cheval with the view of spending the following two days in working this northern end of the Gulf of Manaar, above the recognised paars.

In the intervals of dredging and when moving from place to place, we were now continuously engaged in examining the parasites of the pearl oysters and their influence upon pearl-formation. We also decalcified such small pearls as were found. This work was continued as time permitted during the next few weeks, and also by Mr. Hornell after I left. We found various parasites, in the liver especially, some of which were Platyhelminthian and others Sporozoan in their nature, and some of which were enclosed in calcareous capsules. Mr. Hornell afterwards determined that these were Tetrarhynchus larvæ of Cestodes, and we have no doubt that they are in many cases the nucleus of the pearl, and the irritating cause of its formation.

On March 7th, at 7 A.M., the sea-temperature was 79·5° F. and at 6 P.M. it was 80° F., about 10 miles south of Adam's Bridge. This day and the following one were spent in continuous dredging in the northern end of the Gulf of Manaar, south of Adam's Bridge, from south of Thanni-Kodi on Rameswaram Island to south of Talamanaar on Manaar Island. Eight hauls were taken on the first day and 13 on the second, but although a wide extent of ground, about 18 miles from west to east, was worked over no natural limits present themselves, and I consider it best to unite the 21 hauls as a single locality (Station LIV.). We started at about 15 miles south of Thanni-Kodi and worked westwards into shallower water for two hauls and then southwards into much deeper water (30 fathoms), the dredge eventually falling "out of soundings." The 5th haul was in 40 fathoms at about 16 miles south of Thanni-Kodi. Here we obtained *Panthalis melanonotus*, in a muddy mucous tube very like the condition in which we find the same genus in water of the same depth in the Irish Sea. We then ran north into 15 fathoms (6th haul) and dredged eastward for the two remaining hauls in depths of 10 to 8½ fathoms, at about 10 miles south of Adam's Bridge. We anchored for the night with Thanni-Kodi bearing north, 18° W., and distant 10 miles.

The following morning we began dredging at the same spot and worked eastwards and then south-east through depths averaging 8 or 9 fathoms. In the 8th haul, south of Talamanaar, we came upon a rough bottom of living coral at 4 to 5 fathoms.

The 11th haul was upon the Anaivelundan Paar where some of the elephant's-ear coral (*Turbinaria cinerascens* and *T. crater*) from which the paar gets its name was brought up. The two final hauls were a little south of this on sand and dead shells, and then we ran for the south end of the Cheval Paar where the barques were then at anchor.

STATION LIV.—In northern part of Gulf of Manaar, south of Adam's Bridge; depths from 4 to 40 fathoms; bottom varied, from sand to living Coral—over 20 hauls of the dredge during two days.

Nullipores, *Halimeda*, *Corallina* and other Algæ;

Orbitolites complanatus, *Heterostegina depressa*, *Amphistegina lessonii* and other Foraminifera;

Petrosia testudinaria, *Halisarca* sp. (black), and other Sponges;

Pennatulids, various dendritic Alcyonaria, *Sclerophytum gardineri*, and *Lobophytum hedleyi* (?), *Sphenopus marsupialis*, *Fungia crassitentaculata*, *Goniopora* sp., *Pachyseris* sp., *Pocillopora grandis*, *Turbinaria cinerascens* and *T. crater*, *Porites arenosa*, *Cœloria sinensis*, and other Corals;

Hydroids—*Plumularia setacea*, *Monostachys dichotoma*, *Pasithea hexodon*, *Sertularia* (? n. sp.);

Phyllacanthus baculosa, *Linckia biforis*, *Astropecten hemprichii*, *Pentaceros lincki* and *P. nodosus*, *Actinometra parvicirra*, and *Antedon palmata*, *Holothuria atra*, *H. kurti*, *H. monacaria*, *Colochirus doliolum*, *Col. quadrangularis* and the new variety *mollis*, *Havelockia herdmani*, n. gen. et sp. (PEARSON) and many Ophiuroids;

Worm tubes (*Serpula*, *Sabella*, &c.), *Physcosoma asser*, *Panthalis melanonotus*, *Thelepus* sp., *Terebella* sp., *Nothria* sp., *Lingula*;

Polyzoa—many, belonging to the genera *Crisia*, *Buskia*, *Amathia*, *Ætea*, *Alcyonidium*, *Cellepora*, *Cellaria*, and *Porella*;

Lambrus sp., *Dromia* sp., *Pinnotheres* sp., *Leucosia urania*, and other Crabs;

Pearl oysters (very few—scattered), and *Modiola* (in gelatinous nests), Nudibranchs, *Ranella albivaricosa*, *Triton* sp., *Pleurotoma crispa*, *Turritella maculata*, *T. candida* and another sp., *Nassa rufula*, *N. micans* and *Dolabella* sp.;

Leptoclinum (several spp.); *Asymmetron cingalense*; Syngnathid with dendritic filaments.

TOW-NET gatherings taken both on the surface and at 12 fathoms, on March 7th, showed vast quantities of diatoms—chiefly *Biddulphia* with some *Ceratium tripos* and some small Radiolaria; also *Trichodesmium erythræum*, *Sagitta* and over 20 species of Copepoda, including:—

Paracalanus crassirostris, *Centropages furcatus*, *Calanopia elliptica*, *Labidocera minuta*, *Ectinosoma atlanticum* and *E. roseum*, *Oithona similis*, *O. plumifera* and *O. rigida*, *Corycæus obtusus* and *Euterpe gracilis*.

On March 8th we obtained, in addition to most of the above:—

Calanus vulgaris, *Centropages orsini* and *C. kroyeri*, *Labidocera acuta*, *Pseudodiaptomus serricaudata*, *Acartia erythraea*, *Calanopia elliptica* and *C. minor*.

On March 9th the sea-temperature at 7 A.M. was 79·8° F. and at 5 P.M. was 80·1° F., and the specific gravity was a shade under 1·023.

In the morning we worked with the divers over the south part of the region between the East and West Chevals. The oysters found here were mostly small (6 months old), growing in clumps or attached to the large valves of *Pinna bicolor*, which is very abundant here partly imbedded in the sand (fig. 18) - there are probably about 3 or 4 to the square yard. A shoal extends from this point (about the shoal buoy or south centre of Cheval Paar) southwards to the northern end of Karativo Island some 10 miles away. There is a tradition among the divers

Fig. 18. Large specimen of *Pinna* covered in its upper part with young pearl oysters and in the lower part with tags of byssus, indicating where oysters had been attached.

Fig. 19. Sketch-chart showing the shoal extending northwards from Karativo Island to the Cheval Paar.

that in former days Queen ALLIYARASANI, an Amazonian princess who ruled the Tamils in the northern part of Ceylon and personally superintended her pearl fisheries, used to sit on the north end of the long island of Karativo and watch the divers at work on the Cheval Paar. Karativo is now out of sight of the Cheval and there is no reason to think that the paar ever extended further south; but the soundings along the shoal (see fig. 19), taken along with the evidences of coast erosion that we found at Kodramallai Point and along the shores of the Bight of Kondatchi (see fig. 20, showing an old cannon near the Doric, at Aripu, nearly toppled over through the

Fig. 20. Captain J. DONNAN, late Inspector, and Captain J. LEGGE, present Inspector of the Pearl Banks, on an old cannon near the ruins of the Doric: to show the erosion of the coast in the bight of Kondatchi—from a photograph taken February, 1902.

washing away of the land by the sea), render it highly probable that Karativo in former times extended northwards along the line of the shoal; and so, possibly, the tradition of Queen ALLIYARASANI is a record of the time when Karativo reached the Cheval Paar.

On March 9th we dredged about the southern part of the Periya Paar. The first haul was taken across the paar, and immense quantities of small oysters (about 6 months old) and a bucketful of large ones (3 years old) were obtained.

The remaining three hauls (Station LV.) were outside the paar, and to the south, and extended westwards to "out of soundings."

STATION LV.—To the west and south-west of southern end of Periya Paar; depth 11 to 24 fathoms; bottom sand, Nullipores and dead Corals; dredged.

Codium bursarium, *Bryopsis*;

Orbitolites complanatus, *Heterostegina depressa*, &c.;

Axinella tubulata, *Suberites inconstans*, var. *digitata*;

Some Corals, Antipatharia, *Juncella juncea*;

Nemertine, *Physcosoma agassizii*, *Clœia ceylonica*;

Toxopneustes pileolus, *Cidaris metularia*, *Echinolampas oviformis*, *Lovenia elongata*, *Maretia planulata*, *Schizaster* sp.; *Stichopus variegatus*;

Balanus sp., various Macrura, *Lambrus* sp., and other Crabs;

Pearl oysters (both large and small), *Modiola* sp. (in gelatinous nests), *Murex tenuispina*, *Melibe* sp., *Doridium* sp., *Hexabranchus* sp., and small Octopods.

On March 10th we had a long day of dredging (17 successful hauls) on and outside Dutch Modragam, Karativo, and Col. Hamilton's Alentura paars, all lying outside the northern part of Karativo Island.

The hauls may be grouped into three stations (LVI. to LVIII.).

STATION LVI.—West of Kodramallai Point, about 10 miles off shore, on and around Dutch Modragam Paar; depth 8 to 9 fathoms; bottom coarse quartz sand, with red weed (*Hypnea musciformis*, &c.) in places on which were immense quantities of pearl-oyster spat; 4 hauls of dredge.

Virgularia sp. (several);

Laganum depressum, *Echinodiscus auritus*;

Sipunculus sp., *Hermione ridgewayi*, n. sp., *Lepidonotus carinulatus*, *Chlœia ceylonica*, *Sabella phæotænia*, *Sigalion mathildæ*;

Leucosia sp., and other small Crabs;

Pearl oysters (young, 6 months old), *Aplysia* sp.; *Asymmetron cingalense*.

STATION LVII.—To the west of last station, outside Dutch Modragam Paar; $11\frac{1}{2}$ to 36 fathoms; bottom Orbitolites sand, Nullipores and dead Corals; 5 hauls of dredge.

Orbitolites complanatus, *Heterostegina depressa*;

Petrosia testudinaria and other sponges;

Stephanoseris rousseaui (with Gephyreans), Pennatulids, Gorgonids, and Reef Corals;

Phyllacanthus imperialis, *Laganum depressum*, *Clypeaster humilis*, *Fibularia volva*, *Actinometra parvicirra*, *Antedon bella* and *A. milberti*;

Nemertines, *Aspidosiphon* sp., *Sigalion mathildæ* (in Coral), *Elasmopus subcarinatus*, and other Amphipods; *Isocardia* sp. and *Doriopsis* sp.

STATION LVIII.—Further south than last Station, on and outside Karativo Paar and the adjacent Colonel Hamilton's Alentura Paar; depths mainly 9 to 26 fathoms, but once or twice the dredge may have slipped into deeper water—we were close to "out of soundings"; bottom Orbitolites sand, and some Nullipore and Coral fragments; 8 hauls of the dredge.

Orbitolites complanatus, *Heterostegina depressa*, *Rotalia calcar*, *Alveolina boscii*;

Various sponges;

Gorgonia sp., *Juncella juncea*, *Sphenopus marsupialis*, Corals (from living reef);

Antedon sp., *Holothuria atra*, *Stichopus chloronotus*, var. *fuscus*;

Hyalinœcia sp., *Distomum* sp. (on gills of pearl oyster), *Stylochus* sp.;

Lysianassa (? n. sp.), *Leptophoxus uncirostratus*, *Elasmopus subcarinatus*, and a new species of *Lambos*;

Pearl oysters (a few old and young), and *Avicula vexillum;*

Ascidia-like Clavelinid, *Branchiostoma lanceolatum*, var. *belcheri* (several).

A tow-netting taken below the surface, at 6 to 10 fathoms, gave amongst other things a large new Ostracod, a new species of *Centropages, Mecynocera clausi, Metaealanus aurivillii, Oithona plumifera, Clausocalanus furcatus*, and *Pseudodiaptomus serricaudatus*—over 20 species of Copepoda.

On March 10th, at 7 A.M., south of Cheval, the sea-temperature was 79·8° F.; on the 11th, at 6.30 A.M., off north end of Karativo Island, it was 80° F., and at 6 P.M., on Periya Paar, it was 81·1° F., the specific gravity as usual being about 1·023.

On March 11th, we continued dredging amongst the smaller paars to the south of the Cheval district and lying outside Karativo Island. The 9 hauls may be grouped in two sets, as follows:—

STATION LIX.—On and around DONNAN'S Muttuvaratu Paar; in shallow water, $6\frac{1}{2}$ to 9 fathoms; bottom Nullipore and dead Coral fragments; 5 hauls of dredge.

Tetractinellids, and other sponges;

Madrepora (spp.) and other living Corals, *Sarcophytum* sp. and *Selerophytum densum;*

Clypeaster (young), *Culcita schmideliana;*

Palmyra aurifera, Stylarioides parmatus, Lepidonotus carinulatus, Eunice teretiuscula, Ammochares sp., *Sabella phæotænia, Elsia indica;*

An Ascomyzontid Copepod which will require a new genus;

Pearl oysters, *Doris* sp., *Casella* sp., and a number of small Octopods.

STATION LX.—Outside DONNAN'S Paar; in deeper water, 20 to 30 fathoms; bottom Orbitolites sand, a little Nullipore and dead Coral; 4 hauls of dredge.

Orbitolites complanatus, and other Foraminifera;

Raspailia thurstoni, and other sponges;

Pennatulids, *Umbellula* and other Alcyonaria, *Sphenopus marsupialis*, and some living Corals, Antipatharia;

Phyllacanthus baculosa, Astropecten polyacanthus, Culcita schmideliana, Nardoa tuberculata, Ophiocoma scolopendrina, Cucumaria tricolor;

Various Molluscan shells (undetermined) and some Nudibranchs (*Doriopsis*).

A TOW-NETTING taken at the same time gave:—Amongst 28 species of Copepoda, *Pontella securifer, Calocalanus pavo, Oithona plumifera* and *Candaeia ethiopica.*

We now returned, northwards, to the Periya Paar in order to investigate its condition more thoroughly, as it was evidently the deepest and furthest seawards of the paars where oysters in any quantity were to be found. It was also by far the most extensive area covered with young oysters, and yet its past history has shown that it cannot be relied upon to yield fisheries. Again and again it has been reported as covered with young oysters, again and again they have all disappeared.

Captain DONNAN in his forty years' experience has only had one fishery on the Periya Paar—the only one to his knowledge (he told us) that had ever occurred. It has frequently, at an inspection, been found to have abundance of newly deposited small oysters, while at the next inspection these oysters have gone and a fresh deposit of younger ones may be in their place. Occasionally a few may have remained for a second year, but they have always disappeared before becoming large enough to fish, except in the one case of the fishery in 1879—and even that was of limited extent and only involved a small part of the bank.

The shallow-water plateau round the coast in the northern part of the Gulf of Manaar, upon which the pearl-oyster paars are placed, can usually be distinguished very clearly by the navigator on account of the difference in the tint of water. Even 20 miles from shore, in fine weather, the yellow sandy bottom shows up through the clear water, and the slope is so steep that there is an abrupt change from the dark blue of the deep ocean "out of soundings" to the lighter tint of the plateau. I am told that captains who know the district, making for the Pamban Pass, know it is useless to take soundings for the banks until the lighter coloured water is reached; and the line of junction is usually sharply marked.

Now the Periya Paar is close to the edge of the plateau, about 18 miles from land and at a depth of 8 to 10 fathoms (fig. 21). It runs for about 11 nautical miles north and south, and varies from 1 to 2 miles in breadth, and this—for a paar—large extent of ground has been called by the natives the "mother-paar" under the impression that the young oysters, that come and go in fabulous numbers, arise there and migrate or are carried inwards to supply the inshore paars with their populations. During a careful investigation of the Periya Paar and its surroundings we satisfied ourselves that there is no basis of fact for this belief, and it became clear to us that the successive broods on the Periya Paar, amounting probably within the last quarter century alone to many millions of millions of pearl oysters, which if they had been saved would have constituted enormous fisheries, have all been overwhelmed by natural causes, due mainly to the configuration of the ground and its exposure to the south-west monsoon.

The following table shows in brief the history of the Periya Paar for the last twenty-four years :—

February, 1880. .	Abundance of young oysters.
March, 1882. . .	No oysters on the bank.
March, 1883. . .	Abundance of young oysters, 6 to 9 months old.
March, 1884. . .	Oysters still on bank, mixed with others 3 months old.

March, 1885. . .	Older oysters gone and very few of the younger remaining.
March, 1886. . .	No oysters on bank.
November, 1887 .	Abundance of young oysters, 2 to 3 months old.
November, 1888 .	Oysters of last year gone and new lot come, 3 to 6 months old.
November, 1889 .	Oysters of last year gone; a few patches present of 3 months old.
March, 1892. . .	No oysters on the bank.
March, 1893. . .	Abundance of oysters of 6 months old.
March, 1894. . .	No oysters on the bank.
March, 1895. . .	No oysters on the bank.
March, 1896. . .	Abundance of young oysters, 3 to 6 months old.
March, 1897. . .	No oysters present.
March, 1898. . .	No oysters present.
March, 1899. . .	Abundance of oysters, 3 to 6 months old.
March, 1900. . .	Abundance of oysters, 3 to 6 months old; none of last year's remaining.
March, 1901. . .	Oysters present of 12 to 18 months of age, but not so numerous as in preceding year.
March, 1902. . .	Young oysters abundant, 2 to 3 months old. Only a few small patches of older oysters (2 to 2½ years) remaining.
November, 1902 .	All the oysters gone.

It is shown by the above that since 1880 the bank has been naturally re-stocked with young oysters at least 11 times without yielding a fishery.

The 10-fathom line skirts the western edge of the paar and the 100-fathom line is not far outside it (fig. 21). An examination of the great slope beyond is sufficient to show that the south-west monsoon running up towards the Bay of Bengal for 6 months in the year must produce a current which will beat with full force on the

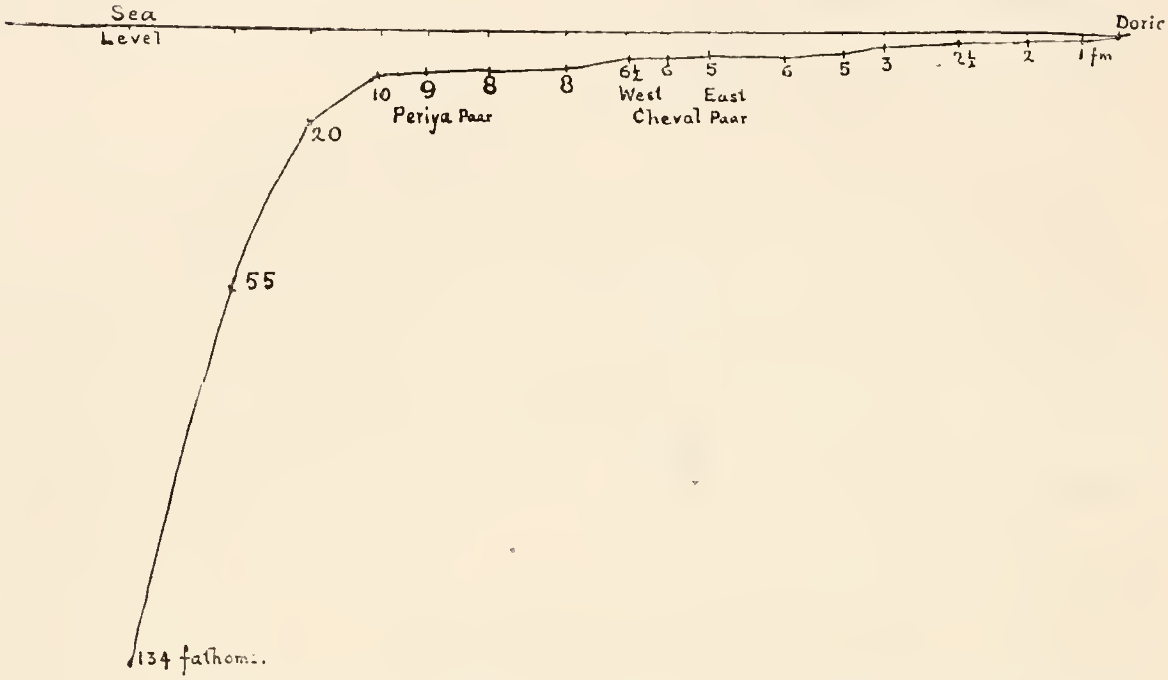


Fig. 21. Section across the sea from the Doric at Aripu westwards through the Cheval and Periya paars into deep water. Horizontal scale, ¼ inch = 1 mile; vertical scale, ¼ inch = 10 fathoms.

exposed seaward edge of the bank and cause great disturbance of the bottom. Figure 21 shows diagrammatically the sudden change in slope outside the paar.

In our previous hauls on the Periya Paar we had found very large numbers of young oysters, and wishing to ascertain how extensive the bed was, on March 12th we steamed in the "Serendib" to the northern extremity of the paar and then south for over 6 miles along its length, diving at intervals. We have the details of 18 dives recorded, and all of them except two give "small pearl oysters in abundance." We were convinced both from this day's work and our previous experiences when dredging that the Periya Paar was covered in March 1902 over the greater part of its extent with enormous quantities of young oysters. Now the area of the paar we take to be, from Captain Donnan's charts and our own observations, about 16 square miles, and we estimated at the time that the oysters were so closely placed that the bank must have held not less than about a hundred thousand millions. In the preliminary Report to the Colonial Government, written in July, 1902, I gave this rough estimate and stated my belief that these young oysters were doomed to destruction and ought to be removed at the earliest opportunity to a safer locality further inshore. Mr. Hornell was authorised by the Government of Ceylon to carry out this recommendation, and went to the Periya Paar early in November with boats and appliances suitable for the work, but found that he had arrived too late. The south-west monsoon had intervened, the bed had apparently been swept clean, and the enormous population of young oysters which we had seen in March, and which might have been used to stock many of the smaller inshore paars, was now in all probability either buried in sand or carried down the steep declivity into the deep water outside. This experience, taken along with what we know of the past history of the bank as revealed by the Inspectors' reports, shows that whenever young oysters are found on the Periya Paar, they ought without delay to be dredged up in bulk and transplanted to suitable ground in the Cheval district—the region where the most reliable paars are placed.

From this example of the Periya Paar it is clear that in considering the vicissitudes of the pearl-oyster banks we have to deal with great natural influences which cannot be removed, but which may to some extent be avoided, and that consequently it is necessary to introduce large measures of cultivation and regulation in order to increase the adult population on the grounds, give greater constancy to the supply, and remove the disappointing fluctuations in the fishery. The depth of water at the spots where our divers went down on the Periya Paar varied from 9 to 12 fathoms, the bottom is hard, so-called "rock," in most parts; in some places the flat "rock" is covered by a thin layer of coarse quartz sand. A certain amount of dead shells, bored by Gastropods, occurred, and a good many "Oorie" were brought up. Some coral fragments were found in places, and a few other animals, Terebellids in sandy tubes, and small fish (*Gymnapistus niger*), &c., were obtained.

The sea-temperature on the Periya Paar at 7 A.M. was 80·3° F., and in the evening (6 P.M.) on the Periya Paar Kerrai, much further inshore and north of the Cheval, it was 82° F., the specific gravity on both being 1·023.

We then, on March 12th, had 4 hauls of the dredge off the northern end of the Periya Paar to the west and south-west. These may be united as—

STATION LXI.—To the west and south-west of northern end of Periya Paar; 12 to 14 fathoms; bottom sand, Nullipore and Coral, with Sargasso weed.

Axinella tubulata and *A. donnani*, *Petrosia testudinaria;*

Heterocyathus aequicostatus (with Gephyrea) and other Corals;

Physcosoma scolops (in *Axinella tubulata*), *Nicomache* sp., *Gastrolepidia clavigera;*

Phyllidiella sp.; *Asymmetron* (*Heteropleuron*) *cingalense.*

The TOW-NET at the same time gave some Copepoda, including *Pontellopsis strenua* and *Corycaus gracilicaudatus.*

On March 13th the day was spent in dredging from Periya Paar Kerrai westwards, across Periya Paar and outwards to the west and south into deep water. Thirteen hauls were taken, which may be grouped as two Stations—

STATION LXII.—Between Periya Paar Kerrai and Periya Paar, working westward; depth 7 to 13 fathoms; bottom coarse quartz sand, some Orbitolites sand and Nullipores. Three hauls of dredge.

Orbitolites complanatus, and other large Foraminifera;

Chætopterus appendiculatus, *Sabellaria bicornis*, *Filograna* sp., a tube-building Amphipod (*Cerapus* sp.);

Echinostrephus molare, *Echinodiscus auritus*, *Stichopus chloronotus;*

Craspedochiton laqueatus (several), Pearl Oysters (small very abundant), "Suran," *Ostrea* sp., *Venus* sp., *Murex* sp., *Ficus ficoides;*

Molgulids, flat Polystyelid colony (on oyster shell);

Branchiostoma belcheri (11 specimens), "Sand-eels" (*Trichonotus* sp.).

STATION LXIII.—To the west of Periya Paar, going south; depths 17 to 55 fathoms (we sounded in 80 fathoms when the dredge was put over for one haul, but it is doubtful whether the dredge touched the bottom before we drifted in to about 40 fathoms); bottom Orbitolites sand, some dead Coral, shells and pieces of Nullipore. Amongst the animals were:—

Orbitolites complanatus, *Heterostegina depressa;*

Ciocalypta tyleri, var. *manaarensis*, *Spirastrella* sp., and other sponges;

Heteropsammia michelini (orange), with Gephyreans, *Flabellum rubrum*,* *Dendrophyllia* sp., *Juncella* (? n. sp.), *Pteroeides* sp.;

Actinometra parvicirra, and another species, *Salmacis dussumieri*, *Clypeaster scutiformis*, *Lovenia elongata*, *Echinolampas oviformis*, *Fibularia volva*, *Echinoneus cyclostomus*, *Pectinura gorgonia*, *Ophiopteron elegans*, *Astropecten polyacanthus;*

Chlœia sp., *Serpula* sp.; *Hippa*, *Thia*, and other Crabs;

Polyzoa—*Lepralia edax*, and *L. robusta*, and species of the genera *Scrupocellaria*, *Adeona*, *Gemellipora*, *Schizoporella*, *Membranipora*, *Microporella*, *Bowerbankia* and *Ascopodaria;*

Mollusca—including, *Mitra crebulirata*, *M. militaris*, *Cerithium armatum*, *C. citrinum*, *Strombus pulchellus*, *Natica albumen*, *Pleurotoma tigrina*, *Nassa* sp., and *Dentalium* sp.; Molgulids.

The sea-temperature at 7 A.M. on the west of the Periya Paar Kerrai was 81° F., and at 6 P.M. on the Vankali Paar was 82°·1 F., the specific gravity as usual being 1·023.

We tow-netted during the day, and obtained on the surface numerous deep blue Copepoda (*Labidocera acuta*) a deep blue Porpita and colonies of Compound Radiolaria (*Collozoum* sp.) with black pigmented individuals, also Erichthus and other larval

* Mr. STANLEY GARDINER informs me that this belongs to the "facies" or variety which has the form known formerly under the name *F. stokesi* (ED. and H.). See GARDINER 'Mar. Invests. in S. Africa,' p. 117, 1902.

Crustacea and much *Trichodesmium erythræum*. Twenty-four species of Copepoda have already been identified by Mr. ANDREW SCOTT from this haul.

The deep TOW-NET brought up *Sagitta*, a violet Appendicularian, filamentous Algæ forming balls, a large new Ostracod, and 15 species of Copepoda including *Clausocalanus furcatus* and *Ectinosoma atlanticum*.

In the evening, at 9 P.M., the sea was dotted with bright phosphorescent lights of considerable size singly placed at some distance apart. These for over an hour continued to glow with a pulsating appearance *in harmony*—all shining brightly at the same moment, and then all flickering out together, to re-appear simultaneously a few seconds later. We went out at once with a net and obtained a sample of the plankton, but could not be sure that we had caught any of the pulsating forms. The gathering contained *Sagitta* (very many), *Appendicularia*, Copepoda—half-a-dozen common species and *Sapphirhina sinuicauda*, *Pontella fera*, *Calocalanus pavo* and some smaller forms, along with half a-dozen one-inch-long Heteronereids of a reddish-brown colour. We suspected the light to be due to the last-named, and if that is so, possibly the periodicity was a result of the epitocous condition and was accompanied by a simultaneous discharge of genital products.

On March 14th, at 7 A.M., at the southern end of Pamban Pass, the sea-temperature was 82°·5 F. (5 degrees higher than it was at the same spot on February 5th) and the specific gravity was 1·022. At 6 P.M. in Palk Bay, the sea-temperature was again 82°·5 F. ($4\frac{1}{2}$ degrees higher than on February 6th) and the specific gravity was 1·021. We anchored for a couple of hours one mile off the village of Rameswaram and landed in the boat, examining the beach, the coral shoals on the way in, and the raised coral platform along the shore alluded to by THURSTON ('Notes on the Pearl and Chank Fisheries, &c.,' Madras Museum, 1890).

Two long hauls of the large shrimp-trawl were now taken in Palk Bay on the way across to Jaffna. The first was over the same region trawled on February 6th (Station XVIII.), but at right angles to our former course (see fig. 22). Starting due east of Rameswaram, about $4\frac{1}{2}$ miles off shore at a depth of 5 fathoms, we towed for about 10 miles to the north-east, towards the island of Catchetivo, the water deepening gradually to 7 fathoms. The bottom was soft grey-blue mud, containing small concretionary nodules and many casts of the interior of Gastropod shells. The animals obtained were mostly the same fish and invertebrates as on February 6th, a few small Crabs, Molluscs and Echinids; also a species of *Arcania* with large lateral projections of a deep violet colour on the carapace. Several pearl oysters were obtained in this haul, and a sea-snake.

The second haul was taken to the south-east of Catchetivo Island, in a depth of 7 fathoms. The trawl was worked rather more rapidly with the result that it did not hug the bottom so closely, and brought up no mud and very few invertebrates, but a large haul of small Scopelid fishes which filled half-a-dozen ship's buckets and numbered over 2500 specimens. They apparently belonged to only 3 or 4 species

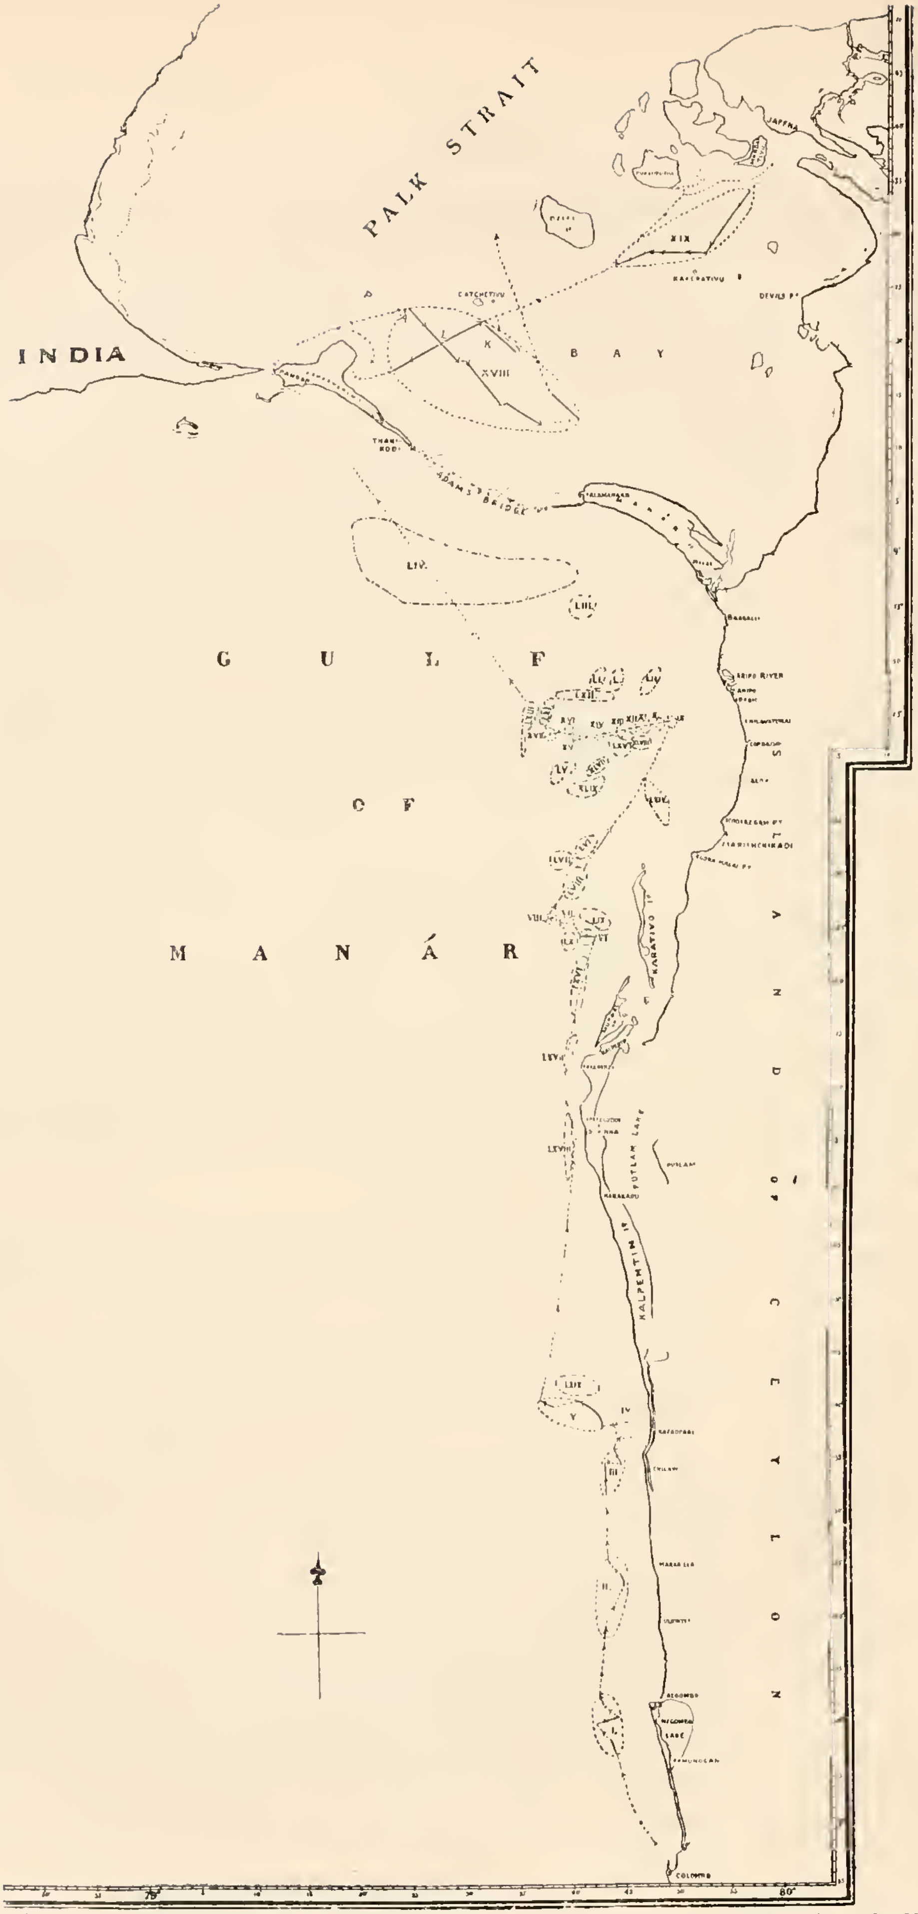

Fig. 22. Sketch-map of Gulf of Manaar and Palk Bay, showing Stations I. to XIX. and XLVII. to LXIX. The course of the first cruise is shown by the dotted lines with arrows. The stations of the second cruise are surrounded by dot-and-dash lines.

(*Saurus indicus*, *S. myops* and *Saurida tumbil*), all of silvery aspect. The trawl also contained 6 sea-snakes, 2 small Octopods (*Polypus granulatus* and another species), and 6 or 7 very fine prawns (*Penæus* sp.).

On March 15th we lay at anchor off Jaffna, taking in supplies and arranging for Sir WILLIAM TWYNAM to join our party. At 8 A.M. the sea-temperature was 82°·8 F. and the specific gravity 1·021; at 8 P.M. both readings were the same.

On March 16th we trawled in the northern part of Palk Bay, down the broad passage between the islands from Mandativo to Delft Island at depths increasing gradually from 4½ fathoms outwards to 8. About 12 miles were covered in 3 hauls, the first southwards from off Mandativo towards Kakerativo; the second from east to west about 2 miles north of Kakerativo, depth 7 fathoms; and the third half-way between Kakerativo and Delft Island, depth 8 fathoms. The last haul was on the mud with concretions, as at Station XVIII. (March 14th), but the two previous ones were on sand and shells with some living Coral. I consider all this day's work as being one locality (see fig. 22).

STATION XIX.—In north part of Palk Bay, east of Delft Island; depth 4½ to 8 fathoms; bottom sand and shells to mud; sea-temperature, 7 A.M. off Mandativo Island 82·8° F., 5 P.M. off Jaffna 84° F., specific gravity in both localities 1·020; 3 hauls of the large shrimp-trawl.

Various sponges;

Medusæ (*Nausithoë*, &c.), *Turbinaria cinerascens* and other Corals;

Some Amphipods, Erichthus, Phyllosoma, Prawns and Crabs;

Arca tortuosa, *A. compacta*, *A. tetragona* (?), *A. virescens* (?), *Mytilus barbatus*, *Cerithium citrinum*, *Mitra pyramidalis* (?) and other shells, and Octopods (*Polypus*);

A number of Polyzoa belonging to the genera, *Bugula*, *Cellepora*, *Lepralia*, *Schizoporella*, *Smittia* and *Crisia*;

Leptoclinum (2 species), *Rhabdocynthia* sp., *Rhodosoma* sp., *Polycarpa* sp., and *Salpa runcinata-fusiformis* (large, many);

Small Sole (*Solea oculus*).

On the way back to Jaffna to pick up Sir WILLIAM TWYNAM, we anchored for a couple of hours on the edge of the large shoal lying south and east of the Island of Punkudutivo (marked on the chart "Pearl beds") and went off in the boat to examine the coral reef and see if any trace could be found of the pearl-oysters said to have formerly existed there. We expected from the chart to have to row for at least a mile before coming to the reef, but in a couple of hundred yards progress was stopped by coral growing to within a foot or so of the surface, and on trying several other passages inwards to the land all were found blocked by luxuriant coral growth. We had then to leave the boat and wade over the coral plateau on the tops of enormous branched Madrepores and other flattened expanded colonies (the largest I saw anywhere round Ceylon) which crushed and snapped under one's weight and occasionally gave way altogether, letting one down into a hole with much laceration of skin on legs and arms. No traces of pearl oysters were seen, but possibly we were not able to get far enough inshore. On returning to the ship we found she had shifted her position, as on swinging round to her anchor in what according to the chart was 3 fathoms of water, she hit the rudder against the edge of a mass of growing coral reaching to within a couple of feet of the surface. The officers, from the deck, had fished up several large pieces of colonies for me with boat-hooks. It is evident that the coral reef is extending rapidly at this spot. It must not be supposed that a coral reef once it is surveyed remains stationary. Under some conditions it may become reduced in size, and under others it may show rapid growth both horizontally and vertically. The most abundant forms we obtained were:—*Madrepora cervicornis* and several other allied species, *Pocillopora grandis* and *P. cæspitosa*, *Porites palmata*, several species of *Montipora*, and various Astræids.

On March 17th in Pamban Pass at 7 A.M., the sea-temperature was 82° F., and the specific gravity 1·0206; at 6 P.M., on Kallatidel Paar, the temperature was 82·7° F., and the specific gravity 1·023. After rejoining Captain DONNAN and the inspection boats in the South Cheval district, we took 4 hauls of the dredge between the South Modragam Paar and Kodramallai Point. These may be united as:—

STATION LXIV.—From between South Modragam and Jaggerboom paars along a line south-east towards Kodramallai Point; depth $4\frac{1}{2}$ to $5\frac{1}{2}$ fathoms; bottom coarse sand, with much fine green-weed and small pearl oysters.

Some Renierid sponges;

Lytocarpus (? n. sp.), *Campanularia juncea*, *Fungia dentata* (many), large solitary Corals, and some Pennatulids;

Echinaster purpureus, *Pentaceros lincki* and *P. nodosus*, and many Ophiuroids;

Chlæia sp., *Harmothoë imbricata*;

Many Amphipoda including a new species of *Lambos*, *Lysianassa* (? n. sp.) and a remarkable new species of *Leptochelia* with immense chelæ considerably longer than the body;

Craspedochiton laqueatus, *Margaritifera vulgaris* (many small), *Turbinella rapa* (large), *Pleurotoma crenulata*, *Nassa reticosa*, *Pterocerus* sp., *Vertagus uluco*, *Vermetus* sp., *Lamellaria* sp., *Dolabella* sp., *Aplustrum thalassiarchi*.

The fine green-weed from the bottom had very young spat of pearl oysters on it. The small oysters dredged were about 8 or 9 months old, and were in quantity at about $3\frac{1}{2}$ miles off Kodramallai Point. A tow-netting on March 17th gave us a new species of *Centropages* with a prominent dorsal spine.

On March 18th the sea-temperature on Kallatidel Paar, at 7 A.M., was 82·2° F., and on Cheval Paar, at 6 P.M., was 82·7° F.

In the morning I visited Aripu Coral Reef in one of the boats, and waded over parts of it. It was very rich zoologically, the coral growth being exceedingly luxuriant. The most prevalent forms were :—several species of *Madrepora*, *Montipora*, *Turbinaria*, *Goniastræa*, *Favia* and *Porites*. Large *Cypræa tigris*, large *Ascidia* sp., a pinkish *Rhabdocynthia*, *Cynthia* sp., *Eurythoe latissima*, *E. longicirra*, *Notocirrus trigonocephalus*, and some Holothurians (including *Holothuria monacaria*) were amongst the other conspicuous forms collected.

In the afternoon we dredged round the shoal buoy at the south end of the Cheval Paar, and in a north-westerly direction.

STATION LXV.—From shoal buoy up West Cheval Paar; depth $7\frac{1}{2}$ to 8 fathoms; bottom white quartz sand; 4 hauls of dredge.

Campanularia juncea; *Pseudoboletia* sp.;

Hyale nilssoni (variety), *Pisa* sp. (many) and other Crabs;

A few adult and very many young Pearl Oysters, *Doris* sp., *Aplysia* (green coloured);

Branchiostoma lanceolata, var. *belcheri* (9 specimens), and the long worm-like fish *Opichthys timorensis*.

On March 19th, at 6.30 A.M., on the south-east of Cheval the sea-temperature was 82·5° F., and at 7 P.M. it was 83·5° F. The day was spent in dredging down the coast from DONNAN'S Muttuvaratu Paar (Station LXVI.) through Mudalaikuli Paar and Talaivillu Paar (Station LXVII.) to Coppeluddi and Navakaddu Paar (Station LXVIII.). Eight hauls were taken, grouped in three stations.

STATION LXVI.—From south of DONNAN'S Muttuvaratu Paar along the west of the northern part of Mutwal Island as far as off Mudalaikuli Paar; depths 10 to 35 fathoms; bottom Nullipore and Orbitolites sand, some red Algæ and dead Coral; three hauls of dredge.

Orbitolites complanata, *Alveolina boscii*;

Tetilla poculifera, n. sp. (DENDY), *Stelletta* sp., a Calcisponge and others.

Halicornaria setosa, *Sarcophytum*, Pennatulids and other Alcyonaria, *Flabellum* sp., *Heterocyathus æquicostatus* (with Gephyreans), and living Madrepores;

Phyllodoce foliosopapillata and *Mystides* sp. (afterwards found in our pearl-oyster cages at Galle, and may have come from this paar), *Aspidosiphon corallicola*;

Antedon palmata (?), *Holothuria atra* and *H. kurti*, *Cucumaria imbricata*;

Mæra rubromaculata;

Terebra sp., *Pteroceras* sp., *Phyllidia nigra* and small Octopods (*Polypus* sp.);

Cynthia dura (?), *C.* sp., *Polycarpa* sp., *Leptoclinum* sp.

STATION LXVII.—On and off Talaivillu Paar, off south end of Mutwal Island; depth 10 to 14 fathoms; bottom dead Coral and Nullipore; 2 hauls of dredge; *Halimeda tuna*, *Padina commersonii*. No Pearl Oysters.

Various sponges, chiefly Tetractinellids; *Stephanoseris rousseaui* and *Hetero-*

psammia michelini (with Gephyreans), *Caryophyllia* sp., *Lobophytum pauciflorum*, *Sclerophytum* (? n. sp.), and *Alcyonium pachycladis*;

Hermione sp. and other Annelids; *Asterina cepheus* and *Echinanthus* sp.;

Dexamine sp. and other Amphipods;

Vertagos pharos, and various undetermined Molluscs;

Branchiostoma lanceolatum, var. *belcheri* (several) and *Rhodosoma* (? *papillosum*).

STATION LXVIII.—From off Coppeluddi southwards to Navakaddu Paar; depth 8 to $18\frac{1}{2}$ fathoms; bottom Nullipores (*Lithothamnion fruticulosum*), Coral and muddy Orbitolites sand; three hauls of dredge.

Orbitolites complanatus and other Foraminifera;

Auletta aurantiaca, *Axinella tubulata*;

Various living Corals—*Cœloria* sp., *Madrepora* (sev. spp.), *Fungia crassitentaculata*, *Flabellum* sp.;

Colochirus sp. (?);

Pagurids and various small Crabs;

Molluscan shells (undetermined), *Doris* sp. (with black branchiæ).

A Tow-net gathering yielded many Copepoda of a bluish colour, including *Pontellopsis armatus*, *Pontellina plumata*, *Labidocera kroyeri* and *L. acuta*.

On March 20th Mr. Hornell and I were on our way back to Colombo, on the "Lady Havelock," with a cargo of oysters for Galle. We dredged at two points, (1) on the north end of Chilaw Paar, just north of Station V., and (2) off Negombo. At the latter spot we were again on the bed of oysters we had found on January 31st (Station I.) and obtained some young (about 6 months) on a bottom of coarse yellow sand containing *Caulerpa plumaris* and *Halophila ovata*. At the Chilaw Paar locality we had three hauls which are united as—

STATION LXIX.—On and to the east of the north end of Chilaw Paar; depth 8 to 11 fathoms; bottom yellow quartz sand, with some Coral fragments. Yellow Algæ with Oyster-spat; dredged.

Heterocyathus æquicostatus (with Gephyreans);

Echinodiscus auritus, *Clypeaster humilis*, *Actinometra* sp. (deep olive-brown with yellow tips to pinnæ, harbouring an olive-brown *Alpheus* striped with grey);

Aspidosiphon corallicola, Lumbriconereids and other Worms;

Balanus sp., Amphipods and some Decapoda;

Large and small Pearl Oysters and some other common Lamellibranchs, gelatinous Nudibranchs (*Melibe fimbriata*);

Large colony of a reddish Polystyelid, many Leptoclinids (white and drab), *Branchiostoma lanceolatum*, var. *belcheri* (numerous).

A Tow-netting at the same locality gave us, amongst other Copepoda, the large blue *Pontella princeps* and *P. securifer*, *Pontellopsis armatus* and *Labidocera kroyeri*.

We reached Colombo at 4.30 P.M., and this brought to an end the second cruise of the "Lady Havelock," which had lasted for three weeks and four days. We had left Captain DONNAN before the end of his inspection of the banks, because now that I had seen all possible spots on the coast which might serve for a biological laboratory and had selected Galle as being unquestionably the best, it seemed desirable—as the result of correspondence with the Lieutenant-Governor—that I should see for myself the several quarters at Galle that had been proposed and plan out with Mr. HORNELL the necessary alterations and fittings. We took with us various samples of living oysters, both large (3 years old) and small (about 6 months) which were conveyed safely from the pearl banks to Colombo in our steamer tanks and from Colombo to Galle by train in large earthenware "chatties" of sea-water. The journey occupied, with our necessary stoppages, four complete days at a very hot time of year. We were, however, able at the end of it to deposit most of these oysters in a living condition in the sea at Galle on the evening of March 22nd. They soon recovered activity, and were found next morning to be climbing up the chatties and on the netting in which we had enclosed them. The next three days were spent at Galle in examining, along with Mr. H. W. F. C. BRODHURST, the Government Agent, and Mr. T. TWYNAM, the Master Attendant, certain offices and bungalows in the Fort, in the native Bazaar and near Bayley's Villa on Glosenburg (see fig. 7, p. 46). Notwithstanding Professor HAECKEL's favourable opinion of the last named as a site, given 20 years ago, we found it necessary to reject that end of the bay in favour of the Fort; and in the end for several reasons, which I reported to the Lieutenant-Governor, a portion of the former Military Hospital conveniently situated on the ramparts at Akersloot or Sailors' Bastion, close to a good supply of clean sea-water, was selected as being the locality best fitted for adaptation as a marine laboratory (fig. 25). This report was acted on soon after I left Ceylon, with the result that Mr. HORNELL, upon his return from the pearl-banks in April with a further supply of oysters, was very soon established in a simple but efficient laboratory at Galle—carrying on the work I had left in his hands. Since then Mr. HORNELL has, by fortnightly letters, and frequent longer reports, drawings and specimens, kept me in close touch with all the details of his work; and I have sent him what information and instructions were necessary from time to time. The results of these observations at the Galle Laboratory will be given in the later parts of this report.

After having settled matters at Galle so far as was then possible, and having deposited our pearl oysters in bags and baskets suspended from buoys and spars anchored out in the bay (fig. 23), Mr. HORNELL and I returned to Colombo late on March 25th. The following day was occupied in seeing the Lieutenant-Governor in regard to the laboratory at Galle, and other business, and in packing and despatching some of the collections. Early in the morning of the 27th we started by coach to Chilaw, whence we went on by small boat next day to join the "Serendib," which was sent down the coast by Captain DONNAN to meet us. I had now only about ten days left in Ceylon and was anxious to spend most of that time on board the inspection barque seeing

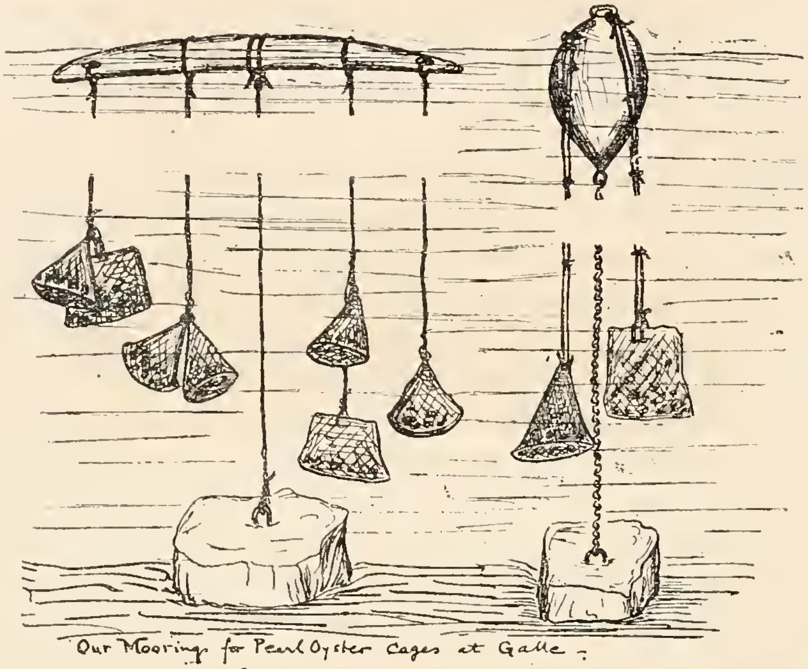

Fig. 23. Experimental oyster cages moored in Galle Bay.

the divers at work and following their results day by day. We reached the "Rangasameeporawee" on the Muttuvaratu Paar in the evening of the 28th, and rejoined Captains DONNAN and LEGGE and Sir W. TWYNAM. On the 29th March we were working on DONNAN'S Muttuvaratu Paar all day. There were plenty of oysters, and the divers brought us up samples and other specimens enough to keep all hands busy. Amongst other interesting forms found here was a new species of Chitonidæ, *Ischnochiton ravanæ*, n. sp. We had now re-started all the tanks and tubs and had many experiments under observation. The paar was estimated to have about 277,000,000 of oysters between $1\frac{1}{2}$ and $2\frac{1}{2}$ years old, but quite a number of them, in the samples we examined, were found to have a dwarfed or ill-grown appearance, accompanied by a yellow discoloration of the mantle and other tissues. We carefully examined this yellow and stunted condition of these oysters both at the time and since, and shall discuss it later on in the report. A good deal of our time was now occupied in examining the food in the stomachs and the sexual condition of the oysters (fig. 24 shows our work place on the barque). We also took tow-net gatherings and obtained samples of the bottom and the bottom fauna by means of the divers, but we had no further dredging or trawling.

The TOW-NET on March 29th, over DONNAN'S Paar, yielded *Trichodesmium*, *Sagitta*.

Pteropods, and 35 species of Copepoda including—*Corycaeus venustus* and *C. speciosus*, *Clytemnestra scutellata*, *Ectinosoma roseum*, *Acartia erythraea*, *Oncaea mediterranea*.

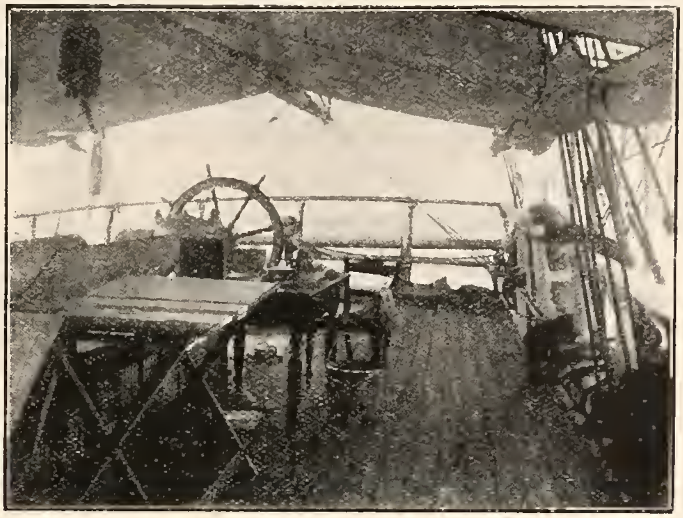

Fig. 24. The deck laboratory on the "Rangasameeporawee," from a photograph by J. HORNELL.

Rhincalanus cornutus, *Euchaeta marina*, *Eucalanus subtenuis*, *Setella gracilis*, *Tortanus forcipatus*, *Calocalanus pavo* and *C. plumosus*. We also obtained from this paar a remarkable Copepod, described below (see p. 245) as the type of a new genus *Ridgewayia*, in honour of His Excellency Sir J. WEST RIDGEWAY, Governor of Ceylon at the time of these investigations.

The sea-temperature on March 29th at 5.30 P.M. was 84° F., and specific gravity was 1·023. The temperature in our wooden tanks on board at the same time was 83° F., and we generally managed, by covering the tanks with moist canvas, to keep the temperature of their contents a degree or two below that of the sea.

The weather was now very hot. On March 30th, the sea-temperature at 7 A.M. was 84° F., and at 5 P.M. was 85° F. We now moved to the southern part of the paar, and in the afternoon rowed to the coral reef lying off Dutch Bay, where Captain LEGGE and I waded over the reef and collected various samples of the fauna.

On March 31st the weather was still warmer. The sea-temperature was 85° F. in the morning and 88° F. in the afternoon, but we managed to keep that in our tanks on board down to 83°·5 F. to 84° F., and the oysters remained very healthy. We moved this morning to the Mudalaikuli Paar, which we found to be practically a living coral reef with no oysters. Fine coral colonies (*Cœloria sinensis*, *Prionastraea* sp., *Pachyseris* sp., *Goniopora* sp., *Hydnophora microcona*, *Galaxea* sp., and *Fungia patella*) and sponges (*Axinella carteri*, *Phyllospongia holdsworthi*, *Spongionella nigra*) were brought up by the divers, but not a single oyster. In the afternoon we took boat and landed at Kattanattu Point, where a long sandy spit runs out to the north-west with a coral reef continuing onward in the same direction and others parallel outside it, so as to give some shelter to a little bay inside the point. We found however that the locality was quite unsuitable for oyster cultivation. In the south-west monsoon the surf evidently breaks over the spit and without doubt churns up the water and the bottom of the bay. This opinion was entirely corroborated by what we heard from the natives on shore.

The Tow-netting on March 30th over the Mudalaikuli Paar gave very much the same results as on the previous day. As additional forms obtained may be noted—

Calanopia elliptica, *Centropages orsini* and a new species of *Centropages*, *Pseudodiaptomus serricaudatus*, and *Eucalanus monachus.*

On April 1st we moved the barque to Talaivillu Paar, where again we found no oysters, the bottom being practically a living coral reef. At 8 A.M. the sea-temperature was 86° F., and at 5.30 P.M. 87° F., and the water in our tanks 84° F. The specific gravity was 1·0229. On Talaivillu Paar we obtained, on a brown (largely calcareous) sand with much *Halimeda* (*H. gracilis* and *H. tuna*)—

Axinella donnani, various incrusting and some Tetractinellid sponges;

Cœloria sinensis, *Porites arenosa*, *Fungia crassitentaculata*, *F. patella*, Madrepora (sev. spp.), *Montipora* sp., *Favia* and other Astræids, *Flabellum* sp., *Sarcophytum roseum*, and other Alcyonaria;

Clæosiphon aspergillum, *Sabellaria bicornis;*

Dexamine sp. and other Amphipods;

Phyllidia varicosa and *P. ceratosoma; Leptoclinum* sp.

The Tow-nets gave 22 species of Copepoda, amongst which may be mentioned:—

Setella gracilis, *Oncæa mediterranea*, *Corycæus longistylis*, *Acartia erythræa*, *Pseudodiaptomus aurivillii*, *P. serricaudatus*, and *Tortanus forcipatus.*

On April 2nd, at 6.40 A.M., the sea-temperature was 85° F. and at 6 P.M. it was 86·5° F., the specific gravity being 1·0228. We had moved to the Navakaddu Paar, where the usual diving operations were continued all forenoon. The bottom here consists largely of great blocks of dead Coral much encrusted with Polyzoa, Nullipores, compound Ascidians, &c., together with a certain amount of living Coral, such as Astræids and *Porites.*

Amongst other organisms brought up on Navakaddu were:—*Halimeda gracilis* and various red Algæ (*Hypnea musciformis*, *Polysiphonia*, &c.).

Asterina cepheus and *Antedon* sp. (? *A. palmata*);

Chætopterus appendiculatus, *Trophonia* sp.

Amphipods, Compound Ascidians, and a new species of Chitonidæ, *Callochiton sublævis*, n. sp. (Sykes). There were no pearl oysters.

The Tow-nets this day, in addition to *Trichodesmium* (very abundant) and *Ceratium*, contained a number of Copepoda, including *Setella gracilis*, *Corycæus venustus*, *Calanus minor*, *Ectinosoma atlanticum* and *Oithona plumifera.*

In the afternoon, still continuing south, we moved down upon the Udupankarai Paar. We found that there were no oysters on the ground, and not likely to be, as this paar, like several of the smaller ones in this neighbourhood, is now practically a living and growing coral reef; but from the older records it seems probable that in Dutch or Portuguese times these ranked amongst the productive oyster banks.

On April 3rd we moved down south to the Jokkenpiddi Paar, the last I was able to examine personally. The sea-temperature at 7 A.M. was 85·5° F. We anchored the barque on the north end, and in the "Serendib" ran south for about 7 miles and then steamed slowly back, sending the divers down every $\frac{1}{4}$ mile. Most of the dives gave a "rock" bottom with dead, and occasionally living, coral, and in several places young oysters (3 to 6 months) in quantity; depth $8\frac{1}{2}$ to 10 fathoms. Amongst the animals brought up were:—

Axinella donnani, an abundant lilac *Chalina* and other sponges;

Various Gorgonoids and common living corals;

Echinostrephus molare (in deep burrows in coral blocks), *Antedon* sp. (with commensal *Alpheus comatulorum*);

Sabellaria bicornis and other Worms; Dromiad and other small Crabs;

Chama foliata, and some coral-boring Lamellibranchs, Pearl Oysters, "Suran" (*Modiola*) and "Oorie" (*Sistrum*); *Leptoclinum* sp.

At 10 P.M., on April 3rd, I had to leave the barque "Rangasameeporawee," and was conveyed by the "Serendib" down to Colombo—as I was booked to leave Ceylon on April 7th, and had still to discuss various matters with the Lieutenant-Governor, transact business at the Master-Attendant's and other Government Offices in Colombo and see to the preservation and packing of many specimens. Mr. HORNELL remained with Captain DONNAN for a few days longer to complete the inspection of the southern paars, and obtain a supply of pearl oysters of various ages to take with him to the marine laboratory at Galle. He examined the Jokkenpiddi, Karkapanni, Chilaw, Oolawitti and Negombo paars, and brought a quantity of young oysters from these banks to Colombo, where they were suspended in coir baskets from the stern of the barque lying in the harbour. He then took the "Serendib" north to the Muttuvaratu Paar, obtained a supply of large oysters (3 years old), returned to Colombo, picked up the young oysters and conveyed the whole cargo round to Galle, where they arrived in splendid condition, not one oyster having died on the way. This shows the practicability of conveying the pearl oysters, both old and young, from place to place in a healthy condition by the means we adopted. Great care is, however, necessary if the temperature be high (the sea averaged about 85° F. during our operations) and if the run be more than 36 hours without

a stop. On that account the November inspection would probably be a better time for transporting, as the temperature is lower then than in March and April.

For some time after this Mr. HORNELL was fully occupied in looking after his oysters sunk or suspended in bags and baskets and "chatties" from boats, and buoys and booms in various parts of Galle Bay; and in superintending the fitting up of the marine laboratory at Akersloot Bastion. In addition to the large rooms (fig. 25) obtained from the old Military Hospital, on the ramparts of the Dutch Fort, which had to be sub-divided and furnished with work-tables, shelving and cupboards, an outside shed formed of "cadjan" (the large leaves of the talipot palm) was erected as a tank-house (fig. 26) to accommodate the wooden tanks and glass aquaria containing

Fig. 26. Aquarium shed with wooden tanks at the Galle Marine Biological Station.

the oysters under experiment and observation. Care was taken in the site and construction of this tank-shed to make it as cool as possible, and the sides were closed in with "tat"-blinds (split bamboos tied together), as being airier and lighter than cadjan flaps. The tanks were connected with the sea by a semi-rotary pump and water pipes which were carried about 20 feet outwards from the base of the rampart in order that the intake might be placed in a deep clear pool lined with living coral. The reservoir into which the pump discharges and from which the sea-water runs through the tanks is formed of two large iron tanks such as are used for citronella oil, with their upper ends cut out, and joined by a pipe at the base. The various observational tanks and aquaria (which had been brought out from Liverpool) were joined up by means of glass and rubber tubing, and were provided with arrangements devised by Mr. HORNELL for distributing air in finely sub-divided bubbles throughout the water. This marine laboratory has proved in every way satisfactory and suitable for our work during the last year. Mr. HORNELL—as the later parts of this report will show—has been able to investigate there the greater part of the matters I left in his hands; but there is still much useful work connected both with the Pearl Fisheries and with other marine industries that he could continue to carry on in this scientific workshop. Moreover, with a little extension of accommodation and permanent equipment it would be an eminently desirable and well-fitted establishment for general marine biological investigation, and would add to the scientific resources and attractions of the Colony. As examples of this it may be mentioned that during the past year (1) Mr. HORNELL has been able to supply specimens of marine algæ to workers at the Peradeniya Botanical Gardens, and types of marine animals to the Medical College at Colombo; (2) a Swedish Botanist, Dr. NILS SVEDELIUS, from Upsala University, has already made use of the laboratory as a place of research, and has expressed the opinion that it is very favourably situated for a tropical Marine Biological Station; and (3) it would naturally afford accommodation and material to the other scientific men of Ceylon. It is conveniently and centrally situated in the Fort, easy of access from the railway station and near the boat jetty, close to pure sea-water, opposite the Vellikoko Reef, adjoining good collecting grounds and with a living coral reef fringing the base of its walls—it seems in short an ideal spot for the purpose. Dr. ARTHUR WILLEY, F.R.S., Director of the Museum at Colombo, writes to me in regard to this Galle Marine Station (May 8th, 1903)—"I shall certainly hope to see the Laboratory which you established at Galle made a permanent institution after the publication of your report. . . . I have been twice to Galle and have seen HORNELL there hard at work, and he has shown me the admirable though simple appliances which render so much service."

Mr. HORNELL's work at the Galle Laboratory since April, 1902, has been chiefly on the following points—all of importance in connection with our understanding of the mode of life, the prosperity and the reproduction of the pearl oyster:—

1. Byssus formation, attachment, detachment, casting off the byssus and re-attachment.

2. Locomotion, both in old and young, crawling by means of the foot, and movement of the shells.

3. Effect of being partially or completely buried in sand. A healthy oyster can free itself from a thin layer of sand, and usually does so; but it cannot get out of 3 inches of sand and soon dies when buried.

4. The sexual condition of the oyster, the production of eggs and spermatozoa, their emission, the fertilisation and the early stages of development.

5. The "spat"—its characters and stages, and comparison with small species of *Avicula*.

6. Food and feeding, and the respiratory and nutritive currents of water. Varying "condition" of different oysters.
7. Growth, increase of the shell and repair of injury.
8. Parasites—Sporozoa, Cestodes, Trematodes, Nematodes, &c., and Commensals: their effect upon the oyster.
9. Other diseased and abnormal conditions of the oyster.
10. Pearl-production, both artificial and natural.

Some of these inquiries were merely the continuation of observations and experiments we had made during our work in the "Lady Havelock," others were undertaken with the object of settling definitely doubts that had been expressed or difficulties that had been raised in the Inspectors' reports and other previous writings, such as Sir W. C. TWYNAM's "Report on the Ceylon Pearl Fisheries," Colombo, 1900—a most useful summary of many previous documents, illuminated by a personal experience of nearly half a century. Our results, although no doubt they could be added to by further work, are I believe conclusive so far as they go; and consequently must be recorded even when, as in some cases, they merely corroborate or extend what was observed by KELAART, THOMAS, HOLDSWORTH, THURSTON or others.

The powers of locomotion we found to be unexpectedly great, especially in the case of young oysters (see some instances we gave on p. 58); and the capability of detachment and re-attachment, and of renewed byssus-formation, is considerable. These are clearly points of great practical importance in connection with our recommendations as to the thinning out and transplanting of young pearl oysters. Such transplantation could only be successfully undertaken in the case of oysters able to find suitable stations in their new environment and to re-attach themselves securely. The effect of burying in sand throws light upon some of the catastrophes that have affected promising beds of oysters in the past, and the knowledge will be useful in leading us to remove the stock in dangerous positions from such risks in the future. The sexes are separate, and, as our experiments show, remain the same from season to season: each individual is permanently either male or female. The natural emission of both ova and spermatozoa has taken place in our tanks at the Galle Laboratory, and we have reared the young pearl-oyster from the egg to a shelled larval stage similar to one obtained in the tow-nets. On all the other points we have I believe made some additions to knowledge which will be discussed below in the special articles.

In October, 1902, Mr. HORNELL carried out my suggestion of a further examination of Trincomalee Harbour and Tamblegam Lake. He gave ten days to the work and got satisfactory results which I have already noted (see p. 41).

Early in November he joined Captain LEGGE in the inspection of the pearl banks for the purpose of obtaining a sample of oysters to be valued by the pearl experts at Colombo in view of the proposed fishery. The following paars were inspected :— South, East and West Cheval, and Periya Paar Kerrai in considerable detail, and from these samples were lifted (fig. 27); while the following were less fully examined :— Kondatchi Paar, Dutch Modragam Paar, Muttuvaratu Paar, Chilaw Paar, and the ground off Negombo. Mr. HORNELL examined large numbers of oysters from the

Fig. 27. Valuation sample of pearl oysters from the Cheval Paar, being brought on board the "Rangasameeporawee" from the inspection boats—from a photograph by J. HORNELL.

various paars as regards their sexual condition, parasites and the occurrence of pearls. He also investigated the plankton as fully as possible, and found, on Muttuvaratu Paar, the youngest stages of the larval Cestode which we regard as the chief cause of pearl-formation free-swimming in the water.

Mr. HORNELL also took a considerable number of living oysters round with him from Muttuvaratu and Chilaw paars to Galle, where he placed them at various chosen spots in the lagoon for observation and experiment.

The official samples of pearl oysters taken from the Cheval Paars and Periya Paar Kerrai in November were valued in Negombo by five expert native merchants and Captain LEGGE, the Inspector of Pearl Banks, with the following results :—

12,000	oysters	from the	South-East part of the Cheval Paar,	at Rs. 10 25 c.	per 1000
1,000	,,	,,	East Cheval Paar,	at Rs. 18 17¼ c.	,,
2,000	,,	,,	North-East part of the Cheval Paar,	at Rs. 23 12½ c.	,,
2,000	,,	,,	Periya Paar Kerrai	at Rs. 13 25 c.	,,

As a result of this valuation it was decided to hold a pearl-fishery in the spring of 1903; and it was announced in the Ceylon Government Gazette Extraordinary No. 5896, of December 22, 1902, that the fishery would take place at Marichchukaddi, which is about 8 miles south of Chilavaturai, on or about 22nd February, 1903.

The paars announced for fishing were :—

South-East Cheval Paar,	with 49	million	oysters	sufficient	for 120	boats	for 40	days
East Cheval Paar,	,, 11	,,	,,	,,	28	,,	40	,,
North-East Cheval Paar,	,, 13	,,	,,	,,	32	,,	40	,,
Periya Paar Kerrai,	,, 8	,,	,,	,,	20	,,	40	,,

Making in all . . . . . 81 millions of pearl oysters estimated as fishable.

Mr. Hornell left Galle on January 27th and arrived off Marichchukaddi, the head-quarters of the fishery, on January 31st, and in this neighbourhood he remained for the next three months, leaving on April 23rd and arriving back at the Galle Laboratory on 4th of May.

The fishery did not commence until March 3rd and it ended on April 15th, having lasted for 38 days and resulted in a revenue of Rs. 830,151 93 c. Thirty-nine millions of oysters are estimated to have been obtained from the eastern Cheval paars, and an inspection made by Captain Legge at the conclusion resulted in the estimate that 22 millions of adult oysters were still left on these paars alone. This demonstrates one of the obvious imperfections of the method of fishing by means of native divers. When the divers have made enough money, or are wearied of the work, or find that the scattered condition of the oysters makes it more difficult to fill their baskets, they can declare that the bank is exhausted and so cause a premature stoppage of the fishery. Under such circumstances most of the oysters left at the bottom might still be recovered by dredging.

In addition to the paars fished, a number of the neighbouring smaller paars were inspected, and Mr. Hornell was able, by means of the European diving suit which was now available, to make a personal examination of the bottom and acquire a fuller knowledge of the conditions than had before been possible. He made about 40 descents in all—upon the Cheval, North and South Modragam, Periya Paar Kerrai, Kondatchy, Aripu, Periya, Dutch Modragam, Naddakudda, Vankali, Anaivel-unden, Karativo, Alentura and Muttuvaratu paars. On the larger paars several descents were made, eleven upon the Cheval as the one deserving most attention. One important result of this personal inspection of the bottom was to establish—if that was necessary—the correctness of the conclusion we had arrived at during our work on the "Lady Havelock," that the greater part of the bottom on the pearl-banks is suitable for dredging, and that the oysters could be obtained from the paars during a fishery much more effectively and speedily by dredging from one or more small steamers than by diving. On the Muttuvaratu Paar Mr. Hornell reports that three dives showed a dredgable bottom, while the fourth dive was on a spot where the dredge could not be worked as the "rock rose from the bottom in great plateau-like ledges." A similar condition was found at one spot on the Dutch Modragam Paar, but otherwise the bottom all over the productive paars is perfectly suitable for dredging. The Cheval paars and the North and South Modragams present ideal bottoms for dredging, or even for working a small trawl upon, being level and consisting mainly of a thin layer of sand covering a firmer substratum of the cemented material known as "rock." I shall return to this matter of dredging for the pearl oysters, in place of diving, in my Recommendations at the end of the Report.

During this period Mr. HORNELL also examined large numbers of pearl oysters of various ages and from different paars and so was able to confirm and extend our previous observations. He was especially successful in obtaining stages in the formation of pearls, and in the life-history of the pearl-causing parasites. The details obtained during this three months' work on the pearl-banks have been incorporated with our other investigations (1) on the condition of the ground (see p. 99); and (2) on the parasites and pearl-formation, in the parts that follow.

For some weeks after this Mr. HORNELL was engaged at Galle in completing his notes and records of observations and in packing off to me the specimens which had to be examined in Liverpool, and so finished his work as my Assistant in this investigation. If he is enabled to continue his observations as a Marine Biologist at the Galle Laboratory, judging from the industry, energy and ability he displayed during the time we were associated in work, I can confidently predict that he will render signal service to the pearl, sponge, trepang and other marine fisheries of the colony.

The inspection barque "Rangasameeporawee."

Fig. 28. Chart of the Northern Paars.

DESCRIPTION OF THE PEARL-OYSTER BANKS OF THE GULF OF MANAAR.

The following account of the physical and biological characteristics of the various "paars" on the Ceylon side of the Gulf of Manaar is drawn up partly from the information obtained by dredging over the ground from the ss. "Lady Havelock," partly from our lines of dives from the "Serendib" during the inspection of March, 1902, and partly from the additional information which Mr. Hornell obtained during the fishery of 1903. On this last occasion a European diving dress was available for use—which we had not had in 1902—and consequently Mr. Hornell was enabled to descend himself, and so corroborate, correct, and supplement the information derived from the natives* by many further details. The lists of animals found on the "paars" given here are not intended to be exhaustive, or even full. The object is merely to mention a few of the more characteristic organisms in each case.

The paars may be arranged in two groups, the Northern from Adam's Bridge down to Kodramallai, and the Southern from that point onwards; we give a chart (fig. 28 and fig. 37) of each group. The Northern is by far the more important; it contains more paars, they are of larger extent, and have produced most of the recorded fisheries. The pearl-bank plateau, bounded for the most part by the 10 or 12-fathom line, widens greatly in the northern part of the Gulf of Manaar as it approaches Adam's Bridge (see fig. 1, p. 19); for whereas off Negombo and Chilaw it is only 3 to 6 miles from shore, off Aripu and Kondatchi it is from 16 to 20 miles.

This widening of the plateau north of Kodramallai allows the northern paars to form several series, one outside another, and roughly parallel with the coast, the inner series being about 4 and the outer 18 miles from land. Outside the paars the ground shelves away rapidly to 20 or 30 fathoms, which marks the top of the steep slope down to the mud-floored abyss forming the central portion of the Gulf. Along the line of this slope soundings in some places jump in very short distances from 20 fathoms to anything between 100 and 1000, with, of course, interesting differences in the fauna. Within the 10 or 12-fathom line, on the other hand, the ground is for the most part very level, especially on the wider northern part of the plateau. At the Cheval Paar a distance of 12 miles is run from shore before a depth of 7 fathoms is reached—a gradient of 1 in 1700. The surface of this plateau is for the most part

* Mr. Hornell, writing to me of the results of his inspection, says that he finds the diagrams compiled from the divers' reports erroneous, and adds, "On the other hand, the results obtained by dredging—which sometimes clashed with the divers' reports—were proved to be reliable, and indeed wholly accurate. The conclusions based upon this source of information require no emendation—merely amplification."

sand, diversified here and there by outcrops of so-called "rock," generally in the form of flat or slightly-inclined ledges, sometimes stepped to form low terraces, sometimes level with the surface, and sometimes even a few inches under it, the rock being then covered by a thin layer of sand, which shifts from time to time with the currents.

Some of the paars, such as the Muttuvaratu, Karativo, Dutch Modragam, and parts of the Western Cheval, are formed almost entirely of rock, and the small amount of sand found in crevices and sprinkled over parts is mostly of organic origin—*Heterostegina*, *Alveolina*, *Orbitolites*, and other large Foraminifera and fragments of shells. On other paars, such as the East and South Cheval, angular quartz sand predominates, sometimes underlaid by flat rock which crops out at intervals. Mr. J. Lomas, F.G.S., who has examined the samples of "rock" we obtained from the paars, is of opinion that they are all of recent origin, and are in fact merely a consolidation or cementing of the sand *in situ*. Further details of the nature of these modern calcareous rocks or "Calcretes," and of their mode of formation on the paars, will be given in Mr. Lomas' report which follows.

The calcretes naturally vary considerably from place to place, being in some cases mainly composed of terrigenons materials and in others being mainly neritic or formed of organic remains. The rock may be a grit stone formed of the yellow-tinted quartz sand, which is so abundant, cemented by carbonate of lime, or it may be largely dead worn and altered coral, or it may be a shelly mass, an agglomerate of the dead valves of pearl-oysters, cockles, and Pectunculids with Nullipores (*Lithothamnion*) and Polyzoa (Lepralids) intermingled.

In addition to the paars described below, there are a few others, marked on the chart as "Old" or "Old Dutch" (see figs. 28 and 37), which are either erroneous positions of other paars now more accurately determined or are patches which formerly bore oysters and have since changed their character.

We must not, however, try to be too precise in regard to the positions, sizes, and outlines of the paars. Our work in the "Lady Havelock" showed us that some spots around and between them are more or less hard-bottomed, and even in some cases bore oysters and are capable of becoming paars. On the other hand, it is known from the inspections that many parts of the known paars are temporarily, and possibly some parts even permanently, unsuitable for the attachment or rearing of oysters. We may consider, then, the whole plateau as potentially "paar" ground—some parts of it better suited for one purpose and some for another, some parts more constantly covered by the shifting sands, others more regularly bare and hard. This renders possible the farming operations, such as "culching" and transplanting, which we discuss in our "Recommendations."

Cheval Paar.

This is the most important and the largest of the paars, and is the central member of the northern set, most of the other paars being grouped around it (see fig. 28).

It lies from 9 to 13 miles off the coast, opposite the bight of Kondatchi, the northern point being due west of Aripu and the southern of Kallar tower. The paar extends for about $6\frac{1}{2}$ miles from north to south, and $4\frac{1}{2}$ miles from east to west, but is not all occupied by pearl oysters. The depths vary from 5 to $8\frac{1}{2}$ fathoms. The paar is usually divided into an eastern, a western, and a connecting southern portion, and in most of the fishery charts since the time of Steuart (1843), these have been combined to form a conventional horse-shoe shape, which, however, does not now correspond at all accurately with the area covered, or likely to be covered, by pearl oysters.

The parts of the paar differ considerably in character, the east and south being more or less sandy, and the west, and especially north-west, more rocky; and the effect of this difference can be traced in the condition and history of the pearl oysters from these parts.

The Cheval Paar has yielded many important fisheries. During the nineteenth century we find that the whole or parts of it were fished in 1804, 1806, 1808, 1809, 1814 (the largest fishery recorded), 1816, 1820, 1829, 1830, 1831, 1836, 1837, 1855, 1857, 1858, 1859, 1863, 1874, 1877, 1880, 1881, 1887, and 1888. In the earliest records the Cheval and Modragam paars are united as the Aripu banks.

West Cheval.—Here the bottom, especially towards the north, is very rocky, with little sand. The depth is mostly about 7 to 8 fathoms. The rock is a compact shelly limestone with some quartz sand cemented to it by carbonate of lime. It is much overgrown by Algæ and Sponges, and the *Sargassum* weed is especially abundant. Bare parts of the rock are of a reddish-yellow colour from ferruginous staining, and it is all much tunnelled by *Clione* and boring Molluscs. Between the long level stretches of rock are smaller sandy tracts, especially towards the south, where the sand is irregular, rising up into little hillocks, amongst which are scattered Nullipore balls and hemispherical Astræid corals. This large extent of rock, some hundreds of acres of continuous hard bottom, offers favourable conditions for the attachment of spat, and the area is notably prolific. During our inspection in March, 1902, Captain Donnan estimated that there were, on the West Cheval, 123 millions of oysters as against 74 millions on the eastern side of the paar. This abundance carries with it, however, the attendant danger of overcrowding as the oysters grow older, and appears to result in a stunted condition and, it may be, disease and wide-spread mortality. The dwarfed state of the oysters on both the North-west Cheval and the Muttuvaratu Paar has been recognised by the divers, and by the Inspectors in their reports, as the "Koddaipakku" variety (see, for example, Sir W. Twynam's "Report"). Captain Donnan remarks, under date 18th March, 1901, "I have noticed on previous occasions that young oysters on the East Cheval grow much larger and quicker than oysters on the West side of the Cheval." We found the average size of a fair sample of oysters from the North-west Cheval to be (March 27th, 1903): $61·50 \times 58·33 \times 26·84$ millims., while the average size from North-east Cheval was $76·05 \times 71·45 \times 31·45$ millims., and the average from Muttuvaratu was

57·54 × 54·00 × 24·42 millims., all being of the same season, from $3\frac{1}{4}$ to $3\frac{3}{4}$ years old. The stunting, although less marked than in the case of the Muttuvaratu Paar, is apparently a permanent characteristic of the North-west Cheval, and is due, we consider, to the conditions which favour an abundant deposit of spat leading afterwards to overcrowding and insufficient food.

The characteristic organisms on the bottom are:—

Sargassum and other Algæ (*Padina* and small Florideæ) in profusion;

Spongionella nigra, and a few Corals such as *Turbinaria cinerascens* and some Astræids; the large red starfish *Pentaceros lincki*, a fine species of *Cidaris* and *Antedon*. Quantities of *Aplysia* were seen, also *Lamellaria*, *Chromodoris*, *Scyllæa* and *Eolids; Pinna* lay flat on the rock in place of being partially buried in sand. The large pinkish Ascidian *Rhabdocynthia rosea* was also present.

East Cheval.—The bottom here consists of fragments of rock embedded in or covered with a few inches of sand. One piece brought up by the divers from the North-East Cheval ($6\frac{1}{2}$ fathoms) was a tabular calcareous mass, 4 feet by 2 feet by 4 or 5 inches thick, upon which about a dozen pearl oysters were attached, distributed as follows:- One end of the block projected above the sand and bore most of the oysters and some small Algæ, &c.; the other end was covered with a thin layer of sand, but had 5 oysters attached, the byssus passing through the sand to join the rock below—several other byssus tufts were also present; finally the middle, lowest, part was more deeply buried in sand and showed no trace of oysters. This case was typical of many "rocks" examined. The block was composed mainly of dead coral, upon which old worn shells and quartz grains had become cemented; partly by deposition of carbonate of lime and partly by incrusting calcareous Algæ, Polyzoa, and Serpulid tubes. The deeper parts showed ferruginous staining, and the cavernous condition of the interior in this and other blocks was due partly to the irregular disposition of the original components now cemented, and partly to boring by *Clione* and Molluscs. While at the north end of the paar the rock seems to be mainly dead coral, a little further south it becomes a grey-green compact grit stone cemented by carbonate of lime and incrusted with Nullipores and Polyzoa.

Over much of the East Cheval sand predominates on the surface, underlaid by rock, at a depth of 6 inches to 2 feet, from which in places corals and other colonies project above the sand. The pearl oysters, in our experience, were fairly evenly distributed, and in quality they proved to be the best of all those examined or fished. They were well-grown and vigorous (fig. 29), and richer in good pearls than any others.

In the sandy parts the pearl oysters are attached through the sand to buried fragments of rock, coral, or any firm substance. Sometimes one oyster is attached to a piece the size of a walnut, and two or three others are fixed to the shell of the first.

On this part of the paar large Algæ are scarce, but there were plenty of small Florideæ, *Padina*, *Laurencia* (boiled into jelly and eaten by the natives), *Poly-*

siphonia, *Corallina*; and a *Caulerpa* straggles through the sand. Amongst the commoner animals were hemispherical Astræid Corals, a small *Fungia* (*F. dentata*,

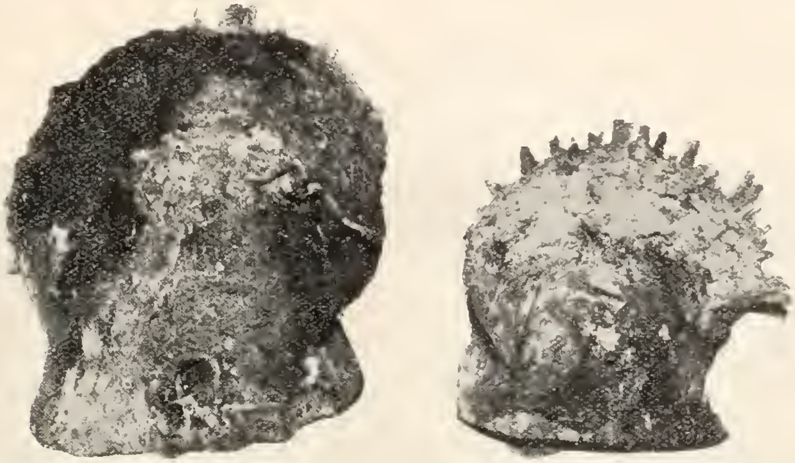

Fig. 29. Pearl-oysters from East Cheval Paar showing growing edges.

young, see fig. 30), a few Holothurians (*H. atra*), and the red *Pentaceros* and very many young *Aplysia*. But the most characteristic animal of this part of the Cheval Paar is the large Hydroid Zoophyte *Campanularia juncea*, which comes up in great bunches not unlike cut "heather," the name by which it has been sometimes indicated in the Inspectors' reports. The sand is largely composed of shell fragments, Nullipores

Fig. 30. *Fungia dentata*, living and expanded specimens from the East Cheval Paar, natural size.—From a photograph by J. HORNELL.

and Foraminifera. Other animals found here were *Spongionella nigra*, *Linckia* sp., orange Gorgonids, and species of *Haliotis*, *Arca*, *Cardium*, and *Turbinella*.

At the south-east corner of the Cheval we found that out of 307 dives 11 brought up adult oysters (7 from rock and 4 from sand), 216 brought up young oysters, 64 were on bare sand and 16 on rock without oysters.

About the middle of the East Cheval there are rocky patches of quartzose gritstone, which are too rugged to be fished by dredging, and yet are crowded with oysters. The few such areas on the pearl-banks might be cleared by divers, or if left unfished would no doubt form valuable breeding reserves.

South Cheval.—Unlike the eastern and western regions to the north, a remarkable uniformity characterises the whole of the southern part. The bottom is very level and is composed of sand and shell gravel, the latter chiefly the broken and worn fragments of pearl-oysters, Pectunculids, and Cockles. Scattered about in great profusion lie also fragments of dead coral, calcareous rock, shell-conglomerate, balls of *Lithothamnion* (fig. 31), from the size of a hazel nut to that of a cricket ball, and dead

Fig. 31. Nullipore ball (*Lithothamnion fruticulosum*) with tags of byssus where pearl-oysters have been attached (to the right), and similar ball still covered with young pearl-oysters (to the left); natural size.

shells. These fragments rarely exceed 6 inches in diameter, but some larger blocks of rock lie buried under the sand. Very rarely, however, is there any sign of extensive rock, such as is seen in the more northern parts of the paar, and none rises above the surface. This, like so much of the ground on the pearl-banks, is excellently suited for dredging over.

The pearl oysters lie for the most part loose on the sand in bunches, each bunch having in its centre one of the fragments of coral, rock, or nullipore. Often one oyster has three or four small stones and shell fragments entangled together in its byssus, while other individuals, usually younger, cling to its valves. There may be any number from 3 or 4 up to 15 or 16 oysters in a bunch. Some of the bunches (fig. 32) are formed of young and old individuals, ranging from 1 month up to nearly 4 years of age, joined together.

Non-calcareous Algæ are scarce here, *Pentaceros* and Holothurians are fairly common, and the Hydroid Zoophyte *Campanularia juncea* is characteristic of the eastern end and extends north along the East Cheval. *Spongionella nigra*, *Fungia dentata*, and Astræid Corals are also common, and a large mass of the delicate Annelid tubes, *Filograna*, was obtained near the shoal buoy. Dead oyster shells are very abundant at the eastern end, and it is here that we find the occasional lumps of shell-conglomerate formed of pearl oyster valves up to 4 years old, shells and casts of

Pectunculids, *Cardium*, *Macra*, *Venus*, &c., cemented together by mere films of carbonate of lime, supplemented in places by patches of *Lithothamnion* and Lepralid Polyzoa. This shell-conglomerate may be ferruginous like the Red Crag Deposits.

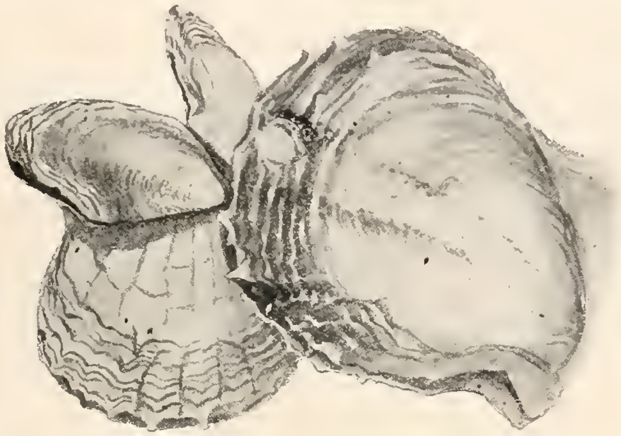

Fig. 32. Four generations of pearl-oysters from the Cheval Paar. The largest is $3\frac{3}{4}$ years old, the next is 18 months, two (above) are 8 months, and one (on the large shell) is about a month old. —From a photograph, March, 1903.

The cup-shaped horny sponge *Phyllospongia holdsworthi* is abundant at the western end, and, though not confined to this region, as has been supposed, is so characteristic that the native divers have named the western part of the bank the Koddai (or "Umbrella") Paar.

A comparison of these different parts of the Cheval Paar shows the great importance of scattered "culch" such as dead coral fragments, Nullipores, and old shells as a basis of attachment for the pearl oysters. The large embayment (fig. 32A) between the East and West Cheval has a bottom of sand, much of which could be made available for oyster cultivation by a system of "culching" with material brought from the beach or from any of the coral patches (Aripu, Kodramallai, &c.) in the neighbourhood. The limits of the paar might also, by the same process, be extended at least half-a-mile further to the east.

Fig. 32A. Proposed culture areas recommended for the Cheval Paar and Periya Paar Kerrai.

Modragam Paar, North.

This paar lies south-east of the central part of the Cheval Paar, at from $\frac{1}{2}$ mile to 1 mile distant, and is nearly 1 mile in diameter. It is about $8\frac{1}{2}$ miles west of Kallar tower. The depth is from $5\frac{3}{4}$ to $6\frac{3}{4}$ fathoms.

The bottom is sandy, ridged and furrowed ; no rock is to be found.

The pearl-oysters are in bunches lying on the sand, chiefly in furrows, each bunch having in its centre some fragment of dead coral, nullipore, calcrete, or other hard substance, to which most of the oysters are attached. In the first four bunches examined the numbers were 10, 8, 21 and 11 respectively. A characteristic feature is the number of barnacles and small rock oysters incrusting the valves.

Caulerpa (? *C. scalpelliformis*) is common here, growing in the sand along with the Phanerogam, *Halophila ovata*, of similar habit.

Amongst the animals noticed were :—*Clypeaster humilis*, *Salmacis bicolor*, *Luidea maculata* and *Pentaceros lincki*.

Captain DONNAN reported that the pearl oysters on this paar were "in great abundance in large clusters" in 1856 and again in 1857. These were fished in 1859 and in 1860. The paar yielded a small fishery in 1877 and a larger one in 1887, and again in 1888, when both Modragams were fished along with the whole of the Cheval Paar. The oysters on this paar are well grown, but seem limited in number for want of a hard bottom for attachment. The benefit of "culching" such a locality as this must be obvious.

MODRAGAM PAAR, SOUTH.

This lies 1 mile south-south-east of the North Modragam, and is about $\frac{1}{2}$ to $\frac{3}{4}$ mile in diameter. It is about 7 miles north-north-west of Kodramallai Point, and has a depth of $5\frac{1}{2}$ to 6 fathoms. The bottom is rocky but very level, and appears to be covered in its entire extent with a thin layer of sand, in which there are many broken shell fragments, especially pearl oysters, *Cardium* and *Pectunculus*. There are some Algæ, but when we examined the paar, very few pearl oysters.

Amongst the characteristic animals are :—the sponges *Axinella donnani* and *Spongionella nigra*, and many Astræid corals—small hemispherical colonies projecting through the sand and apparently attached to underlying rock.

This paar, along with the North Modragam, has usually been fished at the same time as the Cheval, but it apparently yielded important fisheries alone in 1828 and in 1860.

KONDATCHI PAAR.

This lies closer in-shore than the Cheval Paar, and about 1 mile due east of its southern end. It is about 1 mile in diameter, 7 miles off-shore, and has depths of 4 to 5 fathoms.

The greater part of the area is sand. Out of 171 dives 14 only were on rock, 157 on sand. There are occasional little patches of partly buried rock projecting from the smooth sandy surface. This paar is recorded to have only once yielded a fishery—that of 1801. There are now only a few pearl oysters, of mixed sizes, along with *Pinna bicolor*, *Luidea maculata*, and several kinds of *Pentaceros*—one very common species (?) is nearly black in colour, with red tops to the rounded tubercles, another form is grey, and another shows orange blotches and tubercles. Pennatulids, spinous and purple coloured, which had obviously been embedded in the sand, were also brought up. The shells of the pearl oysters were incrusted with small rock oysters (*Ostræa* sp.).

When we saw this bank in March, 1902, it had a crop of pearl oysters estimated at $5\frac{3}{4}$ millions. These had nearly all gone by March, 1903, and it is probable that their disappearance may be accounted for by the very large numbers of starfishes present, especially *Pentaceros lincki* (fig. 33).

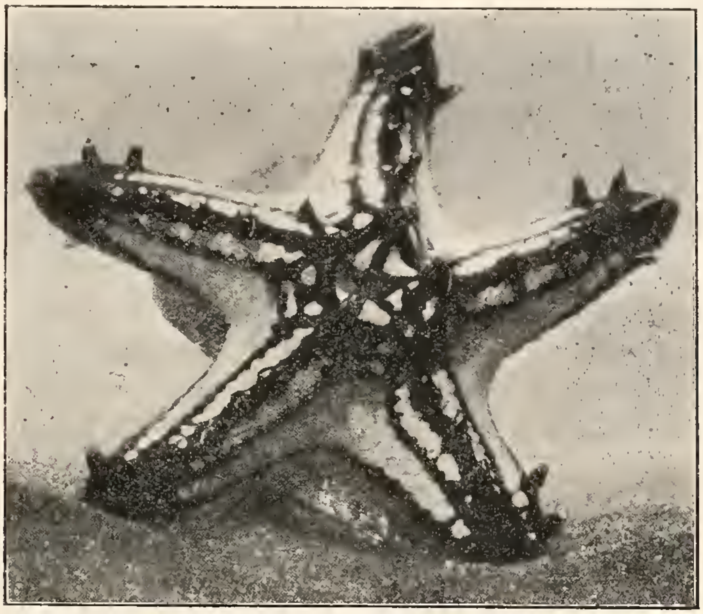

Fig. 33. *Pentaceros lincki*, DE BL., lying on a large pearl-oyster, half natural size.—From a photograph by J. HORNELL.

JAGERBOOM PAAR.

This lies 2 miles south of Kondatchi Paar and about $6\frac{1}{2}$ miles off-shore, opposite Kallar. It is about $1\frac{1}{2}$ miles across and has depths of 4 to $5\frac{1}{2}$ fathoms. The divers brought up pieces of the "rock" bottom, which consisted of rough quartz sand cemented by carbonate of lime, together with fragments of shell.

There are many starfishes (*Pentaceros lincki*) on this paar, as on Kondatchi Paar, and these probably contribute to the mortality of oysters.

An old Dutch "Jagerboom" bank is also marked on the charts about 2 miles south of the West Cheval and outside the Modragams—it is now covered with sand.

KALLATIDEL PAAR.

This little paar lies $1\frac{1}{2}$ miles to the east of the Cheval Paar and is about 7 miles off Aripu. It is nearly 1 mile in diameter and the depth is $5\frac{1}{4}$ fathoms. It is, in its present condition, unimportant.

ARIPU PAAR.

This lies 6 miles due west of Aripu, and 4 miles north-east of the north of the Cheval Paar. It is 1 mile in diameter, and the depth is 4 to 5 fathoms. Some old Dutch paars, marked on the charts as "Aripu," lie close to and outside. They are now covered with sand and are unimportant. About 1 mile further inshore lies Aripu

Coral Reef, round which is a hard patch of nearly 1 mile across, with depths of $2\frac{1}{2}$ to $4\frac{1}{2}$ fathoms. This, although itself unsuitable for oysters, is of value in supplying dead coral fragments, &c., as "culch" to neighbouring grounds. The bottom is level, consisting of sand and shingle lying on a foundation of flat rock. The sand varies from a mere sprinkling to a good depth. There are also some Nullipore balls, coral and shell fragments, and masses of cemented sand. Living corals are more abundant than on any part of East Cheval, no doubt owing to the proximity of the reef.

Amongst the more abundant organisms were :—

Various Algæ (including a *Galaxaura*, a fleshy *Laurencia* and *Halimeda tuna*), *Spongionella nigra*, *Axinella donnani*, *Phyllospongia holdsworthi*, *Turbinaria cinerascens* and *T. crater*, *Sarcophytum* sp., *Pentaceros* sp., *Linckia* sp., and other starfishes, *Holothuria atra* and other species, Ophiuroids and *Palinurus* sp.

The records of important fisheries early in the Nineteenth Century (between 1804 and 1820) on Aripu Paar do not refer to this little patch alone but to the great banks lying "off Aripu," viz., the Cheval and Modragam paars.

When we examined this paar there were comparatively few pearl oysters, but they were of various ages.

Challai Paar.

This little paar lies 5 miles to the east of the Cheval Paar, and about 4 miles south-west of Aripu. It is the nearest paar to land in this region, is about 1 mile in diameter, and $2\frac{1}{2}$ to $4\frac{1}{4}$ fathoms in depth. It does not now support any oysters, and is unimportant.

Periya Paar Kerrai.

This lies about 1 mile north-west of the most northerly point of the East Cheval Paar, and is about 12 miles west of Aripu. It varies from $\frac{1}{2}$ mile to $1\frac{1}{2}$ miles across.

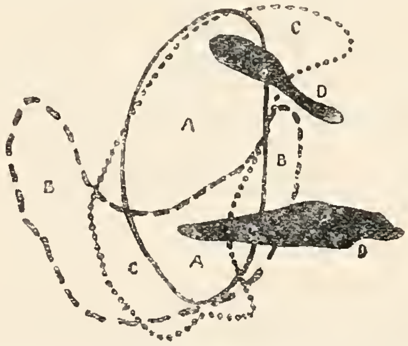

Fig. 34. Plan of the Periya Paar Kerrai. The whole line surrounding A shows the area as inspected in 1882, the dashed line round B shows the paar in 1884, the dotted line round C shows the condition in 1886, while the two black patches indicate the parts fished in 1835 and 1836.

and has depths of from 7 to 9 fathoms. The diagram (fig. 34) shows how the hard area forming the paar has varied in extent and shape from time to time.

The bottom is flat, being a continuous stretch of "rock" overlaid by a thin layer of sand. The samples we obtained were calcretes, largely encrusted with Polyzoa and Nullipores, and some shell conglomerates (fig. 35) formed of casts of the valves of pearl oysters, *Cardium*, *Pectunculus*, *Murex*, and *Cerithium*. Here and there the surface of the rock is exposed and coated by Nullipores and other encrusting organisms, and there pearl oysters (fig. 36, *o.*), or the marks of their byssus (*b.*), are found in quantity. Many crushed valves and broken fragments were also seen, showing that many more pearl oysters had been present lately. We attribute the destruction in this case to the carnivorous fish *Trygon uarnak* browsing over the bottom.

Fig. 35. Shell conglomerate from Periya Paar Kerrai.

Very little coral is present here—a few Astræids only were found. There is some *Sargassum* and a few other Algæ (*Acetabularia*, *Laurencia*, and *Lithothamnion* balls),

Fig. 36. Diagram illustrating the distribution of pearl-oysters and old byssus on "rock" and sand.

some black sponge (*Spongionella nigra*), a few trepang (*Holothuria atra*), and some starfishes (*Pentaceros lincki*). This paar yielded important fisheries in 1833, 1835, 1836, and then was not fished until 1903.

Outer or True Vankali Paar.

This lies 2 miles north-west of Periya Paar Kerrai, and about 14 miles due west of Aripu. It is $1\frac{1}{2}$ miles in diameter and the depth is $6\frac{1}{2}$ to $8\frac{1}{2}$ fathoms.

The bottom is flat "rock" covered with very many dead shells of pearl oysters, and other Mollusca, with comparatively little sand.

Amongst the other animals noticed were:—

Spongionella nigra, Astræids (small colonies), *Juncella juncea*, *Antedon*—black and grey on the Gorgonids, *Psolus* sp., *Balanus* sp. (large), *Galathea comatulorum* (this and a similarly coloured *Myzostomum* were attached to the *Antedon*), *Turbinella rapa*, *Murex regius* and some fishes (Labridæ and species of Balistes).

Inner Vankali Paar.

This lies 6 miles further east and is about 7 miles west of Aripu. It is about $1\frac{1}{2}$ miles in diameter, and the depth varies from 3 to 6 fathoms. This is a patch of rocky bottom, but close outside it are several old paars, named Vankali on the charts, which are now covered with sand.

Young oysters have been found on various occasions on the Vankali paars, but there has never been a fishery. In April, 1862, Mr. Vane reported a large bed of young oysters in this region, covering an extent of 3 miles, but they did not remain.

Anaivelundan Paar.

This is the most northerly paar, and lies $4\frac{1}{2}$ to 5 miles south of Adam's Bridge and nearly 8 miles south-south-west of Talamanaar. It is about $1\frac{1}{2}$ miles in diameter and has depths of 4 to 6 fathoms.

The bottom is composed of level "rock" overlaid with a thin sprinkling of sand. Attached to the rock is found much broad-jointed *Halimeda* (*H. tuna* var. *platydisca*), and also other Algæ, including *Chrysymenia uvaria*, *Udotea flabellata*, *Dictyurus purpurascens*, *Kallymenia perforata* and species of *Laurencia*, *Polysiphonia*, *Corallina*, *Acetabularia*, and quantities of *Sargassum*.

The most characteristic animals of this paar are the corals *Turbinaria cinerascens* and *T. crater*, the so-called elephant's-ear corals, from which the paar takes its native name.

Naddakadda Paar.

This lies $2\frac{1}{2}$ miles east of Anaivelundan Paar and 7 miles south of Talamanaar in Adam's Bridge. It is $1\frac{1}{2}$ miles in diameter, and the depth is $4\frac{1}{2}$ to $5\frac{1}{2}$ fathoms.

The bottom is formed of ridged sand, the underlying rock only showing in a few places. There are some Algæ (*Kallymenia perforata*, &c.) on the bottom, and some *Axinella donnani*, but no coral was found, and no pearl oysters.

The pearl oysters which have sometimes been found on this paar, and are sometimes washed up on the south of Manaar Island, are said to be of a flat shape and to have very few pearls.

To the south of this, and near the north end of the Periya Paar, two old Dutch paars are marked on the charts, which may be either erroneous positions of the Anaivelundan and Naddakadda or may be former paars now covered with sand.

Periya Paar.

This is a very long bank running north-north-west and south-south-east about 16 to 18 miles from land. It is about 11 miles in length and averages $1\frac{1}{2}$ miles in width. It is the paar that lies furthest from the shore, and has only been fished once, and then only the south-eastern part, in 1879. The depth varies over the different parts of the area from $7\frac{1}{2}$ to 13 fathoms, but the greater part of it is about $9\frac{1}{2}$ to 10 fathoms.

The bottom is a few inches of coarse quartz sand covering flat rock. The sand has ridges about 2 feet apart, and has plenty of small "culch," chiefly shells, lying in the hollows. In other parts the rock is exposed and covered with abundance of *Padina* and other Algæ, also Nullipore balls (*Lithothamnion fruticulosum*). The rock is, in the northern part, a fine grained calcareous sandstone much incrusted with Polyzoa, while further south it is a looser, more porous calcrete of a whiter colour.

Amongst the common animals found were :—

Axinella donnani, *Spongionella nigra*, *Petrosia testudinaria*, pink and white mottled Pennatulids, *Heteropsammia*, Astræids and *Turbinaria*, Eunicid worms, *Linckia* sp., *Cassis*, *Pectunculus*, *Arca*, *Chama*, *Venus* and other shells, *Labrus*, *Balistes*, Gobies and other fishes.

Even where the rock is exposed on this paar it would be suitable for dredging over —a matter of great importance, as this is the ground from which the largest supplies of young oysters can be obtained for transplanting to more reliable paars. Some further particulars in regard to this paar will be found in the "Narrative" (p. 76).

The SOUTHERN PAARS form for the most part a single series running north and south parallel with the coast from Negombo to Kodramallai. Off Chilaw, however, they become more extensive and allow of division into an outer paar and several inside it. At the northern end, also, off Karativo Island, the plateau widens, and is occupied by the large and important Muttuvaratu and several smaller paars. The chart of the Southern group (fig. 37) shows the paars from Kodramallai Point down to Navakaddua. The few banks remaining to the south of this (Jokkenpiddi, Oolawitti, and those off Chilaw and Negombo) are too distant to be included in the same figure, and scarcely require separate illustration. Their general position can be seen from fig. 1 and fig. 22, in the "Narrative."

These more southerly paars resemble closely in character the Periya Paar on the outside of the northern group. They are stretches of sea-bottom where the underlying calcrete or modern rock comes to the surface at intervals, or where loose fragments—lumps of calcrete, Nullipore balls, and dead shells—lie upon the surface, forming natural "culch" to which oyster spat can become attached. The exact conditions vary at different points along the coast, and, as might be expected, there are local differences noticeable in the fauna of the paars, which is affected by such factors as differences in depth, degree of exposure, and proximity to inlets of fresh water.

DUTCH MODRAGAM PAAR.

This lies 10 miles due west of Kodramallai Point and about 10 miles south-west of the North and South Modragams, and due north from Karativo Paar. It is $1\frac{1}{2}$ miles in diameter, and varies in depth from 8 to 14 fathoms.

Fig. 37 Chart showing most of the Southern Paars.

The bottom is rocky—a very coarse quartz grit cemented by lime, and with dead coral imbedded in places (*Madrepora*, *Montipora*, &c.). Foraminiferal sand (*Heterostegina*, *Orbitolites*, &c.) is present between the harder parts.

Out of 260 dives, 144 brought up adult pearl oysters, in 7 cases on sand and in 137 on "rock." The remaining dives were 83 on sand and 33 on rock not occupied by oysters. The pearl oysters are not very abundant and look rather stunted, and are overgrown with Leptoclinids, Sponges, small Algæ, and Serpulids; they are very similar to those on the Muttuvaratu Paar. Living *Fungia*, *Manicina*, and a few other corals are found, also *Culcita schmideliana*, *Linckia lævigata*, *Margaritifera margaritifera* (the "black-lip" pearl shell), many fishes, such as *Balistes mitis*, *B. stellatus*, and some Gobies.

This is one of the few paars on which it would be difficult to fish the pearl oyster by means of dredging. The bottom is so uneven and so rough with corals that the nets would be torn to pieces and the frames be broken, unless great care and skill were employed.

This paar is placed a couple of miles further to the north-east in an old Dutch chart. That may either be an erroneous position or may indicate a former patch of hard bottom.

Karativo Paar.

This lies 5 miles due west of the northern end of Karativo Island and 1 mile south of the Dutch Modragam. It is about 1 mile in diameter, and has depths of 8 to 10 fathoms. The bottom is very rocky and uneven, and it is one of the few spots that would be impossible for dredging. The rock is in the form of ledges, steps, or escarpments, with sometimes fully two feet of rise.

Scarcely any pearl oysters were seen, but amongt the few there was a living "black-lip" pearl oyster (*Margaritifera margaritifera*, Linn.). We also noted:—Madrepores, abundant, *Tridacna* sp., *Psolus* sp., *Asterias* sp., and shoals of Plectognathid fishes.

This paar was fished in 1832, and then again in 1890 and 1891, one day in each during the fishing of the Muttuvaratu Paar.

Alantura Paar (Hamilton's).

The paar lies about 1 mile to the south of Karativo Paar and $4\frac{1}{2}$ to 5 miles off Karativo Island. It is nearly 1 mile in average diameter, and the depth is 8 to 11 fathoms.

The bottom is very even—strewn with quantities of Nullipore fragments and other pieces of "culch," under which is *Heterostegina* and *Orbitolites* sand covering the flat

" rock." There are few attached coral colonies, but very many of a thin brown species of *Flabellum* lying on the sand.

This paar presents an excellent bottom both for the deposit of spat and also for dredging.

Muttuvaratu Paar (Donnan's).

This lies 5 miles west of Karativo Island and 3 to 4 miles south of Hamilton's Alantura Paar. It is $2\frac{1}{2}$ miles long (north to south) and $1\frac{1}{2}$ miles wide (east to west). The depth is 5 to 10, mostly 7 to 8 fathoms. On the whole it has a level hard bottom, and any little sand present is Foraminiferal. Of 289 dives, all were upon " rock," and 238 yielded adult oysters. Only the dives to the west part, in deeper water (fig. 39, A), were unproductive. This paar was covered, when we examined it, with plenty of pearl oysters, which are small for their presumed age, but thick, and with little or no signs of rapid or recent growth on the margins.

Oysters on this paar are rather characteristically associated with corals of the genera *Madrepora*, *Porites*, *Pocillopora*, *Montipora*, *Favia* and *Goniastrea*, growing upon the left valves which always lie uppermost in the usual position of the oyster (fig. 38). Some specimens are much overgrown with Polyzoa, sponges, &c. The

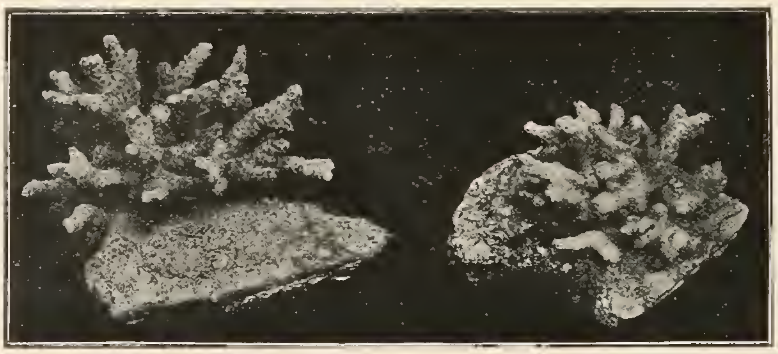

Fig. 38. Old pearl-oysters from the Muttuvaratu Paar, with large Madrepore Corals growing on the shell—half natural size.

oysters are also notably stunted in appearance, and their small size, compared with oysters of the same age from Cheval Paar, is well known, and has been recognised by various writers.

We found the specific gravity of the sea to be unusually low in this neighbourhood (1·0208, at a temperature of 85° F.). This may be due to proximity to the mouth of Putlam Lake, which probably discharges a considerable amount of fresh water derived from the Kala Oya and the Mi Oya Rivers. The bottom on this paar is flat " rock " with many small colonies of *Astræa*, *Cœloria*, and allied low-growing corals, with occasional bushes of large branched Madrepores, such as *M. cervicornis* and *M. cytherea*, rising to 18 inches or 2 feet in height. The pearl oysters on this paar in March, 1903, were "incredibly numerous, thousands in sight, crowding and even hiding the rock to which they anchor. One had to trample on them as one walked—no vacant spots to put the feet." Mr. HORNELL estimated them at about 125 adult oysters to the square yard. Captain DONNAN'S estimate in March, 1902, was 277 millions for the whole paar. This number has probably been greatly reduced since by disease. Fig. 39 gives some idea of the number and distribution of oysters in November, 1902.

Balistes stellatus, the file fish, seemed, during the inspection, to be very abundant on this paar, much more so than in the Cheval district. Many were seen in the water, and the boat's crew caught six in a quarter of an hour. It is interesting to note, in

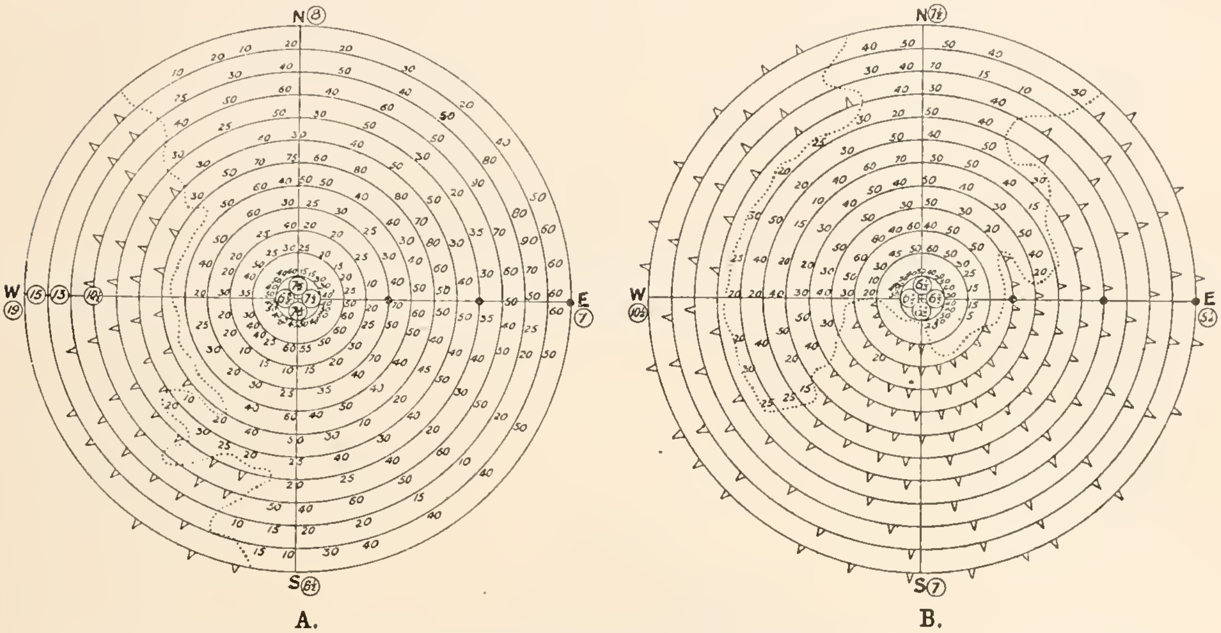

Fig. 39. Inspection charts of (A) northern and (B) southern parts of Muttuvaratu Paar in November, 1902. There are four concentric circles made by the divers' boats between the centre and the ¼-mile buoy, four between that and the ½-mile buoy, and four from that to the ¾-mile. Each complete area is therefore 1½ mile in diameter. The numbers enclosed in rings indicate depths in fathoms. The numbers on the concentric circles give the quantities of oysters brought up at a dive on that spot. The cones indicate dives on a rocky bottom with no oysters. The dotted line therefore surrounds the oyster-bearing area.

connection with this abundance of *Balistes*, that the oysters examined here are infested with Tetrarhynchus cysts to a much greater degree than those from any other bank.

This paar is essentially a rocky bank, well adapted for the deposit of spat, but less suitable than the Cheval Paar for rearing adult well-grown healthy oysters. It is the same type of paar as the Dutch Modragam and the Karativo. Amongst the other animals seen were the sponge *Phyllospongia holdsworthi*, the starfishes *Pentaceros lincki*, *Nardoa tuberculata*, *Ophiocoma scolopendrina* and *Linckia lævigata*, various living corals (*Turbinaria*, *Montipora*), *Sarcophytum*, *Socarnes schmardæ*, *Tridacna* sp., and *Arca* sp.

This paar yielded important fisheries in 1889, 1890, and 1891, the last being one of the most valuable fisheries that has ever been held, over 44 million oysters being fished at a return to Government of over 963,000 rupees. The bank had never been recorded as fished before 1889, and it is said that it was unknown to the Dutch in 1757, although we believe we have evidence that it was the source of fisheries in earlier Portuguese times. Captain DONNAN says that a bed of oysters died on this paar unfished in 1860; another bed disappeared in 1899.

To the north and east of the paar proper, in 7 to 8 fathoms, we found a hard and in some places rough bottom with plenty of "rock" and other hard fragments which would serve as "culch" for oysters. In places there are large branching Madrepores and great vase-like elephants-ear corals (*Turbinaria*); also *Phyllospongia holdsworthi* and other sponges. While the greater part of the ground, like the Cheval, the Modragams and the Periya Paar could be readily worked with the dredge, there are certain parts of this paar and the neighbouring ground which are unsuitable for dredging, and would, if that method of obtaining the pearl oysters were adopted to the exclusion of diving, form valuable preserves where the necessary stock of breeding oysters might remain undisturbed.

There is a diseased condition that the Muttuvaratu pearl oysters seem liable to, in which the body is stunted and shrunken, and the mantle and other tissues become of a markedly opaque yellow colour. This yellow condition has been noticed in the past by Sir W. TWYNAM and by Captain DONNAN. We found some affected specimens during our first cruise in the "Lady Havelock" in February, 1902, and others on every occasion when the bank has been visited since. On 14th April, 1903, out of 227 oysters examined, 25 were affected with the yellow disease, over 11 per cent. This condition, which seems to cause considerable mortality amongst adult oysters, will be discussed in the account of our laboratory work later on in the Report.

HAMILTON'S MUTTUVARATU PAAR.

This bank lies 2 miles south-east of HAMILTON'S Alantura Paar and $2\frac{1}{2}$ miles off Karativo Island. It is 1 mile in diameter, and the depth is from $4\frac{1}{4}$ to $6\frac{1}{4}$ fathoms. The bottom is irregular, partly rock and partly sand.

There were no oysters, and this paar is unimportant.

MUDALAIKULI PAAR.

This lies 3 to 4 miles south of Muttuvaratu Paar and 1 to 2 miles off Mutwal Island. It consists of two areas, an outer rocky part $1\frac{1}{2}$ mile in diameter and $4\frac{1}{2}$ to 8 fathoms in depth, and an inner more sandy part 1 mile in diameter and from $2\frac{3}{4}$ to 5 fathoms in depth.

This and a few small neighbouring paars are comparatively unimportant. They have not, so far as is known, yielded fisheries, but may bear crops of young oysters and so be of use under a system of cultivation.

Talaivillu Paar.

This lies 1 mile off Talaivillu on Kalpentyn Island, and is $2\frac{1}{2}$ miles from north to south, and 1 mile wide. The depth is from 4 to 9 fathoms, and there is much deeper water just over the outer edge. The bottom of the paar is irregular and rocky.

Navakaddu Paar.

This lies about 9 miles south of Talaivillu, less than 2 miles off shore, and 8 miles due west of Putlam Fort. It is over 2 miles from north to south and 1 mile from east to west. The depth is 4 to 14 fathoms, and the bottom irregular and rocky.

Jokkenpiddi Paar.

Jokkenpiddi Paar is one of the paars lying oft Chilaw. In this region there are many little hard patches known as paars, although they rarely bear oysters. Their exact positions are unimportant, as the whole area is potentially paar-ground.

On the bottom patches of "rock" alternate with sandy areas. Out of 312 dives on the southern part of the paar, 236 were on "rock," and 76 on sand. The samples of hard bottom we obtained consist of coarse quartz sand cemented into masses evidently of recent origin, which may be described as a coarse calcrete (fig. 40),

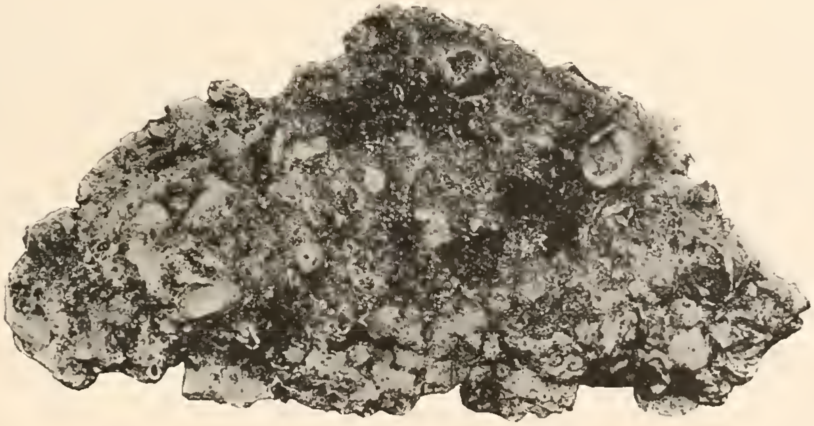

Fig. 40. Lump of calcrete showing large quartz grains and felspars with fragments of coral, shells and worm tubes, along with many Polyzoa colonies. From Jokkenpiddi Paar.

together with blocks of dead and some living coral. All the materials are largely cemented together by colonies of Polyzoa. There are also dark brown ferruginous nodules of phosphates.

We found a plentiful supply of small oysters (1 to 3 months) on some parts of the paar, along with very many dead shells. The living Coral consists of Madrepores and two species of *Turbinaria*. We also noticed :—*Axinella donnani*, *Echinostrephus molare*, *Ophiothrix* sp., *Asterina cepheus*, *Pentaceros lincki*, *Nardoa tuberculata*, *Filigrana* sp., *Trophonia* sp., Serpulids, Sabellaria, Pagurid (scarlet-maroon, hairy) in chank shell, and *Murex regius*, Pearl Oysters, *Avicula*, *Chama*, *Modiola* (suran), and *Vermetus*.

Captain DONNAN reports that a million and a half of large oysters which he found on this paar in April, 1878, had disappeared in the November following. This may become a valuable ground for obtaining a stock for other paars.

CHILAW PAARS.

The outer, largest paar lies about 7 miles off the mouth of the Dedera-oya River, near Chilaw, and is over 8 miles in length and about 2 miles in average breadth. It has a depth of 8 to 9½ fathoms.

The bottom is sand and masses of calcareous sandstone, which may be described as a medium-grained calcrete, with a few larger quartz grains up to ¾ inch diameter.

We found considerable quantities of small pearl oysters (6 months old) in large clusters, attached to one another by byssus and lying on sand, when not attached to the cemented masses. Amongst other animals found were :—Branched Gorgonids, with specimens of *Avicula radiata*, *Salmacis dussumieri*, and a species of *Hesione*.

A large supply of young oysters found here by Captain DONNAN in April, 1875, gradually disappeared during the next three years. Although there have been no fisheries on the Chilaw Paars during recent years, they yielded important fisheries in the past (1803, 1815, and 1884), and there seems no reason why a crop of pearl oysters should not mature upon them at any time. We have evidence* that the Pearl Fisheries controlled by the Singhalese Kings of Kandy were those lying off Negombo and Chilaw, while those of Manaar and Aripu were in the hands of the Tamil Kings of Jaffnapatam.

There are also several smaller paars off Chilaw lying nearer the shore, about 3 or 4 miles off land, and averaging about 1 mile each in diameter; and two further out north-east of the large paar and about 5 miles off-shore; in addition, many other hard patches in this neighbourhood are named as paars by the natives. In fact, there is a good deal of ground here that might at any time become a "paar" and bear crops of pearl oysters.

KARKOPANNI PAAR.

This paar lies off Karkopanni, to the North of Chilaw, about 3 miles off-shore, and at a depth of 7½ fathoms. The bottom is rock and sand intermingled, the latter

* From the Singhalese poem, 'Kovul Sandésaya' (about 1460), and IBU BATUTA'S 'Travels' (1344), and also various Dutch records of the eighteenth century. These have been searched by Mr. HORNELL, who expresses his indebtedness to Mr. P. E. PIERIS, C.C.S., for translations from the Singhalese.

greatly predominating. Only a few pearl oysters were found, on the small patches of rock, when we examined the ground.

The sand here is a coarse, yellow quartz sand, and the "rock" is a coarse, calcareous sandstone—or calcrete—the large quartz grains, up to an inch in length, being apparently embedded in a matrix of carbonate of lime. There are dark, ochreous patches in places. Out of 187 dives, 140 were on sand and 47 on rock.

Scarcely any living Coral was seen, and no Algæ; amongst the commoner animals were:—Branched Gorgonids and Hydroids, Terebellids (many, large), *Arca* sp., *Avicula radiata* (on Gorgonids), and *Leptoclinum* sp.

Oolawitti Paar.

This lies about 8 miles north of Negombo, at a depth of $7\frac{1}{2}$ to $8\frac{1}{2}$ fathoms. On the bottom coarse, yellow quartz sand predominates; but there is "rock" in patches, and there some small (6 months) pearl oysters were found.

The "rock" is consolidated sand, of a dark brown colour, as if iron were present in the cementing material. Mr. Lomas describes it as a "reddish-brown calcrete with the sand rather loosely united."

On these masses, and penetrating them, are found upright, branched, tough leathery tubes in abundance. Professor M'Intosh, in the "Challenger" Report on the Polychæta, figures a similar tube from the Gulf of Manaar, and states his belief that it will prove to be the home of a Eunicid. Mr. Hornell has been able to establish the correctness of this suggestion, as he has removed two fine Eunicids* from these tubes.

Negombo Paar.

This lies off Negombo, about 3 miles off-shore, at a depth of 8 to 9 fathoms. The bottom is sand and patches of "rock" (reddish-brown blocks of calcrete), exactly similar to that of the Oolawitti Paar. The oysters present when we examined the paar were probably from 2 to 6 months old, and were mostly attached to the rock, some in clusters on the sand. They were in considerable abundance.

There is another small paar, south of Negombo, which was found by Captain Donnan in 1901. It is similar in character to the Oolawitti Paar. Neither of these Negombo Paars, however, corresponds to the spot off Negombo where we dredged up young pearl oysters from the "Lady Havelock" in February, 1902. Mr. Hornell, who has been examining the early charts, is of opinion that the "Lady Havelock" paar is the original Oolawitti Paar. That does not matter much. What is of real importance, is to recognise that there are a number of small, more or less hard areas in the shifting sand, on which from time to time "strikes" of young oysters may make their appearance, and may possibly grow to maturity, but more usually become thinned out by their natural enemies or overwhelmed by sand. These small paars

* To be described in Mr. Hornell's Report on the Polychæta, in a later Part.

close to the deep water are evidently unreliable, and yet may be made use of in cultivation, and have probably in the past, on occasions, borne a crop of mature oysters.

The history of the Pearl Fisheries in the past, especially during the nineteenth century, has shown that :—

(1.) Some of these paars, such as Jagerboom, Kallatidal, Aripu, Anaivelundan, and others, are practically worthless from an economic point of view.

(2.) Some, such as the Periya Paar, might be used as most valuable sources of supply of young brood oysters for transplantation; but cannot be relied upon to produce an adult stock suitable for fishing.

(3.) Some, such as the great Cheval Paar, with its various sub-divisions, and the North and South Modragams, the Periya Paar Kerrai, and the Muttuvaratu Paar, are very valuable and reliable grounds upon which most of the successful fisheries of the past century have taken place. Others, such as those off Chilaw and Karativo, are less reliable, but may be valuable on occasions.

It became clear to us during our work on the "Lady Havelock," when we began to understand why it is that the Periya Paar is unreliable and the Cheval so much more satisfactory, that the main hope of introducing constancy of result and a regular succession of fisheries must rest upon a system of transplanting young strikes or broods of oysters when they make their appearance upon useless or unreliable paars, to wherever there is room for them at the time upon ground where we know they will have a better chance of living and growing to maturity.

This raises the whole question of the causes of death of the Pearl Oyster, the reasons of the intermittence in the history of the fisheries, and the conditions which render some paars more reliable than others. As we propose to have a section later on dealing with our observations and experiments on the Pearl Oyster and ending with our Recommendations, into which these matters will naturally fall, it will be sufficient here to give the following summary of our results :—

(1.) The most important agent in causing wide-spread death of Pearl Oysters, both young and old, in the Gulf of Manaar, is the shifting of sand due to the strong currents, to the south-west monsoon, and no doubt occasionally to exceptional storms. We obtained a good deal of evidence as to the manner in which the sand is carried about and piled up by the currents, and is churned up in places by the heavy seas at the time of the south-west monsoon, and we made observations as to the effect of burying oysters of different sizes in various amounts of sand. The successive broods which have appeared and as regularly disappeared upon the Periya Paar during the last quarter-century have, there can be no doubt, been overwhelmed by the bottom currents caused by the monsoon upon the bank which faces the deep water of the Indian Ocean.

(2.) Next in importance come, we consider, the ravages of natural enemies—the most destructive of which are :—

(*a.*) Voracious fishes—chiefly Rays (*Trygon uarnak*) and File-fishes (*Balistes mitis* and *B. stellatus*) ;
(*b.*) Boring Molluscs—chiefly *Sistrum spectrum* and *Pinaxia coronata*, along with species of *Nassa*, *Murex*, *Purpura* and *Turbinella;*
(*c.*) The boring sponge *Clione indica;*
(*d.*) Boring worms (*Leucodore*) ;
(*e.*) Star-fishes—chiefly *Pentaceros* and *Luidea;*
(*f.*) Smothering Mollusca—such as *Modiola barbata*, the "Suran," which weaves nests and other entanglements around masses of young oysters, and may, when present in quantity, cause serious mortality.

(3.) There are still three other causes of death that require mention, and may on occasions be serious, perhaps disastrous, viz. :—

(*a.*) *Overcrowding.*—The older are sometimes buried in masses of younger ones. The young are often piled together in such profusion as to interfere with each other's nutrition and growth. Thinning out must and does take place. If it were done artificially all or nearly all might be preserved ; if we leave it to be effected naturally by survival of the fittest the survivors may be very few indeed ;
(*b.*) *Disease* due to the invasion of parasites—either (1) worm parasites, which are moderately large and usually not very numerous, and which, unless abnormally abundant, do little harm ; or (2) the more minute Protozoon parasites, which may be present in enormous quantities and probably cause epidemic diseases ;
(*c.*) *Overfishing.*—That is, the exhaustion of the breeding stock of the district at a time when no further supplies of young in the larval stages were being brought by currents from neighbouring grounds. This will comparatively rarely happen, and is only likely to be serious during the last year of a series of fisheries. So long as there are three and four-year old oysters on adjoining paars which will be fished in the two succeeding years, it is safe to take every older oyster that can be got off the ground, as those coming on, although not yet ready to fish, are sexually mature and may be relied upon to supply spat ; but in the final year of a series, when no further mature oysters remain for future years, it is important to leave a sufficient stock for breeding purposes.

In the future, however, if transplanting is adopted, it may be expected that such a state of affairs as the last fishery of a series with no younger oysters growing up in the neighbourhood will be very unlikely to recur.

OBSERVATIONS ON THE SEA AROUND CEYLON, AND ESPECIALLY IN THE GULF OF MANAAR.

Although we were not prepared to make detailed physical observations on the sea-water, as I had not considered that necessary for our purpose, we kept a daily record of such approximate temperatures and densities as we could obtain with ordinary laboratory thermometers and hydrometers, sufficient to enable us to compare localities and seasons. During the cruises of the "Lady Havelock" the temperature and specific gravity were taken twice daily, in the morning after we had started the dredging operations—generally at 7 A.M.—and in the evening when work was finished, about 7 P.M. After I left, Mr. Hornell continued the records at Galle, and on occasions at Trincomalee and in the Gulf of Manaar, and took the observations once daily, between 8 and 10 in the morning, generally at 8.30. We also took all opportunities of making such observations as were possible on the surface drift of the sea, and obtained such information as we could as to prevailing currents at different seasons, as these movements of the water must be of great importance in connection with the distribution of the young pearl oysters.

During the period (January to April, 1902) of the two cruises in the "Lady Havelock" and our first inspection of the pearl banks, the sea temperature was steadily rising. At the beginning of the time, in the Gulf of Manaar, it was about 77° F., in February it averaged 79° F., in March 84° F., and in April 86° F. The specific gravity was nearly constant at 1·0230 in the Gulf of Manaar, while at Trincomalee, in February, it was lower—varying from 1·017 to 1·020.

In July, 1902, the sea temperature at Galle ran up to 86° F., and the specific gravity was constant at 1·0236. Mr. Hornell found that the temperature of the water in our shaded aquarium tanks was considerably lower (say 3° F.) than that of the sea outside.

In August the temperature of the water in our aquarium reservoir, taken at 8 A.M., ranged from 78° F. to 82° F., the average being 80·37° F.

In September the temperatures were taken in the open water at the jetty and ranged from 81·5° F. to 85° F., and the specific gravity from 1·0216 to 1·0220.

In October the temperature at Galle jetty fell from 86° F. to 82·5° F.; at Trincomalee the range was 84° F. to 89·5° F., and in Tamblegam Lake 87° F. to 90° F.

In November Mr. Hornell was again on the pearl banks and found that the sea temperatures ranged from 83° F. to 85° F., and the specific gravity from 1·0200 to 1·0227. At Galle jetty at the end of the month the sea temperature was 85° F.

In December, at Galle jetty, the sea temperature was nearly always at 84·5° F., the extremes in range being only 83·5° F. and 85° F.

In January, 1903, at Galle jetty, the range was from 82° F. to 84¼° F., and the specific gravity was close on 1·022. At the end of the month, in the Gulf of Manaar, the sea temperature was 82° F., and the specific gravity slightly above 1·023.

In February, on the pearl banks, the sea temperatures ranged from $80\frac{3}{4}$° F. to $84\frac{3}{4}$° F., and the specific gravities from 1·0229 to 1·0239.

In March, in the same locality, the temperature rose from 83° F. to $86\frac{1}{2}$° F., while the specific gravities lay between 1·0228 and 1·0234.

Finally, in April, in the same locality, the temperature rose from 86° F. to 88° F., while the specific gravity was very constant at 1·0228.

These observations, extending over 15 months, show a range of only 13° F. in the year, 77° F. to 90° F., for the seas around Ceylon; while in the Gulf of Manaar the lowest and highest recorded temperatures are 77° F. and 88° F. THURSTON found the temperature at Rameswaram in July, 1888, to vary from 79° F. to 91° F.

The specific gravity in the Gulf of Manaar is fairly constant at about 1·023, except at occasional spots; off Chilaw, on 22nd November, 1903, it was 1·0194, and on the Muttuvaratu Paar in the same month it varied about 1·0200; while at Galle it is rather lower than the Gulf of Manaar, averaging 1·022, and at Trincomalee it is lower still, 1·019, and at Tamblegam goes down to 1·015.

Further exact knowledge as to the movements of the water over the pearl banks in the Gulf of Manaar is urgently needed. On the "Lady Havelock" we had neither the means nor the time necessary for undertaking this investigation. It is probably the most important matter still requiring settlement, involving as it does the normal distribution of pearl-oyster spat. Till we know more accurately how the surface-drift acts at the chief spatting seasons, we cannot be certain of the source of supply to particular beds, or of the destiny of the larvæ produced from our adult oysters. We have not yet the means of arriving at conclusions as to the conditions of wind and weather which are required in order to constitute a favourable spatting season for the replenishment of say the Periya Paar or the Inner Vankali Paar, where young oysters frequently appear. Nor are we able to say with certainty whether the Cheval Paar supplies the Muttuvaratu, or the southern paars replenish the northern, or whether there is any definite relation as to spat-supply between the Ceylon pearl banks as a whole and those off Tuticorin on the Indian Coast.

We know that there is a general drift of the water over the banks from south to north from about the end of April to the end of September, and from north to south during the height of the north-east monsoon, with intermediate periods of calms and variable winds from February to April and usually again in November. Now it is essential that we should have more definite knowledge as to the resulting surface-drifts in these periods of variable winds between the monsoons, for it is during November and in March and April that the chief spatting seasons of the pearl oyster occur. Information in regard to the stronger and more constant currents which may be sufficient for the purposes of navigation will not suffice for fisheries purposes. We require to know where floating bodies, liberated at certain spots under known conditions, will drift to during given periods of days at different seasons; and this can only be ascertained by systematic "drift-bottle" experiments such as have recently been made for fisheries purposes in several European seas (see, *e.g.*, 'Fishes and Fisheries of the Irish Sea,' by HERDMAN and DAWSON, London, 1902, p. 7). Moreover, it is only after such work has been carried on systematically for two or three years at least, that it will be possible to determine the course taken by the larval pearl oysters between the time of hatching and the deposit of spat, and again between the attachment to floating Algæ and the appearance as young oysters on a paar. These are details which it was impossible for us to settle in the time at our disposal in 1902, but which will naturally, in the future, form an important part of the work of a marine biologist resident in Ceylon.

Our inspection barque "Sultan Iskander" towing the divers' boats to a new position.

OBSERVATIONS AND EXPERIMENTS ON THE LIFE-HISTORY AND HABITS OF THE PEARL OYSTER.

I. Determination of Sex.

At an early date in the investigation it became clear that the pearl oyster is diœcious or of one sex only—whether permanently so or only temporarily was a matter that could not be settled in one season, but which Mr. Hornell determined later on in the Galle laboratory. The dissections made during the cruises of the "Lady Havelock" in the Gulf of Manaar and in Trincomalee showed that each mature individual functions as male or female only. In no cases were even stray ova found in the gonads that were determined as male, nor any spermatozoa in the females—although such traces of hermaphroditism were carefully looked for.

In the Gulf of Manaar, during February and March, 1902, our dissections showed a considerable preponderance of males over females, and further work by Mr. Hornell at Galle showed the same disproportion, to the extent of about 10 per cent. of the total number examined, during other parts of the year. We have several lists, of which the following may be taken as a sample. Here out of 210 oysters from four distinct localities the sex of 158 was determined, 87 being male and 71 female—the remainder were indeterminable owing either to immaturity or their spent condition.

Date.	Males.	Females.	Spent or immature.	Locality.
16 October, 1902 . . .	13	9	4	Trincomalee.
5 November, ,, . . .	13	13	4	Cheval Paar.

Totals	87	71	52	

The further question—the permanence of the sexual condition—was one of those points which could only be settled in a marine laboratory, where the animals could be kept under observation from season to season, and formed a part of the work which I left Mr. Hornell to settle at Galle.

On May 17th, 1902, four of the pearl oysters in our aquarium were found to be emitting sexual elements, three being determined as males and one as female. They were marked individually and put in a separate tank, and later in a cage suspended from a buoy in the bay. On September 23rd two of these verified males were brought into the laboratory and both proved, on dissection (October 1st), to be still in the male condition. Over four months had elapsed since the end of the observed emission of sperms, and the gonads had filled up again for the next breeding season. The larger individual especially showed vigorous growth in all parts, the shell had increased from $\frac{1}{4}$ to $\frac{5}{16}$ inch, in addition to a great development of marginal processes. The gonad was fully developed, creamy yellow in colour, and swollen with active spermatozoa. The two remaining verified individuals were brought in and dissected on October 3rd, and were found after the $4\frac{1}{2}$ months' interval to be still of their respective sexes. The male contained ripe spermatozoa, and the female had the gonad large and swollen with ova in exactly the same condition as those emitted in May. Spawning might have taken place within a day or two had they lived.

Mr. Hornell has observed the natural emission of the eggs in a $2\frac{1}{2}$ years old pearl oyster living healthily in the aquarium tanks of the Galle Laboratory. He was also able, by pouring some of the sea-water charged with freshly laid ova into a tank containing other pearl oysters, to stimulate three ripe males to discharge spermatozoa. The first male commenced within two minutes of the addition of the ova to the tank, and while the stream issued as a milky cloud from the exhalent orifice the animal at intervals snapped its valves together several times, thus effectively dispersing the spermatozoa through the water. One minute after the first a second male commenced to spout and continued to pour out a stream for six minutes. After an hour's interval it re-commenced for four minutes, followed by occasional puffs for nearly half an hour, when the emission ceased finally. The third male became active some hours later, but all proceeded in a similar manner.

These observations show that the ova are extruded direct from the oviducts, by means of the supra-branchial passage, to the sea. They do not pass any time within or upon the gills—and do not undergo fertilization within the parent. The development of the larva takes place entirely in the sea.

II. Embryology and Early Life-History.

We tried artificial fertilization on several occasions, and although we have not yet reared the pearl oyster from the egg to a young shelled Mollusc that would be recognised by the divers, still we have had, in our tanks and under our microscopes, all stages from the fertilized ovum to free-swimming larvæ, similar to those we caught in the tow-net on the pearl banks, and which again we traced into the attached spat on the Algæ. So that we have seen, either in our experimental tanks or in collections from the sea, every stage from the egg to the adult pearl oyster. Mr. HORNELL has made a careful study of the young stages as observed by him at Galle in May, 1902, but as we hope to get still further details, the full account of the embryology will be given later on in this report. It will suffice to state now that the ovum when extruded is pyriform and floats, after fertilization it becomes spherical. The segmentation is complete but unequal, and within 2 hours results in an embryo of one large macromere and six micromeres. After 4 hours, segmentation was completed and the embryos were swimming freely by means of cilia, while about 20 hours after fertilization they were in the trochosphere stage, with a well-marked pre-equatorial band of long cilia, an apical pre-oral tuft and a patch or circlet of cilia at the opposite pole. As the body elongates, the equatorial band moves further and further forwards and becomes a pre-oral circlet, most strongly marked along the anterior margin which becomes the velum. Towards the end of the second day the larva is a veliger, and the shell has commenced to form posteriorly. On the third day the velum was considerably reduced in size and the bipartite shell increased, and this brought the larva to a stage corresponding with the forms we caught in our tow-nets, which bridged over the gap between the latest stage reared from the egg in the tanks and the earliest attached stage or "spat."

From a consideration of the sizes of the free-swimming larvæ and the youngest spat, and knowing the age at which the veliger obtains a shell, we are of opinion that attachment may be made within five days of fertilization. At the same time, from the large size of some of the free-swimming larvæ, it is probable that under certain circumstances, such as the absence of suitable areas for attachment, the period of free-swimming existence may be considerably extended.

One of the earliest free-swimming stages was taken in the tow-net on February 2nd, 1903, on Modragam Paar. It shows some slight advance upon the oldest stage reared in the Galle Laboratory, as rudiments of three branchial filaments and of the otocysts are present. Otherwise, in the form of the shell, the large size of the velum and the sub-central position of the digestive gland the two agree. The digestive gland is yellowish and granular, the cells being filled with large oil-globules.

In the same haul numbers of an older stage (fig. 41, I.), nearly twice the diameter of the last, were also present. In these the shell had developed prominent umbones placed equidistant from the two ends. A few more branchial filaments had appeared and the velum was relatively smaller. The digestive gland is now conspicuously two-lobed, and by great increase in size has come to occupy the interior of the umbones dorsally as well as extending ventrally beyond the plane of the otocysts. The rudiment of the adductor muscle at the anterior end was also visible.

A fortnight later (16th February), while on the Cheval Paar, in plankton taken between 8 A.M. and noon, we obtained a great multitude of shelled larvæ, many of which were in a later stage. The shell-valves showed for the first time a slight asymmetry, the anterior end being now rather sharper than the posterior (fig. 41, II.). The velum was greatly reduced, occupying only a comparatively small space between the anterior adductor muscle and the anterior margin of the gills. The gill filaments were 6 to 7 in number and of larger size. A posterior adductor muscle was also present, and the digestive gland, still markedly two-lobed, had increased in size. In

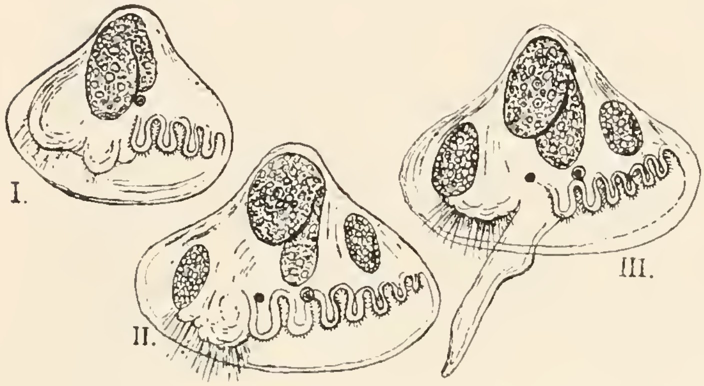

Fig. 41. Free-swimming larval stages of pearl-oyster caught in the tow-net. I. has the ciliated velum retracted. II. and III. show the stage at which the larva becomes attached to Algæ. III. has the mobile foot extended.

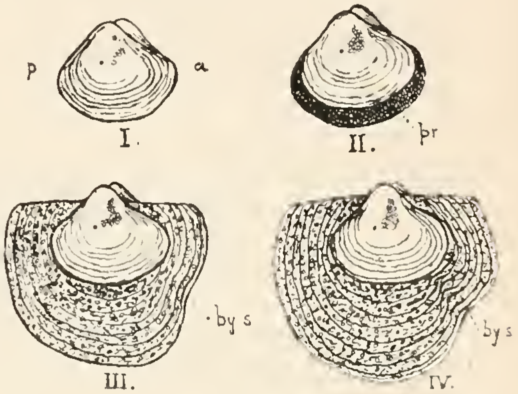

Fig. 42. Stages in the growth of the shell after the attachment of the larva. I. is identical with the latest free-swimming stage; *a*, anterior, *p*, posterior end. II. shows the first formation of prismatic shell (*pr.*). III. and IV. show the change in shape and the byssal sinus (*by. s.*).

several of these larvæ the foot was prominent and active, being frequently protruded and moved about in a tactile manner; a distinct prominence (the byssal gland) is seen about the middle of the posterior edge (fig. 41, III.). The otocysts lie close to the base of the foot, and each is a large clear sac containing 6 to 9 tiny otoliths which were in constant vibratory motion. The shell is still clear and transparent, with no pigment and no sign as yet of prismatic structure.

From this stage, ready to make attachment, we pass to the earliest attached stage ("spat"), where the little Mollusc begins to form shell layers of a different character.

Our youngest spat was found clinging to the Hydroid Zoophyte *Campanularia juncea*, in November, and later stages, still very young, on the Algæ *Hypnea musciformis* and species of *Sargassum*, *Cladophora* and *Polysiphonia* on the Cheval Paar in February and March, 1902. The smallest stage, 0·1 millim. in antero-posterior extent, is identical with the oldest free stage referred to above, and is presumably just attached. From this to a shell length of 0·175, increase is effected by marginal additions which are clear and transparent like the larval shell. These additions show, however, faint circumferential lines, but no prismatic appearance (fig. 42, I.). The dark digestive gland shows conspicuously in the umbonal region, and the rows of branchial filaments are also visible through the thin shell.

After a size of about 0·175 is reached, prismatic shell substance begins to be deposited marginally, as seen in fig. 42, II., III., IV. The embryonic shell persists, but the shape of the valve changes to one which is recognisable as the adult type. The umbones become less prominent, and, as a result of the asymmetrical marginal growth, become more anterior in position. Even at this early period the byssal sinus (*by.s.*, fig. 42) is recognisable, and a very delicate byssus can be seen anchoring the little Mollusc. If the spat be attached, as the young stages, in our experience, generally are, to floating—or for a time rooted—Algæ, they seek the under, shady, side of the branches, and sooner or later drop off and sink to the bottom, being dislodged either by shaking or by the disintegration of the floating weed The further history will then depend upon whether they fall upon ground where there is suitable "culch" for attachment, or upon sandy areas where they probably get buried, scoured out, or rasped to pieces by the constant movements of the sand grains. The enormous number of minute shells of the fry or spat of pearl oysters which we found in some sandy deposits indicates the extent of the destruction which is going on, and which might, in part at least, be prevented by artificially increasing the area covered by "culch."

We have also evidence that the ground may vary from year to year in the covering of fine Algæ which it affords for the attachment of the young spat. This is shown by the following observations :—

On the south end of the Cheval Paar, not far from the Shoal buoy, on February 26th, 1902, we hauled up great masses of mostly green delicate Algæ thickly covered with oyster spat. The Algæ proved to be *Hypnea musciformis,* along with a *Cladophora*, a *Ceramium*, and some *Chætomorpha* and *Polysiphonia*, mostly infested with Cyanophyceæ and various microscopic animals. Much the same assemblage of plants, but of a redder colour, was found on the Modragam paars on March 10th, and we also obtained them in smaller amount elsewhere on the pearl banks. In all cases these weeds supported vast quantities of spat. Later on in the season we found masses of the weed detached and floating on the surface. This season, however (1903), Mr. Hornell finds, after a careful examination of the same grounds in a diving suit, that the weed is entirely absent, and that the sand in these localities is bare and shows no spat. This marked difference in the condition of the bottom on two consecutive years throws an interesting light on the factors which may determine on occasions the productivity of a bed, and lends support to our contention that putting "culch" on the bottom at selected spots would lead to an increase in the amount of spat deposited.

III. The Byssus and Locomotion.

Although the formation of the byssus threads comes more appropriately in the section on the Structure of the Pearl Oyster, still the connection of the byssus with fixation, locomotion, and possible migration or transplantation is so close and so important that we shall give here the results of our experiments on the matter.

Kelaart showed, in 1858, that the young pearl oyster can move from place to place, can detach its byssus and can re-attach in a new spot. Sullivan Thomas, in 1886, added some fresh observations on young oysters, about $\frac{1}{2}$ inch in diameter, which he found moved up the smooth side of a glass 4 inches in 8 or 9 minutes. He also made some observations on the byssus, and found that a young oyster, measuring $1\frac{1}{4}$ inches in diameter, withstood steady tension measured with a spring balance till it reached $2\frac{3}{4}$ lbs., when the byssus came away at the root. He adds:—"I conclude that a pearl oyster is not likely to be dislodged by the force of wave action or current, and that, if it moves, it moves voluntarily."*

Some of our observations on the rapid movements of very young pearl oysters—much younger than those dealt with by Kelaart and Thomas—and on the readiness with which they detach and re-attach, were given in the "Narrative" (p. 68), and we have many others, which, however, it is unnecessary to give in detail. But although the very young are thus actively locomotive, it has been doubted, and may still be doubted by some, whether the adult oyster is capable of movement, or even of re-attaching, if the byssus be torn. Our observations settle this point definitely, as the following examples show:—

A $2\frac{1}{2}$ years old pearl oyster, obtained from the Muttuvaratu Paar on April 11th, 1902, had the byssus broken by being torn from its attachment to rock. Two days later it was marked and suspended in a wire-net cage in Galle Harbour under observation. After 3 days it was found to have re-attached to another oyster in the same cage. On May 9th it was removed to a tank in the Biological Station, and the new byssus was then found to be normal, stout-fibred, and of a bronze-green colour. It was then torn across by force, thus breaking the byssal strands, and was placed in a small glass dish sunk in the tank. On May 10th an inch and a half of sand was put over the top of the oyster. On May 11th it had freed the ventral margin of the valves from the sand, and appeared healthy. On May 12th the shells were half uncovered, and the animal was breathing and feeding normally. On May 13th and 14th the animal still lay unattached. On May 15th, at 8 a.m., the old byssus was still present; at 9 a.m. the foot was protruded, and shortly after a new byssal strand had been formed attaching the oyster to the side of the glass. The old byssus was still retained, but was ejected during the night, as at 8 a.m., on May 16th, it lay just beyond the byssal sinus of the shell, and two additional strands had been added to the new cable. The rest may be quoted from the laboratory diary kept by Mr. Hornell:—

May 17th, 8.10 a.m.—The oyster had travelled $3\frac{1}{4}$ inches during the night, sloughing the 3 byssal strands, formed the night before, together with the common root. The thrown-off byssus remained attached to the glass. At the place of second re-attachment, 5 pale-coloured strands connected the oyster with the glass.

* 'Madras Journ. of Literature and Science' for Session 1886–87.

At 7 P.M.—Watching the same individual by candle light, as it showed signs of unrest, frequently protruding the tip of the foot, I at length saw the foot thrust out to the utmost extent (about 1 inch from the tip to the opening of the byssal gland)

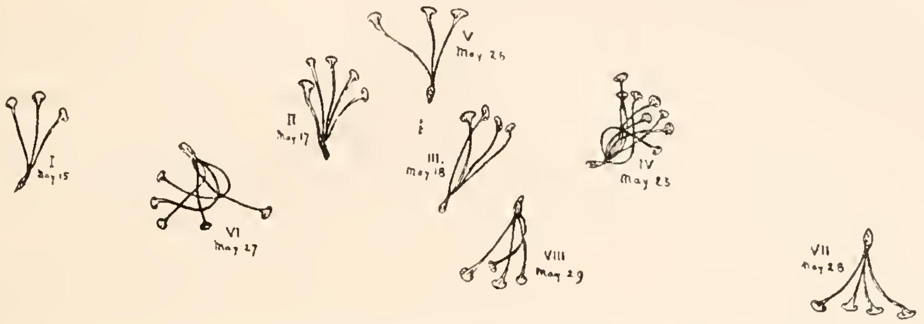

Fig. 43. Diagram showing the eight successive positions in which a pearl oyster formed new byssus strands in a fortnight. One-half natural size.

straight in front of the byssal sinus. A strong contraction then shortened the foot, pulling the animal forwards. For a few seconds it rested, then repeated the operation, during which the base of the last-formed byssus slipped out from within the shell and was cast off. The pearl oyster was now free of its mooring, and in the course of the next hour and a half, after several rests, it travelled $1\frac{1}{2}$ inches. It then settled down; the foot, after feeling about tentatively, remained quiescent at its fullest extent (1 inch) for about 5 minutes, then retracted within the shell, revealing a newly formed byssal thread, clear and almost colourless, attached at the distal end to the glass by an elliptical disc. After an interval of 7 minutes the foot was again protruded, and another strand was added in the same way as the first.

May 18*th*, 8 A.M.—Two additional strands had been formed during the night, making 4 in all (fig. 43, III.).

May 23*rd*, 8 A.M.—During the preceding night this oyster travelled $1\frac{1}{4}$ inches further, re-attaching by 5 new strands, and sloughing the old byssus.

May 25*th*, 8 A.M.—Four additional strands have been formed since 23rd inst. This last move was the fourth re-attachment since brought ashore, and the fifth since removal from the "paar." At sunset, signs of restlessness were again apparent, the foot being occasionally extended in a tentative way. At 6.45 P.M. it began crawling in a definite direction, returning upon its previous course. At the second "step" the byssal root came away. At 7.15, it was still progressing, and had covered 2 inches within 30 minutes.

May 26*th*, 8 A.M.—It had come to anchor $2\frac{1}{2}$ inches from the preceding day's position, with 3 new strands formed (fig. 43, V.).

May 27*th*.—Another nocturnal move of 3 inches—5 new strands.

May 28*th*.—The longest single journey yet made had taken place during the night, to position VII. (fig. 43, where the distances are half actual size).

May 29th.—Another of the usual nightly moves. This time a distance of $3\frac{3}{4}$ inches had been covered, 4 strands being formed at the new anchorage—this was the seventh journey within 14 days. From this date to the time when replaced in the cage at the harbour buoy, 10 days later, no further movements took place—the animal at last appearing contented with its position.

Individual No. 2 was of the same age as No. 1, and had a similar history. On May 9th it was placed in No. 1 tank, and $5\frac{1}{2}$ days later was found anchored by a stout, pale-yellow tinted byssal strand to the outside of a glass vessel, against which it rested. Close by lay its old byssal bundle, with white sloughed-off root. The attachment had been made (as usual) during the night. Pearl oysters are always most active after sunset.

May 16th, 8 A.M.—Three new byssal strands were formed during the night. The older one had now assumed a dark-green colour.

May 17th, 8.30 A.M.—Five new strands have been made since the preceding sunset.

May 18th.—This morning this oyster was removed to another tank, and the byssal attachment was forcibly torn. It was laid under the inflow-pipe, and within 5 minutes thereafter the foot was protruded, feeling slowly all around. Then, after one or two momentary withdrawals into the shell, the foot was placed in position, the anterior part being pressed sucker-like against the tank side. In $4\frac{1}{2}$ minutes the foot withdrew, showing a new byssal thread anchoring the oyster to the tank. The old byssus was thrown out in the course of the next hour. During the rest of the day 4 other strands were formed, and 16 more in the course of the ensuing two days.

May 21st, 8 A.M.—During the night this oyster had cast off the byssus, travelled 2 inches, and then made a re-attachment by 14 new byssal strands.

May 24th showed another night march to have taken place. The distance travelled was 1 inch. The new byssus, the fourth since being brought into the aquarium, consisted of 3 strands. The next night again showed another move of $2\frac{1}{4}$ inches, with re-attachment by 9 new stout silvery fibres. After this it made no further change, remaining affixed to the bottom of the tank till July 3rd, when it was removed. The length of its fully extended foot was $1\frac{1}{4}$ inches from the tip to the centre of the mouth of the byssal gland.

The other oysters of this batch took from 5 to 7 days to form their first re-attachment after being brought in from the cages in the harbour. Subsequently, when the water-circulation in the aquarium was improved, re-attachment of freshly introduced individuals took place much more quickly. Thus, of a number placed in the tanks on June 1st, at 12.30 P.M., one threw off the old byssus, crawled 2 inches, and re-attached, all within 2 hours after being brought in. At 6.30 P.M. (sunset) the same day all the remainder became active—the first sign in nearly every case being the casting away of the old byssal root. A few crawled a short distance, but the majority merely protruded the foot, feeling round, and then at once began the work of forming new cables. At 8.30 P.M., the greater number had made new attachments, and the remainder had thrown off their old byssus and were preparing to attach, probably waiting for the observer's candle to be extinguished.

The next morning all had attached. Several had crawled very long distances; one had gone nearly to the opposite side of the tank, 27 inches (the greatest distance we have seen covered in the 12 hours), another had travelled 8 inches, and a third, 13 inches. This rapidity of re-attachment under healthy conditions (one within 2 hours, the majority within 8, and all within 20 hours) has obviously an important bearing upon the proposed transplantation operations on the pearl banks.

Pearl oysters are extremely sensitive to light when preparing to attach, and there is always difficulty in seeing the actual operation of byssal fixation. While watching the oysters in one tank, those in another will be fixing, and when the light is brought to bear upon these last, they will withdraw the foot as soon as the strand they are engaged upon is finished, and refuse to again protrude until the light is removed.

When the pearl oyster is crawling, while advancing the foot the valves are widely open. When fully protruded the animal contracts the foot to the utmost, thus dragging forward the body. At the same time the valves are usually brought together with a snap, whereby the advance is materially aided.

Our observations show that the disc of attachment of a byssal thread is not formed, as KELAART supposed, by a fosset-like expansion of the pedal groove at the tip of the foot. In reality the pedal groove subserves two distinct functions, the anterior or distal part being used wholly for locomotion and having nothing to do with byssus formation, which is effected by the hinder region of the groove alone. The front end of this hinder section, at its junction with the locomotor surface and about midway between the pedal tip and the anterior margin of the byssal pouch, expands to form an oblong cup-shaped pit or sucker. Behind this again the margins of the groove are usually curved inwards, meeting medianly, to form an extemporised laterally compressed cavity, the pedo-byssal tube: anteriorly this communicates with the median sucker-pit and posteriorly with the byssal pouch.

When the foot is protruded for the purpose of forming a byssal thread, the fore part of the pedal groove is flattened out to act as a sucker, holding the foot in position. The lips of the median pit also expand, forming an oval sucker attachment, while the edges of the hinder part of the pedal surface remain approximated, and may not even touch the surface to which attachment is to be made. For about 4 to 6 minutes, the oyster remains at rest in this position, while a secretion is flowing actively from the byssogenic glands into the extemporised tube along the hinder part of the foot, and so into the median sucker-pit. The latter is the only spot at which the secretion is in contact with the exterior. At the end of the time mentioned the distal part of the pedal surface frees itself, the margins of the proximal tubular region open, and the foot as a whole is gently withdrawn within the shell, leaving behind a pale, glassy-looking, laterally compressed thread attached distally to the extraneous body by an oval disc, and at the inner end to the base of the byssal pouch. The oval attachment-disc is the internal mould of the median pit, and the body of the thread that of the laterally compressed tube formed by the approximation of the margins of the proximal part of the pedal groove. The secretion forming the byssus hardens upon contact with sea water. At first it is pale yellowish in colour and almost transparent; in the course of 48 hours it becomes opaque and of a deep bronze-green with extremely lustrous surface. The sensitiveness to bright light of pearl oysters on the move after sunset, when crawling or when forming new byssal threads, has been noted above. When visiting the tanks it was noticed that no sooner did the candle flash upon them than they either withdrew the foot instantly or did so the moment the thread they were secreting was finished. Locomotion during daylight is very seldom seen, the habit is undoubtedly to travel after darkness sets in—a time when danger from predaceous animals is no doubt reduced.

Pearl oysters are equally sensitive to passing shadows during daylight. In the aquarium tanks the hand passed slowly between them and the sun will cause them to snap-to their valves; and on the sea bottom, at a depth of 6 to 9 fathoms, the same result of a passing shadow can be seen. It must be remembered that on the pearl banks of the Gulf of Manaar the water is so clear that at the depths named the sea bottom is brilliantly illuminated when a bright sun is shining.

To some extent the habits of very young spat are exceptional. Thus when the spat that adhere to floating weed are shaken off into an aquarium tank, they do not, as older individuals would, lie quiescent on the bottom till after sunset, but at once, whatever the condition of the light, start crawling up the sides of the tank, and fix themselves on any objects well above the bottom. Probably an instinctive impulse makes them endeavour to attain a higher level in order to avoid the risk of being buried in the sand on the sea bottom. And it is remarkable what comparatively long distances they cover within a few minutes. We have already shown ("Narrative," p. 68) that minute spat from floating weeds can crawl at the rate of 1 inch a minute.

IV. Food and Feeding Habits.

The food of the pearl oyster is microscopic and of similar character to that of allied Molluscs; it consists largely of unicellular organisms--spores of Algæ, Diatoms, Infusorians, and Foraminifera in the main, with smaller numbers of Radiolarians, the minute embryos and larvæ of various animals, and occasional considerable quantities of delicate algal filaments (chiefly Rhodophyceæ). Non-nutritious particles are also met with in fair amount, such as the spicules of Alcyonarians and of sponges, with small numbers of minute sand grains. On the whole, Diatoms, spores, and embryos are the most important sources of food supply.

Under natural conditions the pearl oyster lies with the right or less convex valve beneath, and with the posterior edge of the shell elevated at an angle of about 20 degrees. If a detached oyster be placed on the bottom on its left or deeply convex valve, its first movement before making a byssal re-attachment is to protrude the foot to the utmost extent, and give a violent contraction so as to cant the shell over on to the right side. When lying undisturbed the pearl oyster separates the ventral edges of the shell to the extent of about $\frac{1}{3}$ inch. This aperture is, however, reduced to a mere slit by the inwardly directed edges of the pallial lobes from either side which nearly meet, and interlock by means of the marginal digitate tentacles.

Through this sieve-like slit, guarded by these sensitive branched processes, an indraught of water is carried by the constant lashing of the cilia covering the gill surfaces. Any large particle unsuitable for food, or any intruding animal touching the pallial tentacles, causes the valves to close with a snap. Otherwise a constant stream of small particles, diatoms, spores, protozoa, and other microscopic organisms, is carried in with the water flowing towards the branchiæ, which function as very fine strainers, able to sift out and arrest every particle from the incoming current. The food particles so arrested are carried by the cilia along the furrows to the crest of the branchial lamella. There the band of specialised cilia forms a path from end to end, along which the particles pass forwards at a rapid rate to the anterior branchial apex, where they are carried into the palpar gutter of that side. In all, four ciliated pathways lead along the branchial crests to the palpar gutters, two on each side.

Occasionally, too, particles find their way into one of the six ciliated paths at the base of the branchial lamellæ. In this case they may either be propelled forward along this basal pathway, or, as usually happens, be drawn away, after travelling a short distance, by the ciliary current of the branchial furrows, and so be transferred to the crest and follow the normal course.

Observations show that the palps can exercise a power of rejection. Thus if there be sediment in the water, the particles of mud after being sifted out by the gills and passed to the palps are retained by the latter until enough accumulate to form a tiny pellet. This is rotated slowly just within the truncated ends of the palps for a time, and is then suddenly ejected by a slight movement of the palps on to the surface of the broad ciliated band that runs outwards to the pallial edge from the base of the palps. Along this the rejected pellet is carried, round the inside of the pallial edge, till, arriving opposite the posterior tips of the branchiæ, it is thrust out. The ciliated path there terminates at the distal end of the lip-like twist of the pallial margin on the ventral border of the exhalent orifice. As the pellet leaves the pallial edge it comes under the influence of the excurrent stream from the gills, and thus is carried some little distance away from the oyster.

On the other hand, nutritious particles received on the palpar surfaces from the branchial ciliated paths are passed on at once to the mouth.

V. Shell-Growth and Repair.

Such subjects as rate of normal shell-growth, power and extent of shell-reparation, and cases of arrest of growth, are all closely related, and may be considered together.

1. Size and Growth.

There are two ways of assessing the rate of shell-growth, first the direct one of keeping marked individuals under observation and noting accurately the dimensions from time to time, and second the indirect method of visiting certain banks periodically and, by taking the average measurements of a number of individuals at each visit, deducing the average growth from period to period. Both these plans were adopted during the present investigation, and the following may be stated as a summary of the conclusions arrived at.

Growth during the first two years of life is very vigorous under healthy conditions and in the presence of an abundant food supply. During the third year the rate of increase is reduced, and in the fourth still further so. After that there is little or no increase superficially, although the shell may grow greatly in thickness.

During the first three years the marginal outgrowths or "fingers" show great development under healthy conditions. Thereafter there is less and less tendency to produce these processes, the activity of the oyster's shell-growth in later years being concentrated upon thickening the nacreous internal layer, largely to counteract the ravages of boring enemies such as sponges and annelids. With variation in the food supply, consequent upon the more or less overcrowded condition seen on several of the "paars," there is marked variation in the rate of growth of the shell (fig. 44).

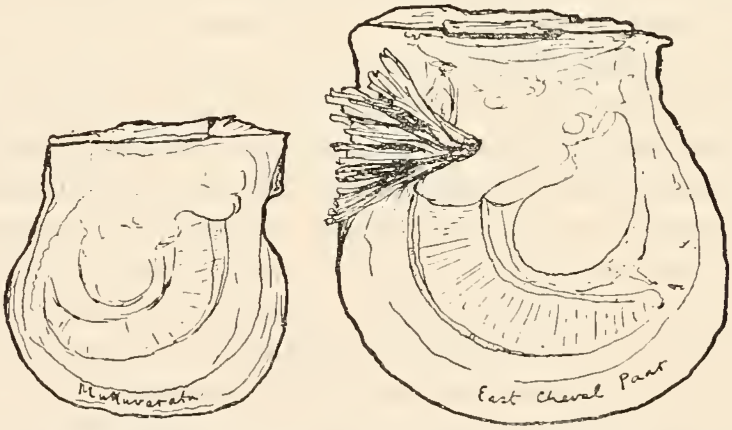

Fig. 44. Pearl oysters of the same age from the Muttuvaratu and East Cheval paars, to show difference in size. Traced from a photograph.

Large numbers of measurements of oyster samples from different paars have been made in the course of this enquiry. It is unnecessary to publish these in full,* so we give here the results of our tables and such comparisons and conclusions as it seems possible to draw. It must be stated that in computing the ages of the oldest oysters now on the pearl banks, we have relied upon the accuracy of Captain DONNAN'S

* I have in my hands considerable lists, tabulated by Mr. HORNELL, which may possibly be inserted as an appendix at the end of the report if it seems desirable.

estimate in March, 1900. In his report on the inspection of that date he announced the discovery of two wide-spread falls of spat over the Cheval and Muttuvaratu paars, which must have taken place about June and December, 1899, respectively, as he gave the ages, when found in March, 1900, as from 3 to 9 months. Consequently the oysters fished from the East Cheval Paar in the spring of 1903 cannot have been older than 3 to $3\frac{3}{4}$ years, a conclusion which makes the yield of pearls in this last fishery an eminently satisfactory one considering the comparative immaturity of the oysters. We must also conclude that, notwithstanding differences in size and appearance, the oldest oysters on the Muttuvaratu Paar and on the Cheval Paar are of the same age, as they are grown from the spat which DONNAN found in March, 1900.

A sample of 50 adult oysters from the Muttuvaratu Paar, measured in April, 1902, gave as the average $2\frac{6}{32} \times 2\frac{1}{64}$ inches, or $55{\cdot}50 \times 51{\cdot}0$ millims.* A sample of 38 oysters from the same bank, measured in November, 1902, gave an average of $58{\cdot}84 \times 54{\cdot}32$ millims., by 22·07 millims. in thickness. Twelve oysters from the same locality, measured in March, 1903, gave an average of $57{\cdot}54 \times 54{\cdot}0$ millims., by 24·42 millims. in thickness.

These figures show an increase during 7 months (April to November, 1902) of 3·34 millims. $\times$ 3·32 millims., with a slight decrease during the ensuing 4 months. The very slight increase during the former period, and the arrest of growth after that, agrees well with the impression we formed as to this bank from the oysters we have seen. Coral growths are very rich on the valves along with other incrusting organisms—Polyzoa, Sponges, Tunicates, and Algæ chiefly. The oysters are small but thick, with no marginal processes or "fingers." If they have ceased to grow superficially, they are adding to the thickness of the shell. Our field notes say (November, 1902): "The pearl oysters on this bank are more thickly crowded than on any other; their size is the most stunted of any yet seen, and they are thin and miserable within, with little food in the alimentary canal in most cases." In March, 1903, when Mr. HORNELL inspected the bank with the diving apparatus, he found that the oysters were densely crowded together, approximately 125 to the square yard, along with various other animals, chiefly corals, which were both on and around the oysters. He noted "The oysters were all small and stunted and unhealthy looking, showing no vigorous shell growth and no marginal processes. On dissection, it was found that all those collected had internally the same stunted appearance. The bodies of all were equally shrunken and thin, the gonads spent or not seasonably developed, and at the best, extremely small; indeed all tissues were equally meagre, even the byssus weak and of few strands." We have other observations, and extracts might be multiplied, all tending to show that the poorly nourished and diseased condition of the oysters on the Muttuvaratu Paar is due to overcrowding.

* The first measurement given is always the depth (dorso-ventrally, at right angles to the hinge), and the second the length (antero-posteriorly).

In marked contrast to the poor growth seen on this bank was the rapid rate of increase shown on transplantation to a locality under better conditions. Two of our experiments may be cited to show this :—

(1.) A number of oysters collected on April 11th, 1902, from the Muttuvaratu Paar, were suspended 5 days later in wire-net cages, at a depth of $3\frac{1}{2}$ fathoms, from the outrigger of a native boat moored in Galle Bay (see fig. 23). By May 9th a marginal increase varying from 1·20 millim. to 1·50 millim. had been effected, and, in addition, numbers of long finger-like processes had appeared, an evidence of very vigorous growth—due, no doubt, to the abundance of food with which the stomach and intestine of specimens examined were found to be crammed. The internal parts had undergone a corresponding increase, and the tissues from being thin and shrunken had now become plump and healthy in appearance. We have the detailed measurements of a number of transplanted individuals, from which we may select three as samples :—

Specimen B, on April 13th, measured 58·50 × 54·50 millims., and by May 9th it had reached 61·60 × 56·70 millims., an increase of 3·10 millims. × 2·20 millims. during 26 days, and not including the finger processes which had begun to form along the margin.

Specimen C (omitting details), from April 15th to May 9th, showed an increase

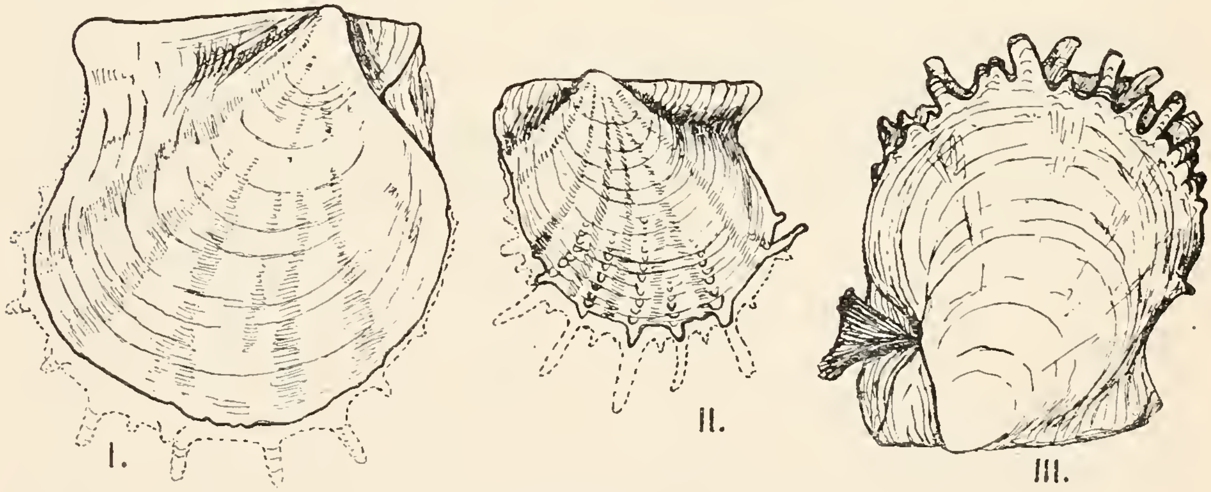

Fig. 45. Three transplanted pearl-oysters showing rapid growth. I. The dotted line shows the new shell formed in 23 days. II. The dotted line shows the new shell formed in 21 days. III. Oyster taken from Muttuvaratu to Cheval, showing a month's growth. All natural size.

varying round the margin from 0·75 millim. to 3·80 millims. ; while if the fingers be included, the growth during these 23 days was 9·50 millims. (see fig. 45, I.).

Specimen D was younger, 6 months old, brought from Chilaw Paar. From April 15th to May 7th the increase was 1·85 millim. on the average, not including "fingers." The latter were present when put out at the buoy in Galle Bay, but a new set, enormously larger, were formed under the more favourable conditions, and some of these were 10 millims. to 11 millims. long (fig. 45, II.).

(2.) A number of the same pearl oysters were transplanted the following year, during the fishery, from the Muttuvaratu Paar, on March 14th, 1903, to the Cheval Paar, where they were kept under observation until April 19th. The great improvement both in external size and internal appearance was especially interesting, since we had an excellent control experiment in the similar oysters left on the Muttuvaratu, which were examined on April 14th and found to be practically unchanged. Those taken to the Cheval Paar had the margin thick and entire, with no new growth and no fingers. After 36 days 4 of them showed the following increase of size (one of these is shown in fig. 45, III.) :—

A	added to	margin	7	millims.,	and fingers	9	millims.	in length.
B	,,	,,	6	,,	,,	8	,,	,,
C	,,	,,	6	,,	,,	10	,,	,,
D	,,	,,	5	,,	,,	$12\frac{1}{2}$	,,	,,

A very striking result, due in part possibly to suspension above the bottom; but the point is that the animal even when adult will re-act rapidly to improved conditions.

Some additional records from our lists of the average sizes of oysters from different localities and of different ages may be of use. They may be conveniently given in tabular form as follows :—

Locality.	Date.	Number.	Age.	Average of measurements.
			months	millims.
South-east Cheval . .	November, 1902	21	11 to 14	50·57 × 47·52.
North-west Cheval . .	,, ,,	14	11 ,, 14	47·64 × 44·36.
South-east Cheval . .	March, 1903	34	15 ,, 18	54·41 × 49·75 × 20·38.
North Modragam . .	,, ,,	12	15 ,, 18	61·17 × 54·50 × 24·28.

These, then, are young oysters in the beginning of their second year, and it will be seen, comparing those of like age, that the North Modragam are larger than the South-east Cheval, and the latter are larger than the North-west Cheval.

Those given below are older oysters, mostly in their fourth year (see next page).

Locality.	Date.	Age.	Number.	Average of measurements.
		years		millims.
Periya Paar Kerrai . .	November, 1902	$2\frac{11}{12}$ to $3\frac{5}{12}$	22	74·36 × 68·59.
,, ,, . .	March, 1903	$3\frac{1}{4}$,, $3\frac{3}{4}$	33	74·76 × 67·15 × 31·25.
North-east Cheval . .	November, 1902	$2\frac{11}{12}$,, $3\frac{5}{12}$	16	80·25 × 74·06.
,, ,, . .	March, 1903	$3\frac{1}{4}$,, $3\frac{3}{4}$	20	76·05 × 71·45 × 31·45.
Mid-east Cheval . . .	November, 1902	$2\frac{11}{12}$,, $3\frac{5}{12}$	8	74·12 × 67·5.
,, ,, . . .	March, 1903	$3\frac{1}{4}$,, $3\frac{3}{4}$	31	75·45 × 68·55 × 31·10.
South-east Cheval . . .	November, 1902	$2\frac{11}{12}$,, $3\frac{5}{12}$	36	69·81 × 64·44.
,, ,, . . .	March, 1903	$3\frac{1}{4}$,, $3\frac{3}{4}$	35	75·77 × 69·57 × 31·00.
North-west Cheval . .	November, 1902	$2\frac{11}{12}$,, $3\frac{5}{12}$	6	71·33 × 67·83 (sandy ground).
,, ,, . .	March, 1903	$3\frac{1}{4}$,, $3\frac{3}{4}$	3	61·5 × 58·33 × 26·83 (rocky).
South-west Cheval . .	November, 1902	$2\frac{11}{12}$,, $3\frac{5}{12}$	36	71·25 × 65·39.
Mid-west Cheval . . .	,, ,,	$2\frac{11}{12}$,, $3\frac{5}{12}$	31	65·68 × 60·39.
Dutch Modragam . . .	,, ,,	$2\frac{11}{12}$,, $3\frac{5}{12}$	18	64·0 × 61·0.
Muttuvaratu	,, ,,	$2\frac{11}{12}$,, $3\frac{5}{12}$	—	58·84 × 54·32.
,, ...	March, 1903	$3\frac{1}{4}$,, $3\frac{3}{4}$	—	57·54 × 54·00 × 24·42.

Taking now the average for all the banks at the November, 1902, and March, 1903, inspections separately, we find that the (say) 3-year-old oysters average 69·96 × 64·79 millims. for all localities, and the (say) $3\frac{1}{2}$-year-old oysters average 70·18 × 64·84 × 29·33 millims. It is, however, probably not instructive to take an average for all of the banks, since two distinct types of oyster occur—those exemplified by the Eastern Cheval and the Muttuvaratu respectively. It is, therefore, better to group the Periya Paar Kerrai with the East Cheval in order to ascertain the normal rate of increase under favourable conditions, at the age considered :—

Locality.	Average size in millimetres. November, 1902, $2\frac{11}{12}$ to $3\frac{5}{12}$ years.	Average size in millimetres. March, 1903, $3\frac{1}{4}$ to $3\frac{3}{4}$ years.
Periya Paar Kerrai	74·36 × 68·59	74·76 × 67·15
North-east Cheval	80·25 × 74·06	76·05 × 71·45
Mid-east Cheval	74·12 × 67·05	75·45 × 68·55
South-east Cheval	69·81 × 64·44	75·77 × 69·57
The averages at the two dates being .	74·63 × 68·53	75·51 × 69·18

This gives an increase of only 0·88 × 0·65 millim. for the 4 months ending March, 1903, which bears out the statement made above that growth after the third year is very slow. Comparison with the growth of the much younger (second year) oysters on the South-west Cheval, from 50·57 × 47·52 millims. in November, 1902, to 54·41 × 49·75 millims. in March, 1903, shows how very rapid the increase is at this age, 3·84 × 2·23 millims. in 4 months.

As, however, the shell can grow in thickness of valve as well as in superficial extent, it is of some importance to consider the weight in relation to age. We are able to give a table of the weights of shells of one generation of pearl oysters as determined by Captain DONNAN annually from the first year to the time when fished at 4 and 5 years of age. As after the third year there is but little increase in size, the figures for the later years may be taken as indicating the additions to the thickness of the shell.

WEIGHT of Cleaned Pearl-oyster Shells.

Locality and date.	Age.	Number weighed.	Average weight per pair of valves.
	year	pairs	drams
North-west Cheval—			
March, 1871	1	13	4
,, 1872	2	13	12
,, 1873	3	50	19
November, 1873	$3\frac{3}{4}$	100	$20\frac{1}{2}$
March, 1874	4 (fished)	45	$24\frac{1}{2}$
,, 1875	5 (fished)	47	30
South-east Cheval—			
March, 1874	1	33	$3\frac{2}{3}$
,, 1875	2	60	$13\frac{1}{2}$
,, 1876	3	150	$21\frac{1}{2}$
,, 1877	4 (fished)	51	30

The stunted condition of the oysters on the Western Cheval which we saw on the ground, and have noted elsewhere in this report, is shown by these figures to have been as marked a quarter of a century ago. While the South-east Cheval produced shells which at 3 years of age weighed $21\frac{1}{2}$ drams each and at 4 years 30 drams, those of the same ages from the North-west Cheval weighed only 19 drams and $24\frac{1}{2}$ drams respectively.

All the above figures, as well as the non-numerical observations which we made upon the banks during two inspections and a fishery, tend to show that, of the reliable paars, the Southern and Eastern parts of the Cheval, the Periya Paar Kerrai and the North Modragam are, at present, those that produce the most rapid growth and healthy development of the pearl oysters. The conditions at these paars which seem to determine the good results are :—

(1.) The local abundance of microscopic food. This was shown by the richness of the plankton in our tow-net gatherings.

(2.) The absence of competing organisms, such as those that are present in quantity on coral ground.

(3.) The impossibility of overcrowding, as there are no extensive sheets of rock emerging from the sand, and therefore the pearl oysters cannot, at these localities, form a continuous layer almost hiding the underlying rock, as they do in some places.

These are all important points, especially perhaps the last. The oysters on these more favoured grounds, although abundant enough, are not overcrowded, but lie in separate bunches or little isolated groups. Sometimes, as on the Periya Paar Kerrai, the foothold consists of little patches of flat rock (see fig. 36, p. 109), 3 or 4 feet in extent and separated by sandy tracts 2 or 3 yards in width. At other places, as on the South Cheval, little or no rock appears on the bottom, and the oysters are attached in bunches to the scattered natural "culch," fragments of dead coral and of calcretes, broken shells and Lithothamnion masses, lying on the sand. A certain amount of sandy bottom, interspersed with harder tracts, and with plenty of "culch" —natural or artificial—scattered over the sand, is probably the most favourable ground for the Ceylon pearl oyster from the point of view of those interested in the fisheries. The presence of more culch in many places would, however, be an improvement. It would give more foothold for new broods of oysters, and at the same time would probably help to stiffen the shifting sand and prevent, in some degree, the wash-out and turn-over of the surface which is caused by a heavy swell.

The reliable paars which produce less rapid growth and are characterised by their stunted oysters (the "Koddaipakku" variety of the divers and the Inspectors' reports) are the Muttuvaratu, much of the West Cheval and the Dutch Modragam. These are all localities with great stretches of continuous rocky bottom which may be covered, during favourable seasons, by myriads of pearl oysters closely crowded together. Thus Captain DONNAN estimated, in 1902, that on the sandy East Cheval (11,804,676 acres) there were 74,413,000 pearl oysters, while on the rocky West Cheval (10,500,000 acres) there were 123,357,600, showing a much denser population per acre in the latter case, but not equalling the density on the Muttuvaratu Paar, where an area of rather less extent (10,206,725 acres) supported in March, 1902, the enormous total of 277,000,000 pearl oysters—which have since suffered great losses, due no doubt to their overcrowded condition.

2. Shell-Repair.

Pearl oysters have considerable recuperative power after injury, and can usually repair damage done to the shell. This is of importance from two points of view, first in connection with the ravages of some of their natural enemies, and secondly, because of its bearing upon occasional pearl-formation. Many cases were noticed in our field work where injuries had been effectively repaired, and it is significant that a number of these were found on the Periya Paar Kerrai during March, 1903, immediately after the time when we have evidence that Rays (*Trygon uarnak*) were feeding on the bank and had crunched up many shells. Some of the oysters we found showed that fragments of the ventral margin had been broken off, others that the anterior or the posterior "ear" had been smashed—all had been repaired more or less perfectly so as to enclose the animal and enable the valves to function.

To ascertain the extent and rapidity of the process of repair, a number of experiments were made both on the pearl banks and at Galle. The following give the details of a few typical cases :—

(A.) During the removal of oysters from the "Serendib" at Galle in April, 1902, a $2\frac{1}{2}$-year old oyster had a large semi-circular fragment broken from the right valve. The oyster remained for the next 26 days suspended in a wire-net cage from one of the buoys in the bay. On May 9th, when brought into the laboratory, the gap was mended completely and an additional marginal growth of 1·4 to 2 millims. had formed. The only departure noticeable from the original condition was that neither of the two involved radial bands of colour had been continued in the repaired area, the pigment being spread out instead in a diffused manner.

(B.) In February, 1903, a number of oysters from the Cheval Paar were purposely damaged in various ways. When examined on the 23rd, 8 days later, they all showed extensive repair. In one case $5\frac{1}{2}$ millims. of new shell had been added at the damaged spot, and in two others $3\frac{1}{2}$ millims.

(C.) This was another oyster which had a piece fully 15 millims. in vertical depth removed from the right valve on February 15th. In 9 days a fresh growth, measuring 7 millims. in depth, had formed, while by March 8th the whole of the damage was made good by a further growth of 8 millims., so that within 21 days a total growth of 15 millims. depth of new shell had taken place.

(D.) Even more rapid repair was shown by some oysters damaged on February 27th, due possibly to the fact that they were suspended in the purest sea-water on the banks for the whole period of the experiment, whereas (B.) and (C.) above were kept in muddy water off Chilavaturai for several days. The growth shown in (D.) was very uniform, and the damage was completely repaired in all cases. Of three photographed on March 8th (two are shown in fig. 46) :—

No. 1	showed	9	millims.	of new	solid shell,	12	millims.	including	the	"fingers,"
,, 2	,,	7	,,	,,	,,	13	,,	,,	,,	,,
,, 3	,,	$7\frac{1}{2}$	,,	,,	,,	12	,,	,,	,,	,,

a surprising growth for 9 days. The colours of the new shell were very brilliant in these cases, rich brown-red and bright yellow.

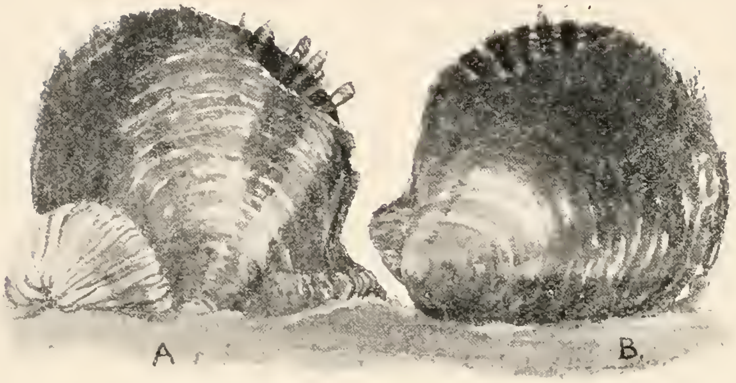

Fig. 46. Two pearl-oysters showing damaged shells repaired in 9 days (February 27th to March 8th).—Copied from the photograph.

Two other oysters of this same series (D.) were photographed on March 10th. Within the 10 days, one had formed 6 millims. of new solid shell and 15 millims. in

Fig. 47. Pearl-oyster damaged on February 27th and photographed on March 10th to show complete repair. The arrows point to the new growth.

all including the "fingers," the other (fig. 47) had formed $11\frac{1}{2}$ millims. of shell and $16\frac{1}{2}$ millims. to the end of the "fingers."

(E.) In the case of a number of oysters damaged on April 21st, new growth varying from 2 to 5 millims. in extent was seen in 2 days.

Many other instances might be given from our note-books, but the above will suffice to show the rapidity and thoroughness with which the pearl oyster makes good injury to its shell, and to effectually dispose of any objections that might be raised to extensive transplantation on the score that the oysters might be damaged and would not survive the operation.

Observations on the damaged oysters kept in our aquarium tanks at Galle throw light upon the methods of repair. Damage may either be marginal or superficial. If the latter, the cause is usually a blow fracturing one of the valves through both nacreous and prismatic layers and depressing the shell on the distal side of the break. In a specimen purposely so injured, the mantle-lobe separated from the proximal part of the shell for some $\frac{1}{4}$ inch, leaving a wedge-shaped recess under the shell-margin at the fracture. In this new position the external pallial epithelium secreted a fresh deposit of nacre, thus perpetuating permanently the crevice under the proximal fractured edge.

Cases where the mantle is extensively pierced or lacerated by the injury may be fatal, not apparently because the animal is unable to make good the damage, but rather because of the difficulty of keeping out small carnivorous animals such as worms and molluscs. In several cases, however, we have seen complete recovery from extensive laceration, the margins of the wound gradually approximating and finally uniting. While the temporary aperture exists, water may be drawn in through it, and the tip of the foot is sometimes protruded through the hole in the mantle and moved round the rough edge of the broken shell, with the result that loose fragments and dirt particles that accumulate between the mantle and the nacre, and which probably cause irritation, are removed. No repair-nacre is secreted until the damage to the mantle is made good.

When a fragment of the shell-margin is broken away, the mantle within is retracted in proportion to the extent of the damage, not only at the place of injury but for some distance on either side. Consequently, when the pallial edge begins to form a new shell-margin, it starts in the uninjured part from a point about $\frac{1}{8}$ to $\frac{3}{16}$ inch behind (internal to) the former edge. Along the line of fracture the pallial edge is advanced much closer, or quite up to the margin, beyond which the pallial tentacles can be seen projecting. This method of starting the new growth behind the existing edge in the case of injuries is also the normal method of adding to the margin of the valves in growth. Under normal conditions growth is discontinuous, periods of activity alternating with what appear to be periods of rest. Each fresh layer begins from a line about $\frac{1}{16}$ inch inside the edge; which process results in the formation of a number of successive layers of shell with projecting margins outside, the older overlapping the younger in imbricate fashion. Young rapidly growing pearl oysters show this imbrication most markedly, especially during the first two years. As they get older, attrition and the ravages of attacking and incrusting animals tend to remove the thin projecting margins and their delicate processes, and new ones are less frequently formed as the shell ceases to grow in extent but becomes thicker by deposits of nacre on the inside. The distance apart of the successive marginal ridges is a good guide to the vigour of the oysters, healthy conditions being indicated when the distances are considerable, and overcrowding or scarcity of food when they are massed thickly together, especially at the margin. Many of the Muttuvaratu oysters show this latter appearance to a marked degree, the edges of the shell, instead of being thin and delicate as they are on the South-east Cheval, being comparatively thick and formed of a number of very slight layers of growth, which do not imbricate, but are massed at the same level, so as to show like the edges of a pack of cards.

The connection of shell-repair with occasional pearl formation depends upon the fact that the pearl oyster has to withstand the attacks of various animals—sponges, worms, molluscs—which bore into the shell. In attempting to repair such ravages the oyster thickens the nacreous layer, and in some cases piles up pearly excrescences on the interior of the shell which may be separated as pearls of an inferior quality. It is probable, also, that when the shell is damaged fine particles, either splinters of nacre or foreign bodies, gaining access to the interior, may serve as the nuclei of free pearls. Finally, it must be remembered that shell-growth and pearl-growth are similar and comparable processes. In both cases limy salts in an organic matrix are deposited by the living tissues—in the one process on the outside of the body, and in the other around some internal particle, which in the case of the finest pearls is the Cestode larval *Tetrarhynchus*. I shall return to these matters in the later section of this Report, which will treat of pearl formation.

REPORT

ON

SEA-BOTTOMS AND CALCRETES

COLLECTED BY

PROFESSOR HERDMAN, AT CEYLON, IN 1902.

BY

J. LOMAS, A.R.C.S., F.G.S.,

LECTURER IN PHYSIOGRAPHY IN THE UNIVERSITY OF LIVERPOOL.

[WITH ONE PLATE AND TEXT FIGURES.]

THE samples of sea-bottom, about thirty in number, were dredged mainly from four districts round the coasts of Ceylon :—(1) About Point de Galle, (2) Trincomalee Bay, (3) Palk Bay, and (4) the Gulf of Manaar—and most of them were from the last locality (see map, p. 161).

In addition to the material brought up by the dredge, about twenty specimens of rock were broken off from the bottom by divers, chiefly from the paars in the Gulf of Manaar and along the west coast of Ceylon.

The majority of the deposits were obtained from shallow water, 4 to 10 fathoms, but a few from the Gulf of Manaar and off Galle are from a greater depth.

POINT DE GALLE AND NEIGHBOURHOOD.

In **Galle Bay,** from depths of 6 to 8 fathoms, shells with sand were dredged. Large drifted shells, such as *Arca*, *Anomia*, *Ostrea*, *Cucullæa*, and *Turritella*, mostly in a rotten condition, made up the bulk of the coarse material, along with large barnacle valves and a few shark's teeth. The shells were worn, many brown in colour and polished, indicating a partial conversion into a phosphatic condition. Encrustations of Nullipores, Serpulæ, and Polyzoa covered the shells, and *Clione* borings were common in those shells composed of calcite, while aragonite shells were often not affected.

The finer material, obtained by sifting through a sieve with a mesh of 1 millim., contained from 61·41 to 62·52 per cent. of carbonate of lime, and included small Molluscs, Echinoid spines, plates and anchors of Holothurids, spicules of *Alcyonium* and *Leptoclinum*, as well as numerous Foraminifera, such as *Heterostegina*, *Globigerina*, *Textularia*, and *Spiroloculina*, Nullipores and *Crisia*. While the smaller organisms have a fresh appearance, and are indicative of the life at present in the district, the larger organisms are mostly dead, and evidently very old.

The inorganic constituents were quartz grains, clear and well rounded, not very plentiful, kyanite, corundum, zircon, rutile, tourmaline, and mica. A considerable amount of coal, well rolled, in pieces ranging up to $\frac{3}{4}$ inch in diameter, is no doubt due to the proximity of a coaling station.

At **Welligam,** to the east of Galle Bay, two samples were dredged. One, a fine calcareous mud with shells, yielded 76·50 per cent. of carbonate of lime; and another, obtained from a depth of 4 to 6 fathoms, contained many rotten shells, brown in colour and bored by *Clione*, barnacle valves and *Halimeda* in a fresh condition; a few quartz fragments, angular, ranged up to $\frac{1}{2}$ inch in diameter. The fine material in both hauls consists of a smooth mud which cakes on drying, and contains a few small quartz grains, tourmaline, zircon, spicules of sponges and *Leptoclinum*, Holothurian plates, and diatoms, especially *Coscinodiscus*. Foraminifera are not common.

Trincomalee Bay.

Off the mouth of Trincomalee Bay, at a depth of 12 fathoms, Foraminiferal sand was dredged, containing 67·7 per cent. of one form, *Heterostegina depressa*. Mollusca, including *Arca*, *Trochus* and *Patella*, mostly rolled and encrusted, made up 4·8 per cent., Corals and Polyzoa (*Retepora* and *Cellepora*) 0·2 per cent., Nullipores 8·0 per cent., *Alveolina* (two species) 0·9 per cent., and a few specimens of *Echinocyamus*. The material which passed through the fine sieve, 16·5 per cent., consisted almost entirely of small Foraminifera, including *Pulvinulina*, *Textularia*, *Discorbina*, *Miliolina*, *Cristellaria*, *Nonionina*, *Polytrema*, and *Nummulites*. Pteropods and *Alcyonium*, Holothurid and Sponge spicules were fairly abundant.

The inorganic constituents include quartz grains, well rounded and ranging up to 3 millims. in diameter, and a black powder, much of which could be removed by a magnet. The non-magnetic portion was fractionated by means of the double iodides of mercury and barium, and showed a great number of small garnets, corundum, tourmaline, and kyanite in the heavier fractions, while a little sub-angular quartz and a few grains of mica made up the lighter portions.

Palk Bay.

North of Rameswaram, in Palk Bay, where shallow water (6 to 7 fathoms) conditions extend over a great area, and where there is an almost complete absence of currents, a very extraordinary deposit occurs: it consists mainly of concretions, irregular in form, with here and there a cast of shell and a few large shells in a fairly fresh but broken condition. The shells include *Arca*, *Cardium*, *Chama*, *Pecten*, *Murex*, *Nassa*, and the pearl oyster. No double valves are found and the calcite shells are sometimes bored by *Clione*. The concretions on treatment with a weak acid effervesce strongly and yield a large percentage of fairly coarse sand. Plate I., fig. 1, shows shells, casts and concretions from this deposit.

The casts, which contain 64·80 per cent. of carbonate of lime and 2·2 per cent. of phosphate of lime, fall to mud when placed in water, and it was necessary to soak in thin balsam and harden before a section could be obtained. Round the periphery of the casts is a thin layer of calcite, which moulds itself into the inequalities of the shell's interior surface; this is succeeded by a darker layer, and then the whole interior is seen to consist of sand grains, quartz, tourmaline, felspar, and zircon embedded in a mass of secondary calcite. The sand grains increase in size on proceeding from the exterior inwards (fig. 1), and remind one of the well-known fact that when grains of different dimensions are shaken in a basin, the finer material sinks to the bottom and the coarser rises to the surface. It is probable, then, that the grains were rocked to and fro when in a loose condition inside the shell, and the cementing took place subsequently. Afterwards, owing to altered conditions, the outer shell was dissolved and the cast left. It is impossible, owing to the rolled and imperfect condition of the casts, to tell what shells formerly held the casts, but most of them have a form not unlike Natica. It is noteworthy that felspars are found in these casts, while they are absent, as a rule, from sea sands. They were probably embedded soon after breaking away from the parent rocks and before kaolinisation could reduce them to clay.

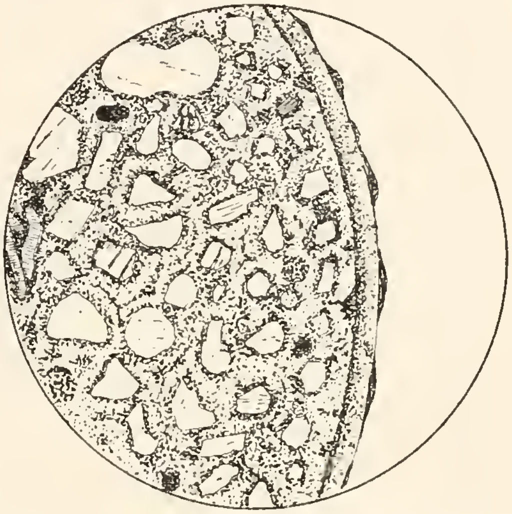

Fig. 1. Section of internal cast of shell from Palk Bay; showing the part in contact with the shell, and sand grains cemented by carbonate of lime in the interior. × 25.

The inorganic material dissolved out from the concretions by acids and fractionated showed a great preponderance of garnets. The heavier portions were pink in colour on this account. Other minerals found were corundum, tourmaline, zircon (enclosed in garnet and free), kyanite, quartz, mica (biotite), and felspar. A number of black grains were composed of ilmenite.

Further East and North of Adam's Bridge, at a depth of 7 fathoms, a fine black mud occurs which, on analysis, gives:—

Silica	55·00 per cent.	Alumina	15·80 per cent.
Carbonate of lime .	3·50 ,,	Magnesia	2·75 ,,
Phosphate of lime.	2·25 ,,	Water and organic matter	16·60 ,,
Ferric oxide. . .	4·10 ,,		

A few heavy minerals, zircon, tourmaline, and kyanite, occur; but the bulk is made up of a fine impalpable mud, smooth to the feel, with minute grains of quartz. Only a few organisms, one Foraminifer and a small shell fragment, were found in the sample examined.

Gulf of Manaar.

South of Palk Bay, and separating it from the Gulf of Manaar, is Adam's Bridge. Rameswaram Island and Manaar Island, which form the two chief links in the chain of islands almost joining Ceylon with Southern India, consist, according to Foote* and Walther,† of calcareous sandstone. This is continued across the Pamban Strait and forms the "sandstone quay" of the Tonitoray spit on the west and the coastal part of North Ceylon on the east. The smaller islands between Rameswaram and Manaar also show a similar rock, while through the passages separating them are loose drifting sands. The north coast of Rameswaram is fringed by an ancient coral reef, while living reefs are found in shallow water immediately to the north and to the south.

South of Adam's Bridge, the Gulf of Manaar stretches as a low sloping beach, deepening fairly evenly at the rate of about 1 fathom in two miles to 20 fathoms, where it sinks more rapidly to great depths. Along the west coast the slope of the shore is more rapid, and deep water is reached sooner. At places along the west coast, and also south of Manaar Island, spits of sand stretch across the platform, mainly near the mouths of rivers. They probably result from the detritus brought down by the rivers, and their general trend towards the north-west may be due to the combined flow of the streams and the prevailing inshore currents.

On the western shores of the Gulf, and in Palk Bay, the rivers form deltas of large size, and similar spits of sand extend near the river mouths towards the north-east. The coasts of India and Ceylon are swept by great marine currents running up or down the coast according to the monsoons, but owing to the longer duration of the south-west monsoon it produces greater effects, and all rivers flowing into the Gulf have a tendency to extend their deltas towards the north.‡ The sands covering the floor of the Gulf become coarser on approaching the west, and there can be no doubt that the material has been carried down from the high grounds by rivers and then distributed by currents on the ocean floor. The granulitic rocks of central Ceylon

* 'Memoirs of Geol. Survey of India'—Geology of the Madura and Tinnevelly Districts.

† Petermann's 'Mittheilungen,' Ergänzungsheft No. 102, 1891.

‡ Foote, *op. cit.*

are usually found in a friable sandy condition,* and thus provide material already disintegrated which can easily be transported by rivers to the sea. The sand forming the floor of the Gulf has, in many places, been cemented *in situ* into calcareous sandstones or "calcretes," locally known as "paars." In the north part the paars arrange themselves roughly into three groups, running parallel with Adam's Bridge, north-north-west to south-south-east. The first line is found at a depth of $3\frac{1}{2}$ to $4\frac{1}{2}$ fathoms, the second at 6 to 8 fathoms, and the third at 9 to 10 fathoms. Further south, on the West Coast, they have a north and south alignment, here again following the outline of the coast.

It would appear that the calcretes have grown out radially from centres, the smaller ones are mainly circular in outline, while the larger ones seem to have been formed by the growth and fusion of a number of smaller ones. Outliers exist in many cases near the larger paars, which seem to suggest that they too will eventually become fused with the main paars. Dredging and diving operations were mainly conducted in the neighbourhood of the paars, and most of the samples handed to me for examination were obtained from these localities. Hence the descriptions which follow readily group themselves round the most important paars.

Periya Paar.—This is the most westerly of the paars, and lies about 20 miles south-west of Manaar Island. It extends 11 miles north-west—south-east, and averages about $1\frac{1}{2}$ miles in width. Smaller paars exist as outliers at the northern and southern extremities. The rocky bottom has a depth varying from $8\frac{1}{2}$ to 10 fathoms, with a thin layer of sand covering the flat surface of the calcrete.

Outside the paar, to the west, the bottom rapidly sinks to 20 fathoms, and further out 80 fathoms and over are reached. Five specimens of the bottom were dredged in the neighbourhood of the paar and calcretes from three localities were broken off by hammers and brought to the surface by divers.

West and South-west of the North end of Periya Paar, at a depth of 10 fathoms, the contents of the dredge showed many shells in a fresh condition, Polyzoa, such as *Cellaria* and *Scrupocellaria*, *Halimeda*, and numerous Nullipores. These were accompanied by a fairly coarse angular quartz sand. The fine material yielded 27·64 per cent. of carbonate of lime, and under the microscope was seen to consist of quartz, sometimes stained with iron, many black grains of ilmenite and magnetite, tourmaline and zircon, and, as organic constituents, numerous Foraminifera, *Crisia*, and sponge spicules.

North-west of the Paar, at 12 fathoms, Foraminiferal sand with shells was dredged. The shells included *Pectunculus*, *Arca*, *Chama*, *Venus*, pearl oyster, and with these, forming the coarse material, were *Heteropsammia*, Echinoderms and a brown Alga. The smaller forms were Foraminifera—*Heterostegina* in great profusion—Nullipores, Polyzoa and Serpulæ. Only a few clear quartz grains were present.

* A. K. Coomáraswámy, 'Geol. Mag.,' August, 1903, p. 348.

From the surface of the actual Bank, at 9 fathoms, a quartz sand was obtained. It contained, in addition, numerous shells, not overgrown with encrusting organisms, *Lithothamnion*, brown Algæ and horny worm tubes. The fine material—24·20 per cent. of carbonate of lime—was principally clear quartz sand well rounded, and as rarer constituents, tourmaline, garnets, zircon, kyanite, rutile, and ilmenite.

Comminuted shell fragments, Echinoid spines, and Foraminifera—*Heterostegina* principally—made up the bulk of the calcareous portion.

Outside the Paar, to the West, at 20 fathoms, a Foraminiferal sand containing very little inorganic matter was obtained. The fine stuff yielded 85·86 per cent. of carbonate of lime. *Heterostegina depressa* and *Alveolina* were the principal constituents, and there were also included Polyzoa—*Crisia* and *Scrupocellaria*—*Alcyonium* spicules, Holothurian plates, and the spat of young bivalves.

Another haul, Outside, on the West, from 80 fathoms, brought up Foraminiferal sand with no large forms except a few broken shells. It contained 76·50 per cent. of carbonate of lime. Unlike the Foraminiferal sand from shallower depths, *Heterostegina* was not abundant, giving place in this group to small *Nummulites*, *Globigerina*, and *Textularia*; while Pteropods, the fry of Molluscs, Echinoid spines, nodes of *Crisia*, Nullipores, *Halimeda*, *Alcyonium* and *Leptoclinum* spicules, and a simple Coral were the other notable contents.

Turning now to the rocks occurring on this paar, we find :—

The North Part is composed of a fine-grained calcareous sandstone or calcrete, grey in colour, and containing a considerable number of black grains in patches.* The block brought up is thickly encrusted with Polyzoa, both adnate and erect, and Nullipores, green and white. Shells, such as *Chama*, are attached to the stone, and these in turn are covered with encrusting organisms. On the fractured surface, the centre is seen to be compact, but a thin band of less compact texture separates the interior from the organisms on the surface. Sometimes the Polyzoa lie directly on the sandstone, at other times a thin layer of Nullipore intervenes.

The quartz is clear and of fairly even grain, and between the particles the calcite is seen filling up spaces or lying as thin rods across the grains. A few shell fragments and Foraminifera occur along with the quartz.

A thin slice examined under the microscope shows quartz, mostly angular, and averaging about 1 millim. in diameter, with inclusions of apatite, zircon and tourmaline, felspars, both orthoclase and plagioclase, showing no signs of kaolinisation, green tourmaline, shell fragments, and sections of Nummulites.

Calcite occurs as a granular mass filling up spaces between the grains, and often as curved rods. The rods, as a rule, enclose sand grains; they are sometimes pitted transversely, and a dark line in some cases runs down the length of the rod. Brown

* FOOTE, *op. cit.*, mentions a sandstone containing magnetic iron sand as occurring in Valimukkam Cliffs, on the coast of India.

chitinous patches are often associated with the calcite rods. Their nature and origin will be discussed in the next example from the middle portion of the Paar.

Middle Part.—Nine specimens, labelled "*half way up Periya Paar*," consisted of loose porous calcretes, white in colour and heavily encrusted, and a large Chank shell filled with calcareous sand and coated with Polyzoa, Nullipore, calcareous worm tubes, byssus of pearl oysters, and sponges. Sections of the calcretes were obtained showing the encrusting organisms *in situ*. This was a matter of some difficulty, owing to the friable nature of the material, but on soaking in thin balsam and hardening, slices were cut and rubbed down on carborundum blocks.

On examining a thin slice with recent colonies on the outside, the surface layers showed Polyzoan cells arranged in parallel rows, two or three deep, with the avicularia, vibracula, and opercula in position. The irregular surfaces served to entrap and retain sand grains and Foraminifera drifting over them. Naturally, only those were held which fitted closely into the spaces provided, and thus a sifting action took place. Occasionally two small grains would fill the space in place of one of larger dimensions. Below the surface layer other cells were seen, nearly all of which contained a grain. The base and side walls were perfect, but the top wall had broken down to admit the sand grain, carrying with it the chitinous operculum. Proceeding towards the centre, succeeding layers have less prominent walls, owing to secondary calcite growing from them in tiny scalenohedra towards the interior of the cell, and finally we reach a stage when a thin dark line marking the junction of adjacent walls, the roughly linear arrangement of uniform grains, and the occasional remains of chitinous opercula are all that remain to indicate the former presence of Polyzoa. Cells which escape being occupied by sand grains become filled with secondary calcite showing a radial structure (see fig. 2).

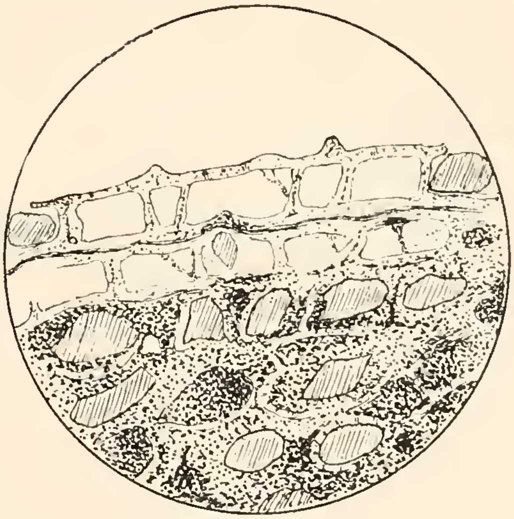

Fig. 2. Section of Calcrete with recent Polyzoa on surface, from Periya Paar Kerrai. The two upper layers represent sections of Polyzoon cells, and the lower part shows sand grains (shaded) in a calcareous matrix and fragments of the walls and opercula of the Polyzoa. × 25.

Nullipores sometimes alternate with Polyzoa and enclose grains, but it is not difficult to distinguish between the two even when structure has been lost. The grains cemented by Nullipore are sporadic in their distribution, there is no sifting into grains of uniform size, and when they appear in linear series they are mostly radial, not concentric. The action can be seen in masses of *Lithothamnion*, which send out club-shaped extensions from their surfaces. The spaces between the branches are often filled with loosely-held sand grains, and subsequent growth may enclose them. *Lithodomus* crypts and worm tubes, when deserted by their occupants, may also be filled with sand and become incorporated in the substances of the Nullipore. We shall return to this subject when discussing a Nullipore deposit from Chilaw. It is sufficient for the present to point out the importance of Polyzoa as cementing organisms, and indicate the criteria by which we can recognise their action.

South end of Periya Paar.—Here four pieces were obtained. Three of these were calcretes cemented mainly by Polyzoa, exactly similar to the one described, and containing grains of quartz, rutile, tourmaline, felspar, corundum and ilmenite, with shell fragments, Foraminifera, and sponge spicules; while the fourth was a piece of dead Coral, very rotten, covered with encrusting organisms, and bored by *Saxicava*.

Cheval Paar.—This paar lies to the south-east of Periya Paar. It is U-shaped, consisting of east and west arms with a connecting bar at the south.

The east arm is 6 miles long by 1 mile broad, and the depth averages $6\frac{1}{2}$ fathoms. Outliers to the north are seen at Periya Paar Kerrai, and Vankali Paar, and to the south lie Kondatchi and Jaggerboom paars.

The west arm measures 4 miles long by $1\frac{1}{2}$ to 2 miles broad, the depth is 7 to 8 fathoms. The connecting piece at the south end is 5 miles broad, runs north-east to south-west with a prolongation at the middle towards the south-east. Two small isolated paars, North Modragam and South Modragam, extend south-east from the prolongation.

Seven samples of the dredged material were kept from the parts surrounding the Paar, and 10 specimens of rock were obtained from the Paar itself and Periya Paar Kerrai.

Pearl Banks off Chilavaturai, $6\frac{1}{2}$ fathoms.—The coarser part of this haul consisted mainly of drifted shells, including Pearl Oyster, *Mactra*, *Pectunculus*, *Venus*, *Nassa*, and *Trochus*. They were nearly all broken, rotten, and some were bored by *Clione* and encrusted with Nullipore, Polyzoa, and Serpulæ. Echinids and Starfish also contributed to the contents of the sample as dredged. The only living organisms were Polyzoa.

The portion of medium size consisted of clear and milky quartz grains, well rounded and polished, averaging 5 millims. in diameter, echinoid spines and a few shell fragments.

The part which passed through a sieve of 1 millim. mesh was mostly quartz sand with 7·04 per cent. of carbonate of lime. On concentrating the heavy minerals by a high-density fluid magnetite, ilmenite and leucoxene, garnets, kyanite, tourmaline, rutile, corundum, and zircon were found; while in the lighter fractions were comminuted shells, Nullipores, Foraminifera, Echinoid spines, and spicules of *Holothuria*, *Alcyonium*, and sponges.

The material has all the appearances of a drifted shell bank swept by strong currents.

North of Cheval Paar, 7 fathoms. This consisted of a fine quartz sand with black grains, contained 28·36 per cent. of carbonate of lime, and included a few encrusted shells and *Echinocyamus*.

South-west Corner of Cheval Paar, 8 fathoms.—A fairly coarse shelly sand, with uniform grains about 5 millims. diameter, made up the bulk of the material. *Natica*, Pearl Oysters. Starfish arms, large *Heterostegina*, Nullipores and spines of Echinoderms also occurred in the coarser part.

The finer portion contained very little quartz, a little ilmenite and kyanite, sponge spicules, and the 34·32 per cent. of carbonate of lime was made up principally of Foraminifera and young Molluscs.

Middle of South End of Cheval Paar, 7 fathoms, immediately North of Shoal Buoy. This was nearly all fine sand of a light grey colour.

Pearl Oyster, *Pectunculus*, *Lima*, *Natica*, *Modiola*, and Chank shells were common, not very fresh and thickly encrusted. Barnacle valves, Sabellaria tubes and Echinoderms also occurred. Several pieces, about 1 inch long, of a chalky white stone on cutting proved to be decomposed Nullipore on the outside, and dark brown compact limestone with quartz and garnets in the interior.

The fine material yielded 22·20 per cent. of carbonate of lime, and contained quartz, zircon, kyanite, garnets, tourmaline, corundum, rutile, and mica with shell fragments, Foraminifera, and sponge spicules.

Shoal Buoy, $3\frac{3}{4}$ fathoms, is near the north-west termination of a spit of sand which extends from Karativo to Cheval Paar.

The bottom consisted of clean white sand with shells, 3·09 per cent. of carbonate of lime, and included a number of small black grains. The largest sand grain was 7 millims. in diameter. The shells were fresh, and some had the two valves in position.

In addition to quartz, garnets, kyanite, corundum, tourmaline, rutile, and ilmenite, were a few Foraminifera.

South Cheval Paar, $5\frac{1}{2}$ fathoms.—This was made up of a coarse sand with shells, some of the latter very fresh, with valves in apposition and retaining the epidermis.

The sand cakes on drying, owing to the presence of a considerable amount of mud. Pearl Oysters, *Modiola*, *Arca*, *Pectunculus*, *Nassa*, *Murex*, *Lithothamnion*, and a shark's tooth, occurred in the coarser stuff, and quartz well rounded, ilmenite, magnetite, garnet; tourmaline, zircon, and sillimanite were contained in the finer. No sponge spicules and very few Foraminifera were found.

South of Cheval Paar a coarse quartz sand occurs.

Dealing now with the rocks brought up from the Cheval Paar we find:—

Northernmost end of East Cheval is a mass of broken down coral. It is white in colour, with black grains filling in the pores. There is a slight iron stain round each grain. Only a few pieces of quartz are found adhering. The mass is bored with *Lithodomus*, and worm tubes are seen in section on the bottom surface. Some of these have a few grains of sand attached to the interior of the tube.

A few Nullipore patches of a white colour, scarcely distinguishable from the coral, are attached to the surface, but no Polyzoa.

A thin slice examined under the microscope shows that one or two pieces of shell and quartz have been enclosed in the walls of the coral, and towards the margin the thecas have been filled with secondary calcite and numerous Foraminifera.

North Central part of East Cheval and the Middle of West Cheval have calcretes exactly like those described from Periya Paar. They are thickly encrusted with Polyzoa, Nullipore, and worm tubes, and in section evidence of Polyzoa structure can be seen even in the middle parts of the blocks. The masses are cavernous, especially near the surface, and large worm tubes adhere to one side only of the cavities. The cavities have not been formed by boring animals, but are probably due to influences proceeding from the movements of the worm itself in setting up currents and thus preventing the growth of cementing organisms in the immediate neighbourhood. One block which has no worm tubes attached is not cavernous.

In the South Central part of East Cheval, the Central part of the Southern portion, North end of West Arm, and in the South-west part of the Paar a brown compact limestone occurs. It is usually encrusted with Polyzoa, Nullipores, and worm tubes. affords attachment to the byssus of the pearl oyster, and shells, especially *Chama*, are frequently adherent. In all cases the limestone is bored by Molluscs and *Clione*, but only for a short distance from the margin. It is slightly phosphatic, two specimens examined contained 0·21 and 0·36 per cent. respectively of phosphate of lime. In section we find a fine granular, light brown matrix with spots and streaks of reddish material at intervals. Traversing the matrix are zig-zag and branching lines of clear calcite, evidently filled-in cracks. Patches of Coral are seen showing clear calcite outlines with dark granular infilling. Quartz grains, mostly angular, occur, sometimes in patches, at other times in lines. Zircon, apatite, and garnet accompany the quartz, and magnetite occurs sporadically, usually showing a reddish border, which is, no doubt, due to the alteration of this mineral. The ground mass is mostly composed of shell fragments, Foraminifera, and small broken pieces of Nullipore. Incipient oolitic structure occurs round some of the grains. I should regard this limestone as the ultimate stage in the alteration of a coral reef. Coral structure is still to be seen in places, and we can trace the changes, step by step, by which a coral rock like that occurring at the north end of East Cheval is converted into compact limestone.

Periya Paar Kerrai.—Samples were obtained from three localities. Two of them were calcretes, showing Polyzoa and Nullipore structure among the grains, the third consisted of casts of drifted shells (Plate I., fig. 2).

Casts of pearl oysters were most frequent. All the valves were turned in one direction and overlapping. Lying on the sea floor with their concave surfaces facing upwards, they have been filled with sand. This has afterwards been cemented, and the shells subsequently dissolved. Thus viewing the specimen from one side we see the smooth cast of the interior of the shells, and on turning over only sand is visible. Other shells attached to the mass and still retaining their tests are *Cardium*, *Pecten*, *Murex*, and *Cerithium*. Colonies of Polyzoa and worm tubes have attached themselves to the smooth surfaces of the casts since the shells were removed.

Dutch Modragam Paar, to the southwards, lies 10 miles due west of Kodramallai Point. It is $1\frac{1}{2}$ miles in diameter and has a depth of 8 to 14 fathoms.

From this paar two specimens were obtained, one a piece of Madrepore coral about 2 inches thick, with numerous borings of Molluscs proceeding downwards and obliquely from the upper surface. White Nullipore covered parts of the upper surface, and the byssus of pearl oysters occurred attached to both the top and bottom.

The other sample was a coarse calcrete, consisting of sand grains very uniform in size, each measuring 3 to 4 millims. in diameter. The grains were clear, well rounded quartz and felspar, loosely cemented by carbonate of lime and thickly encrusted by Nullipore and Polyzoa.

Muttuvaratu Paar lies 5 miles west of Karativo, and has a depth of 5 to 10 fathoms. Here dead coral, bored in all directions by Molluscs, was brought up. It was covered by green Nullipore, a few colonies of Polyzoa and worm tubes, and much byssus of pearl oysters was adherent to both upper and lower surfaces.

Dredging in the neighbourhood, at a depth of 7 fathoms, showed the bottom to consist of calcareous sand containing 78·36 per cent. of carbonate of lime. *Heterostegina depressa* was the chief constituent, and some of the larger forms were covered with green Nullipore. Other organisms present were *Alveolina*, small univalves, Diatoms, and spicules of *Leptoclinum*, Holothurian plates and shell fragments.

Chilaw Paar, the largest paar on this southern part of the west coast, lies 7 miles west of Chilaw. It is 8 miles in length and averages 2 miles in width. The depth varies from $9\frac{1}{2}$ to 10 fathoms.

N o r t h o f t h e P a a r, at 10 fathoms, a calcareous sand was obtained, the finer material of which on analysis gave 95·5 per cent. of carbonate of lime. The small amount of inorganic matter present consisted of quartz grains, ·5 millim. in diameter, plagioclase felspar, zircon, garnet, tourmaline, kyanite and rutile.

Among the larger organisms present were shells and Nullipores in about equal proportions, containing such forms as *Pecten*, *Arca*, *Pectunculus*, *Astarte*, *Turbinella*, *Capulus*, *Nassa*, *Turritella* and *Echinocyamus*. Most of these were rotten and covered with Nullipores, Polyzoa and Serpulæ.

The finer material comprised many Foraminifera, including *Heterostegina*, *Polytrema*, *Alveolina* and *Globigerina*, Echinoid spines, young Molluscs, *Crisia*, Pteropods, and spicules of sponges, *Holothuria*, *Alcyonium* and *Leptoclinum*.

S o u t h o f C h i l a w, at $8\frac{1}{2}$ fathoms, the bottom was mostly composed of Nullipores, corals and Sabellaria. *Lithothamnion fruticulosum* was the commonest species among the Nullipores, and many of the balls were overgrown with Polyzoa and worm tubes, and fine sand frequently adhered in the spaces between the branches.

On breaking, the exterior was seen to be white and compact (Plate I., fig. 4), while the interior consisted of a brick-red spongy mass, almost of a powdery consistency and containing grains of sand. A thin slice examined under the microscope showed the white margin to be composed of fresh Nullipore with clusters of quartz grains and magnetite enclosed and irregularly disposed. Nearer the interior the plant structure became less distinct, and no trace of structure could be distinguished at the centre. The spongy core evidently has resulted from the breaking down of the Nullipore and the staining is due to the hydration of the magnetite. The sand can be accounted for by irregular growth of the Nullipore enclosing grains attached to the surface.

Two pieces of calcrete from Chilaw Paar were very like those obtained from Dutch Modragam, except that the grains were larger and less uniform in size.

Jokenpiddi Paar.—The floor is found to be composed of a very coarse calcareous conglomerate. It contains large well-rounded clear quartz, felspars, and rounded pieces of a brown limestone resembling that described from Cheval Paar. Simple Corals, *Chama*, and tangled masses of calcareous worm tubes cover the block, and colonies of Polyzoa find lodgment in sheltered cavities. A delicate tracery of Polyzoa can be seen among the sand grains on a freshly fractured surface (Plate I., fig. 3).

Karkopany Paar, lying off Chilaw at $7\frac{1}{2}$ fathoms, consists of a medium grained calcrete with a few large well-rolled pebbles of quartz of larger size. Dark brown ochreous patches occur in places. Some parts are compact, others loosely cemented. Polyzoan walls can be seen with the naked eye all through the mass cementing and covering the grains. Large shells, corals, and worm tubes cover the exterior.

Oolawittee Paar lies north of Negombo, at $8\frac{1}{2}$ fathoms. Here two samples were obtained. They consist of a loose sandy reddish-brown material, with a white coating of Polyzoa completely covering the exterior. Simple Corals, *Chama* and worm tubes are attached to the surface, the latter being mostly found lining the walls of cavities.

The rock from Negombo Paar is exactly like that obtained from Oolawittee. In a thin section we see clear quartz and felspar embedded in a dark brown opaque matrix. Polyzoa structure is visible, and can readily be traced out from among the sand grains.

General Remarks.

In considering the deposits as a whole, one cannot help commenting on the fact that nothing has been found in them which gives the slightest clue to the character of the solid rocks forming the bottom of the sea. All are of recent origin and can be accounted for by the action of causes now at work. Rivers bring down large quantities of disintegrated material from the interior of the land, particularly in the season of the south-west monsoon; this is spread over the sea floor by the combined action of the rivers and ocean currents, and organisms living in the surrounding seas are responsible for the calcareous material which forms a considerable proportion of the deposits laid down in places distant from the shore.

As no rocks of undoubted Tertiary age are found on the adjacent coasts, it would appear that all through that period the district has been in a state of equilibrium. SUESS* has remarked on the fact that no distinct line can be drawn between the Miocene and succeeding formations in the east, no break is seen in the deposition, and newer beds have quietly overlapped those of earlier date. In the absence of any signs of tectonic movements during the Tertiary period, which, if they had existed, would certainly have left some traces in the rocks of Ceylon and India, we are driven to the conclusion that the shallow platform surrounding Ceylon and connecting it with India on the north is due to the filling up of the sea by detritus derived from the land (see map, p. 161).

On the west coast of Ceylon, near the mouths of rivers, spits of sand stretch across the submerged platform, towards the north-west, while across the Gulf of Manaar from the opposing shores of Southern India similar banks of sand extend to the north-east. Near the coasts the spits consist of coarse fragments, while further out the sands become successively of finer grain. Long continued growth of these spits would result in the formation of a platform arching to the north and produce exactly the conditions we find in the Gulf of Manaar and Palk Bay. WALTHER† records that to the north of Palk Bay, between Calimene Point and Jaffnapatam, there extends a string of shoals less than 3 fathoms under the surface, and these may represent a bank in the act of forming.

In describing the deposits it has been shown that in the Gulf of Manaar the loose material is at the present day being cemented into calcareous sandstones or calcretes at the "paars," chiefly through the agency of Polyzoa and Nullipores.

The important part played by Polyzoa in this connection has not hitherto been recognised. I am convinced that many square miles of the rocky paars are due to this cause alone. Coral reefs in all stages of decay, from living reefs to compact limestones showing but few traces of coral structure, are associated with the calcretes.

If an area of this character were raised above the sea level and acted upon by the waves of the sea, we should expect the harder paars and limestones to exist as islands, between which would be areas of loose drifting sand. Such is exactly the structure of Adam's Bridge—a remarkable chain of islands and shoals which stretches across the platform from Ceylon to India. According to FOOTE‡ and WALTHER§ one of these islands, Rameswaram, has an ancient coral reef along its northern border, and a

§ *Op. cit.*

further exposure of coral rock, which has been described as a fossil atoll, lies in the interior immediately to the North of the Temple of Rameswaram. A large part of the island is covered by sand dunes which extend as a long spit as far as Thanni-Kodi on the south-east. These dunes hide the solid rocks of which the island is built, but a series of trial borings made across the island from north to south, two miles east of Pamban Town, did not show any southward extension of the coral reef, but a coarse calcareous sandstone—very modern looking and imperfectly consolidated. It is unfortunate that a piece of this rock was not available for comparison with the calcretes found on the paars, but from the detailed descriptions of FOOTE and WALTHER, it corresponds exactly with those found in the Periya and Cheval paar areas.

The chain of small islands east of Thanni-Kodi, and Manaar Island itself, also consist of similar calcareous sandstones. They are continued to the west across Pamban Strait and are seen bordering the coasts of Tonitoray Spit. On the east, according to RICHTHOVEN, the low lying plain forming the northern extremity of Ceylon has a coralline formation for its substratum. Similar rocks can be seen at intervals all along the East Coast of India, and have been described under the name of Cuddalore Sandstone. Again, along the West Coast of India, occurs the "littoral concrete," described by OLDHAM* as "an agglutinated calcareous shelly grit raised a little above sea level in several places." "It consists of shells, corals, pebbles, and sand cemented more or less thoroughly by carbonate of lime." "The beds may have originally been sand spits or beach deposits." All these deposits contain none but recent shells, exactly like those now living in the neighbouring seas.

SUESS† attributes the emergence of Adam's Bridge and the "littoral concrete" to a negative eustatic movement of the sea level in post-Tertiary times, and brings together a mass of evidence to show that the negative movement was widespread, embracing a large portion of the northern hemisphere. He surmises that the emergence may have been so recent that the great Hindu epic, the Ramayana, which treats of the building of Adam's Bridge, may be a poetical rendering of events witnessed by man. Although we have no certain evidence that the Bridge was at any time continuous, we have historic data to prove that the Island of Rameswaram was once united with Tonitoray Spit. If, as I suggest, the various links in the chain of islands represent emerged "paars," we have no reason to suppose, judging from the distribution of those now forming, that they were ever united.

In any case, the barrier, whether continuous or broken, would profoundly influence the deposits laid down in Palk Bay. Cut off from the currents sweeping up the coasts from the south, the conditions would be favourable to the deposition of mud, such as we find covering the floor of the bay, and sand would be confined to the shores. It will be noticed, however (p. 149), that casts of shells occur in the mud, and these are composed of sand. The shells have been completely removed, and the

casts themselves, in many instances, have been reduced to shapeless spongy masses of cemented sand. It is not improbable that these shells were filled with sand previous to the building of the Bridge, when the currents were sufficiently powerful to carry coarser material.

Some of the deposits, as at Galle Bay and Palk Bay, are evidently very old. They represent the remains of a fauna where solution and chemical changes have been at work. The shells left are mostly composed of calcite, not aragonite, and many of them have become partially converted into phosphate of lime.

Stable minerals such as quartz, garnet, kyanite, tourmaline, and zircon are found everywhere, whereas the less resistent felspars only occur near the coasts in the Gulf of Manaar in places where material has been recently deposited, or in calcretes, or in the interior of shells where they have been preserved from kaolinisation.

My thanks are due to Professor Herdman for much kindly help, and to Mr. C. C. Moore, F.I.C., of Liverpool, for the care he has taken in analysing some of the deposits for the purpose of this report.

LIST

OF

MARINE ALGÆ

COLLECTED BY

PROFESSOR HERDMAN, AT CEYLON, IN 1902,

WITH

A NOTE ON THE FRUCTIFICATION OF HALIMEDA.

BY

ETHEL S. BARTON (MRS. A. GEPP).

[WITH TEXT FIGURES.]

THE list of species represented in the small collection of ALGÆ from the Gulf of Manaar sent to me by Professor HERDMAN is as follows:—

CHLOROPHYCEÆ.

Codium tenue, KÜTZ.

Geogr. distr. :—Indian Ocean, Red Sea, West Indies.

C. ovale, ZAN.

Geogr. distr. :—New Guinea.

C. sp. (? *elongatum*, AG.).

Valonia, sp. ; a fragment only.

Caulerpa fergusonii, G. MURR.

Geogr. distr. :—Ceylon.

C. plumaris, AG.

Geogr. distr. :—All tropical seas.

Avrainvillea papuana, MURR. et BOODLE.

Geogr. distr. :—Indian and Pacific Oceans.

Halimeda tuna, LAM., forma *platydisca*, BART.

Geogr. distr. :—Mediterranean Sea, Atlantic, Indian and Pacific Oceans.

H. gracilis, HARV., with sporangia (see below, p. 165).

Geogr. distr. :—Indian and Pacific Oceans.

H. opuntia, LAM.

Geogr. distr. :—Tropical zone.

PHÆOPHYCEÆ.

Padina commersonii, BORY.

Geogr. distr. :—Indian, N. and S. Pacific and tropical Atlantic Oceans.

Dictyota, sp.

Sargassum; a fragment only, but Professor HERDMAN'S notes show that a species is present in great profusion on some parts of the pearl banks, and is of importance in connection with the attachment of the young pearl oysters.

FLORIDEÆ.

Galaxaura obtusata, LAM.

Geogr. distr. :—Warm Atlantic and N.W. Pacific Oceans.

G. rugosa, LAM.

Geogr. distr. :—Warm Atlantic, Indian and Pacific Oceans.

Actinotrichia rigida, DECNE.

Geogr. distr. :—Red Sea, Indian and N. and tropical Pacific Oceans.

Brachycladia marginata, SCHMITZ.

Geogr. distr. :—Indian, Pacific and tropical Atlantic Oceans.

Gastroclonium opuntia, KÜTZ.

Geogr. distr. :—Indian Ocean.

Hypnea musciformis, LAM.

Geogr. distr. :—Mediterranean Sea, tropical and sub-tropical oceans.

Dr. HERDMAN informs me that this species is of a green colour when alive, and that, along with a species of *Cladophora*, a *Ceramium*, *Chætomorpha* and *Polysiphonia*, all infested with Cyanophyceæ, it forms great masses, mostly of a green colour, on parts of the Cheval and Modragam banks, where it has many young pearl oysters attached to it.

Laurencia sp.; young plants.

Neurymenia fraxinifolia, J. AG.

Geogr. distr. :—Indian Ocean.

Polysiphonia sp.; sterile.

Dasya sp.; fragment with tetraspores.

Ptilota fergusoni, GRUN.

Geogr. distr. :—Ceylon.

Haloplegma preissii, SOND., var. *flabelliformis*, HARV.

Geogr. distr. :—Australia, Tasmania.

Dr. HERDMAN noted the presence of a few Algæ on the Coral reef at Galle, but was unable to bring any specimens. From what he says of them, and the rough sketches, I should suggest that they might be the following species, but it must be understood that this is mere suggestion :—

Caulerpa racemosa, var. *uvifera*, J. AG., or *C. sedoides*, AG.

Halimeda tuna, LAM.

Padina commersonii, HARV.

Peyssonelia rubra, J. AG.

Caulerpa plumaris, AG.

Vanvoorstia spectabilis, HARV.

Corallina sp.

A characteristic of the above is that they were all observed on dead corals.

A *Caulerpa*, which he noted as occurring on the Pearl banks, in the Gulf of Manaar, but of which he has no specimen, would appear from his sketch to be *C. scalpelliformis*, AG. Associated with it in quantity was a plant with ovate glossy dark green leaves, which from the sketch appears to be *Halophila ovata*, GAUDICH. They were growing through coarse quartz sand at a depth of 5 or 6 fathoms, about 10 miles from land.

The field diaries kept by Professor HERDMAN and Mr. HORNELL also contain records of the following Algæ from the Pearl banks :—

Halimeda tuna, f. *platydisca*, *Chrysymenia uvaria*, *Udotea flabellata*, *Dictyurus purpurascens*, *Zonaria lobata* (?), *Kallymenia perforata*, *Laurencia* sp., *Polysiphonia* sp., *Corallina* sp., *Acetabularia* sp., and "great quantities of *Sargassum* sp. both on the bottom and floating on the surface." These are all forms which are quite likely to have occurred.

Dr. HERDMAN has asked me whether any comparison can be drawn between the Algæ of the Maldive and Laccadive Islands and those of Ceylon. The only collection known from the former groups of islands was made by Mr. J. STANLEY GARDINER, and gathered on the coral reefs. It contained 23 species, chiefly of the Indian Ocean type, more than half of which had previously been recorded from Ceylon. The actual number of species common to that collection and Dr. HERDMAN'S is only two: *Halimeda tuna*, f. *platydisca*, and *Galaxaura rugosa*.

NOTE ON THE FRUCTIFICATION OF HALIMEDA.

Many of the specimens of *Halimeda gracilis*, HARV., are in fruit, a condition of this species which has never been noted or described. The only species of *Halimeda* of which the sporangia have hitherto been observed, are *H. tuna*, LAM., *H. platydisca*, DECNE, and *H. macroloba*, DECNE. In a paper published in December, 1901 ('The genus Halimeda, Siboga-Expeditie, Monographe LX.,' Leiden) I showed that *H. platydisca* should be regarded as a form of *H. tuna*, although Professor SCHMITZ

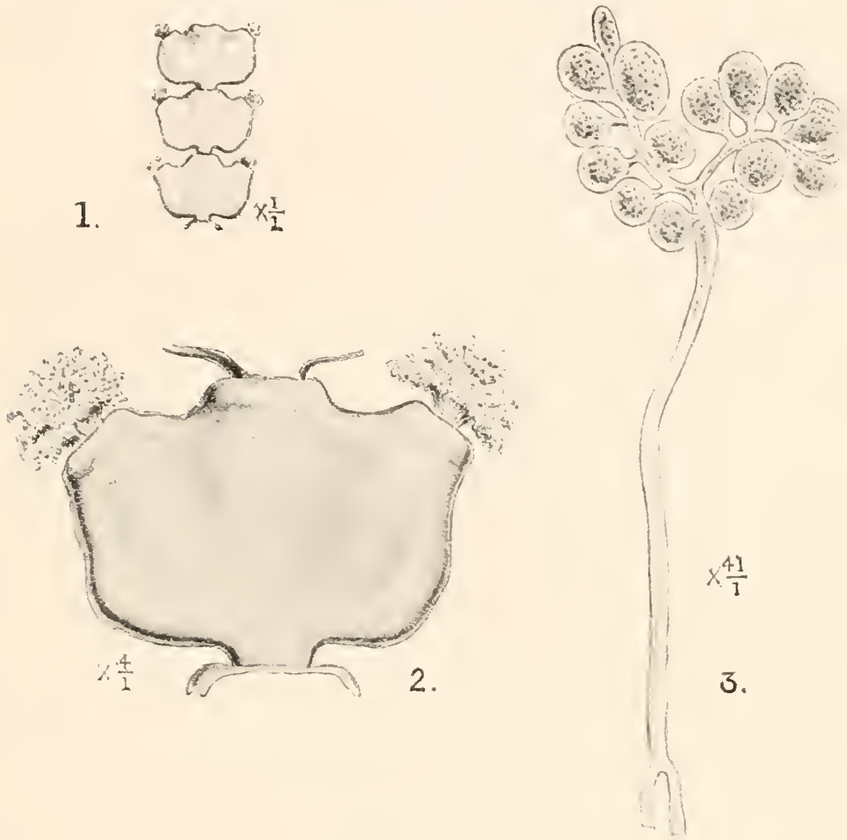
('Sitzungsber. d. Nied.-rhein. Gesellsch., Bonn, 14. Juni 1880,' p. 146) maintains that there are differences between *H. tuna* and *H. platydisca*, as regards the position of the sporangia on the sporangiophores, but he does not give any figures.

As to *H. macroloba*, the sporangia are mentioned by ZANARDINI ('Icon. Phyc. Adriat. et. Medit.,' vol. 3, p. 131) as having been seen by him, and they are stated to be similar to those of *H. tuna*. This remark on the fruits of *H. macroloba*, DECNE, is inserted by ZANARDINI in his description of Plate CXII., which represents a fruiting specimen of *H. tuna*. Hence the reader might be led to imagine that the fructification figured was that of *H. macroloba* and not that of *H. tuna*; ZANARDINI, however, merely emphasizes the point that he had not himself personally collected the fruiting specimens of *H. tuna* which he figures, and that he had in his possession fruiting plants of *H. macroloba*, from the Red Sea, a district which was outside the scope of his memoir. There is, therefore, no figure extant of the fruits of either *H. platydisca* or *H. macroloba*.

The fruits of *H. gracilis* grow out in small, short tufts from the margin of a joint (see text-figures), but these tufts are confined to those points on the margin at which the branches of the central strand emerge; and these branches, instead of continuing their course so as to form a new side-joint, grow out into tufts of fruiting filaments (figs. 1 and 2). In appearance, the fruiting joints of *H. gracilis* differ from those of *H. tuna*, which, according to the figures, bear a fringe of fruiting filaments along the upper margin, and in some cases even in an isolated tuft from the flattened surface of the joint. It is not quite easy to understand how this wide, marginal fringe in *H. tuna* can arise, since the strand of central filaments, from which the sporangiophores spring directly, runs up through the centre of the plant and branches inside a joint to form the side joints. If, as is always stated, the fruiting filaments of *Halimeda* arise only from the filaments of the central strand and its branches, then the points on the margin (or rarely surface) of a joint, where these strands emerge from the thallus, are clearly the only points at which fruiting filaments can be borne.

An examination of the fruiting material of *H. gracilis* shows that the sporangia are borne, as in *H. tuna*, on sporangiophores, which form a continuation of the filaments of the branches of the central strand. According to the system of classification of species followed in my paper referred to above, the distinguishing feature of *H. gracilis* lies in the complete fusion of the filaments of the central strand in pairs at the apex of a joint, the fused portion branching later trichotomously in the next joint. When the fused portion is destined, however, to bear sporangiophores instead, it branches dichotomously to form two sporangiophores, from which the sporangia emerge all round and form a kind of loose raceme (fig. 3). In the material from the Pearl banks of the Gulf of Manaar, most of the sporangia are empty, but it has been possible to find specimens in which the protoplasm still fills the sporangia and the apex of the sporangiophore. The protoplasm is studded with small, black dots, and the condition is probably one shortly preceding the ejection of the zoospores.

MM. Derbés and Solier ("Mém. Physiol. d. Algues," 'Compt. Rend.,' Suppl., vol. I., 1856, Plate XII., fig. 3) have figured a condition of the fruits of *H. tuna*, showing the sporangiophores and sporangia filled, all but the actual apex, with a dense, dark



Halimeda gracilis.

Fig. 1. Joints with fructification. Nat. size.

Fig. 2. One joint with fructification. × 4.

Fig. 3. Sporangiophores bearing sporangia in a condition shortly preceding the ejection of the zoospores. The point of fusion of the two filaments of the central strand is shown at the base. × 41.

green protoplasm. In the condition figured in this note, the development has advanced a stage further, and the dense protoplasm has become almost entirely concentrated in the sporangia and the apex of the sporangiophore.

Of the subsequent escape of the zoospores I can say nothing.

REPORT

ON THE

GEPHYREA

COLLECTED BY

PROFESSOR HERDMAN, AT CEYLON, IN 1902.

BY

ARTHUR E. SHIPLEY,

FELLOW AND TUTOR OF CHRIST'S COLLEGE, CAMBRIDGE, AND UNIVERSITY LECTURER ON THE ADVANCED MORPHOLOGY OF THE INVERTEBRATA.

[WITH ONE PLATE.]

THE collection of Gephyrea, made in Ceylon by Professor HERDMAN during his Expedition to inquire into the Pearl Fisheries of that Island, was small, but it contained at least two specimens of great morphological and systematic interest. These two specimens, obviously belonging to the same species, I have placed in a new genus which I have called *Centrosiphon*, their nearest allies amongst the Sipunculoids being *Aspidosiphon* and *Cloeosiphon*, and I have dedicated the species to its discoverer. The collection also included many specimens of the coral *Heteropsammia michelini*, ED. and H., with its associated commensal *Aspidosiphon corallicola*, SLUIT. There were also specimens of the corals *Heterocyathus æquicostatus*, ED. and H., and *Stephanoseris rousseaui*, ED. and H., which no doubt contain also their appropriate species of *Aspidosiphon.* Further, there were three specimens of *As. spiralis*, SLUIT., a single specimen of *As. steenstrupii*, DIES., a single specimen of *Cloeosiphon aspergillum*, QUATR., a few specimens of three species of *Physcosoma*, and a fragment of a *Sipunculus.* The Echiuroids were represented by a single specimen of *Bonellia pumicea*, SLUIT.

SIPUNCULOIDEA.

Aspidosiphon corallicola, SLUITER, Plate I., figs. 1, 2, 3, 11 and 12.

A few specimens of this species, recently described by SLUITER,* were found living in coiled tubes which penetrate the calcareous skeleton of the solitary coral

* C. PH. SLUITER, 'Die Sipunculiden und Echiuriden der Siboga-Expedition,' Leiden, 1902.

Heteropsammia michelini, Ed. and H., kindly identified for me by Mr. J. Stanley Gardiner. The specimens were all in a highly contracted condition, and most of them showed hardly any portion at all of the introvert, but Mr. Gardiner was able to place at my disposal a collection of the same species, made off Madras by Ramunni K. Menon, a former pupil of mine. The external appearance of one or two of these is shown in Plate I., figs. 1 and 2.

Sluiter's material enabled him to confirm Bouvier's view that the original home of the *Aspidosiphon* is a Gasteropod shell on which the young coral comes to rest. This shell becomes gradually embedded in the stony framework of the *Heteropsammia*. The smallest of Sluiter's examples showed the small Gasteropod shell, belonging to the genera *Cerithium*, *Natica*, and others, only partly overgrown and the young Gephyrean living wholly within the shell. In older stages the corallum spreads until it reaches and finally grows past the mouth of the shell, but the shell, according to Sluiter, is not absorbed, but can still be detected if carefully sought for.

On the body, mostly towards the posterior end and therefore, as the animal lies most remote from the opening, of several of Professor Herdman's examples, were a number of minute molluscs which Mr. Edgar A. Smith has kindly examined, and he is of the opinion that they might range with the genus *Mysella* of Angas. The animals are, however, so minute, that their exact determination is a matter of great difficulty.

These were so closely adpressed to the skin of the *Aspidosiphon* as to indent it, appearing as little pearls set in a matrix. The advantage they obtained by taking up such a position is not very evident, but there they were, and as far as one could judge they were, until Professor Herdman dropped them into his collecting jar, flourishing.

The whole question of such commensalism as exists between the *Aspidosiphon* and the coral is an interesting one. Commensalism is usually looked upon as conferring some mutual advantage on the contracting parties, and one or the other of these usually seeks the other out. But in the case in question the mutual advantage is far to seek. It can hardly help the coral to have a large portion of its base burrowed by a spacious canal, but the fact that the Gephyrean pulls the otherwise immovable coral about may be, and probably is, an advantage to the Cœlenterate. On the other hand, the Gephyrean gains protection and a home more spacious than the Gasteropod shell affords. The *Aspidosiphon* can hardly find, or attract the larval coral to come to rest on its burrowed shell, and it is unlikely that the larva is especially on the outlook for such shells as are inhabited by Gephyrea. It seems more probable that the *Aspidosiphon* may select for its home a Mollusc shell which already bears a young coral, but the whole matter seems to demand more careful study. It is certainly remarkable that three distinct genera of coral, each with but one species, should be inhabited by three distinct species of *Aspidosiphon*, and that neither commensal has hitherto been found apart from the other.

The specimens were obtained at various localities in the Gulf of Manaar (Stns. I., II., IV., &c.), and also off Trincomalee (Stns. XX., XXII.), and off Galle (Stns. XXXIX., XLII., and XLIII.).

The Ceylon collection also contains specimens of the corals *Heterocyathus æquicostatus*, Ed. and H., and *Stephanoseris rousseaui*, Ed. and H., showing perforations obviously made by burrowing Gephyrea.

Aspidosiphon spiralis, Sluiter.

Three specimens of this interesting species described by Sluiter from the Siboga Expedition were found living in the shell of three species of *Murex*, *M. fuscus*, *M. haustellum*, and *M. tenuispina*. The species is interesting because it resembles *Phascolion* in living in Mollusc shells, and because in the slight development of the posterior shield, and in the absence of a sharp line of division between the shields and the general surface of the body, it resembles *Physcosoma*.

The body is highly adapted to its home. Coiled spirally, it closely follows the contours of the Murex shell. The stout, tough circular anterior shield, on which the introvert opens excentrically but not quite at the edge, forms an effective guard to the entrance of the shell. This shield is supported by a stout, very muscular part of the body-wall which extends for some tenth or twelfth of the total body-length ; after this the skin becomes extremely thin and transparent. In two of the specimens collected by Professor Herdman the anterior shields were deep black, in the third it had a pinkish hue.

Between the Gephyrean and the Mollusc shell was a packing of sand held together by some secretion. This had a permanent opening at the mouth of the shell through which the introvert could be protruded.

Aspidosiphon steenstrupii, Diesing.

A single specimen, probably a young one, as the calcareous deposit was not visible. The musculature agreed, however, with that of this species, and differed clearly from that of *A. truncatus*. *A. steenstrupii* is the commonest *Aspidosiphon* in the Indian Ocean. The specimen in question was taken at East Cheval Paar, in the Gulf of Manaar, from a cavity in a block of coral.

Centrosiphon herdmani, n. g. et sp.—Plate I., figs. 4–10.

The length of the two specimens, taken at Cheval Paar, Gulf of Manaar, from the oral shield to the posterior end was 3 centims. The diameter of the oral shield was 3 millims., of the posterior shield 2·5 millims. The body between these shields was of rather smaller diameter, and from each shield the skin seemed gradually to grow thinner as it passed towards the centre of the body.

The colour in the spirit specimens was in the main a yellowish-gray, with tinges of a chestnut-brown. In one specimen this colour was very marked around the edge of the oval shield and extended a little way down the body, further on one side than on the other, and then gradually faded out to reappear in a slighter degree on the posterior shield. The same specimen also showed a few irregularly placed and ill-defined blotches of chestnut colour near the centre of the body.

The proboscis was not fully extended in either specimen. It was protruded from the *centre* of the oral shield and extended in one specimen some 3 millims., in the other somewhat less. The proboscis bears anteriorly several rows of chitinized processes obviously homologous with the hooks of other forms. Further back it bears prominent rounded papillæ, which are continuous with those on the anterior shield (fig. 5). This shield, like the posterior one, is separated from the sides of the body by a well marked rim. The papillæ on the anterior shield are uniformly scattered, but on the posterior shield they run in radiating lines from the rim to the thickened and somewhat indented centre. The walls of the body are comparatively smooth, with at best a few low papillæ, and these mostly at the two ends.

I opened one specimen with a longitudinal incision, and the following is an account of the arrangement of the internal organs. Unfortunately the specimen had had its alimentary canal broken, and the contents, consisting of sand and fragments of shell, were all over the place, and much impeded observation.

The longitudinal muscles of the skin are continuous, as in some of the species of *Aspidosiphon*, and the interior of that covering presents a smooth glistening gray surface. The alimentary canal seemed slightly coiled, but it was impossible to determine if there was a spindle muscle or not.

There are four retractor muscles, two ventral and two dorsal; only two, and these are often fused, occur in *Aspidosiphon* (fig. 8). The ventral are far stouter than the dorsal, and arise further back at about the level of the junction of the anterior quarter with the posterior three-quarters of the animal. The dorsal muscles are hardly half so thick as the ventral. They have their origin a little to right and left of the anus and at about the same level, which is some 2 or 3 millims. behind the edge of the oral shield.

At the base of the attachment of the large ventral muscles is a well marked fringe which obviously gives rise to the reproductive cells.

A single pair of nephridia lie one on each side of the anus. Their external openings lie close to the edge of the dorsal shield, and probably just behind it.

The introvert of both specimens was half everted, and I cut sections of one of them. Unfortunately there was a little sand in the interior of the introvert, and some of the sections were much broken. I was, however, able to make out that the number of tentacles is somewhere about twelve to fifteen. Each tentacle is triangular in section, with a well marked ciliated groove continued down into one of the grooves which line the beginning of the œsophagus. The transverse section also shows the three spaces continuous with the body cavity which communicate at the tip, and which by allowing the entrance of the cœlomic fluid extend the tentacle. As far as I could make out, the tentacles arise from a ring and not from a horseshoe, and the mouth is in the centre of the ring.

Behind the bases of the tentacles were little projections of the epidermis bearing thickened, cuticular projections (fig. 10). These morphologically resemble hooks, but no part of the tip is bent over, and the whole structure is something like a blunt spear-head. They are undoubtedly the homologues of the hooks in other unarmed Gephyrea, and in structure they fairly closely resemble the processes called "hooks" in *Sipunculus australis*, the only member of the genus *Sipunculus* which has "hooks." The spear-head projections were apparently arranged in rings, but with the somewhat broken sections, obliquely cut, it was not possible to definitely make out how many rings there were. Figure 10 also shows the very prominent papillæ of the posterior part of the introvert—the outer layer in the figure—the continuous layer of muscles, the nervous system cut twice, and the almost completed fusion of the retractor muscles around the base of the head.

Part of the brain is shown in section in figure 9, which has been cut through the pigmented, concave layer of cells which forms the eye.

Genus: **Centrosiphon**, n. g.

The new genus may be characterized as follows:—Sipunculoids with circular anterior and circular posterior thickened, chitinoid shields; the introvert emerges from the anterior shield in the centre, and is not inclined to one side more than to any other, it is quite central; both shields are separated from the side walls of the cylindrical animal by a prominent ridge; the papillæ are very prominent on the introvert, and on it and the anterior shield they are uniformly scattered, on the posterior shield they are in radiating lines; anteriorly and just behind the mouth are rows of spear-head-shaped chitinized projections obviously homologous with the hooks of other species.

Species: **Centrosiphon herdmani**, n. g. et sp., Plate I., figs. 4, 5, 6, 7, 8, 9 and 10.

With only two specimens at one's disposal, and those of the same species, to attempt to pick out the specific characters partakes of the nature of prophecy, but, judging by other and allied Gephyrea, the following, or some of them, will probably rank as specific characters:—Longitudinal muscles in a continuous sheath; four retractor muscles, of these the ventral are very thick and inserted about a quarter of the animal's length behind the anterior shield, and the dorsal are very slim and inserted one on either side of the anus, a very little way behind the anterior shield; the nephridia are rather dorsal in position and open close to the edge of the dorsal shield; the tentacles are few in number, some twelve or fifteen, and probably surround the mouth as a simple ring; eyes well developed; no calcareous deposits on either shield.

Systematic Position.

Centrosiphon belongs to the same group of Sipunculoids as *Aspidosiphon* and *Cloeosiphon.* All three genera possess a posterior and an anterior shield, the latter being placed but slightly in front of the anus and at the base of the introvert. *Centrosiphon* differs from *Aspidogaster* in that its introvert emerges from the centre of a round shield, quite symmetrically, and in a line corresponding with the long axis of the body. In *Aspidosiphon* the anterior shield is shaped something like a cockle-shell, and the introvert emerges at or near the narrow end and is at an angle with the main axis of the body. *Centrosiphon* differs from *Cloeosiphon* in the absence of the very characteristic calcareous ring round the base of the siphon, with its lozenge-shaped areas, and in the absence of true hooks, though the latter are represented by chitinized prominences. It resembles *Cloeosiphon* in its central proboscis and in its continuous sheath of longitudinal muscles. In *Aspidosiphon* the sheath may or may not be continuous. It differs from both genera in possessing four retractor muscles, and in the fact that its anterior shield forms a flat platform and not a radially or bilaterally symmetrical cone.

Cloeosiphon aspergillum, Quatr.

A single specimen, from Stn. XLIV., West of Pantura, 30 fathoms. This species is common in the Indian Ocean and parts of the Pacific. The "Siboga" took this form at thirteen stations, and in his account of the Gephyrea collected by the Expedition on that vessel, Sluiter records his view that the variety *javanicum* should be dropped.

Physcosoma agassizii, Sel. and de Man.

A single specimen was taken at Stn. LV., South-west of Periya Paar, in the Gulf of Manaar; depth, 11–14 fathoms.

Physcosoma asser, Sel. and de Man.

Three specimens; one from the Pearl Banks off Aripu (Stn. LIV.), and another from the Lagoon, Galle. Since my paper in the 'Fauna and Geography of the Maldive and Laccadive Islands,' this form has been recorded by Sluiter from four of the "Siboga" stations.

Physcosoma scolops, Sel. and de Man.

Three specimens of this genus are described as coming "out of a scarlet-ball sponge (*Axinella tubulata*), Cheval Paar (Stn. IX., 7 fathoms)," and also West of Periya Paar, 12–14 fathoms, in the same sponge. The species is very common all over the Indian Ocean from the Red Sea and the East Coast of Africa to the East Indies.

Sipunculus, sp.

A fragment of a *Sipunculus*, which was insufficient to allow of identification, was taken at Stn. LVI., south of Dutch Modragam Paar; depth, 8–9 fathoms.

ECHIUROIDEA.

Bonellia pumicea, Sluit.

The only Echiuroid in the collection was a *Bonellia*, from Galle, which I rather doubtfully identify with Sluiter's *Bonellia pumicea* ('Natuurk. Tijdschr. v. Nederl. Ind.,' vol. 50, 1890, p. 111).

EXPLANATION OF PLATE I.

Figs. 1, 2, 3, 11, and 12 are of *Aspidosiphon corallicola*; figs. 4–10, inclusive, are of *Centrosiphon herdmani*.

Fig. 1. Side view of *Aspidosiphon corallicola*, Sluit. × 10. The introvert is extended, but not quite to its full extent.

Fig. 2. View of anus of the same species, with the thickenings of the anterior shield sloping away from it.

Fig. 3. View of head of the same species showing the ring of tentacles.

Fig. 4. Side view of *Centrosiphon herdmani*, n. g. et sp., with the introvert slightly extended from the anterior shield. × 8. The chestnut-coloured patches seen on one of the specimens are well shown here.

Fig. 5. A view of the anterior plate and introvert of the same specimen seen from above. × 8.

Fig. 6. A view of the posterior plate of the same specimen seen from below. × 8.

Fig. 7. A transverse section through one of the papillæ around the base of the head of the same species showing the chitinous thickening. Highly magnified.

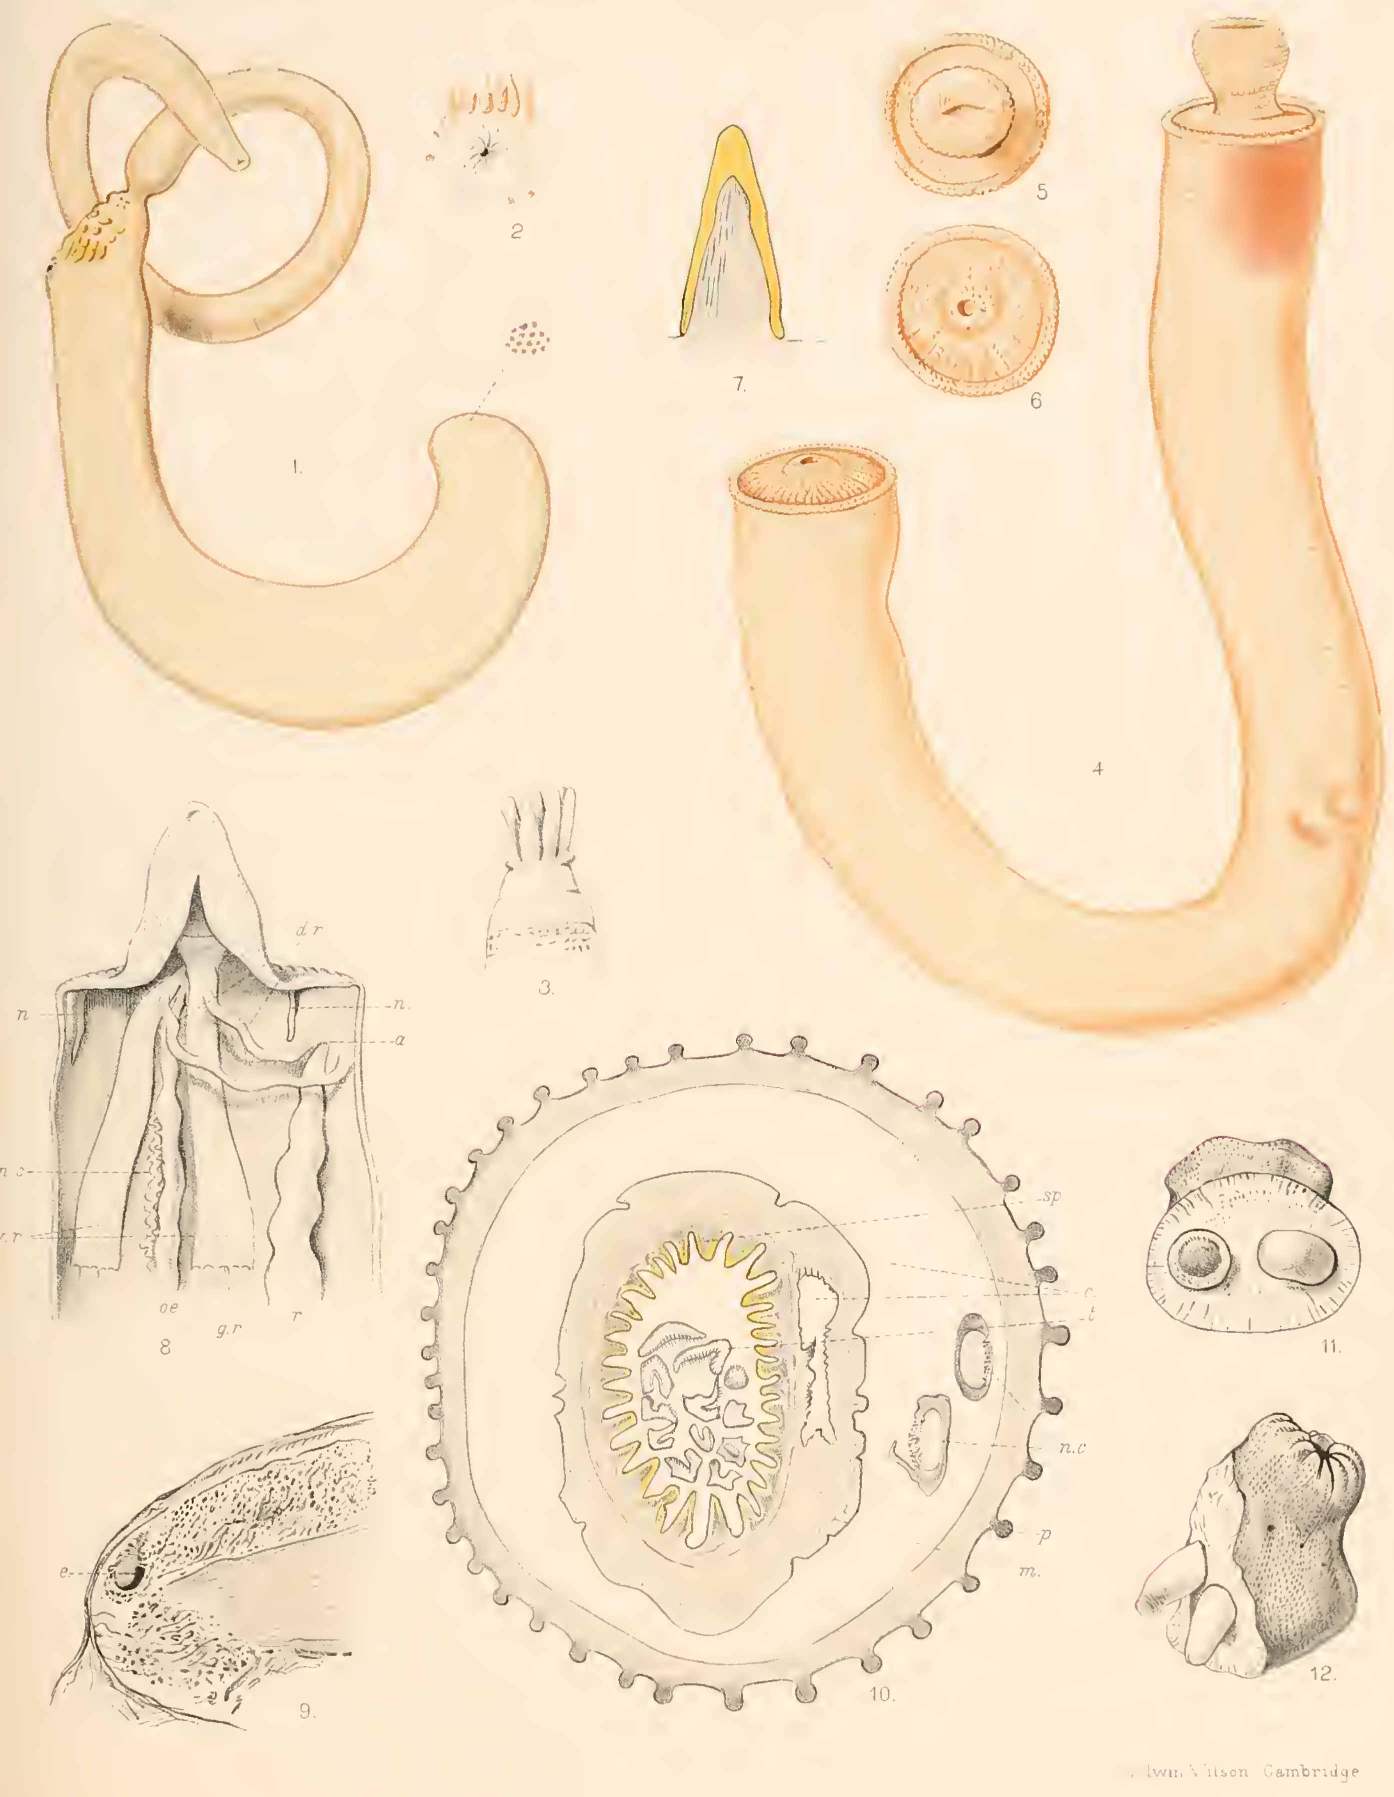
Fig. 8. View of the anterior end of the same species, cut open so as to expose the viscera. × 16 *a.*, position of anus; *d.r.*, the short, slender dorsal retractor muscles; *œ.*, œsophagus; *g.r.*, genital ridge at the base of the ventral retractor muscles; *n.*, nephridia; *n.c.*, ventral nerve cord; *r.*, rectum; *r.r.*, ventral retractor muscles.

Fig. 9. View of a section through the supra-œsophageal ganglion of the same showing *e.*, the eye. Highly magnified.

Fig. 10. Transverse section through the introvert partly retracted, showing the small group of grooved tentacles and the rows of chitinized spines. Highly magnified. *c.*, body-cavity, the isolated portion of this space runs up between the ventral retractors and soon disappears, as the four retractors fuse to form the muscular sheath *m.* round the head; *n.c.* nerve cord, which, owing to the retraction of the introvert, is bent, and thus cut across twice; *p.*, papillæ on the lower part of introvert; *s.p.*, chitinized spines round the base of the head; *t.*, transverse sections of tentacles.

Fig. 11. A *Heteropsammia michelini*, Ed. and H., broken across transversely, showing the head end to the left, and the tail end to the right of an *Aspidosiphon corallicola*, Sluit. × 2.

Fig. 12. Another specimen of the same, fractured longitudinally. The head end of the *Aspidosiphon* is above. The coral shows three pores on its side which communicate with the coiled tube in which the Gephyrean lives.



Edwin Wilson Cambridge

SIPUNCULIDS FROM CEYLON.

REPORT

ON THE

POLYPLACOPHORA

COLLECTED BY

PROFESSOR HERDMAN, AT CEYLON, IN 1902.

BY

E. R. SYKES, B.A., F.L.S.

[WITH ONE PLATE.]

THE large proportion of species described as new in the following pages is not so surprising as it might appear, since we know but little of the fauna of Ceylon, so far as the Chitons are concerned.

The collection includes nine species. Of these, three are identified (one doubtfully) with known forms; five are described as new; and, in one case, that of a single specimen of an *Ischnochiton*, I have thought it wiser to give no specific name.

Callochiton sublævis, n. sp.—Plate I., fig. 3.

Shell in shape, sculpture and girdle pattern similar to *C. lævis* (MONT.). Colour a uniform dark red, the interior of the valves being the same colour. The valves slightly concave in front of the line dividing the lateral and central areas. Valve slits: anterior 14, median 1, posterior 15.

Length, when alive, about 12 millims.

Hab. :—Navakaddua Paar, 7 fathoms, on Coral (one specimen).

The only salient features that I can trace to sever this form from the European *C. lævis* are the median valves having only one slit, the dark red colour inside the valves, and the slight concavity before the line dividing the lateral and central areas.

There is, in the British Museum, a single specimen from the Philippines, bearing the manuscript name of *sublævis*, CARPENTER, which probably belongs to the present species.

Callochiton platessa (Gould) ?

A single specimen, not in very good condition, from the lagoon inside the coral reef at Galle.

Ischnochiton ravanæ, n. sp.—Plate I., fig. 4.

Shell elongate, well elevated. Ground colour white, blotched and marbled with varying colours, black and purple predominating. Sculpture on the lateral areas, well-marked riblets, generally with an angle in the centre of the ribs, pointing towards the girdle; median areas smooth to the eye, but microscopically punctate. Sculpture of the posterior portion of the posterior valve similar to the lateral areas. The anterior valve is marked by slight depressed distant riblets, similar to lines of growth. Interior white, slightly tinted with yellow. Anterior valve with 8, median 1, posterior 15 slits.

Girdle scales broad, flat, thick, strongly striated.

Length, when alive, about 25 millims.

Hab. :—Donnan's Muttuvaratu Paar, 8 fathoms (one specimen).

Ischnochiton herdmani, n. sp.—Plate I., fig. 6.

Shell much elongated, narrow, moderately elevated. Ground colour a greenish-grey with delicate marking of brown, green, yellow, &c.

The sculpture is difficult to describe; the anterior valve and posterior area of the posterior valve are marked by a number of concentric ridges, the edges of these ridges being broken and roughened; the lateral areas of the median valves are similarly sculptured; the anterior portion of the posterior valve and the median areas are marked by a number of crossing lines, which give the appearance of the shell having been stabbed with a broad, blunt dagger; on the jugal tract these lines lengthen out and the stab-marks become finer and much more elongate. Interior white, tinged with pink. Anterior and posterior valves with 9, median with 1 slit.

Girdle wide, with squarish flat, well striated, scales.

Length, when alive, about 40 millims.

Hab. :—The lagoon inside the coral reef at Galle (three specimens).

Related to *I. alatus*, Sby, but more depressed and differing in sculpture.

Ischnochiton ferreus, n. sp.—Plate I., fig. 5.

Shell ovate, eroded and covered with a brown rusty staining, but apparently whitish below. Sculptured on the median valves with about ten radiating riblets on the lateral areas and distant longitudinal riblets on the median areas. The anterior valve and posterior valve (behind the mucro) appear to be sculptured as the lateral areas.

Interior white, stained with brown. Anterior valve with 13, median 1, posterior 13 slits.

Girdle with broad, flat, finely striated scales; some scales do not show the sculpture, but this is, I think, due to erosion.

Length, when alive, about 15 millims.

Hab. :—Trincomalee (one specimen).

Ischnochiton, sp.

A single specimen, from the Gulf of Manaar.

Craspedochiton laqueatus (SBY).—Plate I., fig. 7.

> **Chiton laqueatus**, SBY: 'P. Zool. Soc.,' 1841, p. 104.
>
> ———————: REEVE, 'Conch. Icon.,' Plate XX., fig. 135.
>
> **Craspedochiton laqueatus**, SBY: SHUTTLEWORTH, 'Bern. Mittheil.,' 1853, p. 67; PILSBRY, 'Man. Conch.,' vol. 14, p. 285.
>
> **Angasia tetrica**, CARPENTER: PILSBRY, 'Man. Conch.,' vol. 14, p. 287.

Hab. :—South of Modragam Paar (Stn. LXIV.), 5 fathoms; and North of the Gulf of Manaar (Stn. LXII.), 7–13 fathoms (several specimens).

I am unable to sever the Philippine shell from the Ceylon form described as *A. tetrica*. The species has a varied generic history, as it forms the type of *Craspedochiton*, SHUTTLEW., *Angasia*, CARPENTER, nec WHITE, and *Phacellozona*, PILSBRY.

A single specimen from "Palk Bay, February, 1902," I refer here with some doubt, as it is slightly more elevate, the posterior valve shows no trace of the radiating lines, and there are other minor differences.

Acanthochites penicillatus (DESH.)—Plate I., fig. 2.

> **Chiton penicillatus**, DESHAYES: 'Moll. Réunion,' p. 41, Plate VI., figs. 8–10.
>
> **Chiton (Acanthochites) penicillatus**, DESH.: MARTENS in MÖBIUS' 'Reise Mauritius,' p. 300.
>
> **Acanthochites penicillatus**, DESH.: PILSBRY, 'Man. Conch.,' vol. 15, p. 15, Plate IV., fig. 84, Plate VIII., figs. 29, 30.

Hab. :—Gulf of Manaar (two specimens).

I identify the Ceylon with the Mauritian shell with a little doubt, as I know the latter only from figures and descriptions.

Tonicia pectinoides, n. sp.—Plate I., fig. 1.

Shell ovate, broad, elevated. Colour, reddish to yellowish-green. Lateral areas well raised. The central areas and anterior portion of the posterior valve are sculptured with longitudinal, broad, flattened riblets, the interstices marked by minute, crossing riblets, somewhat as is frequently seen in the Pectinidæ. Anterior valve, posterior portion of posterior valve, and lateral areas marked with flattened nodules, those on the median valves being fewer in number, irregular in size, and more widely separated. Mucro posterior and much elevated.

Interior white. Median valves with 1, anterior with 8, posterior valve with numerous small slits.

Girdle microscopically setose.

Length, when alive, about 18 millims.

Hab.:—Pearl-banks in the Gulf of Manaar and deep water off Galle (Stn. XL.), 34 fathoms (two specimens).

SPECIES OF POLYPLACOPHORA

REPORT

ON THE

HOLOTHURIOIDEA

COLLECTED BY

PROFESSOR HERDMAN, AT CEYLON, IN 1902.

BY

JOSEPH PEARSON, B.Sc.,

SCHOLAR IN ZOOLOGY IN THE VICTORIA UNIVERSITY, AND NATURALIST TO THE ULSTER FISHERIES AND BIOLOGY ASSOCIATION.

[WITH PLATES I. TO III.]

THE HOLOTHURIANS obtained by Professor HERDMAN during his expedition to Ceylon have proved to be a very interesting and extensive series.

The collection consists of 70 specimens, which are distributed amongst 10 genera and about 30 species. Of these I find that seven are new to science and there are also at least two new varieties. One of the new species requires the formation of a new genus, *Havelockia*, near to *Colochirus* in the Dendrochirotæ.

In the main I have followed the classification and nomenclature adopted by LUDWIG (12).* I have, however, taken JEFFREY BELL'S (16, 17) suggestion with regard to the generic name *Actinopyga*.

The following is a list of the species in the collection :—

Synapta striata, Sluiter.
Synapta beselii, Jäger.
Synapta, sp. (?).
Synapta, sp. (?).
Cucumaria tricolor, Sluiter.
C. turbinata (Hutton).
C. imbricata (Semper).
C. conjungens, Semper.
Thyone fusus, var. *papuensis*, Théel.
Thyone sacellus (Selenka).
Thyone (?) *fusca*, n. sp.
Thyone (?) *hornelli*, n. sp.
Thyone (?) *calcarea*, n. sp.
Phyllophorus cebuensis (Semper).
Actinocucumis donnani, n. sp.
Colochirus quadrangularis, Lesson.
Col. quadrangularis, var. *mollis*, nov.
Col. doliolum (Pallas).

* The numbers in brackets refer to the List of Literature on p. 206.

Colochirus, sp. (?).
Havelockia herdmani, n. gen. & sp.
Actinopyga mauritiana (Quoy and Gaimard).
Actinopyga serratidens, n. sp.
Holothuria kurti, Ludwig.
H. monacaria (Lesson).
H. vagabunda, Selenka.
H. tenuissima, Semper.
H. marmorata (Jäger).
H. atra, Jäger.
H. gallensis, n. sp.
Stichopus chloronotus, Brandt.
St. chloronotus, var. *fuscus*, nov.
St. variegatus, Semper.

In addition to these, the field notes made by Professor HERDMAN and Mr. HORNELL show that they observed two species (or varieties) of *Psolus*, the one black and the other grey, on the East Cheval Paar.

So far as I am aware, this is much the largest collection of Holothurians that has been yet obtained from the seas of Ceylon. Until about twenty years ago no Holothurians had been definitely recorded from that coast. Owing mainly to the work of Drs. PAUL and FRITZ SARASIN, of Mr. EDGAR THURSTON, of Madras, and others, the number on record had lately reached the total of 37 species. Professor HERDMAN'S Holothurian collection, in addition to a number of the forms previously known, contains at least 20 species and distinct varieties which are now recorded from Ceylon for the first time, thus bringing the total number of known species and varieties up to 57, as shown in the following list. The first column gives those species reported by Mr. THURSTON (**19**) from the Gulf of Manaar, the second those described by Professor JEFFREY BELL (**8**), the third shows those collected by Drs. P. and F. SARASIN, chiefly at Trincomalee, and described by Professor LUDWIG (**9**), the fourth those few collected by Professor HAECKEL, and described by Dr. WALTER (**18**), and the fifth column gives those collected by Professor HERDMAN in 1902, and described in the present report.

Geographical Distribution.

An examination of the geographical distribution of the Ceylon Holothurians shows clearly that they are typically Indo-Pacific forms; and that their recorded occurrences form an equatorial belt, ranging from the east coast of Africa to the South Pacific.

It will be seen from the following table that only four of the 53 named species have been found in the North Pacific, namely, *Holothuria fusco-cinerea*, *Colochirus armatus*, *Thyone sacellus* and *Actinocucumis typica*; while the Atlantic fauna is only represented by three species, which occur, two in the Caribbean Sea (*Holothuria atra* and *H. impatiens*) and one at the Cape of Good Hope (*Colochirus doliolum*).

The table shows the recorded distribution of Ceylon Holothurians in the great oceans of the world. The concentration in the right-hand columns, which indicate the Indo-Pacific region, is most marked.

I wish finally to express my thanks to Professor Herdman for allowing me to examine this most interesting collection, as well as for the advice and assistance which he was always willing to give in the solution of points of difficulty.

HOLOTHURIOIDEA.

Order: PARACTINOPODA.

Family: SYNAPTIDÆ.

Synapta striata, Sluiter (10)—Plate I., fig. 1.

Eight specimens from the outer part of Yard Cave, Trincomalee (Stn. XXVI.), 2–8 fathoms.

Lengths range from 15 millims. to 85 millims. The smaller specimens are evidently in a contracted condition.

The following is Professor Herdman's description taken from the living animal;—

"Living amid sponge branches. Colour, striped lilac on a white ground. The five rays of the body are marked by five narrow white bands. The region between these rays is marked with numerous delicate lilac stripes forming a pattern which is variable in different individuals. The tentacles are used for progression and are flattened for two-thirds of the way from the apex."

There are 13 tentacles present, each having 19 digits. Plate I., fig. 1, shows the flattened extremity of a tentacle, as drawn from the living animal in Professor HERDMAN'S note-book.

There are about 18 Polian vesicles in the specimen dissected, 6 being large and the rest smaller. There is one madreporic canal. The alimentary canal is looped.

The deposits agree with SLUITER'S figures. I have found, however, that some of the anchor plates differ from the usual form in having *smooth* holes. There are also present in the skin numerous miliary granules which are arranged in groups of six or seven, having typically one central granule surrounded by numerous granules in a circle. This species appears to be very closely allied to *S. recta* and *S. indivisa.*

This species is now recorded from Ceylon for the first time.

Distribution :—Java and Ceylon.

[**Synapta beselii**, JÄGER.

A large *Synapta*, measuring 6 feet in length, was found by Mr. HORNELL at Galle. The specimen has not reached me, but the size and description agreed so well with *S. beselii*, already known from Ceylon, that there can be little doubt as to the species.

Distribution :—Indian Ocean, Philippines, South Pacific and East Indies.]

Synapta, sp. (? n. sp.).

This is a fragment from the south west of Palk Bay (Stn. XVIII.), 7 fathoms, in mud. Only the posterior portion of the body remains.

The fragment is 50 millims. long, and the body is evidently in a very contracted condition. All the internal organs are torn away. Still the specimen clearly belongs to a species of *Synapta.*

Deposits :—The anchor plates are in all cases imperfect. The plates are covered with short spines and are perforated by a large number of small holes of various sizes. The anchors are large, and the handle is serrated. So far as I am able to determine, these spicules do not resemble those of any known species, but the incomplete state of the specimen does not permit me to make a definite decision with regard to its identity, nor to describe it more fully.

Synapta, sp. (? n. sp.).

One specimen from Galle. This specimen is in a poor state of preservation, so that I cannot be absolutely certain as to its identity.

There are 12 tentacles, each having 5 digits.

Deposits:—The anchor arms are not always symmetrically placed. They are slightly serrated. The anchor handles are strongly serrated. The anchor plate is perforated irregularly—the arrangement differing in different plates. There are several larger holes with serrated margins, and also several smaller smooth holes. There is no handle to the plate. There are also a number of short rods scattered throughout the skin, having a small hole at each end.

Neither this nor the preceding species can possibly belong to any of the species previously recorded from Ceylon, viz., *S. striata*, *S. recta*, *S. grisea*, and *S. beselii*, and in their spicules they seem to differ from all known species of the genus. Consequently, they probably both of them represent new species, but they are too fragmentary to be described.

Order: ACTINOPODA.

Family: DENDROCHIROTÆ.

Cucumaria tricolor, Sluiter (15).

One specimen from near Donnan's Paar (Stn. LX.), Gulf of Manaar, 28 fathoms.

Length of body, 30 millims.

The following is a description of the colour of the living animal as noted by Professor Herdman:—"The interambulacra are violet-purple, and the ambulacra appear as light yellow bands, on which are situated pedicels of a deeper yellow." There are also a couple of sketches in the notes which agree with Sluiter's figures and show the characteristic form of body.

The body is curved so that the anus is thrown on to the dorsal surface, thus making the trivium longer than the bivium. The pedicels on the trivium are arranged in three well-defined series, each series being composed of two or three rows. The pedicels on the bivium are not so easily determined, and only on careful examination can an irregular and feebly marked single row of scattered pedicels be distinguished on each side of the dorsum.

The mouth, which is terminal, is surrounded by five very prominent rows of protuberances which terminate the five ambulacra of the body. These prominences, of which there are three in each row, do not appear to be tube feet, but are more probably papillæ. The anus is armed with five teeth, and is surrounded by four papillæ similar to those surrounding the mouth. Gonads are not present.

No deposits were found in the skin.

The calcareous ring is small and consists of ten pieces, without any posterior prolongations. It agrees with Sluiter's drawing.

The only serious difference between Sluiter's description and the above is with regard to the calcareous deposits. The Ceylon specimen has no deposits; but since it has been kept for several months in a solution of formol, it is by no means safe to attach importance to this fact.

There is a slight disagreement in the arrangement of the pedicels. SLUITER'S specimen had five well-marked series of pedicels, those on the trivium consisting of five or six rows, and those on the bivium of two or three rows. But the smaller number of pedicels on the Ceylon specimen may be explained by the fact that it is evidently much younger, being only one-fifth the size.

There is also a slight difference of colour. The pedicels of SLUITER'S specimen were red; those of the Ceylon specimen were a "deep yellow." This is probably of no importance.

This species is now recorded from Ceylon for the first time. Its known distribution is Aru Islands and Ceylon.

Cucumaria turbinata (HUTTON), Plate I., figs. 2–6.

Labidodesmus turbinata, HUTTON (3), 1878.

One specimen from Gulf of Manaar (Stn. VI.), 6 to 9 fathoms.

HUTTON described this species under the name *Labidodesmus turbinata*, but THÉEL, in his "Challenger" report, places it in the genus *Cucumaria*, with the remark that a re-description of the animal is necessary.

So far as I can ascertain from HUTTON'S scanty description, the Ceylon specimen is identical with his New Zealand species, the type specimen of which is now in the British Museum. Professor HERDMAN has kindly examined for me the British Museum specimen, and compared it with my description and drawings of the Ceylon specimen, and was convinced that both belong to the same species. As HUTTON, in his description, said nothing about deposits, Professor F. JEFFREY BELL kindly allowed me to examine a small piece of the skin of the British Museum specimen. I found that there were no deposits present, but since the specimen has been preserved for 25 years, it is by no means safe to conclude that the skin of the living animal was devoid of calcareous spicules. I am now, therefore, able to supply what THÉEL stated was necessary, namely, a re-description of HUTTON'S species.

The following is a description of the Ceylon specimen, which I believe to be that species:—

Length, 25 millims. Greatest width, 12 millims.

The colour of the spirit specimen is dark brown on the bivium, and lighter brown on the trivium. The body (Plate I., fig. 6) is widest at the middle, and at the anterior end tapers into a cylindrical neck which is about one-third of the length of the body. At the posterior end the body suddenly contracts and ends in a point at the anus.

The New Zealand specimen ends in a "short pointed tail" at the posterior end. There is no actual process or "tail" in the Ceylon specimen, but it is not inconceivable that during life the animal may have had a short posterior projection which has become retracted. The difference, however, between the British Museum specimen and the Ceylon specimen is, Professor HERDMAN informs me, not now very marked in this respect.

There are five series of pedicels; each series consists of a double row on the "neck," but on the wider portion of the body each series of the trivium consists of about four rows, while each series of the bivium consists of two or three rows. At the posterior end the series are not so well defined, each having only one or two rows of pedicels. There are also one or two pedicels on the interambulacra.

The sucking discs of the pedicels are dark brown or almost black in colour, thus being easily distinguished on the lighter skin.

There are no anal teeth. The tentacles have been cast off.

Deposits:—The spicules (Plate I., figs. 2 to 4) are of one kind and are numerous. Typically they are like a cross having four arms in one plane and with two additional arms arising at right angles to this plane at the junction of the four arms. There are many variations of this, some appearing like a short rod covered with many spines.

The calcareous ring (Plate I., fig. 5) is 5 millims. long and consists of ten pieces. The inter-radials are small and are separate from the radials. The radials are bifurcated posteriorly, and the bifurcations are composed of several small pieces.

There is one stone canal and one Polian vesicle.

The retractor muscles are remarkably long, and are attached to the longitudinal muscles halfway down the body.

Distribution:—New Zealand, Ceylon. Now recorded from the Indian Ocean for the first time.

Cucumaria imbricata (SEMPER).

Ocnus imbricatus, SEMPER (2), 1868. **Ocnus javanicus**, SLUITER, 1880. **Ocnus typicus**, THÉEL (7), 1886.

Ten specimens from (1) Pearl Banks (Stn. LXVI.), Gulf of Manaar, (2) West of Kaltura (Stn. XLIII.), 22 fathoms, and (3) Back Bay, Trincomalee (Stns. XX. and XXI.). Lengths varying from 20 millims. to 50 millims.

Although THÉEL in his "Challenger" report retained the genus *Ocnus*, he expressed some doubts as to its validity. LUDWIG believed that the three forms *O. imbricatus*, *O. javanicus*, and *O. typicus* were identical, and in his Holothurians of BRONN'S "Klassen und Ordnungen des Thierreichs" he placed them all in the genus *Cucumaria*, under the name *C. imbricata*.

Eight of the Ceylon specimens I identified as THÉEL'S species *O. typicus*, and the other two I considered at first to be SLUITER'S species *O. javanicus*. But except for some slight differences in the calcareous ring, in the arrangement of the pedicels, and in the scales and colour of the body, the two forms appear to be very similar. So, on the whole, I now think it best to unite them.

The number of the pedicels on each of the five rows shows some variation, one specimen only having from eight to ten pedicels in each row, whilst those of the *O. javanicus* type have as many as from twenty to twenty-three. The average number, however, in each row is about eighteen. In one specimen the rows of pedicels showed a somewhat irregular arrangement. In the anterior half of the body all of the five rows are in a straight line. At the middle of the body, however, each of the rows makes a deviation and then continues to the posterior end of the body in a straight line. So that the five rows in the posterior half alternate with the five rows in the anterior half of the body.

Another specimen which is very much flattened dorso-ventrally is remarkable in having the pedicels arranged in distinct rows only on the trivium. At a rough glance the bivium appears to be altogether devoid of pedicels, and it is only on a very close examination that a few very small and irregularly scattered pedicels can be distinguished.

The character of the scales is not similar in all the specimens.

It happens that all the individuals which I had identified as *O. typicus* are yellowish-white, in alcohol; and the two others (the *O. javanicus* form) were of a dark brown colour.

The deposits in all the specimens are very similar, and agree with the description of *O. typicus* given by Théel.

Distribution :—Hong-Kong, Bay of Bengal, Java, Ceylon.

Cucumaria conjungens (Semper) (2).

One specimen from Pearl Banks, Gulf of Manaar. Length, 14 millims.

The specimen agrees very closely with Semper's description, both in the nature of the deposits and the calcareous ring.

Owing to the small size of the specimen, the arrangement of the dorsal pedicels into three rows, as described by Semper, is not very clearly marked. The pedicels on the ventral surface are much more numerous than the dorsal pedicels and are irregularly scattered.

The body tapers at both ends, being more pointed at the posterior end.

This is recorded from Ceylon for the first time.

Distribution :—Bay of Manilla, Ceylon.

Thyone fusus (Müller), var. **papuensis,** Théel (7)—Plate I., figs. 7, 8.

Two specimens from the Gulf of Manaar (Stn. IV.), 6–9 fathoms.

Lengths, 25 millims. and 22 millims.

The body is pointed at both ends. The pedicels are scattered all over the body, but show an arrangement into longitudinal series not only on the ambulacra but also on the interambulacra. This arrangement is somewhat obscure in some parts of the body.

The calcareous ring is, comparatively, of very large size, being 11 millims. long in the smaller specimen. The posterior prolongations are composed of several smaller pieces.

The deposits consist of tables which are very thinly scattered. They have four large central holes and also four smaller peripheral holes. In the larger of the two specimens the tables are imperfect, the circumference being broken at several places (Plate I., fig. 8). Whatever may have been the cause of this breaking up, there is no doubt they were originally similar to those of the smaller specimen (fig. 7), which agree with Théel's figure.

There is no doubt that these specimens agree more closely with Théel's variety, *papuensis*, than with the species. *Thyone fusus* is a northern form, and Théel's variety was obtained by the "Challenger" Expedition in Torres Straits. It is now recorded from Ceylon for the first time.

Thyone sacellus (Selenka)—Plate I., figs. 9, 10.

Stolus sacella, Sel. (1), 1867. **Thyone rigida**, Semper (2), 1868. **Stereoderma Murrayi**, Bell (4), 1883.

Two specimens from five miles off Negombo (Stn. I.), 12–20 fathoms, January 31, 1902. Lengths, 75 millims. and 50 millims.

Colour in spirit—light yellow with irregular brown spots.

The skin is hard and rigid. The tentacles are retracted.

The pedicels are irregularly scattered over the body. They are very small and numerous, showing an arrangement in three double rows on the trivium. These rows are not continued to the extremities, but are confined to the middle of the body.

The calcareous ring is typical of the species.

Deposits:—These consist of four-holed plates having on each side a half ring arising from the centre of the plate at right angles (fig. 9). In addition to these I find numerous plates having more than four holes and having short spines on the surface (fig. 10).

These specimens are evidently the same as Bell's *Stereoderma murrayi*, which is now included in Selenka's species, *Thyone sacellus*.

Distribution:—Kurachee, East Coast of Africa, Torres Straits, Japan, and Ceylon.

Thyone (?) **fusca**, n. sp.—Plate I., figs. 11–13.

One specimen from Back Bay, Trincomalee (Stn. XXI.), 8–12 fathoms; 18 millims. long and 10 millims. broad.

The colour of the spirit specimen is brown. The pedicels are the same colour as the general integument.

There are no tentacles present in the preserved specimen.

The pedicels are irregularly scattered all over the body, being slightly more crowded on the ventral surface than on the dorsal. There are no papillæ present.

The calcareous ring is small, being only 4 millims. long. It is composed of ten separate pieces. The radials are notched anteriorly and bifurcated posteriorly. Each posterior prolongation is composed of about four small pieces. The inter-radials are simple (fig. 11).

There is one stone canal and one Polian vesicle. There are no gonads present in this specimen and the alimentary canal is eviscerated. Both the right and the left branches of the respiratory tree are well developed. There are no anal teeth.

Deposits :—These are very scarce, and imperfectly formed. This leads me to believe that the animal may have been preserved originally in formol, but I have no record of this. The deposits are small plates having many holes, and probably slightly hollow (figs. 12 and 13). These are very rare. The pedicels have well-developed terminal plates.

Owing to the tentacles being absent, I am unable to assign the specimen to its genus with certainty, although it is, in all probability, a *Thyone*.

Thyone (?) hornelli, n. sp.—Plate I., figs. 14–16.

One specimen from the lagoon inside the Reef, Galle.

Length, 50 millims. ; breadth, 20 millims.

It is broader at the anterior end, and is slightly narrower at the posterior end.

The colour of the formol specimen is light brown, spotted irregularly with small black marks. The sucking discs of the pedicels in some parts of the body are of a rusty-red colour, and in other parts they are the same colour as the general integument. Beneath the brown epidermis the skin is of a very light violet hue.

The pedicels, which are large, numerous and well formed, are irregularly distributed over the body, showing no arrangement into rows. There are no papillæ.

The tentacles are absent, and there are no anal teeth.

The calcareous ring is composed of five radial pieces and five inter-radials, which are, however, not clearly separated from one another. The radials are notched anteriorly and are bifurcated posteriorly, the posterior prolongations being composed of several smaller pieces. The calcareous ring is fairly massive, being 15 millims. long (fig. 14). There is one Polian vesicle and one stone canal.

The gonads are attached to the dorsal mesentery in one bunch.

The right and left branches of the respiratory tree are large, and both extend to the anterior end of the body.

The internal organs and mesenteries are coloured a light violet, like the skin.

The longitudinal muscle bands are very well developed.

Deposits :—The spicules are very thinly scattered, and consist of small perforated plates having a spiny surface (figs. 15 and 16). Since the animal has been preserved in formol, it is doubtful whether this was originally the exact shape of the deposits.

I cannot be quite certain as to the genus of this form since the tentacles are not present, but it is probably a *Thyone*.

Thyone (?) calcarea, n. sp.—Plate I., figs. 17–20.

One specimen from Cod Bay, Trincomalee (Stn. XXVII.), 6 fathoms.

Length, 20 millims.

The colour in spirit is yellowish-white.

The tentacles are not present.

The pedicels are small and numerous, and are the same colour as the skin. They are scattered all over the body, and are more numerous on the ventral surface than the dorsal. They form a double row on the five ambulacra, but only at the central portion of the body. Those on the three rows of the trivium are longer and more distinct than those of the two rows of the bivium.

There are five small calcareous teeth. The integument is thin but fairly hard.

The animal has a remarkably large calcareous ring, which is half the length of the body. It consists of ten pieces, the five radials having posterior bifurcations which are made up of a number of small pieces. Both radials and inter-radials are notched anteriorly. The inter-radial pieces of the ring are not all of the same length (fig. 17).

There is one Polian vesicle, 4 millims. long, and one madreporite. The gonads are attached to the dorsal mesentery. The alimentary canal is much convoluted.

Deposits:—The spicules are numerous and overlapping. They consist of tables only. These are irregular in shape, mostly triangular or polygonal, and have from five to a dozen holes. The spire consists of two upright rods which join at the top and terminate in one or two blunt points (figs. 18–20).

As in the two previous species, the genus of this form, although probably *Thyone*, cannot be decided with certainty because of the absence of the tentacles.

Phyllophorus cebuensis (Semper)—Plate II., figs. 22–24.

Thyonidium cebuense, Semper (2), 1868. See also Théel (7).

One specimen from Gulf of Manaar (Stn. II.), 8–9 fathoms (see Note, p. 205).

Length, 22 millims., and breadth, 13 millims.

Colour in spirit:—Brown epidermis covering a white skin.

The mouth is slightly dorsal, so that the trivium is a little longer than the bivium.

In the middle of the body the pedicels are irregularly scattered, being more numerous on the trivium than on the bivium. At each end of the body, however, the pedicels are arranged in five double rows.

There are five small anal teeth.

The calcareous ring agrees with Semper's description. Each of the radials has four anterior processes, and also two posterior prolongations, each of which is made up of four small pieces. The inter-radials are simple (fig. 24).

Deposits:—Numerous tables of one kind only. Each table has a central hole surrounded by about eight slightly smaller holes. The spire is tall and massive, and consists of four upright rods, the adjacent ones being connected by four or five bars.

The top of the spire is hemispherical and is covered by numerous spines (figs. 22 and 23).

The Ceylon specimen agrees very closely with SEMPER'S description. Unfortunately that author does not give any satisfactory account or figures of the spicules. THÉEL found amongst the "Challenger" Holothurians one which he believed to be identical with SEMPER'S species. The deposits in the "Challenger" specimen were of two* kinds and differed considerably from those of the Ceylon specimen (see THÉEL (7)). Seeing that there is this difference in the deposits, the "Challenger" specimen and the Ceylon specimen cannot be identical. And yet the Ceylon specimen agrees very closely with SEMPER'S original description. On the other hand, THÉEL expresses some doubt as to the identity of the "Challenger" specimen with SEMPER'S species. Consequently I feel justified in assigning the Ceylon specimen to SEMPER'S species; and I suggest that the "Challenger" specimen be placed as a variety of the species, which might be named var. *théeli.*

Distribution :—Philippines, Ceylon.

Actinocucumis donnani, n. sp.—Plate II., figs. 25–30.

One specimen, from deep water off Galle (Stn. XLI.).

It is 15 millims. long, and 9 millims. broad at the widest portion of the body.

The colour of the spirit specimen is white.

The body is in a contracted condition, so that the exact arrangement of the pedicels is not very easy to determine. There appear to be, however, five series of pedicels, each series consisting of four or five fairly straight rows. The dorsal rows are more irregular than the ventral ones. Owing to the width of each of the five series, the interambulacral spaces are very narrow. The pedicels have well-developed sucking discs, and in the preserved specimen are very short and distinctly cylindrical. Amongst the pedicels of both the dorsal and ventral surface there are scattered a few papillæ, which are easily distinguished from the pedicels, because of their greater length, their shape, and their delicate appearance.

There are no anal teeth.

Deposits :—These are very thinly scattered, and consist of small oval perforated plates (figs. 26–28). In the pedicels there are numerous small slightly branched bodies similar to those described by THÉEL as "incomplete rosettes" (figs. 29 and 30). The pedicels have well-developed terminal plates.

The calcareous ring is comparatively large, being 8 millims. long. Each of the five radials is composed of two separate pieces, both of which are prolonged posteriorly. The inter-radials are five in number. They do not extend so far anteriorly as the radials, neither have they any posterior prolongations. The radials and inter-radials are made up of a number of small pieces (fig. 25).

* SEMPER'S species evidently had only one kind of table.

There is one large Polian vesicle, 4 millims. long, and a single stone canal.

The gonads are present only on the right side of the dorsal mesentery.

Although the tentacles are not present, I have decided to place this specimen in the genus *Actinocucumis*, because of the arrangement of the pedicels, and also because of the presence of papillæ.

Colochirus quadrangularis, Lesson.

Colochirus cœruleus, Semper (2), 1868. See also Théel (7).

Four specimens from South of Adam's Bridge (Stn. LIV.).

Lengths, 75 millims., 60 millims., 30 millims., and 40 millims.

These specimens agree well with Théel's description.

Colour in spirit :—Yellow and dark brown, with a very faint tinge of violet.

Distribution :—Philippines, E. Africa, Australia, E. Indies, Ceylon.

Colochirus quadrangularis, var. **mollis**, nov.—Plate II., fig. 21.

One specimen from South of Thanni-Kodi, Adam's Bridge (Stn. LIV.), 8½ fathoms. Length 100 millims.

This differs from *Colochirus quadrangularis* in the texture of the body wall. Instead of being very hard, thick, and rough, as in *Col. quadrangularis*, the skin is soft, thin, and comparatively smooth.

Although this specimen is larger than any of those of *Col. quadrangularis* in the collection, yet the papillæ at the four angles of the body are much smaller comparatively.

The colour of the animal also differs from that of the Ceylon specimens of *Col. quadrangularis*. The following is the account of the colour of the living animal, as noted by Professor Herdman :—

"Colour of body a uniform orange, slightly mottled with a paler tint. The crown of tentacles are mottled yellow on a dark brown ground. The region between the five valves at the base of the tentacles is white." Plate II., fig. 21, is from a drawing in Professor Herdman's notes showing the living animal with tentacles expanded.

I think it advisable to call this specimen a new variety of *Col. quadrangularis*, with which it agrees in other characters.

Colochirus doliolum (Pallas).

Actinia doliolum, Pallas, 1766. **Colochirus australis**, Ludwig (9), 1875. Also Théel (7).

Two specimens from South of Adam's Bridge (Stn. LIV.).

Lengths, 20 millims. and 8 millims.

The larger of these specimens agrees very closely with the descriptions of this species, both in the form of the body and also in the nature of the deposits.

The smaller specimen is evidently of the same species, although its small size and its contracted condition prevent me from verifying all the characters in detail.

This species is new to the Ceylon fauna.

Distribution :—Australia, Ceylon.

Colochirus, sp. (?).

Navakaddua Paar (Stn. LXVIII.), 8–18½ fathoms.

This specimen, which is only 7 millims. long, is too small to identify with any certainty. The general external form of the body, together with the nature of the deposits, leads to the conclusion that it is a *Colochirus*.

The body is quadrangular, having the pedicels on the trivium arranged in three double rows. The body tapers at the posterior end.

Deposits :—These consist of reticulate cups, knobbed buttons, and very large perforated plates.

The specimen is evidently young, but does not obviously fall into any of the other species. It is perhaps nearest to *C. doliolum*, but differs in the tapering posterior extremity.

Havelockia herdmani, n. gen. et sp.—Plate II., figs. 31–35.

One specimen from South of Adam's Bridge (Stn. LIV.), 4–40 fathoms.

Length 45 millims. and greatest breadth 17 millims.

The colour of the spirit specimen is brown with a dark streak of violet along the middle of each side.

The body is indistinctly quadrangular, but pentagonal at each end. The mouth is surrounded by five valves and there are five smaller valves around the anus.

The ambulacral appendages consist of pedicels and papillæ. The pedicels are confined to the ventral surface. They are arranged in three series traversing the entire length of the ventral surface from the mouth to the anus. The central series consists of about eight rows of pedicels, and the other two series are not quite so broad. There are also a few scattered pedicels on the ventral interambulacra. The papillæ are absent on the ventral surface, but are scattered irregularly over the remaining three sides, being most thinly scattered along the middle of the sides (fig. 31). The anus is devoid of calcareous teeth.

The tentacles are not present. They have evidently been thrown off.

Deposits :—These consist entirely of numerous tables, which are of two kinds :—

(1) Those scattered throughout the skin generally.—These are small tables, generally having four large holes and four smaller peripheral holes (fig. 32). The number of the holes, however, varies. The spire is made up of two rods which unite at the top and give off generally four short projections (fig. 33).

(2) Tables in the papillæ.—These are much larger than those of the general integument, and are not regular in shape (fig. 34). They have a similar spire to the smaller tables.

The calcareous ring is not very large, being 8 millims. long and 8 millims. broad. It consists of ten pieces. The five radials are slightly notched anteriorly and are bifurcated posteriorly. The posterior prolongations are composed of a number of smaller pieces. The five inter-radials have no posterior prolongations and are pointed anteriorly. Retractor muscles are present (fig. 35).

There is one Polian vesicle, and no stone canal can be seen. The gonads are present in two bunches—one on each side of the dorsal mesentery. The right respiratory tree is larger than the left. There are no Cuvierian organs.

The presence of posterior prolongations to the calcareous ring, together with the possession of retractors, prove that this form is a Dendrochirote, although the tentacles are absent.

It possesses a certain external resemblance to the genus *Colochirus* in the general shape of the body; in the arrangement of the pedicels in three rows on the ventral surface, and of the papillæ on the dorsal surface; and also in the presence of the five valves around the mouth.

But there is no doubt that the species is *not* a *Colochirus*, because:—

(1) The pedicels extend the *entire* length of the ventral surface (in *Colochirus* they are absent at both ends).

(2) The deposits, which consist entirely of tables, are different from those of the genus *Colochirus*.

(3) The calcareous ring has posterior prolongations.

Neither does this species agree with any other genus of the Dendrochirotæ, so that I feel compelled to form for it a new genus which may be defined as follows:—

Havelockia,* n. gen.

The body is indistinctly quadrangular, and the mouth and anus are each surrounded by five valves. The ambulacral appendages consist of (1) pedicels, arranged in three series on the ventral surface, each series extending from the mouth to the anus, and consisting of several rows of pedicels; (2) papillæ, which are scattered irregularly over the bivium.

The deposits consist entirely of tables. Each table has a spire consisting of two rods, which are surmounted by three or four short blunt projections.

The calcareous ring has posterior radial bifurcations.

* Named after the SS. "Lady Havelock," from which Professor HERDMAN worked during the greater part of his expedition in the seas round Ceylon.

Family: ASPIDOCHIROTÆ.

Actinopyga mauritiana (Quoy and Gaimard).

> **Holothuria mauritiana**, Q. & G., 1833. **Mülleria varians**, Selenka, 1867. **Mülleria mauritiana**, Semper, 1868. See also Théel (7).

One specimen from the lagoon inside the Reef, Galle. Length, 140 millims.

The specimen possesses most of the characters of the species. There are, however, no white rings around the dorsal papillæ.

On the ventral surface there is a well-marked white symmetrical patch which is quite distinct from the brown dorsal surface.

In Théel's description this marked difference in colouring is not emphasised, and he leads one to believe that the brown on the dorsal surface is *gradually* changed for the lighter colour of the ventral surface. It is interesting to note that the specimens of this species, which Professor Herdman kindly examined for me, with Professor Jeffrey Bell, in the British Museum, showed transitions between those described by Théel and the striking condition seen in the Ceylon specimen. So that it is evident that the nature of the colouring of the ventral surface, with relation to its distinctness from that of the dorsal surface, is susceptible of considerable variation in the species.

The pedicels of the ventral surface are capable of great extension, and have white sucking discs. The white integument of the ventral surface is closely covered with small but conspicuous pores, suggesting the singular appearance of a white colony of the Compound Ascidian *Leptoclinum*.

Distribution:—Indian Ocean from E. Africa to East Indies; Funafuti, in the central Pacific.

Actinopyga serratidens, n. sp.—Plate III., figs. 36–41.

One specimen from the lagoon inside the Reef, Galle. Length, 180 millims.

Colour of spirit specimen is brownish-black.

The tentacles are partly retracted, so that it is difficult to ascertain their exact number. There are, however, 20 tentacular ampullæ, so that there will also be 20 tentacles. The colour of the tentacles is dark brown.

The mouth is ventral, and is surrounded by a distinct brim formed by a folding of the integument. The anus is surrounded by five distinctly serrated teeth, each tooth being 3 millims. in length.

The pedicels are irregularly scattered over the ventral surface, showing no arrangement in rows. They are distinctly cylindrical with well-developed sucking discs. The dorsal surface is covered with papillæ, which are more slender than the pedicels. They appear, in many cases, to have small rudimentary terminal discs, so that it is difficult to distinguish them from true pedicels. Both pedicels and papillæ are of the same colour as the general integument, so that they are not very conspicuous.

The specimen has a typical Aspidochirote calcareous ring.

There is one large Polian vesicle, 30 millims. long, and there are about eight stone canals attached to the dorsal mesentery.

The right respiratory tree is much larger than the left. This form also possesses Cuvierian organs.

The general body wall is very thick, about 5 millims. This is probably, to a certain extent, due to contraction.

Deposits :—Not very thickly scattered. They consist typically of a short straight rod with dichotomising ends (figs. 36–38). Sometimes the spicules are dumb-bell shaped or bone-shaped (figs. 39–41). The pedicels have no supporting rods, nor spicules of any kind, except a terminal plate. The character from which I have taken the specific name, viz., the serration of the anal teeth, is a very distinct one, and would serve alone to distinguish the species.

Holothuria kurti, Ludwig.—Plate III.; figs. 42–45.

H. lamperti, Sluiter, 1889 **(10)**, **(15)**.

One specimen from Pearl Banks, Gulf of Manaar (Stn. LXVI.); three specimens from south of Adam's Bridge (Stn LIV.), 4 to 40 fathoms.

The lengths of the specimens vary from 25 millims. to 40 millims. The specimens agree with Sluiter's description.

Deposits :—The spicules agree in the main with Sluiter's description. There are two kinds of table—round tables and cross-shaped tables, each kind being surmounted by a comparatively tall tower ending in numerous teeth. The size of the tables varies very much. In the papillæ there are also knobbed "buttons," having six or seven pairs of holes as figured by Sluiter. In some of the specimens there are also some smooth buttons scattered about in the skin, having six or seven pairs of holes.

So far as I can determine, the cross-shaped tables are derived from the round tables by pieces having become broken or dissolved away; so that there is really only originally the one kind of table, the cross-shaped form being only a stage in the dissolution of the round form. I found all stages between the two extremes (see figs. 42–45). Consequently, in a young specimen, we should expect the round form to predominate, and as the animal grows bigger, the cross-shaped form of table would increase in number.

This species is now recorded from Ceylon for the first time.

Distribution :—Java, Ceylon.

Holothuria monacaria (Lesson).

Psolus monacaria, Lesson, 1830. See also Théel (7).

One specimen from Aripu reef (March 18th); and one specimen from northern part of Gulf of Manaar (Stn. LIV.), 4 to 40 fathoms.

Lengths, 75 millims. and 38 millims.

The colour in alcohol is brown, with yellow rings around the papillæ. The pedicels are light brown. The tentacles are yellow.

There are papillæ on the dorsal surface, and pedicels on the ventral surface. At the anterior third of the body the papillæ are arranged in five distinct longitudinal rows. In the posterior two-thirds they are more irregular. The pedicels are also arranged in five more or less irregular rows on the anterior third of the ventral surface, and they are more irregularly scattered over the remaining two-thirds.

The mouth is surrounded by a crown of small papillæ.

Deposits:—These agree with those figured by Théel. Although the Ceylon specimens differ in the arrangement of the pedicels and papillæ from Théel's description of *H. monacaria*, yet I think there is no doubt as to their identity with that species.

Distribution:—Indian Ocean, E. Indies, Australia, Pacific Islands.

Holothuria vagabunda, Selenka.

Stichopus (sub-genus **Gymnochirota**) **leucospilota**, Brandt, 1835. See also Selenka (1), Semper (2), Théel (7).

One specimen from the lagoon inside the Reef, Galle. Length, 180 millims.

This specimen agrees with the descriptions of the species.

Distribution:—E. Africa, Indian Ocean, E. Indies, Hong Kong, Pacific Islands.

Holothuria tenuissima, Semper (2). See also Théel (7).

Two specimens from the lagoon inside the Reef, Galle; one specimen from off Negombo (Stn. I.). Also elsewhere in Gulf of Manaar (Stn. IX.), 7 fathoms.

Lengths of two specimens, which were in a very contracted condition, 130 millims. Length of other specimen, 80 millims.

The specimens agree with the descriptions of the species.

The pedicels, which are scattered irregularly all over the body, are more numerous on the ventral surface. The anus is slightly pentagonal, with a group of papillæ at each angle.

The smallest of the specimens is evidently a young form, but it agrees with the larger specimens in most respects. Its body wall is very thin, doubtless owing to its immature condition. There is also a small circular area around the mouth—about 15 millims. in diameter—where the skin is much thinner and devoid of pedicels.

These specimens also agree with the descriptions of *H. vitiensis*, *H. kœllikeri*, and *H. clemens*, and it is very probable, as THÉEL suggests, that they all belong to one and the same species, which is susceptible of great variation.

Distribution :—Indo-Pacific region.

Holothuria marmorata (JÄGER).

Bohadschia marmorata, JÄGER, 1833. See also THÉEL (7).

One specimen from the lagoon inside the Reef, Galle. The species was also, Professor HERDMAN'S notes show, found at Trincomalee. Length, 240 millims.

Colour in alcohol.—The ventral surface is a dark brown with a violet tinge. The dorsal surface is lighter, especially at the posterior end. The colour on the dorsal surface is not uniform, but there is not the striped appearance that is typical of the species.

The pedicels are scattered all over the body, the skin being considerably darker at the base of each pedicel.

The anus is pentagonal and is surrounded by five groups of papillæ, each group consisting of five papillæ.

The deposits are typical.

This specimen is very similar in most respects to *H. tenuissima*. It differs slightly from the latter in the nature of the deposits, the spicules not dichotomising to such an extent but having rather the appearance of perforated granules. The papillæ around the anus also are more prominent than in *H. tenuissima*. Nevertheless, in spite of these differences, it is highly probable, as THÉEL suggests, that *H. marmorata*, *H. tenuissima*, together with other allied forms are only, at the most, varieties of the one species.

Distribution :—Indo-Pacific region generally.

Holothuria atra, JÄGER.

H. (sub-genus **Microthele**) **affinis**, BRANDT, 1835. See also THÉEL (7).

There are seven specimens, most of them being very much contracted. This species was found at various localities round Ceylon—in the Gulf of Manaar, at Trincomalee, and at Galle.

The colour in alcohol is dark brown on the dorsal surface and lighter on the ventral. Professor HERDMAN'S notes state that at least some of the specimens when alive were quite black above, but of a pink colour below.

The dorsal papillæ are smaller than the ventral pedicels.

The deposits are typical. The discs of the tables are smooth and have no peripheral perforations.

The gonads are absent in all specimens. Cuvierian organs also are not present in any of the specimens, so that it is highly probable that this species does not possess Cuvierian organs.

In all the specimens the spicules are similar in density and form.

Although the tentacles are retracted in most of the specimens, there appear to be 20 tentacular ampullæ in each specimen.

In every specimen the left respiratory tree is much larger than the right, the former extending to the extreme anterior end of the body.

Appended is a table showing some of the variations noticed in the seven specimens examined :—

Locality.	Length.	Greatest breadth.	Polian vesicles.		Stone canals.	Longest tentacular ampullæ.
			Number.	Greatest length.		
	millims.	millims.		millims.		millims.
Pearl Banks, off Aripu .	125	23	4	22	19	25
Trincomalee	155	38	—	—	17	15
Off Periya Paar	185	34	1	14	11	15
Reef Galle	155	34	5	12	12	14
Off Galle	105	28	2	18	9	10
G. of Manaar.	75	30	1	15	27	7
S.W. Cheval Paar . . .	135	35	1	9	13	14

Holothuria gallensis, n. sp.—Plate III., figs. 46–50.

Three specimens from the lagoon inside the Reef, Galle.*

Lengths, 230 millims., 150 millims., and 70 millims.

The tentacles are not present in any of the specimens; but there are 20 tentacular ampullæ, so that although the tentacles themselves are absent, we may safely conclude that the animal had 20 tentacles.

The body is divided into a distinct dorsal and ventral surface. The dorsal surface is black and is crossed by numerous conspicuous transverse yellow streaks (Plate III., fig. 46). The pattern, however, varies somewhat in different specimens, the yellow streaks in the smallest not being very evident. On the ventral surface the colour is light yellow, mottled all over with small dark grey patches.

Ambulacral appendages :—On the dorsal surface there are small papillæ, which are very thinly scattered and inconspicuous. The appendages on the ventral surface are much more numerous, and are easily distinguished because each one is generally situated in the centre of a dark grey patch. These appendages, which are mostly retracted, are evidently true pedicels. They have only a small terminal plate, and they are strengthened by spicules similar to those found in the general integument.

* This species was, evidently, from Professor HERDMAN'S notes, also found in China Bay, Trincomalee.

The mouth is ventral, and is surrounded by a small brim of papillæ. There are no anal teeth.

Deposits consist of two kinds :—

(1.) Closely packed tables having, in the older specimens, a large central hole and about eight smaller peripheral holes. This is surmounted by a spire having four upright bars. There is one tier of horizontal bars. The spire terminates in a round top having numerous spines (figs. 47 and 49).

(2.) Knobbed "buttons," having generally three pairs of holes (fig. 48).

The tables in the smallest specimen are much better developed than in the older specimens. The buttons in the youngest animal have about five pairs of holes, whilst those in the older specimens invariably have only three (see figs. 49 and 50). These facts incidentally bear out MITSUKURI'S (14) statement with regard to the changes in growth of spicules.

The calcareous ring is simple, like that of a typical Aspidochirote.

There are two long Polian vesicles in the specimen dissected. No stone canals are seen.

It is noteworthy that although this species has never been previously described, it is evidently a fairly common form on the Ceylon coast. It is one of the species used as "Trepang," and has apparently not been distinguished from some of the other large species of *Holothuria*. Possibly, on account of its mottled appearance, it has been confused with *H. marmorata*, from which, however, it differs in many respects. The yellow transverse stripes (see Plate III., fig. 46) on the dorsal surface and the mottling on the ventral are very characteristic.

Stichopus chloronotus, BRANDT.

St. cylindricus, HAACKE, 1880. See also THÉEL (7).

One specimen from East Cheval paar, $5\frac{1}{2}$ fathoms. Length, 140 millims.

This specimen agrees very closely with THÉEL'S description. There are, however, only 19 tentacles in the Ceylon specimen.

There are four longitudinal series of protuberances on the dorsum, the two dorsal series being double, while the two ventral series have a more or less zig-zag arrangement.

The pedicels are irregularly distributed over the ventral surface. Professor HERDMAN'S notes state that the body was of a dark green colour when alive.

Distribution :—Pacific Islands, Indian Ocean from E. Africa to Malay Peninsula.

Stichopus chloronotus, var. **fuscus**, nov.

Three specimens from Pearl Banks, Gulf of Manaar (Stn. LVIII.), 9–26 fathoms. Lengths, 170 millims., 200 millims., and 110 millims.

The mouth is surrounded by a crown of papillæ.

The number of tentacles is different in each specimen. There are 18 in the largest, 14 in the next, and 16 in the smallest. In the two latter it is highly probable that some tentacles are retracted.

There are four irregular rows of protuberances—one row along each side of the body. In this it differs from *Stichopus chloronotus*, which has two *double* rows on the dorsal surface. The pedicels are irregularly scattered on the ventral surface, showing a slight indication of forming three rows.

The deposits agree with those of *Stichopus chloronotus*, except that the C-shaped deposits are very rare indeed.

These two spirit specimens are very much darker in colour than the spirit specimen of *St. chloronotus*, the former being a dark chocolate-brown.

I consider that the differences between these specimens and *St. chloronotus* justify the formation of a new variety.

Stichopus variegatus, Semper.

St. naso, Haacke, 1880. See Semper (2), Théel (7).

Two specimens from S.W. of Periya Paar (Stn. LV.), 11–24 fathoms.

Lengths, 85 millims. and 75 millims.

The specimens are very much contracted and in a poor state of preservation.

The tentacles in one specimen are dark brown and in the other yellow. I am unable to count them owing to their poor state of preservation, but in other respects the specimens agree with Semper's description.

The pedicels are arranged in three series on the ventral surface, each series having about four rows.

Distribution :—Indo-Pacific, Mauritius, E. Indies, Ceylon.

Note.—While this Report was in the press another specimen (from Gulf of Manaar, February, 1902) was found which is nearly related to *Phyllophorus cebuensis*, but may be distinct, as it differs in the deposits, having additional rosette-shaped buttons.

REPORT

ON THE

CEPHALOCHORDA

COLLECTED BY

PROFESSOR HERDMAN, AT CEYLON, IN 1902.

BY

WALTER M. TATTERSALL, B.Sc.,

SCHOLAR IN ZOOLOGY OF VICTORIA UNIVERSITY.

[WITH ONE PLATE.]

INTRODUCTION.

THE collection of Acraniates made by Professor HERDMAN during his recent expedition to Ceylon was kindly placed in my hands for examination during my year of post-graduate research work at University College, Liverpool. I here wish to express my thanks to Professor HERDMAN for giving me the opportunity of examining this most interesting series, and also for the ever-willing and kindly help which he has given me in the discussion of literature and other difficulties. The collection was a most interesting one, and comprised in all 98 specimens, 92 obtained by dredging and 6 taken in the surface tow-net. They were collected for the most part in the shallower waters round Ceylon between February 1st and April 1st, 1902; and as the specimens belong to no fewer than seven usually recognised species, they serve to indicate the richness of the Acraniate fauna of the Ceylon seas.

The previous knowledge of the Cephalochorda of the Ceylon coast is very scanty. ANDREWS (3),* in Appendix I. to his paper on *Asymmetron*, notes *Branchiostoma lanceolatum* as doubtfully known to him from Ceylon. In Appendix II. to the same paper, in which the Lancelets of the Smithsonian Museum are enumerated, bottle 34,003 is labelled—"Amphioxus sp., 5 soft specimens from Ceylon." Miss KIRKALDY (6) examined these specimens later and found that four belonged to a new species, which she named *A. cingalense*. The other one she placed provisionally and doubtfully in

* The numbers in brackets refer to the List of Literature cited on p. 226.

the species *B. belcheri*. Thus, at most, three species, represented by six specimens, were then known from Ceylon; and during the course of Miss KIRKALDY'S work she received four more specimens from Ceylon which proved to be *A. cingalense*.

The present collection, therefore, is by far the largest yet made known from Ceylon. The species include—*Branchiostoma lanceolatum*, *B. lanceolatum*, var. *belcheri*, *Asymmetron* (*Heteropleuron*) *cingalense*, *Asymmetron* (*Heteropleuron*) *cultellum*, *Branchiostoma* (*Dolichorhynchus*) *indicum*, *Branchiostoma pelagicum* (the six tow-net specimens), and *B. californiense* (?).

The specimens were preserved, some in alcohol and others in formol, and the latter were in a most excellent state of preservation, being rendered slightly transparent, while the exact outlines and shapes of the fins were splendidly maintained. The spirit specimens were not nearly so good, so far as regards the external appearance, although better in some respects for histological examination.

The group Cephalochorda has a single family, Branchiostomatidæ, containing two genera, *Branchiostoma* and *Asymmetron*. In discussing the Ceylon species, I shall follow the classification and nomenclature given in my recent paper published by the Liverpool Biological Society (**10**).

GENUS I.—BRANCHIOSTOMA, COSTA.

Metapleural folds end symmetrically just behind the anus, separated by the ventral fin; gonads disposed in two lateral series; ventral fin with fin chambers which may or may not have fin rays; oral cirri when present have sense-papillæ; atrial chamber prolonged behind the atriopore in a single (right) cæcum.

Branchiostoma lanceolatum (PALLAS)—Plate I., figs. 1, 2.

Limax lanceolatus, PALLAS, 1776.

Branchiostoma lubricum, COSTA, 1834 and 1843.

Amphioxus lanceolatus, YARRELL, 1836, and others.

Branchiostoma lanceolatum, GRAY, 1851, and others.

This species, which has only before been doubtfully recorded from Ceylon (ANDREWS (**3**)), was represented by ten specimens in the collection.

They were from the following localities:—

(1.) Galle (Stn. XXXV.), February 14th, 7 fathoms. Two specimens.
(2.) Ten miles North of Cheval Paar (Stn. LIII.), March 6th, $7\frac{1}{2}$ fathoms. Three specimens.
(3.) Periya Paar Kerrai (Stn. LIII.), March 4th, $7\frac{1}{2}$ fathoms. One specimen.
(4.) Off Watering Point, Galle (Stn. XXXVIII.), February 17th, 9 fathoms. Four specimens.

The various measurements of these ten specimens will be found in Table I. at the end of the report. The greatest length recorded is 41 millims. and the least 26 millims., the average for the ten being 34·5 millims., considerably lower than Kirkaldy's average figures (6).

Of the ten, four were males and two females, the males being of greater average length, while the sex of the remaining four could not be determined. These latter were those found off Watering Point, Galle, and one of them had a double row of exceedingly minute gonads as if just developing, while the other three had none whatever. This possibly gives us a clue to the spawning time of the species in tropical seas. It will be noticed from Table I. (p. 222) that these four and the two first males from Galle were caught at least a fortnight before the other specimens, and their gonads were in various stages of development. Those caught 14 to 20 days later had larger and almost mature gonads, in spite of the fact that one at least was considerably smaller than those caught at the earlier date. This would give us the middle of March to the beginning of April as the probable spawning time of these Ceylon specimens of *B. lanceolatum*.

In those specimens in which gonads were present they formed a double series of pouches, generally equal in number on the two sides. The average number present was 23 on each side, rather below Kirkaldy's average (6). The Galle specimens, preserved in formol, are of a pink tint and almost transparent; the rest, which are in spirit, vary in colour from fawn to a deep orange and are much more opaque.

The number of myotomes varied between 59–61, not a great range; but the arrangement of the somites varied considerably, as Table I. shows. The preatrioporal myotomes ranged from 35 to 37, the average being 36. This is rather more than Kirkaldy's figures show, but Andrews (3) records several with 37 and one with 38 preatrioporal myotomes. The preanal myotomes varied between 11 and 14, the average being 13. Nos. III. and V. on Table I. show only 11 preanal myotomes. This is the lowest number recorded for the species, but repeated countings have confirmed the figure. This is one more instance of the great variability in the arrangement of the myotomes within a given total. The postanal myotomes vary between 11 and 13, the usual figures for the species.

The fins of these specimens agree closely with Kirkaldy's figures, especially the caudal fin (fig. 1), which is remarkably constant throughout.

The ventral fin has a double series of fin rays, in fin chambers, extending its whole length. The ventral fin chambers are prolonged postanally for a considerable length (fig. 1), and in II., Table I., there certainly is a postanal extension of the fin rays—in spite of Lankester's and Benham's statements to the contrary. The fin rays appear to be better developed both in the dorsal and ventral fins in the older specimens.

The relation of the anterior ends of the notochord and dorsal fin is in all cases as Kirkaldy figures it, *i.e.* the dorsal fin ends conterminously with the myotomes, while the notochord is prolonged further forwards a little way. The nervous system, however, does not always project beyond the dorsal fin, as in one or two of the

Ceylon specimens they ended together. The "Räderorgan" is well developed in these specimens, and has a median dorsal lobe and five or six large lateral lobes on each side. In one specimen examined one of the lateral lobes was branched.

No. IV., Table I., showed an unusual dark oval patch anterior to the dorsal fin and just dorsal to the notochord (fig. 2). No structure could be made out, but when cleared up in clove oil the dark patch was found to have a ventral extension on the left side. Unfortunately the specimen had not been preserved specially for histological work, and so the sections that were made showed no additional structure, the only appearance being a large patch dorsally and to the left side of the notochord, which stained deeply with hæmatoxylin.

Branchiostoma lanceolatum, var. **belcheri**, GRAY.—Plate I., fig. 3.

> **Branchiostoma belcheri**, GRAY, 1847, and others.
>
> **Amphioxus belcheri**, KIRKALDY.

This variety, which is usually regarded as a distinct species, formed the greater part of the collection, being a total of 58 specimens out of 98. It has only been previously recorded from the neighbourhood of Ceylon by THURSTON* in 1890, who mentions the species being dredged 30 miles south of Madras in 1887–88; in fact it has been found but sparingly anywhere before. This large collection, therefore, has offered opportunity for a closer examination of this form, which, I think, has shown that we cannot any longer regard it as specifically distinct from *B. lanceolatum*. This matter is dealt with in detail in my recent paper in the 'Transactions of the Liverpool Biological Society,' where I have given tables compiled from the observations of different workers, showing how the characters of the one form fade gradually into those of the other.

The Ceylon specimens were found in the following localities:—

(1.) Ten miles north of Cheval Paar, June 3rd, 1902, $7\frac{1}{2}$ fathoms. Seven specimens.

(2.) Outside Karativo Paar (Stn. LVIII.), March 10th, 10 fathoms. Two specimens.

(3.) Off Karkopani (Stn. IV.), February 2nd, 8 fathoms. Two specimens.

(4.) Off Mutwal Island (Stn. LXVII.), March 19th, 14 fathoms. Three specimens.

(5.) Periya Paar Kerrai (Stn. L.), $7\frac{1}{2}$ fathoms, sand, March 4th. Four specimens.

(6.) Off Chilaw Paar (Stn. LXIX.), 10 fathoms, March 20th. Six specimens.

(7.) West Cheval Paar (Stn. LXV.), March 18th, $7\frac{1}{2}$ fathoms. Nine specimens.

(8.) Near Periya Paar (Stn. LXII.), March 13th, in Foraminiferal sand, 11 fathoms. Eleven specimens.

(9.) South-west of Cheval Paar (Stn. XLIX.), March 1st, $8\frac{1}{2}$ fathoms. Fourteen specimens.

* Madras Government Museum, Bulletin No. 1, p. 26.

The colour of these specimens varied somewhat. Those found outside Karativo Paar and off Mutwal Island were a deep orange colour; those found near Periya Paar and south-west of Cheval Paar were pure white, while those from west of Cheval Paar, on March 18th, were of a purplish-pink colour.

The measurements of these specimens are recorded in Table II., pp. 223, 224.

In length they vary considerably, from 25 millims. to 56 millims., the average being 41·5 millims. One specimen, XXIV., Table II., was much damaged, all the postanal and one half of the part between the anus and atriopore being missing. The remainder measured, however, 53 millims., giving us 70 millims. as the probable length of the whole animal—quite a giant amongst Acraniates.

Out of the 58 specimens, 28 were females, and only 10 were proved to be males; the sex of 20 could not be determined owing to the absence of gonads.

The size of the animal appears to bear a relation to the period of sexual maturity, which is contrary to what FORSTER-COOPER (8) found for *Asymmetron lucayanum*. Here it is the largest that have well-developed gonads and the smallest that are immature. All the immature ones were under 36 millims. in length. This would show that at a length of about 40 millims. the form *B. belcheri* becomes adult. All these specimens, it may be noted, were caught at about the same time of the year and in much the same locality, and there can be no question of some being taken at the spawning season and others not. It must be that the larger ones only were adult and the others immature. In the spirit specimens the gonads could not, in all cases, be counted, owing to the opacity of the metapleural folds, but in the formol-preserved specimens they were determined with ease.

In all the specimens counted, except one, the gonads of the right side were more numerous than those of the left, the average being 25 right to 23 left. The lowest number was 15 (some had evidently been already shed), and the highest was 30.

A few specimens had peculiar gonads. No. XX., Table II., had unusually small gonads, though itself a large specimen; while No. XXVI., Table II., showed a curious arrangement, some of the gonads being quite small and alternating with large mature ones. Late in March and early in April seems to be about the spawning time of this variety in the Gulf of Manaar.

The variation in the myotomes is striking, not so much in the total number as in the distribution. The total myotomes ranged from 63 to 66, 64 being the average. The commonest formula was 38, 17, 9, which agrees closely with KIRKALDY'S figures (6), and differs considerably from GÜNTHER'S (1). The number of preatrioporal myotomes varied from 36 to 39, by far the greater number, 34 out of 58, having 38. The number of preanal myotomes varied from 16 to 18, 17 being the average; while the postanal myotomes numbered 8 to 10, 9 being the commonest number.

From these figures it will be seen that *B. belcheri* from Ceylon agrees closely with those from Australia examined by KIRKALDY (6), and the two are undoubtedly the same species, and not distinct forms as Miss KIRKALDY suggested.

The fins of *B. belcheri* are fairly constant (fig. 3) and agree with KIRKALDY'S figure, except that she figures the rostral fin proportionately rather small. In ours it is well developed, rather long, and more pointed than her figure shows. In some specimens it is so well developed as to suggest a transition from *B. lanceolatus* to *B. indicus*. The ventral fin has fin chambers and a double series of ventral fin rays.

The extent of development of fin rays appears to vary with the age of the animal.

In the smallest specimens no ventral or dorsal fin rays are present. In those a little larger, dorsal fin rays appear, the ventral ones being still undeveloped; while in those a little larger again, both series are seen.

The fin chambers are not prolonged postanally. The nervous system and the dorsal fin end conterminously, while the notochord is prolonged a little way in front of both.

A fæcal pellet adhering to the anus of No. LIII., Table II., on examination was found to be rich in skeletons of diatoms, which gives an indication of the food.

The intertentacular membrane between the oral cirri of *B. belcheri* is low, and the sensory-papillæ are very large and prominent.

The "Räderorgan" is exceptionally well developed, there being a large median dorsal lobe and six lateral lobes on each side. The liver is exceptionally large and extends for three-quarters of the length of the pharynx on the right side.

Branchiostoma pelagicum, GÜNTHER (1889).—Plate I., fig. 16.

The six specimens taken in the tow-net were found to be poorly preserved, and being also extremely small, their identification is a matter of some difficulty. I think, however, that there can be little doubt that they are *B. pelagicum*, GÜNTHER (2).

Of the six, one was taken in a coarse tow-net in the Indian Ocean, to the south-east of Sokotra, about halfway between Perim and the Maldives, on January 16th, 1902; while the other five were taken with a fine net on January 20th, 1902, in the Indian Ocean, after passing Minikoy Atoll, and therefore between the Maldives and the Gulf of Manaar. There is therefore no doubt as to their all being truly pelagic forms.

The largest measured 8·5 millims., the smallest 4·5 millims., the average for the six being 6 millims. The greatest breadth of the largest specimen was 1 millim. All six are undoubtedly the same species, and agree in detail as far as can be made out.

The notochord extends from the extreme tip of the snout to the end of the tail, projecting some little way beyond the myotomes.

The nervous system stops short of the end of the notochord at both extremities. The eye spot is very large and conspicuous, far larger in proportion to the size of the animal than in the other species. This, in itself, is suggestive of a pelagic life. All along the nerve cord, at regular intervals, occur groups of five or six large pigment spots (fig. 16). This is a character noted in GÜNTHER'S *B. pelagicum*.

The number of myotomes (as nearly as could be determined from the imperfect preservation) was 65. GÜNTHER'S *B. pelagicum* had 67; while one specimen described by FORSTER-COOPER (8) had 60. This specimen was 21 millims. long, twice as long as GÜNTHER'S.

There was no trace of oral cirri to be seen, nor did FORSTER-COOPER find any in his specimen (8). This then appears to be a true character of the species, and not to be due to any imperfection in preservation. It is, moreover, what might be expected. The oral cirri probably have, as one of their functions, to direct currents of water into the oral hood and so to the mouth and alimentary canal. This is absolutely necessary in an animal which leads a sedentary life. But a pelagic form, by virtue of its mode of life and motion through the water, would cause currents in the right direction, and thus the oral cirri would be rendered unnecessary.

No gonads could be observed in any of the six specimens. They were probably immature. In none were the dorsal, ventral, or caudal fins preserved sufficiently well to indicate, in any way, their shape and size. One specimen had traces of a caudal fin which indicated that it was very well developed.

On the whole, it may be said that in general shape, size, number of myotomes, absence of oral cirri, large size of eye-spot, and pigment spots on the nerve cord, our specimens agree with GÜNTHER'S *B. pelagicum*, and it seems quite safe to refer them to this species.

Branchiostoma indicum (WILLEY).—Plate I., figs. 11–13.

Dolichorhynchus indicus, WILLEY, 1901.

Two specimens, one from Galle (Stn. XXXVI.), in $4\frac{3}{4}$ fathoms, and the other taken off Watering Point (Stn. XXXVIII.) in the same locality, in 9 fathoms, I am disposed to refer to this species, although the absence of some details in WILLEY'S description and the lack of figures render the identification a little uncertain.

Both my specimens have long and well-marked preoral lobes, but the proportional length of the lobes does not appear to be quite as great as in WILLEY'S specimens (fig. 11). Moreover, the preoral lobes of the Ceylon specimens do not appear bent as WILLEY'S figures show; but it may well be that the bending was due to some accident or injury, and that the lobes are not bent in life.

One of our specimens measures 17 millims., and the other 36 millims. The latter is a male, and has 29 right gonads and 25 left. The smaller one has no gonads and is evidently immature. The larger one has a myotome formula of 43, 14, 13—total, 70; while the smaller one has 41, 14, 14—total, 69. Both these formulæ agree closely with WILLEY'S description.

The dorsal fin is low and ends conterminously with the myotomes. Its outline in the large specimens is interrupted by a peculiar wavy break (fig. 12), possibly due to an injury and subsequent healing up. The notochord extends a long way in front of the dorsal fin. The nervous system is overlapped by the dorsal fin, while in WILLEY'S description the arrangement is the reverse of that.

The posterior extension of the notochord past the myotomes is not very great. The ventral fin has fin chambers which are also extended postanally, as in *B. lanceolatum* and *Asymmetron hectori*. In the latter species the chambers extend postanally to the antepenultimate myotome, while here they extend only five myotomes posterior to the anus. The ventral fin rays are double, and are not extended postanally as in *A. hectori*. Willey did not notice the postanal extension of the fin chambers in his specimens. Only the larger specimen here has ventral fin rays, showing again what was noticed under *B. lanceolatum*, var. *belcheri*, that it is only in the larger specimens that the ventral fin rays are well developed.

The caudal fin is here well marked off from the dorsal and ventral fins, there being a well marked supra- and infra-caudal lobe in both specimens (figs. 11 and 13). There are about 35 to 40 oral cirri of the usual type, bearing sense-papillæ. On the whole it seems fairly certain that these two specimens belong to the species *Branchiostoma indicum*. The distribution also favours this conclusion, for the Orissa Coast of India, where the species was found, is not far north of Ceylon.

Branchiostoma californiense (?), J. G. Cooper.—Plate I., figs. 14, 15.

(?) **B. capense**, Gilchrist.

There is one specimen, No. V., Table IV., in the collection the identity of which is a little uncertain. I refer it, with some little hesitation, to *Branchiostoma californiense*, J. Cooper. In another paper (**10**) I have expressed doubt as to the distinctness of *B. californiense* and *B. capense*. Since then Professor Herdman has received from Dr. Gilchrist eight well-preserved specimens of his *B. capense*, and has placed them in my hands for examination. In these I find no trace of an eye-spot. The specimens range from 51 to 63 millims. in length, and the number of myotomes from 74 to 76. The formula varies within 46 to 48, 18 or 19, 9 or 10—47, 19, 9 being the most frequent form. There are 35 pairs of gonads. This formula is so close to that of *B. californiense*, and the two agree so well in proportions and characters of the head, that notwithstanding the absence of an eye-spot I should hesitate to consider the Cape form distinct until further specimens of the Californian species have been examined.

The Ceylon specimen was taken in the Cheval district (Stn. XI.), at 6 fathoms, on February 4th, and was 42 millims. long. It had no gonads and was evidently immature. Its myotome formula was 40, 20, 12—total, 72.

The rostral fin is separated from the dorsal fin by a shallow notch. The dorsal fin is low, and has a series of fin rays. The caudal fin is very slightly marked off from the ventral and dorsal fins and has its infra-caudal lobe slightly the larger and deeper. The ventral fin is very long indeed, and has a series of double fin rays running its whole length. Neither the ventral fin rays nor chambers are prolonged postanally. The metapleura have a symmetrical termination, thus determining the genus to which the specimen belongs.

The oral cirri are long, and number about 30. They bear well-marked sense-papillæ. The "Räderorgan" is of the usual type, and has a median dorsal lobe and two or three lateral lobes on each side.

The notochord projects far in front of the anterior end of the myotomes and projects posteriorly a little way beyond the last myotome. The dorsal fin ends conterminously with the myotomes. The nervous system projects anteriorly beyond the dorsal fin. A well-marked eye-spot is present.

From the above description it will be noticed that this specimen agrees with *B. californiense* in all particulars except in the arrangement of the myotomes.

The total number of myotomes is the same in both, but the preatrioporal part is shorter, and the postanal portion longer in ours than in *B. californiense*. The geographical distribution may, at first sight, be supposed to be against this identification, for the species is only recorded from San Diego Bay, California, and it is certainly a noteworthy fact that it should turn up at the other extreme end of the Indo-Pacific region. But it is not more remarkable than the case of *Asymmetron lucayanum*, which was first found in the Atlantic and then in the Pacific Ocean.

Our specimen differs from *B. capense*, as described by Gilchrist (**9**), in the number and arrangement of the myotomes and in the presence of an eye-spot, which is absent in *B. capense*. But variation has not yet been much studied in *B. capense*, and possibly the full range of the myotomes is not known. It may be, therefore, that this specimen, and those named *B. capense*, are only variations of *B. californiense*, similar to those shown for other species in the tables at the end of this report.

The habitat of *B. capense* (Cape Colony) bridges the gap between California and Ceylon, and it may be added that other species of Acraniates known from the Maldive Archipelago have been found also at Zanzibar.

It will be seen, therefore, that our Ceylon specimen differs but very slightly from either *B. californiense* or *B. capense*. Both these forms are still comparatively little known, and a re-examination of both is highly desirable, and would probably confirm the view I have ventured to express, that these two species are not really distinct. I believe I am justified in referring this specimen provisionally to *B. californiense*.

Genus II.—ASYMMETRON, Andrews.

Left metapleuron stops just behind the anus, the right is continuous with the median ventral fin; gonads disposed in a single (right) series; oral cirri with or without sense-papillæ; intra-buccal tentacles 10 to 16; ventral fin with or without fin chambers or rays; post-atrioporal cæca 1 to 2 in number.

Asymmetron cingalense (Kirkaldy).—Plate I., figs. 4–7.

Heteropleuron cingalense, Kirkaldy, 1895.

This species was represented by nineteen specimens found sporadically, like *B. lanceolatum*, var. *belcheri*, in Foraminiferal sand in the Gulf of Manaar.

The colour of this species had practically the same range as the others—deep orange, purplish-pink, and pale fawn tints being found. The dimensions of the specimens are recorded in Table III. The total length varied from 20 to 36 millims., the average being 26·5 millims.

The specimens were found in the following localities:—

(1.) Half a mile East of Dutch Modragam Paar (Stn. LVI.), March 10th, 8 fathoms. Two specimens.

(2.) South of Adam's Bridge (Stn. LIV.), March 8th, 8 fathoms. One specimen.

(3.) Off Karkopani (Stn. IV.), February 2nd, 8 fathoms. One specimen.

(4.) Between the Cheval Paars (Stn. XLVIII.), March 4th, $7\frac{1}{2}$ fathoms. One specimen.

(5.) South-west of Cheval Paar (Stn. XLIX.), March 1st, 8 fathoms. Two specimens.

(6.) West of Periya Paar (Stn. XVII.), February 4th, 11 fathoms. Eight specimens.

(7.) West of Periya Paar (Stn. LXI.), March 12th, 12 fathoms. Four specimens.

Although so small compared with the specimens of the form *B. belcheri*, nearly all were sexually mature—thus showing that the average length of the adult *A. cingalense* is much smaller than that of the adult *B. belcheri*.

Of the nineteen specimens, ten were males and seven were females, while the sex of two could not be determined. The number of gonads varied from 18 to 26, always on the right side, the average being 24.

The total number of myotomes varied between 61 and 64, 63 being the average and most frequent number. The most common myotome formula was 39, 16, 8, which occurred 10 times out of 19 specimens. The preatrioporal myotomes varied between 37-39, the preanal between 15 and 17, and the postanal between 6 and 8. This species thus has a comparatively short postanal portion.

The variation in the total number of the myotomes and in their arrangement is less in this species than in any other species of the group. The fins are fairly constant throughout the specimens (figs. 4 and 6), and agree well with KIRKALDY'S figures (**6**). The dorsal fin is deeper anteriorly than in the rest of its extent, recalling in a lesser degree the condition of *A. cultellum* (PETERS). It has fin chambers with single fin rays. The dorsal fin in all cases overlaps the nervous system. The ventral fin is very shallow and has fin chambers with double fin rays which are very small and difficult to see. The ventral fin chambers are not prolonged postanally.

In only one of the 19 specimens is the relation of the dorsal fin to the anterior end of the notochord as figured by KIRKALDY. In that figure the anterior end of the notochord is but a little way in front of the anterior end of the dorsal fin. This is seen in but one of the Ceylon specimens, No. X., Table III. (see fig. 5). In the remaining 18 (fig. 6) the anterior end of the dorsal fin is much further behind the anterior end of the notochord. The relation of these two structures to one another is evidently susceptible of some variation. This receives support from what we know in another species. In *Asymmetron lucayanum*, from the Maldive Archipelago, FORSTER-COOPER (8) has figured the dorsal fin and notochord as ending almost conterminously at the anterior end, while in ANDREWS' original figure (3) and in KIRKALDY'S figure (6) of that species the anterior end of the notochord is far in front of that of the dorsal fin.

In one or two specimens I was able to count the oral cirri. They vary from 26 to 32 in number. The intertentacular membrane between the oral cirri of this species is much deeper than is seen in *B lanceolatum*, var. *belcheri*, and extends from one-third to half the way up. The sensory-papillæ, on the other hand, are much less marked. In one preparation of the oral cirri of this species one cirrus was seen to be branched about one-third of the way up, and the branch was about half as long as the cirrus.

In No. XIII., Table III., a curious structure (fig. 7) was noticed in the dorsal fin just behind the level of the mouth. At this place a break in the fin occurs. A slit runs downwards and backwards for about the length of 2 myotomes. The slit is lined throughout by the epithelium that covers the rest of the body. Posterior to the slit, and continuous with it, is a darker stretch of tissue which looks like a closure of a former extension of the slit. Sections do not show much more, but the structure seems to be confined to the dorsal fin. The nervous system, notochord, and other neighbouring organs are quite unaffected. It is probably the result of some accident arresting the growth of the fin at this spot during its development.

Asymmetron cultellum (PETERS).—Plate I., figs. 8–10.

Epigonichthys cultellus, PETERS, 1876; GILL, 1895; WILLEY, 1901.

Branchiostoma cultellum, GÜNTHER, 1884; and WILLEY, 1894.

Heteropleuron cultellum, KIRKALDY, 1895.

Only two specimens of this interesting species were present in the collection, one from near the coral reefs off Vangali (Stn. LII.), March 5th, in 3 fathoms, and the other from the East Cheval (Stn. XI.), February 4th, in 6 fathoms. They were both quite small, one measuring 23 millims. and the other 25 millims. Both had well-developed gonads, one being a male (the smaller of the two), and the other a female.

It is evident, therefore, that this species, like *A. cingalense*, is a small one as compared with *B. lanceolatum* and its variety *belcheri*.

The male had 17 gonads and the female 20 gonads, both on the right side. The myotome formula for the male specimen was 35, 12, 7—total, 54; while that of the female was 35, 12, 8—total, 55. There is, therefore, quite a close agreement between the two.

The best distinguishing feature of this species is the dorsal fin, which is so markedly swollen at its anterior end. This feature alone is usually quite a sufficient indication of the species (fig. 8). In *A. cingalense* the dorsal fin is slightly swollen at its anterior end. This condition is somewhat more emphasised in *A. maldivense*, a new species lately described by FORSTER-COOPER, from the Maldives (8). This new species seems to bear a remarkable resemblance to the specimens of *A. cultellum*, from Ceylon. The resemblance in the shape of the fins in particular is striking. In both the Ceylon specimens of *A. cultellum* the fin rays are absent from the ventral fin chambers.

The female specimen is well preserved and shows the notochord to be distinctly knobbed, one of the chief characters of the species (fig. 8). The male specimen is not so well preserved and does not show this knobbed notochord. In both specimens the dorsal fin overlaps the nervous system, and the notochord is prolonged in front of the dorsal fin rather more than KIRKALDY shows (figs. 8 and 9). The caudal fin also differs somewhat from KIRKALDY's figures, for while in the latter it is deeper and well marked off from the rest of the fins, in the Ceylon specimens the dorsal and ventral fins fade insensibly into the caudal fin, as shown in *A. maldivense* (8).

I have been able to confirm KIRKALDY in finding sensory-papillæ on the oral cirri of this species. WILLEY (4) had previously stated that the cirri were smooth. The papillæ were distinctly present in the female specimen from Ceylon.

CONCLUSIONS.

The whole collection has proved of very great interest in many ways. Although no new species are recorded, the fact that seven species (including var. *belcheri*) of the group occur round Ceylon, indicates the great wealth of the Acraniate fauna of these waters.

Four species are recorded from this neighbourhood for the first time—*Branchiostoma pelagicum*, *B. californiense*, *B. indicum*, and *Asymmetron cultellum*; while our knowledge of the geographical distribution of nearly all the species has been extended by this collection.

As regards the habitat of the animals, we have some indication in this collection that they live commonly in a clean coarse sand, made up, at least to some extent, of the shells of the large Foraminifera *Orbitolites* and *Heterostegina*.

The depths at which the specimens were taken range from 3 to 14 fathoms, in all cases comparatively shallow water.

The food of these tropical forms appears to consist largely of diatoms, especially of forms found growing over zoophytes, corals, shells, and other submarine objects. In nearly all, the alimentary canal was seen to contain the skeletons of such forms, and fæcal pellets showed the same.

The tables at the end of the report show how extremely variable the species of the group are, and the more extended our knowledge of this group becomes, the less distinctly do the species appear to be separated. The spawning time of the group in tropical seas appears to be the latter half of March, rather earlier in the year than in more temperate seas.

B. lanceolatum is recorded from the Indian Ocean for the first time. It appears to be a cosmopolitan species, being by far the most widely distributed of all the species. The tropical forms differ but slightly from their Mediterranean relations.

The variety (as I consider it) *B. belcheri* is the predominant form in these waters, and constitutes 60 per cent. of the present collection.

A. cingalense, as might be expected, is also well represented in the collection.

The fact that only two specimens of *A. cultellum* were found, suggests that Ceylon may be nearly at the limit of its distribution, and that it becomes more numerous as we approach Australia.

The re-discovery of *B. indicum* is interesting, and extends somewhat its known distribution.

Perhaps the most interesting specimens of the collection were those I have referred to *B. pelagicum*, and it is to be regretted that their state of preservation did not admit of a more complete study of their anatomy, which would probably show points of interest. The collection demonstrated, however, definitely, that this species is truly pelagic.

The most surprising find is *B. californiense*, which, though showing some slight variation, is in most respects the same as its American relations.

Finally, this tropical part of the Indian Ocean seems to be either the home of this group, or is exceedingly well populated, as no less than eight out of the eleven well characterised species have now been recorded from the seas around Ceylon, as follows:—

Branchiostoma lanceolatum	Ceylon	(Herdman), (Andrews ?)
Ditto, var. *belcheri*	Ceylon	(Herdman),
	Singapore	(Bedford).
Branchiostoma indicum	Orissa Coast of India	(Willey),
	Ceylon	(Herdman)
Branchiostoma pelagicum	Indian Ocean	(Gardiner)
	Gulf of Manaar	(Herdman)

Branchiostoma californiense (?)	Gulf of Manaar	(Herdman).
Asymmetron cingalense . . .	Ceylon	(Kirkaldy), (Herdman).
Asymmetron maldivense . . .	Maldives and Zanzibar . .	(Gardiner).
Asymmetron cultellum . . .	Ceylon	(Herdman).
Asymmetron lucayanum . . .	Maldives	(Gardiner),
	Zanzibar	(Crossland).

The following tables give the numerical details in regard to every specimen in the collection :—

REPORT

ON THE

COPEPODA

COLLECTED BY

PROFESSOR HERDMAN, AT CEYLON, IN 1902.

BY

ISAAC C. THOMPSON, F.L.S., AND ANDREW SCOTT, A.L.S.

[WITH PLATES I. TO XX.]

THE COPEPODA contained in the collections brought home by Professor HERDMAN may be conveniently divided into four sections, viz. :—(1) those obtained during the voyages out and home; (2) those collected by the tow-net around the Island of Ceylon; (3) those obtained by examination of washings from dredged material (Ascidians, Sponges, Corals, Pearl Oysters, &c.); and (4) the parasitic species found attached to fishes. The collection was contained in 122 bottles, each bottle representing a gathering from one of the stations shown in the appended list. The free-swimming species naturally form by far the largest part of the collection, although they do not contain most of the novelties. Some of the gatherings were preserved in formol, and others in alcohol. Out of the total number, those marked 1 to 41 were collected on the voyages to Ceylon and home, and most of the others during Professor HERDMAN's three months' work round Ceylon, while some have been sent since by Mr. HORNELL as the result of his further work. Professor HERDMAN's method of collecting material from a fast steamer has already been described in the 'Transactions of the Liverpool Biological Society.' The water containing the material enters the ship some feet below the surface and is pumped into the tank from which baths, &c., are supplied. On this occasion he was fortunate enough to have the entire use of one of the bath-rooms, a tow-net being fixed to the tap so that sea-water was running through it day and night. By this means it is practicable to collect material from the whole of the route traversed, and mostly in good condition.

This collection of Copepoda has proved to be exceedingly rich and varied, containing as it does no less than 283 species, of which 76 are new to science, while at least ten new genera are required. The list of new forms is as follows :—

Ridgewayia typica, n. gen. & sp.
Centropages tenuiremis, n. sp.
C. dorsispinatus, n. sp.
Pontella danæ, var. *ceylonica*, nov.
Labidocera pectinata, n. sp.
L. kroyeri, var. *stylifera*, nov.
,, var. *gallensis*, nov.
Pontellopsis herdmani, n. sp.
Sunaristes inopinata, n. sp.
S. longipes, n. sp.
S. curticaudata, n. sp.
Tegastes imthurni, n. sp.
T. donnani, n. sp.
T. twynami, n. sp.
T. chalmersi, n. sp.
Stenhelia brevicornis, n. sp.
S. gracilicaudata, n. sp.
S. longicornis, n. sp.
S. perplexa, n. sp.
S. dentipes, n. sp.
S. minuta, n. sp.
S. knoxi, n. sp.
Parastenhelia hornelli, n. gen. & sp.
P. similis, n. sp.
Ameira minor, n. sp.
A. tenuipes, n. sp.
Ceylonia aculeata, n. gen. & sp.
Laophonte hirsuta, n. sp.
Laophontella typica, n. gen. & sp.
Tetragoniceps dubia, n. sp.
T. minor, n. sp.
Dactylophusia dentata, n. sp.
D. havelocki, n. sp.
D. hirsuta, n. sp.
D. ceylonica, n. sp.
D. hamiltoni, n. sp.
D. robusta, n. sp.
D. laticaudata, n. sp.
D. æmula, n. sp.
D. platysoma, n. sp.
Peltidium ovale, n. sp.
P. angulatum, n. sp.
P. speciosum, n. sp.
P. serratum, n. sp.
P. perplexum, n. sp.
Porcellidium brevicaudatum, n. sp.
P. acuticaudatum, n. sp.
P. ravanæ, n. sp.
Pseudanthessius maximus, n. sp.
P. chelifer, n. sp.
P. concinnus, n. sp.
Lichomolgus gracilis, n. sp.
L. ieversi, n. sp.
L. lankensis, n. sp.
L. buddhensis, n. sp.
L. simplex, n. sp.
L. elegans, n. sp.
L. robustus, n. sp.
L. gigas, n. sp.
L. dentipes, n. sp.
Paralichomolgus curticaudatus n. gen. & sp.
P. longicaudatus, n. sp.
Hermannella robusta, n. sp.
H. serendibica, n. sp.
Hersiliodes leggii, n. sp.
H. tamilensis, n. sp.
H. dubia, n. sp.
Asterocheres manaarensis, n. sp.
A. major, n. sp.
A. minor, n. sp.
Asteropontius typicus, n. gen. & sp.
A. attenuatus, n. sp.
Collocheres giesbrechti, n. sp.
Lepeopsyllus typicus, n. gen. & sp.
L. ovalis, n. sp.
Doropontius denticornis, n. gen. & sp.
Cletopontius serratus, n. gen. & sp.
Stephopontius typicus, n. gen. & sp.
Chondracanthus cynoglottidis, n. sp.

The large majority of these new species were found in the gatherings from the pearl banks in the Gulf of Manaar, where Professor HERDMAN and Mr. HORNELL were working for some weeks. The dissection and drawing of so many new forms has involved a vast amount of close labour and diligent research, and Mr. THOMPSON must here be allowed to state that this portion of the work, and indeed the chief part of the laborious examination of the material, was undertaken and has been skilfully carried out by Mr. ANDREW SCOTT, whose previous experience of this group of animals makes his co-operation invaluable.

The species, known and new, from the collection represent the families as follows :—

Calanidæ	44 species.	Oncæidæ	8 species.
Centropagidæ . . .	29 ,,	Corycæidæ	29 ,,
Pseudocyclopidæ . .	1 ,,	Lichomolgidæ . . .	13 ,,
Candaciidæ	10 ,,	Asterocheridæ . . .	18 ,,
Pontellidæ	31 ,,	Ergasilidæ	2 ,,
Cyclopidæ	8 ,,	Caligidæ	4 ,,
Ascidicolidæ	3 ,,	Chondracanthidæ .	2 ,,
Harpacticidæ . . .	78 ,,	Lernæopodidæ . . .	3 ,,

LIST OF COLLECTING STATIONS.

as it does no less than 283 species, of which 76 are new to science, while at least ten new genera are required. The list of new forms is as follows :—

Ridgewayia typica, n. gen. & sp.
Centropages tenuiremis, n. sp.
C. dorsispinatus, n. sp.
Pontella danæ, var. *ceylonica*, nov.
Labidocera pectinata, n. sp.
L. kroyeri, var. *stylifera*, nov.
,, var. *gallensis*, nov.
Pontellopsis herdmani, n. sp.
Sunaristes inopinata, n. sp.
S. longipes, n. sp.
S. curticaudata, n. sp.
Tegastes imthurni, n. sp.
T. donnani, n. sp.
T. twynami, n. sp.
T. chalmersi, n. sp.
Stenhelia brevicornis, n. sp.
S. gracilicaudata, n. sp.
S. longicornis, n. sp.
S. perplexa, n. sp.
S. dentipes, n. sp.
S. minuta, n. sp.

[illegible]

D. robusta, n. sp.
D. laticaudata, n. sp.
D. æmula, n. sp.
D. platysoma, n. sp.

Peltidium ovale, n. sp.
P. angulatum, n. sp.
P. speciosum, n. sp.
P. serratum, n. sp.
P. perplexum, n. sp.
Porcellidium brevicaudatum, n. sp.
P. acuticaudatum, n. sp.
P. ravanæ, n. sp.
Pseudanthessius maximus, n. sp.
P. chelifer, n. sp.
P. concinnus, n. sp.
Lichomolgus gracilis, n. sp.
L. ieversi, n. sp.
L. lankensis, n. sp.
L. buddhensis, n. sp.
L. simplex, n. sp.
L. elegans, n. sp.
L. robustus, n. sp.
L. gigas, n. sp.
L. dentipes, n. sp.
[illegible]

[illegible], n. gen. & sp.
Cletopontius serratus, n. gen. & sp.
Stephopontius typicus, n. gen. & sp.
Chondracanthus cynoglottidis, n. sp.

The large majority of these new species were found in the gatherings from the pearl banks in the Gulf of Manaar, where Professor Herdman and Mr. Hornell were working for some weeks. The dissection and drawing of so many new forms has involved a vast amount of close labour and diligent research, and Mr. Thompson must here be allowed to state that this portion of the work, and indeed the chief part of the laborious examination of the material, was undertaken and has been skilfully carried out by Mr. Andrew Scott, whose previous experience of this group of animals makes his co-operation invaluable.

The species, known and new, from the collection represent the families as follows:—

Calanidæ	44 species.	Oncæidæ	8 species.
Centropagidæ	29 ,,	Corycæidæ	29 ,,
Pseudocyclopidæ	1 ,,	Lichomolgidæ	13 ,,
Candaciidæ	10 ,,	Asterocheridæ	18 ,,
Pontellidæ	31 ,,	Ergasilidæ	2 ,,
Cyclopidæ	8 ,,	Caligidæ	4 ,,
Ascidicolidæ	3 ,,	Chondracanthidæ	2 ,,
Harpacticidæ	78 ,,	Lernæopodidæ	3 ,,

List of Collecting Stations.

I. Voyage Out (Stations 1 to 24).

1.	English Channel to Gibraltar	(36 species)	Dec. 28–31, 1901.
2.	Gibraltar to Marseilles	(25 ,,)	Jan. 2, 1902.
3.	Marseilles to Messina	(38 ,,)	,, 5
4.	Messina to Port Said	(38 ,,)	,, 8
5.	Port Said to Suez	(31 ,,)	,, 9
6.	Gulf of Suez	(28 ,,)	,, 10
7.	South end of Gulf of Suez to 300 miles south	(44 ,,)	,, 11
8.	Red Sea	(43 ,,)	,, 12
9.	South end of Red Sea (coarse net)	(37 ,,)	,, 13
10.	,, ,, (fine net)	(45 ,,)	,, 13
11.	Perim to 200 miles into Indian Ocean (fine net)	(43 ,,)	,, 14
12.	,, ,, ,, (coarse net)	(33 ,,)	,, 14
13.	Indian Ocean, south of Socotra (fine net)	(53 ,,)	,, 15
14.	,, ,, ,, ,, (coarse net)	(53 ,,)	,, 15
15.	,, ,, going east (fine net)	(59 ,,)	,, 16
16.	,, ,, ,, (coarse net)	(47 ,,)	,, 16
17.	,, ,, ,, (fine net)	(41 ,,)	,, 17
18.	,, ,, ,, (coarse net)	(39 ,,)	,, 17
19.	,, ,, ,, (mostly fine net)	(36 ,,)	,, 18
20.	,, ,, ,, (coarse net)	(35 ,,)	,, 18
21.	,, ,, off Minikoi (coarse net)	(56 ,,)	,, 19
22.	,, ,, ,, (fine net)	(56 ,,)	,, 19
23.	,, ,, Maldives to G. of Manaar (coarse net)	(40 ,,)	,, 20
24.	,, ,, ,, ,, ,, (fine net)	(42 ,,)	,, 20

II. Voyage Back (Stations 25 to 41).

25.	Colombo to Minikoi (return voyage)	(17 species)	April 8–9, 1902.
26.	Minikoi onwards to west	(41 ,,)	,, 9–10
27.	Indian Ocean, further west	(41 ,,)	,, 10–11
28.	,, ,, ,,	(36 ,,)	,, 11–12
29.	,, ,, ,,	(40 ,,)	,, 12–13
30.	,, ,, ,,	(33 ,,)	,, 13–14
31.	South of Aden to Red Sea	(27 ,,)	,, 14–15
32.	Red Sea	(33 ,,)	,, 15–16
33.	,,	(22 ,,)	,, 16–17
34.	,,	(26 ,,)	,, 17–18
35.	Gulf of Suez and Suez Canal	(21 ,,)	,, 18–19
36.	Suez Canal (12 hours)	(12 ,,)	,, 19
37.	Port Said, Mediterranean onwards	(23 ,,)	,, 20–21
38.	South of Crete (air 63° F., sea 63·5° F.)	(20 ,,)	,, 21–22
39.	Crete to Messina	(16 ,,)	,, 22–23
40.	Messina to Sardinia	(6 ,,)	,, 23–24
41.	Strait of Bonifacio to Marseilles	(9 ,,)	,, 24

III. Round Ceylon.

42.	Four hauls off Negombo (Station I.*)	(11 species)	Jan. 31, 1902.
43.	Off Chilaw (Station III.)	(25 ,,)	Feb. 1
44.	Chilaw Paar (Station V.)	(18 ,,)	,, 2
45.	Off Kalpentyn Island—night and early morning	(11 ,,)	,, 2–3
46.	Muttuvaratu Paar, 11.30 A.M.	(18 ,,)	,, 3
47.	Cheval and Periya paars	(29 ,,)	,, 4
48.	Pamban Pass, 8 A.M.	(18 ,,)	,, 5
49.	Palk Bay (Station XVIII.)	(6 ,,)	,, 6
50.	Back Bay, Trincomalee (Station XX.)	(8 ,,)	,, 7
51.	,, &c., Trincomalee	(9 ,,)	,, 8
52.	Surface, 5 miles east of Arugam Bay	(26 ,,)	,, 12
53.	Galle, after dark, 9 P.M.	(11 ,,)	,, 14
54.	,, ,, 8 P.M.	(9 ,,)	,, 15
55.	,, surface outside bay, daylight	(36 ,,)	,, 17
56.	Off Pantura, south of Colombo	(26 ,,)	,, 19
57.	North of Karativo, Kodramallai Point	(22 ,,)	,, 25
58.	$2\frac{3}{4}$ miles S.S.W. of Chilavaturi, bottom 15 fathoms	(14 ,,)	,, 26
59.	To south of Cheval Paar	(41 ,,)	,, 26
60.	Modragam Paar	(19 ,,)	March 1

* Stations with roman numerals, in brackets, are the dredging stations (see "Narrative," p. 17).

61.	Off south bar, Manaar, surface.	(10 species)	March	3, 1902.
62.	Off Manaar Island	(12 ,,)	,,	3
63.	Cheval Paar	(35 ,,)	,,	4
64.	,, ,, ...	(21 ,,)	,,	4
65.	North of East Cheval Paar (Station LII.) . . .	(28 ,,)	,,	5
66.	10 miles N. of Cheval, bottom net, 7 fms. (Sta. LIII.)	(22 ,,)	,,	6
67.	South of Adam's Bridge, 12 fathoms.	(15 ,,)	,,	7
68.	,, ,, ,, surface	(23 ,,)	,,	7
69.	,, ,, ,, ,, ...	(22 ,,)	,,	8
70.	Dutch Modragam Paar, surface	(17 ,,)	,,	10
71.	Karativo Paar, 6 to 10 fathoms	(23 ,,)	,,	10
72.	Donnan's Muttuvaratu Paar, 8 fathoms . . .	(28 ,,)	,,	11
73.	West of Periya Paar, deep net	(15 ,,)	,,	13
74.	Vankali Paar, 9 fathoms (phosphorescent) . . .	(15 ,,)	,,	13
75.	South-east of Modragam	(10 ,,)	,,	17
76.	Off Mutwal Island	(12 ,,)	,,	19
77.	Chilaw Paar (Station LXIX.)	(12 ,,)	,,	20
78.	Donnan's Muttuvaratu Paar	(35 ,,)	,,	29
79.	Mudalaikuli Paar	(21 ,,)	,,	30
80.	Talaivillu Paar, all day	(22 ,,)	April	1
81.	Navakaddu Paar	(11 ,,)	,,	2
82.	Galle	(5 ,,)	June	5
83.	,, Bay	(4 ,,)	,,	14
84.	,, Harbour	(7 ,,)	July	3
85.	,, 9 A.M.	(3 ,,)	,,	7
86.	,, Harbour	(8 ,,)	,,	12
87.	,, ,, ...	(16 ,,)	,,	15
88.	,, ,, 8 A.M.	(3 ,,)	,,	20
89.	,, ,, 9 A.M.	(2 ,,)	,,	31
90.	,, ...	(6 ,,)	August	1
91.	,, 5 P.M.	(1 ,,)	,,	8
92.	Pearl banks, washed from Medusæ	(11 ,,)	(no date)	
93.	Galle, 3 P.M.	(4 ,,)	August	12
94.	South-east Cheval Paar, at anchor	(15 ,,)	Nov.	11
95.	East Cheval Paar, centre	(2 ,,)	,,	6
96.	,, ,, ...	(9 ,,)	,,	7
97.	,, ,, ...	(3 ,,)	,,	8
98.	Periya Paar Kerrai, daylight	(10 ,,)	,,	9
99.	,, ,, night	(9 ,,)	,,	9
100.	West Cheval	(12 ,,)	,,	10
101.	,, ,, ...	(8 ,,)	,,	11

102. Periya Paar, night	(9 species)	Nov.	13, 1902.
103. South-west Cheval	(2 ,,)	,,	14
104. Kondatchi Paar	(5 ,,)	,,	17
105. Muttuvaratu Paar	(4 ,,)	,,	19
106. ,, pearl oyster washings	(46 ,,)	,,	19
107. Cheval Paar	(8 ,,)	Feb. & Mar., 1902.	
108. Pearl banks, washings from dredged débris.	(6 ,,)	,,	
109. Washings from young pearl oysters	(3 ,,)	,,	
110. ,, ,, deep water dredgings, Pt. de Galle	(3 ,,)	,,	
111. General washings of dredged Invertebrates	(41 ,,)	,,	
112. Washings from dredgings, G. of Manaar sponges.	(13 ,,)	,,	
113. Tow-net off Marichchukaddi	(11 ,,)	Feb.	1, 1903.
114. Modragam Paar, surface	(15 ,,)	,,	2
115. Karativo, shoal buoy	(14 ,,)	,,	2
116. South-east Cheval Paar, surface	(12 ,,)	,,	4–5
117. East Cheval, surface	(8 ,,)	,,	7
118. Cheval Paar	(14 ,,)	,,	9
119. ,, ,,	(only young *Calanus vulgaris*)	March	10
120. ,, ,,	,, ,, ,, ,,	,,	20
121. East Cheval Paar	(5 species)	April	18
122. Washings from Cheval Paar pearl oysters	(1 ,,)	,,	

Distribution of Species.

The Numbers refer to the Stations in the preceding List.

Calanus helgolandicus, 1, 2, 3, 37, 38, 41.

,, gracilis, 4, 21, 22, 38.

,, minor, 2, 3, 4, 7, 8, 9, 10, 11, 12, 13, 14, 16, 17, 18, 19, 20, 21, 22, 24, 31, 34, 38, 39, 41, 43, 46, 47, 48, 49, 69, 78, 81, 92.

,, pauper, 3, 4, 6, 7, 8, 10, 11, 12, 13, 14, 15, 16, 17, 19, 21, 22, 24, 26, 27, 28, 29, 30, 31, 32, 33, 34, 42, 43, 47, 49, 51, 52, 54, 55, 56, 60, 62, 63, 64, 65, 67, 68, 69, 70, 71, 72, 73, 74, 75, 76, 79, 80, 94, 96, 98, 99, 102, 113.

,, darwini, 5, 9, 10, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 26, 27, 28, 29, 30, 31, 32, 33, 54, 68, 74, 80, 103.

,, vulgaris, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 20, 21, 22, 23, 24, 26, 27, 28, 29, 30, 31, 32, 33, 34, 42, 44, 45, 46, 47, 49, 50, 52, 53, 55, 56, 57, 59, 60, 62, 63, 64, 65, 66, 67, 68, 69, 70, 71, 72, 73, 74, 75, 76, 77, 78, 79, 80, 92, 94, 100, 101, 102, 104, 116, 117, 118, 119, 120.

Calanus robustior, 21.
Eucalanus attenuatus, 8, 10, 11, 12, 13, 14, 15, 16, 17, 18, 20, 21, 22, 23, 24, 59, 64, 71.
,, pileatus, 8, 9, 24, 55.
,, crassus, 9, 56, 57, 100, 117.
,, subcrassus, 9, 10, 12, 21, 32, 47, 50, 55, 57, 63, 66, 69, 72, 93, 95, 97, 98, 99, 100, 101, 102, 104, 105, 107, 115, 116, 118
,, subtenuis, 47, 55, 62, 63, 65, 74, 76, 78, 79.
,, monachus, 46, 79.
Rhincalanus cornutus, 13, 14, 15, 16, 17, 18, 19, 56, 57, 78.
,, nasutus, 14, 15, 17, 18, 20, 21, 56, 64.
Mecynocera clausi, 7, 8, 13, 14, 15, 18, 19, 20, 21, 22, 25, 27, 28, 29, 30, 31, 32, 33, 34, 37, 42, 43, 56, 65, 71, 72, 76.
Paracalanus parvus, 1, 2, 3, 4, 6, 7, 8, 10, 11, 13, 14, 15, 16, 17, 18, 21, 22, 24, 25, 26, 27, 29, 30, 31, 32, 33, 34, 35, 42, 43, 45, 47, 50, 51, 52, 53, 55, 56, 58, 59, 60, 64, 65, 66, 68, 69, 70, 71, 72, 76, 78, 79, 80, 81, 94, 95, 96, 107, 113, 114, 115, 116, 117, 118, 121.
,, crassirostris, 42, 43, 47, 50, 51, 55, 63, 65, 68, 69, 70, 78, 79, 80, 94, 113.
Metacalanus aurivillii, 26, 27, 28, 29, 43, 47, 48, 55, 58, 59, 60, 64, 65, 66, 69, 70, 71, 72, 92, 96, 107, 113, 114, 115, 116, 118, 121.
Acrocalanus gibber, 6, 22, 59, 64.
,, longicornis, 7, 8, 9, 10, 11, 13, 15, 16, 18, 24, 28, 32, 34, 42, 43, 55, 56, 59, 60, 63, 65, 66, 67, 68, 73, 78, 79, 94, 96, 107, 114, 115, 117.
,, gracilis, 7, 10, 11, 19, 20, 21, 22, 27. 64.
,, monachus, 27, 29.
Calocalanus pavo, 1, 2, 3, 4, 7, 8, 11, 13, 15, 16, 17, 18, 19, 20, 21, 22, 24, 25, 26, 27, 28, 29, 30, 32, 33, 37, 52, 55, 69, 72, 74, 75, 78.
,, plumulosus, 4, 5, 7, 10, 11, 15, 18, 22, 24, 56, 71, 78.
Clausocalanus furcatus, 1, 3, 4, 6, 7, 8, 10, 11, 13, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 27, 28, 29, 30, 31, 32, 33, 34, 37, 38, 39, 40, 41, 42, 43, 52, 55, 56, 62, 68, 70, 71, 72, 73, 74, 75, 77, 78.
,, arcuicornis, 1, 2, 3, 4, 6, 8, 9, 15, 26, 27, 28, 29, 30, 31, 37, 38, 39, 40, 41, 68.
Pseudocalanus elongatus, 1, 2, 3, 4, 6.
Ætideus armatus, 3, 4, 6.
Undeuchæta minor, 1, 16, 21.
Euchirella rostrata, 21, 23.
,, messinensis, 26.

Euchæta marina, 1, 2, 3, 4, 7, 8, 9, 10, 12, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 26, 27, 28, 29, 30, 31, 32, 50, 55, 56, 57, 71, 74, 78, 94, 99.
,, spinosa, 2, 3, 30.
,, acuta, 3, 4.
,, concinna, 9, 10, 34, 100, 102, 104, 105.
,, barbata, 28, 29.

Scolecithrix danæ, 12, 14, 16, 17, 18, 19, 20, 21, 22, 23, 24, 26, 27, 28, 29, 30, 74, 77.
,, bradyi, 3, 14, 15, 21. 22, 23.
,, chelipes, 34.
,, auropecten, 8.
,, tenuipes, 8.

Ridgewayia typica, n. gen. & sp., 106.

Phænna spinifera, 1, 9, 20.

Centropages chierchiæ, 1, 2, 21, 22, 64.
,, typicus, 2, 3, 37.
,, violaceus, 3, 7, 13, 16, 18, 37, 38, 40, 41, 52, 59.
,, furcatus, 6, 9, 10, 11, 13, 14, 15, 16, 24, 26, 27, 31, 32, 34, 35, 46, 48, 55, 56, 59, 63, 64, 65, 66, 68, 69, 74, 78, 115.
,, elongatus, 7, 15, 21, 22, 24, 27, 30, 34.
,, gracilis, 7, 10, 16, 17, 18, 22, 26, 28, 29, 30, 34, 35, 55, 56.
,, kroyeri, 13, 14.
,, calaninus, 15, 17, 18, 19, 20, 21, 26, 27, 56, 59, 72.
,, orsini, 30, 46, 59, 64, 65, 70, 71, 76, 78, 79, 80.
,, tenuiremis, n. sp., 13, 43, 47, 53, 54, 56, 59, 60, 63, 64, 65, 69, 70, 71, 79, 94, 96, 98, 99, 101, 107.
,, dorsispinatus, n. sp., 75.

Isias clavipes, 1.

Pseudodiaptomus salinus, 5, 6, 7, 35, 36, 37.
,, serricaudatus, 11, 13, 15, 43, 53, 54, 55, 57, 58, 59, 61, 70, 71, 72, 79, 80, 91, 92, 107, 113.
,, aurivillii, 47, 48, 59, 60, 65, 66, 69, 80.

Temoropia mayumbænsis, 6, 7.

Temora longicornis, 1, 4.
,, discaudata, 4, 5, 6, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 20, 21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31, 32, 33, 35, 42, 43, 45, 47, 48, 52, 55, 56, 57, 59, 60, 61, 63, 64, 65, 66, 68, 69, 70, 71, 73, 74, 75, 76, 98, 99, 100, 101, 114, 116, 118.
,, stylifera, 9, 10, 11, 12, 13, 14, 15, 16, 17, 20, 21, 22, 23, 24, 43, 52.
,, turbinata, 43, 59, 64, 73, 82.

Metridia lucens, 1, 2, 3, 4, 5.

COPEPODA.

Family: CALANIDÆ.

Calanus helgolandicus (Claus).

One of the commonest northern species. Taken at 6 stations in this collection, but not further south than the Mediterranean.

Calanus gracilis, Dana.

Less common than the preceding species, occurring at 4 stations, but similar in distribution.

Calanus minor (Claus).

Common throughout the route traversed, from the Mediterranean to the Indian Ocean, occurring at 33 stations.

Calanus pauper, Giesbr.

Taken at 58 stations; distribution similar to that of the last species.

Calanus darwini (Lubbock).

Less plentiful than the two preceding species, occurring at 27 stations, from the Red Sea southwards through the Indian Ocean.

Calanus vulgaris (DANA).

The most generally distributed of any species throughout the route traversed, occurring at 70 stations, from the Red Sea southwards.

Calanus robustior, GIESBR.

Only once taken, at Station 21, off Minikoi, in the Indian Ocean; previously known from the Atlantic and Pacific Oceans.

Eucalanus attenuatus (DANA).

Occurred plentifully at 18 stations, from the Red Sea southwards through the Indian Ocean to Ceylon.

Eucalanus pileatus, GIESBR.

Taken at 4 stations only, twice in the Red Sea and twice in the Indian Ocean, which adds to its hitherto known distribution in the Atlantic and Pacific.

Eucalanus crassus, GIESBR.

Occurred once in the Red Sea and at 4 stations round Ceylon; previously reported from the Indian Ocean.

Eucalanus subcrassus, GIESBR.

Occurred at 27 stations; twice in the Red Sea, and throughout the Indian Ocean.

Eucalanus subtenuis, GIESBR.

A few specimens were found from 9 stations, all in the sea round Ceylon.

Eucalanus monachus, GIESBR.

A rare species hitherto known only from the Mediterranean. Specimens were found, off Ceylon, at 2 stations, thus extending its known range to the Indian Ocean.

Rhincalanus cornutus (DANA).

Reported from 10 stations, all in the Indian Ocean. Previously known from the Mediterranean, the Atlantic, and the Pacific.

Rhincalanus nasutus, GIESBR.

Similar in distribution to the last species. Occurred at 8 stations in the collection.

Mecynocera clausi, I. C. THOMPSON.

Found at 27 stations, extending from the Red Sea throughout the Indian Ocean, the latter being an addition to its hitherto known distribution.

Paracalanus parvus (Claus).

One of the most widely distributed species throughout the regions traversed. Occurred at 65 stations, extending from the British coasts to the Ceylon pearl banks.

Paracalanus crassirostris, F. Dahl.

Found at 16 stations, all in the sea round Ceylon; not previously known from the Indian Ocean.

Metacalanus aurivillii, Cleve—Plate II., figs. 18 to 20.

Occurred at 27 stations, all in the sea round Ceylon; previously known only from the Malay Archipelago. We show the female abdomen and the male and female fifth natatory legs of this species, as they are not represented in sufficient detail by Cleve.

Acrocalanus gibber, Giesbr.

Found sparingly at 4 stations, from the Gulf of Suez and Indian Ocean.

Acrocalanus longicornis, Giesbr.

A much commoner species than the preceding, occurred at 33 stations, extending from the Red Sea throughout the Indian Ocean and around Ceylon.

Acrocalanus gracilis, Giesbr.

Occurred at 9 stations; general distribution similar to that of the two preceding species.

Acrocalanus monachus, Giesbr.

A few specimens of this rarer form were found at 2 stations between Minikoi and Sokotra. Previously known from the Pacific and Indian Oceans.

Calocalanus pavo (Dana).

This beautiful species, easily recognised by its elegant plumose furcal setæ, although rarely found perfect, has a wide range throughout the Atlantic, Pacific and Indian Oceans, and occurred at 33 stations, extending from Gibraltar through the Mediterranean, Red Sea, Indian Ocean, and around Ceylon.

Calocalanus plumulosus (Claus).

Similar in distribution to the last species, but less common. It occurred at 12 stations.

Clausocalanus furcatus (Brady).

Well distributed throughout the entire traverse, occurring at 47 stations.

Clausocalanus arcuicornis (Dana).

Rarer than the preceding species, but similarly distributed. It occurred at 20 stations.

Pseudocalanus elongatus (Boeck).

One of the commonest British species; occurred at 6 stations, extending as far south as the Gulf of Suez.

Ætideus armatus, Brady.

A species widely distributed throughout the Atlantic, Pacific and Indian Oceans, but only taken at 3 stations in this collection, from the Mediterranean to the Gulf of Suez.

Undeuchæta minor, Giesbr.

Occurred off Gibraltar, and at 2 stations in the Indian Ocean; the latter are additions to its hitherto known range.

Euchirella rostrata (Claus).

Occurred twice in the Indian Ocean.

Euchirella messinensis (Claus).

Only once taken, off Minikoi, west of Ceylon, thus considerably extending its southern range; the Mediterranean and the Gulf of Gascony being the only previous records.

Euchæta marina (Prestand.).

A common ocean species; occurred at 36 stations, extending throughout the entire traverse.

Euchæta spinosa, Giesbr.

Found very sparingly off Gibraltar and in the Mediterranean, and again off Ceylon; not previously reported from the Indian Ocean.

Euchæta acuta, Giesbr.

Taken at 2 Mediterranean stations, between Messina and Port Said.

Euchæta concinna, Dana.

Occurred at 3 stations in the Red Sea and at 4 stations round Ceylon.

Euchæta barbata, Brady.

Occurred at 2 stations in the Indian Ocean near Ceylon. Known previously only from the Atlantic.

Scolecithrix danæ (LUBBOCK).

Taken at 18 stations in the Indian Ocean and round Ceylon.

Scolecithrix bradyi, GIESBR.

Occurred once in the Mediterranean, and at 6 stations in the Indian Ocean, the latter being an addition to its known range.

Scolecithrix chelipes, GIESBR.

Taken only at one station, in the Red Sea, its only known habitat.

Scolecithrix auropecten, GIESBR.

A rare species—was found in the Red Sea, an addition to its known range in the Mediterranean and Atlantic.

Scolecithrix tenuipes, T. SCOTT.

Like the preceding species, this was found in the Red Sea, its only previously known habitat being the Gulf of Guinea.

Ridgewayia, n. gen.

Body cyclopoid in form, 6 cephalothoracic segments well defined. Abdomen 4-jointed, anterior antennæ 25-jointed. Posterior antennæ 2-branched, the outer branch consisting of 2 joints, the inner branch of many joints and longer than the outer. Mouth organs very similar to those of *Calanus* and *Temora*.

Outer and inner branches of 1st to 4th natatory legs all 3-jointed. Outer branch of 5th pair 3-jointed; inner branch 2-jointed.

The male of the one species occupying this genus being unknown, it is not easy to fix with certainty the exact systematic position. In the anterior and posterior antennæ, as well as in the mouth organs of the female, it closely resembles the Calaninæ. In the segmentation of the first 4 pairs of natatory legs it agrees with *Calanus*, but not in the 5th pair. On the whole we think that the position of the genus should be amongst the Calanidæ. At the suggestion of Professor HERDMAN we have named this genus in honour of Sir WEST RIDGEWAY, who was Governor of Ceylon when the pearl oyster investigation was carried on.

Ridgewayia typica, n. sp.—Plate I., figs. 1 to 13.

Length, female 0·85 millim.; male unknown.

Cephalothorax 6-jointed, the cephalic segment equal in length to the four following combined. The 5th thoracic segment has a strong hook pointing downwards on its ventral surface. Rostrum short, broad and pointed. Abdomen 4-jointed, the genital segment very wide and equal in length to the following two united; it bears a similar hook to that of the last thoracic segment on its right side posteriorly. Furcal rami about twice as long as broad, each bearing 4 long terminal setæ.

Anterior antennæ 25-jointed, nearly equalling in length the cephalothorax. The proportional lengths of the joints are as follows :—

1.	2.	3.	4.	5.	6.	7.	8.	9.	10.	11.	12.	13.	14.	15.	16.	17.	18.	19.	20.	21.	22.	23.	24.	25.
15.	20.	7.	7.	7.	7.	7.	7.	7.	7.	7.	7.	8.	8.	8.	9.	8.	8.	8.	7.	7.	11.	17.	21.	20.

Posterior antennæ 2-branched, the outer branch consisting of 2 joints, the inner of 8, the 2 basal and the apical joints being each about double the length of the intermediate ones. Mandible broad with 9 or 10 small teeth, palp 2-branched, one branch having 2, the other 4 joints. Maxilla well developed, inner branch composed of 2 large setiferous digits. First and second maxillipeds similar to those of the Calanidæ.

Natatory legs 1 to 4 with outer and inner branches all 3-jointed, the lateral and terminal spines destitute of serrations and hairs. The inner branch of 5th pair is 2-jointed ; the outer branch 3-jointed, bearing lanceolate spines with serrated edges ; the 3rd joint is attached to the centre of the 2nd joint.

Two specimens, both females, were found in the Muttuvaratu pearl-oyster washings.

This, the only known representative of the genus *Ridgewayia*, is easily recognised by the inner branch of the posterior antennæ, by the hooks on the last thoracic and genital segments, and by the 5th pair of natatory legs.

Phænna spinifera, Claus.

Occurred at 3 stations, near Gibraltar, in the Red Sea, and in the Indian Ocean.

Family : CENTROPAGIDÆ.

Centropages chierchiæ, Giesbr.

Occurred at 5 stations, near Gibraltar, in the Indian Ocean, and about the Cheval Paar and other pearl banks, Ceylon. Not previously reported from the Indian Ocean.

Centropages typicus, Kröyer.

A well-known northern species, common around the British coasts. Occurred at 3 stations in the Mediterranean.

Centropages violaceus, Claus.

Found at 11 stations, extending from the Mediterranean to the Red Sea, and throughout the Indian Ocean.

Centropages furcatus (Dana).

One of the commoner species of this genus. Occurred at 29 stations, from the Red Sea throughout the Indian Ocean.

Centropages elongatus, Giesbr.

Found at 8 stations, from the Gulf of Suez throughout the Indian Ocean.

Centropages gracilis (DANA).

Occurred at 14 stations, the range being much the same as that of the preceding species.

Centropages kroyeri, GIESBR.

Found twice in the northern Indian Ocean, in the vicinity of Socotra. The western Mediterranean appears to be its only previously known habitat.

Centropages calaninus (DANA).

Occurred at 11 stations in the Indian Ocean.

Centropages orsini, GIESBR.

This, like the preceding species, occurs at 11 stations, all in the Indian Ocean.

Centropages tenuiremis, n. sp.—Plate I., figs. 14 to 18.

Length, female 2·0 millims.; male 1·8 millims.

Body somewhat angular, widest anteriorly, slightly tapering to last segment of thorax, which is terminated by long outwardly extended lateral acute projections. Anterior antennæ of female 24-jointed, the proportional lengths being as follows :—

1.	2.	3.	4.	5.	6.	7.	8.	9.	10.	11.	12.	13.	14.	15.	16.	17.	18.	19.	20.	21.	22.	23.	24.
3.	4.	2.	2.	3.	3.	2.	3.	3.	4.	4.	5.	6.	7.	8.	8.	8.	8.	7.	5.	5.	5.	5.	5.

Male right antenna 24-jointed; joints 13 to 17 are considerably thickened; a geniculation occurs between the 18th and 19th joints.

Abdomen of female 4-jointed, of male 5-jointed, the last one very small.

Furcal ramus sub-linear, the length about three times the width. Terminal caudal setæ in the female have the basal portion thickened.

The basal joint of the right 5th natatory leg in the female is acutely produced on the inner side and bears three rows of minute teeth. The 5th legs in the male are in general similar to those of *C. typicus*, as are the other appendages not alluded to.

Large numbers of specimens, both male and female, were found at 21 stations round Ceylon.

The acute lateral terminal thoracic spines, the 5th natatory legs in the female, and the abdomen and furcal rami are the distinguishing features of this species.

Centropages dorsispinatus, n. sp.—Plate I., figs. 19 to 25.

Length, female 1·37 millims.; male 1·24 millims.

Cephalothorax ovate, the posterior segment having a rounded acute terminal projection. Rostrum short, broad and triangular. A remarkable curved beak-like hook adorns the median dorsal line of the posterior edge of the cephalic segment. Anterior antennæ of the female 24-jointed, the proportional lengths being as follows :—

1.	2.	3.	4.	5	6.	7.	8.	9.	10.	11.	12.	13.	14.	15.	16.	17.	18.	19.	20.	21.	22.	23.	24.
3.	5.	1.	1.	1.	1.	1.	1.	2.	2.	3.	3.	5.	5.	5.	6.	6.	6.	6.	5.	4.	3.	3.	4.

The 2nd, 5th, 10th and 11th joints bear spinous projections. Male right anterior antennæ 23-jointed, with a geniculation between the 18th and 19th joints.

Abdomen of female 4-jointed; of male 5-jointed, the last joint very small. Furcal rami slightly curved inwards, about twice as long as the width. Fifth natatory legs attenuated; the second joint of right leg in female has a long plain projecting spine on inner side. The chela of the male right natatory leg is clothed with short hair on the outer side.

The other appendages are similar to those of *C. typicus*. A number of specimens, male and female, were taken in Palk Straits, Ceylon.

The species is easily distinguished by the median dorsal cephalic hook, and by the 5th pair of natatory legs and the abdomen and furcal rami.

Isias clavipes, Boeck.

This British species was only taken once, in the first gathering. It ranges to the Mediterranean and Atlantic Ocean.

Pseudodiaptomus salinus, Giesbr.—Plate II., figs. 21 to 23.

Occurred at 3 stations in the Gulf of Suez and at 3 stations in the Indian Ocean, its only previous record being from the Red Sea.

Giesbrecht's specimen was a female, the male remaining unknown until now; we have the satisfaction to record it from the same stations at which the females were found. The male measures 1·25 millims., and its characters are shown by figs. 22 and 23, on Plate II. The female also measures 1·25 millims., and its fifth pair of legs are shown at fig. 21, Plate II.

Pseudodiaptomus serricaudatus (T. Scott).

Occurred at 20 stations throughout the Indian Ocean and about Ceylon.

Pseudodiaptomus aurivillii, Cleve—Plate II., figs. 24 to 26.

Found at 8 stations in the Indian Ocean. Fortunately the specimens include the male hitherto unknown. The female measures 1·2 millims. and the male ·93 millim. The characteristic appendages of both sexes are shown by figs. 24 to 26, on Plate II.

Temoropia mayumbænsis, T. Scott.

Two records for this rare species were added in the Gulf of Suez. The Gulf of Guinea is its only previously known habitat.

Temora longicornis (Müller).

This common British species was found at 2 stations, from the English Channel to the Mediterranean.

Temora discaudata, Giesbr.

One of the most widely distributed species throughout the regions traversed.

Occurred at 60 stations, from the Mediterranean southwards, throughout the Indian Ocean. and round Ceylon.

Temora stylifera (Dana).

Occurred at 16 stations, from the Red Sea southwards, through the Indian Ocean, and about Ceylon.

Temora turbinata (Dana).

Occurred first in the Gulf of Manaar, and at 4 other stations about the Ceylon Pearl Banks. Has been previously reported from the Pacific, New Zealand, and the Gulf of Guinea, but not from the Indian Ocean.

Metridia lucens, Boeck.

Fairly common, from the English Channel, through the Mediterranean, and as far as the Gulf of Suez, but not further south.

Both the latter localities are an extension of its known range of distribution.

Pleuromamma gracilis, Claus.

Occurred at 24 stations, from the English Channel onwards to the Indian Ocean, and in the open sea around Ceylon.

Pleuromamma xiphias, Giesbr.

This was taken in the first gathering only, probably near Gibraltar.

Its previously known range includes the Atlantic, Pacific and Indian Oceans.

Pleuromamma abdominalis (Lubbock).

Found at 28 stations, from the Mediterranean to the Indian Ocean, as far as Ceylon.

Lucicutia flavicornis (Claus).

Occurred at 21 stations, extending from the English Channel to the Indian Ocean, as far as Ceylon.

Heterorhabdus spinifrons (Claus).

Found once in the Mediterranean and again at 4 stations in the Indian Ocean and twice off Minikoi, near Ceylon.

Heterorhabdus papilliger (Claus).

Heterorhabdus abyssalis (Giesbr.).

Heterorhabdus clausi (Giesbr.).

The above three species were each taken once only. The two former between Perim and 200 miles into the Indian Ocean—the latter near Minikoi. Each record is an addition to the known distribution of the species.

Family: PSEUDOCYCLOPIDÆ.

Pseudocyclops obtusatus, Brady and Robertson.

A few specimens only were obtained in the northern Indian Ocean and about the pearl banks and Cheval Paar, Ceylon.

The British coast appears to be the only previously recorded habitat.

Family: CANDACIIDÆ.

Candacia armata (Boeck).

Taken only in the first gathering. between the English Channel and Gibraltar. It is probable that the tropical records of this species, long known as *C. pectinata*, Brady, refer to other Candacias, as more than one species is included in the figures of *C. pectinata* in the Report on the "Challenger" Copepoda, but none of them are identical with Boeck's *C. armata*.

Candacia simplex (Giesbr.).

Occurred at 19 stations, from the Mediterranean onwards through the Indian Ocean and at several of the Ceylon stations. Not before recorded from the Indian Ocean.

Candacia bispinosa (Claus).

Found on three occasions in the Mediterranean and the Red Sea. Previously reported from the Indian Ocean.

Candacia bradyi, A. Scott.

Occurred at 8 stations, extending from the Gulf of Suez into the Indian Ocean.

Mr. Scott's previous record was from Aden. It is probable that some of the previous records of *C. pectinata* from tropical seas are really this species.

Candacia truncata (Dana).

Occurred at 18 stations, from the Gulf of Suez onwards through the Indian Ocean to Ceylon.

Candacia catula (Giesbr.).

Occurred at 17 stations, the range being similar to that of the preceding species.

Candacia longimana (Claus).

Obtained at 3 stations only, from the south of the Red Sea and from Perim into the Indian Ocean.

Candacia æthiopica (Dana).

Range of this species is similar to that of *C. catula*; obtained at 17 stations.

Candacia curta (Dana).

Of similar range to the last species, but less plentiful; was found at 6 stations.

Candacia pachydactyla (Dana).

Obtained at 11 stations in the Indian Ocean and round Ceylon.

Family: PONTELLIDÆ.

Calanopia elliptica (Dana).

Taken between Port Said and Suez and then fairly continuously through the Indian Ocean and round Ceylon. Occurred at 37 stations.

Calanopia minor, A. Scott.

Of similar range to *C. elliptica*—occurred 25 times.

Calanopia aurivillii, Cleve.

Obtained at 4 stations in the vicinity of Galle and at 4 on the pearl banks. Cleve's specimens were from the Malay Archipelago.

Labidocera acuta (Dana).

Common from Port Said throughout the Indian Ocean and round Ceylon—occurred at 39 stations.

Labidocera minuta, Giesbr.

Occurred first at the southern end of the Gulf of Suez and then at 20 stations throughout the Indian Ocean and round Ceylon.

Labidocera detruncata (Dana).

Occurred at 7 stations in the Indian Ocean, and also found at Back Bay, Trincomalee.

Labidocera pavo, Giesbr.

Obtained at 14 Ceylon stations. Known previously only from the Red Sea.

Labidocera kroyeri (Brady).

Similar in distribution to last species: obtained at 11 Ceylon stations.

Labidocera kroyeri (Brady), var. **gallensis**, nov.—Plate II., figs. 6, 7.

Male differs from *L. kroyeri* in several particulars. The posterior thoracic segment in this variety is rounded at base, and has a trifid projection on the left side instead of a bifid one as in *L. kroyeri*. The 1st abdominal segment has a long narrow spine on its right basal corner. The end of basal portion of the claspers in the 5th natatory legs is very short and the chela more spinous than that of *L. kroyeri*. In other respects there is a close similarity between the species and this variety.

Taken in surface tow-nettings from Galle Harbour and elsewhere, Ceylon.

Labidocera kroyeri (Brady), var. **stylifera**, nov.—Plate II., figs. 8, 9.

Male differs from *L. kroyeri* like the variety *gallensis* in the last thoracic segment and in the 5th natatory legs. The basal portion of the latter is produced into a long rod-like projection. Several specimens were taken at different stations round Ceylon.

Labidocera pectinata, n. sp.—Plate II., figs. 10 to 14.

Length, female, 2·1 millims. Male unknown.

Cephalothorax 5-jointed, robust in centre, slightly tapering towards each end, the terminal segment having strong lateral spinous projections. Rostrum short, bifid at apex. Anterior antennæ 23-jointed, in length about equal to the cephalothorax.

The relative lengths of the joints are as follows :—

1.	2.	3.	4.	5.	6.	7.	8.	9.	10.	11.	12.	13.	14.	15.	16.	17.	18.	19.	20.	21.	22.	23.
6.	16.	2.	2.	2.	4.	4.	6.	5.	5.	8.	10.	10.	12.	16.	14.	16.	16.	10.	10.	10.	9.	9.

Posterior antennæ and mouth organs and 1st to 4th pairs of natatory legs as in the other members of this genus. Abdomen 3-jointed, about one-third as long as the cephalothorax ; the right basal extremity of the genital segment is produced into two curved spines ; the middle joint bears a knobbed protuberance. The furcal rami are slightly asymmetrical, the right one being nearly half as large again as the left ; the inner side of each is lined with fine hairs ; each furca terminating in five short setæ. Fifth natatory legs, each composed of two 1-jointed branches, asymmetrical, the inner branches being differently denticulated ; both branches of the left leg are larger than those of the right. The characters of the abdomen and 5th natatory legs are unlike those of any other species known to us.

Four specimens, all females, were taken in Palk Straits, Ceylon.

Pontella fera, Dana.

Found at 3 stations, viz., twice off Minikoi, Indian Ocean, and at Vankali Paar, Ceylon.

Pontella securifer, Brady.

Taken off Minikoi, Indian Ocean, and at 10 stations round Ceylon.

Pontella princeps, Dana.

Was found once only, at Chilaw Paar, Ceylon.

Pontella tenuiremis, Giesbr.

Was found once only, in Palk Strait, Ceylon. Giesbrecht's specimen was from the Pacific Ocean.

Pontella danæ, var. **ceylonica**, nov.—Plate II., figs. 1 to 5.

Length, female 3·4 millims.

Cephalothorax of nearly the same width throughout, in this respect differing from

P. danæ, which tapers gradually from the second to the posterior thoracic segment. Rostrum nearly straight, length about double the width, and has bifid apex. Fifth natatory legs asymmetrical, the left having outer and inner branches larger than the right branches; the outer one has a large and small spine on the outer side.

First joint of abdomen somewhat globular, whereas that of *P. danæ* is more quadrate. A number of specimens, all females, were found at 5 stations around Ceylon. The 5th natatory legs and the shape of the abdomen serve to distinguish the variety from *P. danæ*, GIESBRECHT.

Pontellina plumata, DANA.

Occurred at 17 stations, south of Gulf of Suez, in the Indian Ocean, and round Ceylon.

Pontellopsis armata (GIESBR.).

Occurred first between the Maldives and the Gulf of Manaar, and then at 9 Ceylon stations. Previously known from the Pacific and Indian Oceans.

Pontellopsis krameri (GIESBR.).

Occurred at 4 Red Sea stations. GIESBRECHT's specimens were also from the Red Sea. The species has been recorded from Fortescue Strait by A. SCOTT.

Pontellopsis regalis, DANA.

The only specimen of this species was taken in the Mediterranean, near Messina.

Pontellopsis strenua (DANA).

Found only at Cheval and Periya paars, Ceylon.

Pontellopsis perspicax (DANA).

Like the last species, this was only taken on the Cheval and Periya paars.

Pontellopsis herdmani, n. sp.—Plate II., figs. 15 to 17.

Length, female 1·9 millims.; male unknown.

Cephalothorax about twice as long as its breadth, having 5 segments, the posterior segment terminating on each side with a triangular acuminated spine. Rostrum long, narrow, and bifid. Anterior antennæ 16-jointed, the relative lengths of the joints being as follows: $\dfrac{1.\ 2.\ 3.\ 4.\ 5.\ 6.\ 7.\ 8.\ 9.\ 10.\ 11.\ 12.\ 13.\ 14.\ 15.\ 16.}{6.\ 7.\ 5.\ 8.\ 3.\ 5.\ 3.\ 5.\ 5.\ \ 6.\ \ 9.\ \ 6.\ \ 6.\ \ 7.\ \ 6.\ \ 6.}$

Posterior antennæ, mouth organs and 1 to 4 pairs of natatory legs as in the other species of *Pontellopsis*. Abdomen about half the length of the cephalothorax, composed of 2 joints, the first being about double the size of the second and having 2 thorn-like projections on the right side. Furcal rami twice as long as broad, with fine hairs on the inner surface and each terminating in 5 short non-plumose setæ.

Fifth pair of natatory legs each 2-branched; each branch composed of one bifid joint, the outer branches each having 3 small spines on outer edge. A few females were found in Galle Harbour and also off Karativo Island in the Gulf of Manaar.

The abdomen and 5th natatory legs distinguish this from any other described form. We have peculiar pleasure in naming it after Professor HERDMAN.

Acartia clausi, GIESBR.

A common British species. Occurred at the first 4 stations as far as the Gulf of Suez, and once off Ceylon at the south end of the Cheval Paar.

Acartia longiremis, LILLJ.

Taken at 9 stations, from the English Channel to the Mediterranean off Messina.

Acartia dubia, T. SCOTT.

Found in the Suez Canal and in the Red Sea.

Acartia erythræa, GIESBR.

Well distributed throughout the traverse, occurring at 53 stations, from the Gulf of Suez, throughout the Indian Ocean, and around Ceylon.

Acartia centrura, GIESBR.

Occurred in Gulf of Suez and the Red Sea, and at 6 stations round Ceylon. Previously reported from the Red Sea and Atlantic Ocean.

Acartia negligens, DANA.

Obtained at 38 stations, from Gulf of Suez onwards through the Indian Ocean, and common around Ceylon.

Tortanus gracilis (BRADY).

One record only from about the Gulf of Suez. BRADY records the species from the Philippine Islands.

Tortanus forcipatus (GIESBR.).

Occurred at 3 Ceylon stations only, viz., off Kalpentyn Island, Cheval and Periya paars, and off Pantura, south of Colombo. GIESBRECHT'S specimens were from Amoy, China.

FAMILY: CYCLOPIDÆ.

Thorellia brunnea, BOECK.

Found in washings from sponges, Gulf of Manaar.

Oithona plumifera, Baird.

A common species, recorded from 40 stations almost continuously throughout the seas traversed.

Oithona similis, Claus.

Commencing at the Gulf of Suez, this species occurred at 38 stations; similar in distribution to *O. plumifera*.

Oithona minuta, T. Scott.

This species, first recorded from the Gulf of Guinea, appears to be abundant throughout the Indian Ocean and round Ceylon, occurring at 35 stations.

Oithona rigida, Giesbr.

Occurred in the Red Sea, about Minikoi, and at 18 stations around Ceylon.

Oithona spinifrons, Boeck.

This common British species, closely allied to *O. similis*, occurred in the earlier gatherings, and in the Red Sea and Northern Indian Ocean, to Ceylon.

Oithona nana, Giesbr.

Occurred at 3 stations on the Pearl banks, Ceylon.

Oithona setigera, Dana.

Taken on 4 occasions in the Mediterranean and once in the Suez Canal.

Family: ASCIDICOLIDÆ.

Doropygus normani, Brady.

A few specimens were taken from the branchial sac of a species of *Cynthia* found at the Aripu reef, Gulf of Manaar.

Doropygus pulex, Thorell.

Found attached to the branchial sac of a species of *Molgula*, from the Cheval and Periya paars, Ceylon.

Botryllophilus ruber, Hesse.

Found in washings from sponges, Gulf of Manaar.

Family: HARPACTICIDÆ.

Sunaristes paguri, Hesse.

A few specimens were found in the general washings from Ceylon Invertebrates.

Sunaristes inopinata, n. sp.—Plate III., figs. 1 to 8.

Length, male 1·3 millims.; female 1·5 millims.

Body resembling *S. paguri*, but all the segments broader in proportion to length. Anterior antennæ of female 6-jointed, densely covered on the upper side with plumose setæ and bearing two long club-like appendages, possibly olfactory.

The relative lengths of the joints are as follows: $\frac{1.\ 2.\ 3.\ 4.\ 5.\ \ 6.}{11.\ 7.\ 7.\ 5.\ 4.\ 15.}$

Anterior antennæ of male short and broad, terminating in a curved hook.

Posterior antennæ and mouth organs as in *S. paguri.* Both branches of 1st to 4th pairs of natatory legs 3-jointed, most of the joints having small bundles of fine hairs on the surface or at the sides. Fifth pair as in *S. paguri.*

Abdomen about the same length as the cephalothorax, composed of joints of which the genital segment is the larger one. Furcal rami twice as long as the breadth, tapering to the apex, and each having a stout spine on inner margin. Several specimens were found in the general washings from Ceylon Invertebrates.

Sunaristes longipes, n. sp.—Plate III., figs. 9 to 11.

Length, female 1·5 millims.; male unknown.

Similar in build to the last species but more robust. Anterior antennæ 6-jointed and similar to *S. inopinata*, except in proportional lengths of joints, which are as follows: $\frac{1.\ 2.\ 3.\ 4.\ 5.\ \ 6.}{15.\ 7.\ 3.\ 5.\ 3.\ 19.}$

Abdomen short and robust, about equal in length to the first 3 thoracic segments. First 2 joints are coalescent, the 4th and especially the 5th very small. Furcal rami long and tapering, the length 3 times that of the breadth; each has a spine on both sides. Mouth organs as in *Longipedia*, *Canuella* and *Sunaristes.* Other organs as in last species, with the exception of 4th pair of natatory legs, which (fig. 10) are very narrow, the inner branch being nearly double the length of the outer one.

The length of the furcal rami and the elongated 4th pair of natatory legs serve to distinguish this species from others of the genus. One specimen only, a female, was found in the general washings from Ceylon Invertebrates.

Sunaristes curticaudata, n. sp.—Plate III., figs. 12 to 17.

Length, female, 1·6 millims. Male unknown.

First segment of cephalothorax equal in length to that of the four following segments combined, and much broader. Abdomen 4-jointed, about three-fourths of the length of the cephalothorax. Anterior antennæ 4-jointed, all adorned with plumose setæ, the second joint having also two spines. The proportionate lengths are as follows: $\frac{1.\ \ 2.\ 3.\ 4.}{12.\ 16.\ 5.\ 7.}$

Mouth organs as in *Longipedia*, *Canuella* and *Sunaristes.*

Other organs similar to those of *S. paguri*, with the exception of the inner branch of the 4th natatory legs, which in this species is 2-jointed (fig. 16). Caudal segments short, their length not much exceeding the width; the anterior inner corner of each is marked off by a dividing line. One specimen only was found in the general washings of Ceylon Invertebrates.

The form of the furcal rami is sufficiently diagnostic to distinguish this from other species of the genus. The fact that this species has the inner branch of the fourth pair of legs only 2-jointed may, sometime, necessitate its removal to a new genus.

Longipedia coronata, CLAUS.

Occurred at 2 stations in the Mediterranean and once in the Suez Canal. Usually a littoral species. Found also in washings from Sponges, Gulf of Manaar.

Longipedia minor, T. SCOTT.

A few specimens of this form were obtained in the tow-net off Marichchukaddy.

Canuella perplexa, T. and A. SCOTT.

One specimen was taken between Port Said and Suez.

Ectinosoma atlanticum (BRADY and ROBERTSON).

The most abundant species throughout the collection. Occurred at 66 stations, from the Mediterranean throughout the Red Sea and Indian Ocean and all around Ceylon.

Ectinosoma roseum, DANA.

Hardly less common than *E. atlanticum*. Fifty-nine stations, similarly distributed.

Ectinosoma normani, T. and A. SCOTT.

Ectinosoma propinquum, T. and A. SCOTT.

Both species found in washings from young pearl oysters and in the general washings from Ceylon Invertebrates.

Setella gracilis, DANA.

Occurred at 44 stations fairly continuously, from the Mediterranean to Ceylon.

Miracia efferata, DANA.

Was obtained in the Indian Ocean, twice off Minikoi, and between the Maldives and the Gulf of Manaar.

Miracia minor, T. SCOTT.

Was taken off Gibraltar, and was also found at 2 stations in the northern Indian Ocean. SCOTT'S specimens were taken in the Gulf of Guinea.

Euterpina acutifrons (DANA).

Well distributed throughout the traverse, occurring at 48 stations, from the Mediterranean to Ceylon.

Tachidius littoralis, POPPE.

One specimen was taken in the Gulf of Suez.

Clytemnestra scutellata, DANA.

Occurred at 10 Indian Ocean stations, and 3 round Ceylon, viz., off Pantura to the south of Colombo, at Cheval Paar and west of Periya Paar, Gulf of Manaar.

Clytemnestra rostrata (BRADY).

Found at 8 stations, from the Mediterranean, Gulf of Suez, Red Sea, and the Indian Ocean, and once at Ceylon, near the Muttuvaratu Paar.

Tegastes sphærica (CLAUS).

One specimen of this littoral species was taken between Port Said and Suez.

Tegastes nigrans (T. and A. SCOTT).

A number of specimens were found in washings from Muttuvaratu pearl oysters.

Tegastes imthurni, n. sp.—Plate IV., figs. 1 to 9.

Length, female 0·6 millim. to 0·45 millim.; male unknown.

Cephalothorax composed of 6 segments; the first broadly falciform, and extending ventrally to double the width of the other segments.

Abdomen 4-jointed, the first extending ventrally into a long projection, truncated at end. A large rounded hook from the centre of the 1st segment projects over the posterior ends of the other segments.

Anterior antennæ 6-jointed, the relative lengths being: $\frac{1.\ \ 2.\ 3.\ 4.\ 5.\ 6.}{25.\ 18.\ 9.\ 4.\ 4.\ 4.}$

Posterior antennæ and mouth organs, with the exception of the 2nd maxillipeds, as in *T. sphærica*. In this species the inner concave edge of the chelate hand, instead of being pectinated, has a small funnel-shaped expansion, the upper circular edge being clothed with fine hairs. The inner projecting corner of the hand has, on the upper edge, about 10 short spines arranged in a pectinate manner.

The 1st pair of natatory legs are similar to *T. sphærica*. The 2nd, 3rd, and 4th pairs differ considerably from that species, however, and also from the generic description in BRADY'S Monograph of British Copepoda. In the 2nd and 3rd pairs of *T. imthurni*, and also in *T. donnani*, and in *T. twynami*, the inner branches are composed of 3 joints, while the outer branches have only 2 joints. The 4th pair has the outer branch 3-jointed, and has only 2 joints in the inner branch. The basal joint of the inner branch of this pair is a wide foliaceous expansion with thickened edges. The 5th pair in this and the following 3 species are also different from the type of the genus, and instead of being 2-jointed, are composed of 1 joint only, which, however, is obviously built up of 2 coalesced joints. Fig. 2 represents a smaller form, not differing in details of structure, except in the absence of hook from abdomen.

Several specimens were found in the washings from the Muttuvaratu pearl oysters.

At Professor HERDMAN's suggestion we dedicate this new species to Mr. E. F. IM THURN, the Lieutenant-Governor of Ceylon at the time of the investigations.

Tegastes donnani, n. sp.—Plate IV., figs. 10 to 12.

Length, female, 0·37 millim.; male unknown.

In appearance and structure this species very nearly resembles *T. imthurni*, the 7-jointed anterior antennæ and the 5th natatory legs being the only important points of difference.

Proportionate lengths of antennary joints : $\frac{1.\ \ 2.\ \ 3.\ \ 4.\ \ 5.\ \ 6.\ \ 7.}{26.\ \ 26.\ \ 12.\ \ 22.\ \ 4.\ \ 8.\ \ 7.}$

Four specimens, all females, were found in the Muttuvaratu pearl oyster washings. We name this species after Captain J. DONNAN, C.M.G., formerly Inspector of the Ceylon Pearl Fisheries.

Tegastes twynami, n. sp.—Plate IV., figs. 13 to 16.

Length, female 0·54 millim.; male unknown.

This species also resembles *T. imthurni* in detail, with the exception of the anterior antennæ, the hand of the 2nd maxillipeds, and the 5th natatory legs. The anterior antennæ are only 6-jointed, the proportionate lengths of the joints being as follows : $\frac{1.\ \ 2.\ \ 3.\ \ 4.\ \ 5.\ \ 6.}{13.\ \ 13.\ \ 10.\ \ 8.\ \ 5.\ \ 5.}$

The inner concave edge of the hand in 2nd maxilliped is strongly pectinated and has a round funnel-shaped protuberance with ciliated edge similar to that of *T. imthurni*; the terminal falcate claw is very stout. Fifth pair of natatory legs like those of *T. donnani*, but larger. Two specimens, both females, were found in the washings from the Muttuvaratu pearl oysters.

The cuticle in the foregoing species is covered with minute circular dots, these are also found on the basal joint of the fourth pair of legs, on the fifth pair and in a lesser degree on the chela of the posterior maxillipeds.

We name this species in honour of Sir WILLIAM TWYNAM, who has long been connected with the Ceylon Pearl Fisheries.

Tegastes chalmersi, n. sp.—Plate IV., figs. 17 to 22.

Length, female, 0·3 millim.; male unknown.

A much smaller form than any of the three preceding. Cephalothorax 5-jointed; length and breadth of 1st joint about equal.

Abdomen 3-jointed, the 1st joint being produced as in the other species of the genus, but different from them in having 4 large denticulations on its outer surface.

Anterior antennæ 7-jointed, the proportionate lengths of the joints being as follows: $\frac{1.\ 2.\ 3.\ 4.\ 5.\ 6.\ 7.}{14.\ 10.\ 6.\ 4.\ 4.\ 4.\ 5.}$

The 2nd maxillipeds differ considerably from those of any of the preceding species. The middle joint is long and narrow, arcuate on one side and flat on the other, with short setæ on one-half of the flat side. The terminal spine is shaped like a scythe and about $\frac{3}{4}$ the length of the middle joint. Natatory legs as in *T. imthurni*, excepting 4th and 5th pairs. In the 4th pair the outer and inner branches are both 3-jointed, and the basal joint of the inner branch is not foliaceous. The 5th legs are less angular than those of the other species, the surface being covered with rows of convolute markings.

Two specimens, both females, were found in the Muttuvaratu pearl oyster washings. The anterior antennæ, the 2nd maxillipeds, and the 4th natatory legs readily distinguish this species from the others of the genus.

This species is named after Dr. A. J. CHALMERS, formerly a Liverpool Student of Science, now Registrar and Professor in the Medical College, Colombo.

Stenhelia brevicornis, n. sp.—Plate V., figs. 1 to 9.

Length, female, 0·9 millim.; male unknown.

Cephalothorax narrow, 5-jointed. Anterior antennæ short, 8-jointed, the relative lengths of the joints being as follows: $\frac{1.\ 2.\ 3.\ 4.\ 5.\ 6.\ 7.\ 8.}{18.\ 12.\ 10.\ 8.\ 3.\ 4.\ 6.\ 12.}$ Most of the joints are shorter than the breadth and bear numerous setæ. The 4th joint is produced on upper side, terminating in a long filament.

Posterior antennæ, mouth organs, and 1st to 4th pairs of natatory legs as in *S. ima*. The basal joint of 5th pair is large and triangular, bearing 6 marginal and apical setæ, two of them plumose; second joint long and narrow, tapering towards apex and bearing six setæ, the apical one much longer than the marginal ones. Abdomen 5-jointed; the posterior margin of the 1st joint has a dorsal hook, the margins of the other joints being fringed with fine hairs. Furcal rami about 3 times as long as broad.

Two specimens only, both females, were found in the Muttuvaratu pearl oyster washings. The short, broad-jointed anterior antennæ, the outer joint of the 5th natatory legs, and the long furcal rami are the chief distinguishing features of this species.

Stenhelia gracilicaudata, n. sp.—Plate V., figs. 10 to 15.

Length, female, 0·67 millim.; male unknown.

Cephalothorax 5-jointed, very robust. Anterior antennæ 8-jointed, the proportional lengths of the joints being as follows: $\frac{1.\ \ 2.\ \ 3.\ \ 4.\ 5.\ 6.\ 7.\ \ 8.}{14.\ 20.\ 10.\ 11.\ 4.\ 5.\ 3.\ 10.}$ They are well clothed with setæ on the upper side. The 4th joint is produced and terminates in a long narrow filament.

Posterior antennæ and mouth organs as in *S. brevicornis*. Natatory legs in general similar to those of *S. brevicornis*, but the 1st pair differs therefrom in the respective lengths of its joints; the 5th pair is less triangular, the second joint being ovate. Abdomen 5-jointed, about the same length as the cephalothorax, but only half the width, and non-setiferous on posterior edges. Furcal rami about 4 times as long as broad.

One specimen only, a female, was found in the Muttuvaratu pearl oyster washings.

The chief distinguishing features are the anterior antennæ, the 1st and 5th natatory legs, and the long narrow furcal rami.

Stenhelia longicornis, n. sp.—Plate V., figs. 16 to 22.

Length, female, 0·8 millim.; male, 0·6 millim.

Cephalothorax similar to that of *S. brevicornis*. Anterior antennæ 8-jointed, long and narrow, the proportional lengths being: $\frac{1.\ \ 2.\ \ 3.\ \ 4.\ 5.\ 6.\ 7.\ 8.}{15.\ 24.\ 12.\ 11.\ 3.\ 4.\ 5.\ 7.}$ The 4th joint terminates in a long narrow filament; the setæ of the various joints as in *S. gracilicaudata*.

Posterior antennæ and mouth organs and 2nd to 4th pairs of natatory legs as in *S. brevicornis*. The 1st pair of legs agrees in form with *S. gracilicaudata*, as also does the 5th pair in the female, with the exception of the spines of the inner joint, which in this species are shorter, more numerous, and mostly plumose. The outer joint has a pellucid circle near the outer edge. Fig. 21 shows the inner branch of the 2nd pair in the male, and fig. 22 the 5th leg of the male, which is much smaller than that of the female.

Abdomen short and broad, the 4th joint having a short tooth on lower edge. The furcal rami are very small, about half as long as broad. A few specimens of each sex were found in the Muttuvaratu pearl oyster washings. The long narrow anterior antennæ, the 5th natatory legs, and the small furcal rami are the distinguishing characters of this species.

Stenhelia perplexa, n. sp.—Plate VI., figs. 1 to 7.

Length, female, 0·6 millim.; male unknown.

Cephalothorax much resembles *S. brevicornis*. Anterior antennæ 8-jointed, the proportional lengths of joints being as follows: $\frac{1.\ \ 2.\ \ 3.\ \ 4.\ 5.\ 6.\ 7.\ 8.}{15.\ 17.\ 12.\ 10.\ 3.\ 4.\ 4.\ 8.}$

Posterior antennæ and mouth organs, with the exception of 2nd maxillipeds (fig. 3), as in *S. brevicornis*. Natatory legs all more or less similar to those of *S. longicornis*.

Abdomen broad, the joints mostly quadrate, posterior margins devoid of setæ. Furcal rami short and broad, produced downwards on inner edges; terminal setæ as in *S. longicornis.*

Several females were found in the washings from Muttuvaratu pearl oysters.

This species in many of its characters resembles other members of the genus, without agreeing with any one in all respects. The jointing of the anterior antennæ and the long 2nd maxillipeds are its chief distinguishing features.

Stenhelia dentipes, n. sp.—Plate VI., figs. 8 to 14.

Length, female, 0·56 millim.; male unknown.

Cephalothorax somewhat angular anteriorly, with long narrow pointed rostrum.

The antennæ in the only specimen found were missing, with the exception of the four basal joints on one side. Mouth organs as in *S. brevicornis*, with the exception of 2nd maxillipeds, the middle joint of which is broadly ovate, and the claw curved and slender.

The inner branch of the 1st pair of natatory legs is double the length of the outer branch; 2nd to 4th pairs as in *S. brevicornis.* Inner branch of 5th pair elongated, terminating in a short dagger-like spine; second joint long and gradually narrowing, ending in a small elegant foot-shaped protuberance having 2 apical and 5 lateral setæ. In this respect it somewhat resembles *S. blanchardi*, T. and A. Scott. Abdomen similar to *S. perplexa;* furcal rami twice as long as the width.

Found with the other members of the genus here described in the Muttuvaratu pearl-oyster washings. It can be readily distinguished by its 5th pair of natatory legs.

Stenhelia knoxi, n. sp.—Plate X., figs. 15 to 18.

Length, female 0·67 millim.; male unknown.

Cephalothorax and abdomen each with 5 segments. Anterior antennæ very stout 6-jointed, the proportional lengths being as follows: $\frac{1.\ 2.\ 3.\ 4.\ 5.\ 6.}{12.\ 6.\ 3.\ 14.\ 8.\ 17.}$

Both branches of 1st to 4th pairs of natatory legs 3-jointed; outer branch of 1st pair has long, strong, lateral and terminal spines; 2nd joint of 5th pair ovate.

Three specimens, all females, were found in the Muttuvaratu pearl oyster washings.

We name this species after Robert Knox, who escaped from the King of Kandy to the coast, at the pearl banks, in 1679.

Although the anterior antennæ are only 6-jointed instead of 8, in all other respects the characters agree with those of *Stenhelia*, so we have thought it best to include this species in that genus.

Stenhelia minuta, n. sp.—Plate VI., figs. 21 to 24.

Length, female, 0·5 millim.; male unknown.

This minute species bears a close resemblance to *S. brevicornis*, both in general form and in its mouth organs, posterior antennæ, and 2nd, 3rd, and 4th pairs of natatory legs. Anterior antennæ 8-jointed, the proportional length of the joints being as follows: $\frac{1.\ 2.\ 3.\ 4.\ 5.\ 6.\ 7.\ 8.}{10.\ 12.\ 6.\ 10.\ 2.\ 3.\ 4.\ 6.}$

In its 1st pair of natatory legs it resembles *S. longicornis*, the 5th pair being similar to those of *S. gracilicaudata*.

One specimen only, a female, was found in the Muttuvaratu pearl oyster washings. Its minute size, the jointing of the anterior antennæ, and the 1st and 5th natatory legs constituted its chief features.

Parastenhelia, n. gen.

Anterior antennæ 9-jointed. Inner branch of posterior antennæ 3-jointed.

Mandible palp with 2 branches each 1-jointed. Second maxilliped like a grasping hand. First pair of natatory legs has outer branch 3-jointed, inner branch 2-jointed. Inner branches of 2nd, 3rd, and 4th pairs all 3-jointed. Fifth pair foliaceous and 2-jointed. Abdomen in both sexes 5-jointed.

The characters which distinguish this genus from *Stenhelia* are the 9-jointed antennæ and the 2-jointed inner branch in 1st pair of natatory legs.

Parastenhelia hornelli, n. sp.—Plate VII., figs. 1 to 10.

Length, female 1 millim.; male 0·77 millim.

In general appearance, and in the jointing of cephalothorax and abdomen, this species much resembles the members of the genus *Stenhelia*.

Anterior antennæ of female 9-jointed, the proportional lengths of the joints being as follows: $\frac{1.\ 2.\ 3.\ 4.\ 5.\ 6.\ 7.\ 8.\ 9.}{21.\ 20.\ 15.\ 12.\ 8.\ 11.\ 4.\ 3.\ 12.}$

The upper surface is plentifully clothed with long setæ. Inner branch of posterior antennæ 3-jointed, the 2 apical joints bearing several plumose spines.

Basal joint of mandible large, with lateral warty protuberance, and 3 rounded teeth at apex. Palp is of pyriform shape, having 3 plumose spines at apex, and laterally has 2 branches, each composed of 1 joint bearing several setæ. Second maxilliped is a grasping hand with ovate middle joint, terminating in a stout claw.

Inner branch of 1st pair of natatory legs 2-jointed, the 1st joint being $1\frac{1}{2}$ times the length of the entire 3-jointed outer branch; terminal joint very small.

Inner branches of 2nd, 3rd, and 4th pairs all 3-jointed in both sexes. Fifth pair foliaceous; basal joint triangular and bearing plumose spines. Second joint in female very long, wide at base and tapering towards apex, the edges having fine hairs, and the apex 6 spines, mostly plumose. Outer branch of male 5th pair half the size of the female and distinctly divided into 3 joints bearing spines, mostly plumose.

Several males and females were found in the washings from young pearl oysters, also in the general washings of dredged material, in deep water off Point de Galle, and in the Muttuvaratu pearl oyster washings. We have pleasure in dedicating this new form to our friend Mr. JAMES HORNELL, who worked with Professor HERDMAN in Ceylon.

The 9-jointed anterior antennæ and the 2-jointed inner branch of 1st pair natatory legs clearly separate this species from the genus *Stenhelia*, with which it in most other points agrees. These characters, together with the 3-jointed inner branch of 2nd pair of natatory legs in the male, as well as the remarkable 5th pair in both sexes, served to distinguish this species from any other genus known to us.

Parastenhelia similis, n. sp.—Plate X., figs. 8 to 14.

Length, female 1 millim.; male unknown.

Has a general resemblance to *P. hornelli*, but differs therefrom in the length of joints of anterior antennæ, in the 2nd maxillipeds, and in the 2nd branch of 5th natatory legs. Anterior antennæ 9-jointed, the proportional lengths of the joints being as follows: $\frac{1.\ 2.\ 3.\ 4.\ 5.\ 6.\ 7.\ 8.\ 9.}{10.\ 9.\ 8.\ 7.\ 5.\ 5.\ 4.\ 2.\ 5.}$

Hand of 2nd maxillipeds gracefully curved; the apical claw long and stout. Inner joint of 5th pair of natatory legs long and wide; laterally lined with fine hairs; the terminal spines plumose. Furcal rami about twice as broad as long. Two specimens, both females, were found in the Muttuvaratu pearl oyster washings.

Ameira minor, n. sp.—Plate V., figs. 23 to 29.

Length, female 0·46 millim.; male unknown.

Cephalothorax narrow, 5-jointed. Anterior antennæ 8-jointed, the proportional lengths of the joints being as follows: $\frac{1.\ 2.\ 3.\ 4.\ 5.\ 6.\ 7.\ 8.}{5.\ 20\ 12.\ 8.\ 4.\ 5.\ 3.\ 5.}$

The 4th joint terminates with a long narrow filament. Posterior antennæ similar to those of *A. longipes*. Mouth organs as in *A. longiremis*.

Natatory legs, 1st to 4th pairs, somewhat similar to those of *A. longipes*. The 5th pair much resemble those of *A. tenuicornis*.

Abdomen 5-jointed, the posterior edges of all the joints lined with minute hairs. Furcal rami subquadrate, each terminating in 2 thick and 3 thin setæ.

A considerable number of females only were found in the Muttuvaratu pearl-oyster washings. This is a very small species bearing a strong resemblance to the genus *Stenhelia*, but distinctly differing from members of that genus in having the inner branch of the posterior antennæ 1-jointed.

Ameira tenuipes, n. sp.—Plate VI., figs. 15 to 20.

Length, female 0·53 millim.; male unknown.

Cephalothorax 5-jointed. Rostrum short and wedge-shaped. Anterior antennæ profusely setose, 8-jointed, the proportional lengths of the joints being as follows:

$\frac{1.\ \ 2.\ \ 3.\ 4.\ 5.\ 6.\ 7.\ 8.}{20.\ 21.\ 12.\ 8.\ 6.\ 6.\ 3.\ 5.}$ The 4th joint terminates with a long filament. The inner branch of posterior antennæ is 2-jointed, the 2nd joint being very small.

Mouth organs and 2nd, 3rd, and 4th pairs of natatory legs as in *A. minor*. First joint of inner branch of 1st pair of legs as long as entire 3-jointed outer branch; 3rd inner joint long and narrow.

Basal joint of 5th pair of legs triangular, bearing 2 short plumose setæ and 3 plain ones. Outer joint long and narrow, 4 times as long as broad; fringed on both sides with fine hairs, and having 4 terminal setæ and 1 lateral.

One specimen only, a female, was found in the Muttuvaratu pearl oyster washings. Although the inner branch of the posterior antennæ is 2-jointed, we have thought it best to include this species in the genus *Ameira*, with which it agrees in all other particulars. The 1st and 5th natatory legs readily distinguish it from other species.

Ceylonia, n. gen.

Cephalothorax and abdomen each 5-jointed. Anterior antennæ 7-jointed. Inner branch of posterior antennæ 1-jointed. Mandible palp with one small branch. Second maxilliped non-prehensile. Inner branches of 1st to 4th pairs of natatory legs all 2-jointed; outer branches 3-jointed; 5th pair foliaceous.

The genus *Ceylonia* is nearly related to *Mesochra*, and might have been incorporated therewith but for the structural difference in the 1st pair of natatory legs and in the maxillipeds.

Ceylonia aculeata, n. sp.—Plate VII., figs. 11 to 23.

Length, female 1·2 millim; male 1 millim.

Body robust throughout; cephalothorax and abdomen each 5-jointed, the first two abdominal joints imperfectly divided. Rostrum short and blunt.

Anterior antennæ short and stout, thickly setiferous, 7-jointed, a long thick filament protruding from the apex of 4th joint. The proportional lengths of the joints are as follows: $\frac{1.\ \ 2.\ \ 3.\ 4.\ 5.\ 6.\ \ 7.}{16.\ 12.\ 16.\ 9.\ 3.\ 6.\ 11.}$

Outer branch of posterior antennæ 2-jointed, the outer edge and apex of 2nd joint lined with 6 stout spines; inner branch composed of one joint with 2 apical spines.

Biting part of mandible consists of 3 large teeth; palp with small branch, spinous at apex. First maxilliped has terminal claw and two 1-jointed branches with apical plumose setæ. Second maxilliped wedge-shaped, non-prehensile, but with small curved rudimentary claw.

Inner branches of 1st to 4th natatory legs 2-jointed; outer branches 3-jointed. Inner branches of 1st pair only $\frac{2}{3}$ the length of outer branch, both bearing strong spines; a remarkable rod-like projection with hirsute termination extends from the centre of 1st joint of inner branch. The middle joint of outer branch of male

3rd pair of legs bears a long stout aculeate spine. Fifth pair of legs foliaceous; outer joint in female roundly ovate, both clothed with long spinous setæ. In the male 5th pair the joints are coalescent and terminate in dagger-shaped spines and plumose setæ. Furcal rami about $1\frac{1}{2}$ times as long as broad, each bearing a long thick terminal spine and short setæ.

Several females and 2 males were obtained from young pearl oyster washings, and from deep water off Point de Galle. The anterior and posterior antennæ, the mouth organs and the 1st and 5th pairs of natatory legs are clear distinguishing characters of this species.

Laophonte serrata, Claus.

Laophonte inornata, A. Scott.

Both of the above were taken at Cheval Paar, and were also found in general washings of Invertebrates from the pearl oyster beds.

Laophonte hirsuta, n. sp.—Plate VIII., figs. 1 to 8.

Length, female 0·5 millim.; male unknown.

Lateral edges of cephalothorax and abdomen fringed with minute hairs, giving the animal a hirsute appearance. First cephalic segment quadrately shield-shaped, produced postero-laterally, and equalling in size the rest of the cephalothorax and abdomen.

Anterior antennæ 6-jointed, the proportional lengths of the joints being as follows: $\frac{1.\ \ 2.\ \ 3.\ 4.\ 5.\ \ 6.}{13.\ 14.\ 14.\ 4.\ 3.\ 10.}$ The upper side is clothed throughout with short setæ, the protuberance of the 4th joint leading to a long narrow filament.

Posterior antennæ and mouth organs, with the exception of mandible, as in *L. horrida*. Mandible elongated and narrow, the palp being long and slender. Inner branch of 1st pair natatory legs remarkably robust, terminating in a very small joint and a short stout curved claw. Outer branch 2-jointed, the 2 joints not half the length of the 1st inner joint. The outer branch in 2nd, 3rd and 4th pairs is 3-jointed, the inner 2-jointed. The 5th pair have small basal joints and a long narrow second joint armed with plumose setæ. Furcal rami small, subquadrate.

Eleven specimens, all females, were obtained from the Muttuvaratu pearl oyster washings and the general washings of dredged Invertebrates.

The 1st and 5th natatory legs are sufficiently diagnostic of this species.

Laophontella, n. gen.

Body somewhat pyriform, the cephalic segment nearly half the animal's entire length. Anterior antennæ 5-jointed. Posterior antennæ and mouth organs appear to be as in *Laophontodes*. The 1st, 2nd, and 3rd pairs of natatory legs have both inner and outer branches 2-jointed, 4th pair with outer branch 3-jointed, and inner branch with 1 joint only; 5th pair 2-jointed, foliaceous.

Laophontella differs from both *Laophonte* and *Pseudolaophonte* in the absence of claws in the 1st natatory leg; from *Laophontodes* in the inner branch of 4th pair being only 1-jointed.

With only one specimen, however (a female), to judge from, the generic characters may in the future require some revision.

Laophontella typica, n. sp.—Plate VIII., figs. 9 to 16.

Length, female, 0·5 millim.; male unknown.

Cephalic segment long and tumid; produced posteriorly into long acute spines.

Lateral edges of abdomen more or less notched. Anterior antennæ nearly half as broad as long, 5-jointed, profusely setiferous, the proportional lengths of the joints being as follows: $\frac{1.\ 2.\ 3.\ 4.\ 5.}{16.\ 8.\ 5.\ 3.\ 4.}$ The 1st joint has two claw-like spines, and the 3rd joint another, of larger size.

Mouth organs similar to those of *Laophontodes*. Branches of 1st pair of natatory legs of equal length; outer branch 3-jointed, as are the outer branches of 2nd, 3rd, and 4th pairs; inner branch 2-jointed, the 1st joint being double the length of the 2nd, both branches terminating in long setæ. Inner branch of 2nd and 3rd legs 2-jointed, and of the 4th 1-jointed, all armed with strong spines. Basal joint of 5th pair small and spinous; outer joint small, bearing 7 spines. One specimen only, a female, was found in the Muttuvaratu pearl oyster washings. The stout rugged anterior antennæ, the notched abdominal segments, and the inner branches of the swimming feet clearly distinguish this species from other genera.

Cletodes linearis (Claus).

Taken in the Suez Canal, and also in various washings of Invertebrates from the Gulf of Manaar.

Tetragoniceps dubia, n. sp.—Plate VIII., figs. 17 to 22.

Length, female, 0·9 millim.; male unknown.

Cephalothorax 5-jointed, the cephalic segment equalling in length the following three combined, and considerably stouter. Rostrum short and blunt. Anterior antennæ 8-jointed, the 1st joint non-setose, but projecting posteriorly into a beak-shaped protuberance. The other joints very setose, the 4th bearing a long narrow filament. The proportional lengths of the joints are $\frac{1.\ \ 2.\ 3.\ 4.\ 5.\ 6.\ 7.\ 8.}{37.\ 14.\ 9.\ 6.\ 4.\ 5.\ 5.\ 9.}$

Posterior antennæ and mouth organs generally like those of *T. malleolata*. Inner branches of 1st to 4th pairs of natatory legs 2-jointed, the outer branches 3-jointed. Fifth legs 1-jointed, with partial segmentation, and having 10 setæ. A pyramidal spine projects from the surface. Furcal rami about twice as long as broad.

One specimen only, and that possibly an immature one, was found in the Muttuvaratu pearl oyster washings. It is nearly related to *T. malleolata*, with which we were at first disposed to place it. The 5th feet are, however, very different from, and the furca much shorter than in that species, so that it seems necessary to separate the present form.

Tetragoniceps minor, n. sp.—Plate VIII., figs. 23 to 28.

Length, female, 0·5 millim.; male unknown.

Closely related to *T. bradyi*; differing, however, from that species in the jointing of the anterior antennæ, and in the long narrow furcal rami. Anterior antennæ 8-jointed, the proportional lengths being as follows: $\frac{1.\ \ 2.\ \ 3.\ \ 4.\ \ 5.\ \ 6.\ \ 7.\ \ 8.}{40.\ 14.\ 8.\ 7.\ 4.\ 3.\ 6.\ 8.}$ A long beak-like hook projects from the 2nd joint, by which it differs from *T. consimilis*.

The posterior antennæ, the mouth organs, and the 5 pairs of natatory legs are much the same as those of *T. bradyi*.

One specimen only was found in Muttuvaratu pearl oyster washings. The beaked 2nd joint of the anterior antennæ sufficiently distinguishes it from others of the genus.

Dactylophusia tisboides (Claus).

This littoral species was taken between Port Said and Suez.

Dactylophusia latipes (T. Scott).

Taken sparingly on the Ceylon pearl banks. Only previous record is Gulf of Guinea.

Dactylophusia dentata, n. sp.—Plate IX., figs. 1 to 10.

Length, female 1·2 millim.; male 0·83 millim.

Cephalothorax robust; cephalic segment about as long as the rest of the thoracic segments combined. Third and fourth segments have remarkably sharp dorsal teeth; abdomen narrow, little more than one-third the length of the cephalothorax; lateral margins of genital segment produced into a large blunt tooth. Anterior antennæ 8-jointed, the proportional lengths being as follows: $\frac{1.\ \ 2.\ \ 3.\ \ 4.\ \ 5.\ \ 6.\ \ 7.\ \ 8.}{10.\ 11.\ 8.\ 9.\ 3.\ 4.\ 3.\ 4.}$

The prolonged apex of joint 4 bears a long broad filament. Inner branch of posterior antennæ 2-jointed. Mandible palp 2-branched, the primary branch having long terminal setæ. Second maxilliped has an angular hand and terminal claw of about the same length. Both branches of 1st pair of natatory legs 3-jointed; the basal inner joint half as long again as the entire outer branch; the other joints very small.

In the male the 2nd joint of inner branch of 2nd pair is produced into a long pointed dagger-like spine, broad at base. Fifth pair of female 2-jointed, foliaceous, the inner joint ovate; those of the male similar but smaller. Furcal rami subquadrate, about twice as long as broad, a thick chitinous band lining the inner edges.

Ten males and 5 females were found in the Muttuvaratu pearl oyster washings. The dentated thoracic and 1st abdominal segments, the 2nd maxillipeds, the male 2nd natatory legs, and the furcal rami clearly distinguish this species.

Dactylophusia havelocki, n. sp.—Plate IX., figs. 11 to 18.

Length, female 1 millim.; male unknown.

Anterior antennæ short, 8-jointed, the joints short, length and breadth of each nearly equal. Fourth joint bears a long narrow filament, and the proportional lengths of the joints are: $\frac{1.\ 2.\ 3.\ 4.\ 5.\ 6.\ 7.\ 8.}{9.\ 8.\ 5.\ 6.\ 3.\ 4.\ 2.\ 6.}$

Mandible palp 2-branched, secondary branch small, distinctly 2-jointed. Hand of 2nd maxilliped rounded on one side, flat on the other; claw slender. Natatory legs similar to *D. dentata;* the inner branch of the 5th pair however is nearly quadrate instead of ovate. Furcal rami nearly twice as broad as long; basal portion of apical spines thick and jointed.

A few specimens, all females, were found in the Muttuvaratu pearl oyster washings. The short anterior antennæ and furca, coupled with the shape of the mandible palp, and the inner joint of the 5th natatory legs, characterize this species.

Dactylophusia hirsuta, n. sp.—Plate IX., figs. 19 to 24.

Length, female 1·2 millim.; male unknown.

All the segments of the abdomen covered with rows of fine short hairs. Anterior antennæ 9-jointed, the 4th joint bearing a long filament.

The proportional lengths of the joints are as follows: $\frac{1.\ \ 2.\ \ 3.\ \ 4.\ \ 5.\ \ 6.\ \ 7.\ \ 8.\ \ 9.}{14.\ 14.\ 7.\ 10.\ 3.\ 5.\ 4.\ 3.\ 9.}$

Basal joint of 2nd maxilliped has a row of small hairs near apex, and three terminal plumose setæ; hand small; the claw 2-jointed, long and narrow.

Inner branch of 1st pair of natatory legs as in *D. dentata*, but with shorter terminal spines; 5th pair not unlike those of *D. dentata*, but the length and armature of the setæ are distinctly different, and each joint has a pellucid patch on its surface. Furcal rami very short and hirsute.

Three specimens, all females, were found in the Muttuvaratu pearl oyster washings. The 9-jointed anterior antennæ, the hirsute abdomen, 2nd maxillipeds and furca, and the 5th pair of natatory legs serve to distinguish this species.

Dactylophusia ceylonica, n. sp.—Plate IX., figs. 25 to 32.

Length, female 1·3 millim.; male 0·96.

Posterior dorsal edges of thoracic and abdominal segments have each a row of fine hairs. Anterior antennæ 8-jointed, the proportional lengths of the joints being as follows : $\frac{1.\ 2.\ 3.\ 4.\ 5.\ 6.\ 7.\ 8.}{11.\ 11.\ 5.\ 8.\ 3.\ 5.\ 2.\ 6.}$ The 4th joint bears a long thin filament.

First pair of natatory legs of female same as in *D. hirsuta* ; the inner branch in male has a remarkably long stout spine equalling in length the 1st joint, projecting from the 2nd basal joint. The 2-jointed inner branch of 2nd pair in male has 3 thick more or less curved spines at apex of 2nd joint. Outer joint of 5th pair in female about equal in size to the 1st joint. In the male both joints are exceedingly small.

Eighteen females and 13 males were found in the Muttuvaratu pearl oyster washings. The chief distinguishing characters of this species are the inner joints of 1st and 2nd male natatory legs, and the 5th pair in the female.

Dactylophusia hamiltoni, n. sp.—Plate X., figs. 1 to 7.

Length, female 1·1 millim. ; male unknown.

Cephalothorax and abdomen each with 5 segments.

Anterior antennæ 8-jointed, the proportional lengths of the joints being as follows : $\frac{1.\ 2.\ 3.\ 4.\ 5.\ 6.\ 7.\ 8.}{12.\ 12.\ 10.\ 11.\ 3.\ 6.\ 4.\ 7.}$

A long filament springs from the prolongation of the 4th joint. Outer branch of posterior antennæ 3-jointed, a 2-jointed inner branch springing from the basal joint. Second maxillipeds large ; the apical claw strong, blunt at end. Inner joint of 5th pair of natatory legs subquadrate, about twice as long as broad. Abdomen long and slender ; furcal rami quadrate, abont twice as long as broad.

One specimen only, a female, was found in the Muttuvaratu pearl oyster washings. The form of the 2nd maxillipeds, and 5th pair of natatory legs, and the abdomen, are characteristic of this species, which we name after Colonel HAMILTON, a former inspector of the pearl banks.

Dactylophusia robusta, n. sp.—Plate X., figs. 19 to 24.

Length, female 0·64 millim. ; male unknown.

A small but moderately robust species with a very tumid cephalothoracic segment. Anterior antennæ 8-jointed. Joints long and narrow, with the exception of the 5th, which is very small ; the proportional lengths are : $\frac{1.\ 2.\ 3.\ 4.\ 5.\ 6.\ 7.\ 8.}{14.\ 24.\ 12.\ 20.\ 4.\ 10.\ 7.\ 12.}$

Posterior antennæ, mandible, and maxilla similar to those of *D. gracilicaudata* ; 2nd maxillipeds have the palm straight and the lower side rounded. Outer branches of the 1st natatory legs much shorter than the inner branches. The middle joint of the outer branches longer than either the basal or apical joints ; 2nd, 3rd, and 4th legs resemble those of *D. tisboides*. The 5th pair have a large primary joint and a moderately long and narrow secondary joint. The primary joint is furnished with 5 setæ, and the secondary with 6 setæ. Abdomen 4-jointed, about half as long as the combined lengths of the cephalic and thoracic portions. Furcal rami small, longer than broad.

A few specimens were found in the washings from the Muttuvaratu pearl oysters.

D. robusta differs from other species in the structure of the anterior antennæ, and the 1st and 5th natatory legs.

Dactylophusia laticaudata, n. sp.—Plate XI., figs. 1 to 8.

Length, female 0·6 millim.; male unknown.

A small flat species of a yellow colour, resembling in general appearance *D. flava.* When only recently preserved, the 1st, 2nd, and 3rd thoracic segments present a band of deep brown madder colour; this band eventually disappears in spirit-specimens, and only the general colour remains. Anterior antennæ 6-jointed, short and robust; the proportional lengths are: $\frac{1.\ \ 2.\ \ 3.\ \ 4.\ \ 5.\ \ 6.}{13.\ 12.\ 9.\ 8.\ 5.\ 4.}$

Secondary branch of posterior antennæ 2-jointed; basal joint very short; 2nd joint long. Mandible as in *D. tisboides;* palp with 2 nearly equal branches. The lower branch is furnished with 2 strong spines situated in the middle of the external margin. Maxilla and 1st maxilliped resembling those of *D. tisboides.* Second maxilliped long and narrow, both surfaces slightly rounded; terminal claw very strong. Outer branch of 1st natatory legs 3-jointed, very short; inner branch has a long and very wide 1st joint and one small terminal joint; 2nd, 3rd, and 4th legs resembling in general those of the genus; the terminal spines have ring-like markings. The 5th legs have the primary joint large and foliaceous, much longer than broad, with 5 short, stout terminal spines; secondary joint small with 2 strong spines on the outer margin, 2 terminal ringed spines and 1 small spine on the inner distal margin. Abdomen 4-jointed, very wide. Furcal rami small and tumid.

Several specimens of this curious species were found in the Muttuvaratu pearl oyster washings.

Dactylophusia æmula, n. sp.—Plate XI., figs. 9 to 12.

Length, female 0·4 millim.; male unknown.

In general appearance very like *D. laticaudata,* but smaller and less robust. The colouring is the same as in that species.

Anterior antennæ narrow, 7-jointed. The proportional lengths of the joints are as follows: $\frac{1.\ \ 2.\ \ 3.\ \ 4.\ \ 5.\ \ 6.\ \ 7.}{13.\ 12.\ 10.\ 11.\ 4.\ 3.\ 6.}$

Posterior antennæ, mandible and palp, maxilla and maxilliped as in *D. laticaudata.* The 1st to 4th natatory legs resemble those of *D. laticaudata,* except that the basal joint of the inner branch of the 1st is less tumid. The 5th legs in this species also have the primary joint large and foliaceous, but proportionally broader than long, and the terminal spines are shorter and less tumid; secondary joint small. Marginal spines, with the exception of the inner sub-terminal one which is very strong, short and slender. Abdomen less tumid than in *D. laticaudata.*

Several specimens, all females, from the same locality as the foregoing species, from which it is distinguished by the structure and proportional lengths of the joints of the anterior antennæ, and by the 1st and 5th legs. The two foregoing species differ in the structure of their appendages, especially in the 1st legs, which have the inner branch only 2-jointed, from the general type of *Dactylophusia*, and may some time require a separate genus.

Dactylophusia platysoma, n. sp.—Plate XI., figs. 13 to 18.

Length, female 0·62 millim.; male unknown.

In general appearance more like a *Porcellidium* than a *Dactylophusia*, and it is only when the appendages are examined that it becomes clear that it is not a *Porcellidium;* neither can it be said to be a typical *Dactylophusia*, though provisionally referred to that genus. Anterior antenna moderately long and slender, 9-jointed; the proportional lengths are : $\frac{1.\ \ 2.\ \ 3.\ 4.\ 5.\ 6.\ 7.\ 8.\ 9.}{13.\ 18.\ 10.\ 9.\ 4.\ 5.\ 2.\ 2.\ 4.}$

Posterior antennæ, mandible and palp, maxilla and 1st maxillipeds nearly as in *D. tisboides;* 2nd maxillipeds elongate, with a strong terminal claw. First natatory legs resembling those of *D. tisboides;* 2nd, 3rd and 4th though generally like those of *Dactylophusia*, are more slender than the corresponding legs of any member of the genus known to us. The 5th feet have the primary joint large and foliaceous. The extremity of the joint is fringed with fine hairs, amongst which are 3 prominent setæ; secondary joint not distinctly separated from the primary one, with rounded margins and furnished with 6 apical setæ. Abdomen very flat, 4-jointed, furcal rami short.

Six females were found in the washings from the Muttuvaratu pearl oysters.

Thalestris mysis, Claus.

Found in the Gulf of Suez and again at Cheval Paar, Ceylon.

Pseudothalestris imbricata, Brady—Plate XI., figs. 19 to 24.

This species was described from a single specimen (a male) in the Report on the "Challenger" Copepoda by Professor Brady. No further specimens seem to have been discovered until now. In the present collection a single female was found in washings from the Muttuvaratu pearl oysters, which from its general resemblance in structural detail we have concluded is the female of *P. imbricata.*

Length, female 0·65 millim.

In general agreement with the recently described species of this genus, it is more like a small *Westwoodia* than a *Thalestris.* The outer branches of the 1st natatory legs are very small and distinctly 2-jointed. Anterior antennæ 6-jointed; proportional lengths as follows : $\frac{1.\ \ 2.\ \ 2.\ 4.\ 5.\ 6.}{9.\ 12.\ 21.\ 4.\ 7.\ 7.}$

Posterior antennæ, mandible, maxilla and maxillipeds similar to those figured by Brady. Natatory legs 1 to 4 also similar. The 5th legs have a large primary joint and a small secondary joint each furnished with a number of hairs.

Furcal rami extremely short, much broader than long.

Harpacticus chelifer (Müller).

A common littoral British species. It occurred only once, in a tow-net gathering from Marichchukaddi, Ceylon.

Peltidium ovale, n. sp.—Plate XIII., figs. 1 to 6.

Length, female 1·6 millim. ; male unknown.

Body ovate, cephalothorax and abdomen not clearly separated. Anterior antennæ short, 6-jointed, the proportional lengths of joints being as follows : $\frac{1.\ \ 2.\ \ 3.\ 4.\ 5.\ 6.}{13.\ 16.\ 10.\ 6.\ 2.\ 6.}$ Most of the joints are densely setiferous, the 3rd and 4th also bearing a long filament.

Posterior antennæ and mouth organs as in *P. purpureum*. Outer branch of 1st pair of natatory legs 2-jointed, with marginal hairs on both sides; inner branch 3-jointed, half as long again as the outer, the middle joint about twice the length of the 1st, and the 3rd joint very small, having at the apex two narrow curved claws. In the 2nd, 3rd, and 4th pair, both branches are 3-jointed, the outer branch armed on outer side with lateral aculeate plumose spines; the inner side and inner branch both bearing plumose setæ. The 5th pair of legs 2-jointed, the basal joint very small and produced on each side; the outer joint long and stout, with terminal aculeate spines.

Three females only were found in the Muttuvaratu pearl oyster washings and in the general washings of Invertebrates. This and the 4 following species all clearly agree with Philippi's original description of the genus except as to the anterior antennæ, which he gives as 9-jointed, whereas our 5 new species are 6- and 7-jointed. Seeing that Philippi knew of only one species, *P. purpureum*, we think the generic character should be altered to read—6- to 9-jointed, to admit these new forms.

The rounded forehead and the 5th pair of natatory legs sufficiently distinguish this species from the others.

Peltidium angulatum, n. sp.—Plate XIII., figs. 7 to 11.

Length, 1·2 millim. ; male unknown.

Body angular, with large anterior protuberance or rostrum. Anterior antennæ 7-jointed, the proportional lengths being as follows : $\frac{1.\ \ 2.\ 3.\ 4.\ 5.\ 6.\ 7.}{16.\ 14.\ 9.\ 6.\ 2.\ 2.\ 5.}$

First pair of natatory legs shorter and stouter than those of *P. ovale*; the basal joint of outer branch bears 2 small elongated processes in place of spines. Basal joint of 5th pair produced on one side into a long linear projection with apical spine; outer joint elongated, narrowing towards apex, armed with strong plain and plumose spines. Two specimens, both females, were found in the Muttuvaratu pearl oyster washings. It differs from *P. ovale* in the anterior antennæ, the 5th pair of legs, and particularly in the arrangement of the chitinous bands or reticulations of the carapace.

Peltidium speciosum, n. sp.—Plate XIII., figs. 12 to 17.

Length, female 1·1 millim.; male unknown.

Body resembles *P. angulatum* in shape, but is differently reticulated, the chitinous bands being thicker. Anterior antennæ stout, 7-jointed, the filaments and setæ as in the two previous species; the proportional sizes are: $\frac{1.\ \ 2.\ \ 3.\ 4.\ 5.\ 6.\ 7.}{22.\ 22.\ 14.\ 6.\ 3.\ 3.\ 6.}$

First pair of natatory legs very robust. In other respects they and the other pairs agree with *P. angulatum*. Fig. 17 represents a smaller form with thinner bands. A number of specimens, all females, were found in the Muttuvaratu pearl oyster washings. The jointing of the anterior antennæ, and the robustness of the 1st pair of natatory legs, serve to distinguish this species.

Peltidium serratum, n. sp.—Plate XIII., figs. 18 to 22.

Length, female 1·6 millim.; male unknown.

Body robust, rostrum broad, with 4 indentations on anterior surface; margins of all the cephalothoracic segments serrated. Anterior antennæ 6-jointed, the proportional lengths of the joints being as follows: $\frac{1.\ \ 2.\ \ 3.\ 4.\ 5.\ 6.}{20.\ 20.\ 14.\ 4.\ 4.\ 7.}$

Outer branch of 1st pair of natatory legs robust. Fifth pair foliaceous, 1-jointed, with a long spear-shaped plumose apical spine and several lateral spines, some of them plumose; anteriorly drawn out into a curved protuberance with terminal spine representing a rudimentary basal joint.

Three specimens, all females, were found in the bottom tow-net at Chilavaturai, Ceylon. The character of the reticulation on the carapace and the remarkable 5th natatory legs clearly distinguish this species from others.

Peltidium perplexum, n. sp.—Plate XIII., figs. 23 to 27.

Length, female 1·1 millim.; male unknown.

Body and character of reticulation resemble *P. speciosum*. Anterior antennæ 7-jointed, the proportional lengths of joints being as follows: $\frac{1.\ \ 2.\ 3.\ 4.\ 5.\ 6.\ 7.}{23.\ 16.\ 9.\ 6.\ 4.\ 3.\ 7.}$

Natatory legs similar to those of *P. angulatum*.

Two specimens, both females, were found in the Muttuvaratu pearl oyster washings. This differs from other species chiefly in the proportional lengths of joints of anterior antennæ. Cleve has formed a genus *Reticulina* for the species *R. aurivillii*, which is certainly a *Peltidium*, but it is not sufficiently well figured to enable us to compare it with any of the foregoing species.

Ilyopsyllus affinis, T. Scott.

Appeared once between Port Said and Suez, and again in the Gulf of Manaar, also at Kodramallai, north of Karativo, and $2\frac{3}{4}$ miles south-south-west of Chilavaturai.

Porcellidium fimbriatum, Claus—Plate XII., figs. 1 to 10.

Length, female 0·7 millim.

Anterior antennæ 6-jointed; proportional lengths of joints: $\frac{1.\ \ 2.\ \ 3.\ \ 4.\ \ 5.\ \ 6.}{12.\ 13.\ 10.\ 6.\ 5.\ 2.}$

A few specimens, all females, of this species, which appear to be identical with Claus' *P. fimbriatum*, were found in the washings from the Muttuvaratu pearl oysters. The chief points that distinguish this species from the others are the 5th feet, the abdomen, and the furcal rami.

Porcellidium brevicaudatum, n. sp.—Plate XII., figs. 11 to 14.

Length, female 0·67 millim.

Anterior antennæ 6-jointed, as follows: $\frac{1.\ \ 2.\ \ 3.\ \ 4.\ \ 5.\ \ 6.}{13.\ 17.\ 12.\ 8.\ 4.\ 2.}$

This species is easily distinguished from the others by its smooth carapace and ciliated margins, the large 5th feet, the short abdomen, and the furcal rami.

Six specimens, all females, were obtained from the Muttuvaratu pearl oyster washings and from the general washings of Ceylon Invertebrates.

Porcellidium acuticaudatum, n. sp.—Plate XII., figs. 15 to 18.

Length, female 0·6 millim.

Anterior antennæ 6-jointed; proportional lengths as follows: $\frac{1.\ \ 2.\ \ 3.\ \ 4.\ \ 5.\ \ 6.}{11.\ 11.\ 8.\ 6.\ 4.\ 3.}$

The chief features of this species are its moderately large 5th feet with rounded apex, the small abdomen produced laterally on each side, and the acutely pointed apex of the furcal rami.

Three females of this distinct species were found in the washings from the Muttuvaratu pearl oysters.

Porcellidium ravanæ, n. sp.—Plate XII., figs. 19 to 22.

Length, female 0·6 millim.

Anterior antennæ 6-jointed; proportional lengths as follows: $\frac{1.\ \ 2.\ \ 3.\ \ 4.\ \ 5.\ \ 6.}{10.\ 18.\ 13.\ 8.\ 5.\ 3.}$

The distinguishing characters of this *Porcellidium* are the moderately wide 5th feet, which taper off to an acute point, the small abdomen, the posterior angles of which are not so much prolonged as in *P. acuticaudatum*, and the obliquely rounded external margin of the furcal rami. Three females of this species were found in the washings from the Muttuvaratu pearl oysters.

Idya furcata (Baird).

A common British littoral species. Occurred at 7 stations from the English Channel through the Mediterranean and Gulf of Suez to the Red Sea.

Idya longicornis, T. Scott.

Found in the general washings from Ceylon Invertebrates. Previously known only from British waters.

Pseudanthessius gracilis, Claus—Plate XIV., figs. 19 to 23.

One specimen was found in the general washings of the Ceylon Invertebrata obtained about the pearl banks. We give some additional figures of this species.

Pseudanthessius maximus, n. sp.—Plate XIV., figs. 1 to 11.

Length, female 3·5 millims.; male 2·7 millims.

Cephalothorax 6-jointed, the lateral spaces between the joints giving it a coarsely pinnatifid appearance. Abdomen of female 4-jointed, male 5-jointed, the 1st segment in the male being much longer and wider than any of the others.

Anterior antennæ 7-jointed, each joint bearing several short spinous setæ, and the proportional lengths being as follows: $\frac{1.\ \ 2.\ \ 3.\ \ 4.\ \ 5.\ \ 6.\ \ 7.}{15.\ 32.\ 7.\ \ 9.\ \ 9.\ \ 7.\ \ 6.}$

Posterior antennæ 4-jointed, the 3rd joint much the smallest; the 4th bears a stout blunt hooked spine. Mandible is produced apically into a long recurved spine with toothed edges, also a smaller toothed spine, and toothed edge. The palp is short, armed with three apical spines and a lateral one. First maxilliped has a stout basal joint, with an outer joint extended into 2 curved hairy spines. Second maxilliped of female has an oval middle joint terminating in a short claw; that of the male is a strong grasping hand, the terminal claw long and stout.

First pair of natatory legs has both branches 3-jointed, the outer one armed with serrated lanceolate spines; both branches have numerous plumose setæ. Fourth pair 2-branched; the outer one 3-jointed, armed with short ovate serrated spines, the inner branch consists of 1 long joint gradually widening to the apex; the lateral posterior edges are produced into spines, between which are 2 terminal plumose setæ. The 5th pair consist each of a long curved joint with 3 terminal plumose spines. Furcal rami about 3 times as long as broad, slightly tapering to apex.

Several males and females were taken by surface tow-net in Galle harbour.

This species is easily distinguished by its large size, by the mandible and posterior antennæ, and by the 4th and 5th pair of natatory legs.

Pseudanthessius chelifer, n. sp.—Plate XIV., figs. 12 to 18.

Length, female 1 millim.; male unknown.

Cephalothorax 6-jointed, ovate. Abdomen 4-jointed, the 1st joint swollen and rounded anteriorly, narrowing to base. Anterior antennæ 7-jointed, the proportional lengths of the joints being as follows: $\frac{1. \quad 2. \quad 3. \quad 4. \quad 5. \quad 6. \quad 7.}{16. \quad 24. \quad 8. \quad 21. \quad 16. \quad 12. \quad 12.}$

Posterior antennæ 3-jointed, the apical joint having 3 long terminal spines and a long broad curved terminal claw dentated on upper side. Mandible small, anteriorly extended into a serrated spine; palp large, having 3 terminal spines. The 1st maxilliped narrow, ending in a denticulate spine and a smaller lateral spine. The 2nd maxilliped consists of a long narrow curved joint having 2 small lateral spines and 3 terminal spines. Inner branch of 4th pair of natatory legs consists of one small narrow joint with terminal spine. Furcal rami about 3 times as long as broad.

Several specimens, all females, were found about the pearl banks. A very distinct species, readily recognized by its posterior antennæ, the 2nd maxilliped and the 4th pair of natatory legs.

Pseudanthessius concinnus, n.sp.—Plate XIV., figs. 24 to 30.

Length, female 0·85 millim.; male unknown.

Cephalothorax ovate, similar to *P. gracilis*, but considerably smaller. Abdomen 5-jointed. Anterior antennæ 7-jointed, the proportional lengths of the joints being as follows: $\frac{1. \quad 2. \quad 3. \quad 4. \quad 5. \quad 6. \quad 7.}{10. \quad 24. \quad 8. \quad 16. \quad 16. \quad 12. \quad 7.}$

Posterior antennæ nearly as in *P. gracilis*. Mandibles consist of a curved joint, tumid in centre, with narrow, blunt termination. First maxilliped 1-jointed, long, narrow towards apex, with strong lateral and terminal spines. Second maxilliped 2-jointed, the first joint rather longer than broad; terminal joint very small with 2 strong apical spines. Both branches of 1st pair of natatory legs 3-jointed; inner branch of 4th pair 1-jointed with truncate base terminating in large serrated lanceolate spine and one plain spine; outer branch 3-jointed, having serrated lanceolate spines. Furcal rami long and narrow.

One specimen only, a female, was found in the general washings from Ceylon Invertebrata.

The mouth organs, the inner branch of 4th pair of natatory legs and the furcal rami are the distinguishing features of this species.

Pseudanthessius liber (Brady and Robertson).

Found amongst the general washings of Invertebrates from the pearl oyster beds.

Lichomolgus minor, A. Scott.

Found at 2 stations only, and far apart, viz., between Port Said and Suez, and amongst the washings of young pearl oysters, Ceylon.

Lichomolgus gracilis, n. sp.—Plate XV., figs. 1 to 9.

Length, male 0·7 millim.; female 1 millim.

Cephalothorax (female) ovate, 6-jointed, abdomen 3-jointed, the 1st considerably longer and wider than the combined succeeding 2 joints. First joint of male abdomen quadrate; more than 4 times the size of the 2nd joint.

Anterior antennæ (female) 7-jointed, the proportional lengths of the joints being as follows: $\frac{1.\ \ 2.\ \ 3.\ \ 4.\ \ 5.\ \ 6.\ \ 7.}{17.\ 25.\ 9.\ 11.\ 12.\ 7.\ 5.}$

Posterior antennæ 3-jointed, the apical joint terminating in a strong curved claw, and having 3 small lateral spines. Mandible has an angular quadrate base, and is pectinated along upper edge; palp short, with 3 spines.

First maxilliped has outer joint triangular, sharp and wedge-shaped, and has a serrated curved lateral spine arising from centre; outer joint of 2nd maxilliped (female) very small, with stout apical spines; in the male it is a grasping hand with long curved claw. Inner branch of 4th pair of natatory legs 2-jointed. Furcal rami divergent, about 4 times as long as broad.

Several males and females were found in the general washings of dredged Invertebrates. The mouth organs, posterior antennæ, and furcal rami sufficiently distinguish this species.

Lichomolgus ieversi, n. sp.—Plate XV., figs. 10 to 17.

Length, male 0·96; female 1·06.

Cephalothorax 6-jointed; cephalic segment subquadrate; abdomen 4-jointed, the genital segment smaller than in the other species of the genus. Anterior antennæ 7-jointed, the proportional lengths of the joints as follows: $\frac{1.\ \ 2.\ \ 3.\ \ 4.\ \ 5.\ \ 6.\ \ 7.}{16.\ 25.\ 8.\ 17.\ 17.\ 12.\ 5.}$

Posterior antennæ 3-jointed; the middle joint small; apical joint longer than the combined 1st and 2nd; with four terminal curved spines, two of which are moderately stout. Mandibles long and narrow, coming to a fine point, edges hairy. Terminal joint of 1st maxilliped drawn out, forming a fine ciliated stylet; there is also one lateral spine; 2nd maxilliped (female) 3-jointed, with very short terminal spine; 2nd maxilliped of male forms a chelate hand with very long rounded claw. Inner branch of 4th pair of natatory legs 2-jointed, the outer branch equals 3 of the inner and has truncated apex; outer branch has 5 lanceolate spines. Furcal rami very long and nearly parallel.

About 20 females and 4 males were found in the Muttuvaratu pearl oyster washings and in the Invertebrata washings. The mouth organs, antennal joints, and the furca are the chief distinguishing features of this species, which is named in honour of Mr. R. W. Ievers, Government Agent of the Northern Province of Ceylon, where the pearl banks are situated.

Lichomolgus buddhensis, n. sp.—Plate XV., figs. 18 to 24.

Length, female 1 millim.; male unknown.

Cephalothorax broadly ovate, about 4 times as long as the abdomen, which is 3-jointed; the genital segment being about 4 times the size of the 2 combined succeeding joints; it is much swollen in the middle. Anterior antennæ 7-jointed, the proportional lengths of the joints being as follows: $\frac{1.\ \ 2.\ \ 3.\ \ 4.\ \ 5.\ \ 6.\ \ 7.}{17.\ 31.\ 7.\ 15.\ 14.\ 13.\ 10.}$

Mandible and palp short. Maxillipeds and natatory legs similar to *P. ieversi*. Furca quadrate, very small.

Several specimens, all females, were found in the general washings of dredged Invertebrates. The very short abdomen and furca are quite characteristic of this species—named in honour of the celebrated home of Buddhism from which it came.

Lichomolgus lankensis, n. sp.—Plate XV., figs. 25, 26.

Length, female 1·0 millim.; male unknown.

Cephalothorax ovate. Abdomen 3-jointed; genital segment about as long as the combined two succeeding joints and furca. Anterior antennæ 7-jointed, the proportional lengths being as follows: $\frac{1.\ \ 2.\ \ 3.\ \ 4.\ \ 5.\ \ 6.\ \ 7.}{22.\ 29.\ 10.\ 14.\ 10.\ 7.\ 5.}$

Posterior antennæ, mouth organs, and natatory legs as in *L. gracilis*.

Three specimens, all females, were found in the general washings of dredged Invertebrates. Its general form, and the comparative shortness of the anterior antennæ and furca, distinguish this species from others of the genus.

Lichomolgus simplex, n. sp.—Plate XV., figs. 27 to 34.

Length, female 0·88 millim.; male 0·8 millim.

Cephalothorax 6-jointed, abdomen (female) 4-jointed, male abdomen 5-jointed, genital segment double in size that of the female; anterior antennæ 6-jointed, the proportional lengths being as follows: $\frac{1.\ \ 2.\ \ 3.\ \ 4.\ \ 5.\ \ 6.}{13.\ 22.\ 8.\ 22.\ 18.\ 18.}$

Posterior antennæ 3-jointed, the middle one very short; terminal joint 3 times the length of the second, with 2 apical spines. Mandible constricted in centre; outer portion somewhat quadrate, with ciliated edges bearing 2 small corner filaments and a plumose spine. Maxillipeds similar to *L. buddhensis*, but stouter. Natatory legs as in *L. gracilis*.

Furcal rami about 3 times as long as broad. A few specimens of each sex were found in the washings from sponges dredged in the Gulf of Manaar. The general shape of the animal and of the abdomen and furca and the jointing of the anterior antennæ serve to distinguish this species.

Lichomolgus elegans, n. sp.—Plate XVI., figs. 8 to 13.

Length, female 1·5 millim. ; male unknown.

Cephalothorax 6-jointed. Abdomen 4-jointed, the genital segment being longer than the 3 succeeding joints combined, and having a wedge-shaped notch near the centre on each side. Anterior antennæ 7-jointed, the proportional lengths being as follows : $\frac{1.\ \ 2.\ \ 3.\ \ 4.\ \ 5.\ \ 6.\ \ 7.}{11.\ 32.\ 4.\ 11.\ 9.\ 7.\ 4.}$

Posterior antennæ 3-jointed, the first joint rather longer and nearly double the width of each of the succeeding joints. The third joint bears a strong apical claw. Maxillipeds resemble *L. buddhensis*, but are stouter. Inner branch of 4th pair of natatory legs 2-jointed, the outer joint being about double the length of the inner. Furcal rami very short, about as broad as long.

One specimen only, a female, was found in the general washings from dredged Invertebrates. The notched abdominal genital segment is the most striking characteristic of this species.

Lichomolgus robustus, n. sp.—Plate XVI., figs. 14 to 20.

Length, female 1·1 millim. ; male unknown.

Cephalothorax robust, ovate, 6-jointed. Abdomen 4-jointed; the genital segment about as long as the combined 2 succeeding joints. Anterior antennæ 7-jointed, the proportional lengths being as follows : $\frac{1.\ \ 2.\ \ 3.\ \ 4.\ \ 5.\ \ 6.\ \ 7.}{15.\ 32.\ 5.\ 11.\ 8.\ 8.\ 5.}$

Posterior antennæ similar to *L. simplex*, but more robust. Mandible stylet serrated on outer edge. Maxillipeds and natatory legs like *L. buddhensis*. Furca about half as long again as broad.

One specimen only, a female, was found in the general washings from dredged Invertebrata. In many points there is a great resemblance between this species and *L. buddhensis;* but in the jointing of the cephalothorax, and more particularly of the abdomen, and in the small size of the 5th natatory legs in this species, the difference is so considerable that we are justified in separating them.

Lichomolgus gigas, n. sp.—Plate XVI., figs. 21 to 26.

Length, female 2 millims. ; male 1·4 millims.

Cephalothorax ovate, 6-jointed. Abdomen, female 4-jointed; male 5-jointed. Anterior antennæ long and slender, 7-jointed; the proportional lengths being as follows : $\frac{1.\ \ 2.\ \ 3.\ \ 4.\ \ 5.\ \ 6.\ \ 7.}{12.\ 32.\ 4.\ 16.\ 12.\ 9.\ 7.}$

Posterior antennæ, mouth organs, and natatory legs and furca nearly resemble *L. simplex*.

One of each sex were found in the general washings of dredged Invertebrata.

The large size and the jointing of the slender anterior antennæ sufficiently distinguish this species.

Lichomolgus dentipes, n. sp.—Plate XVI., figs. 27 to 30.

Length, female 0·86 millim. ; male unknown.

Cephalothorax broadly ovate, the cephalic segment equal in size to the combined 5 following ; the edges of the 3rd and 4th segments are finely serrated. The 5th segment is very small, with sharply-pointed lateral terminations.

Abdomen very short and stout, hardly $\frac{1}{5}$th the length of cephalothorax ; genital segment as long as the combined 2 following and double the width ; 4th joint the same as 1st. Furcal rami equal in length and breadth.

Anterior antennæ 7-jointed, the proportional lengths being: $\frac{1.\ \ 2.\ 3.\ 4.\ 5.\ 6.\ 7.}{11.\ 26.\ 3.\ 7.\ 4.\ 3.\ 2.}$

Mouth organs as in *Paralichomolgus.* Inner branch of 4th natatory legs 2-jointed, both joints straight and very narrow. The 5th pair have each a large tooth projecting from inner side anteriorly.

Of this very striking species one specimen only, a female, was found in the general washings of dredged Invertebrata. It is easily recognisable by its serrated thoracic edges and by the 4th and 5th natatory legs—the tooth on the latter gives the specific name.

Paralichomolgus, n. gen.

Female ; body composed of 10 segments ; cephalothorax rotund or ovate ; 5-jointed ; genital segment much larger than the others, being the 1st and 2nd segments united.

Anterior antennæ 8-jointed. Posterior antennæ, mouth organs, and natatory legs as in *Lichomolgus.* The difference between this genus and *Lichomolgus* consists in the lateral prolongations of the body segments and in the jointing of the anterior antennæ.

Paralichomolgus curticaudatus, n. sp.—Plate XVI., figs. 1 to 7.

Length, female 1·2 millims. ; male unknown.

Cephalothorax ovate, 5-jointed ; the posterior edges of segments 2 to 4 being pointed. Abdomen very short, about $\frac{1}{5}$th the length of the cephalothorax ; genital segment wider than its length and having on each side posteriorly a rounded lobe ; the other joints very small. Furcal rami very small, almost half spheres. Anterior antennæ 8-jointed, the proportional lengths being as follows : $\frac{1.\ \ 2.\ 3.\ 4.\ \ 5.\ 6.\ 7.\ 8.}{12.\ 35.\ 3.\ 8.\ 13.\ 8.\ 4.\ 3.}$

Posterior antennæ 3-jointed ; the 1st and 2nd joints sub-equal ; the 3rd as long as the combined 1st and 2nd ; terminal claw thick, and obtuse at apex. Mandible and palp as in *Lichomolgus buddhensis.* Maxillipeds similar to *Lichomolgus ieversi,* except that the joints of the 2nd are nearly double the width of the latter. Natatory legs also similar to those of latter species ; the 2 joints of inner branch of the 4th pair, however, being equal in length to the 3-jointed outer branch.

Two specimens, both females, were found in the general washings from the dredged Invertebrata. The short abdomen, the wide joints of 2nd maxillipeds, and the jointing of inner branch of 4th pair of natatory legs readily distinguish this species.

Paralichomolgus longicaudatus, n. sp.—Plate XX., figs. 6 to 8.

Length, female 1·1 millims.; male unknown.

Body sub-rotund; 1st to 3rd joints of cephalothorax are pointed posteriorly and with a tooth on each lateral edge of 2nd and 3rd; 4th joint very small. Abdomen about $\frac{1}{4}$ the length of cephalothorax; genital segment large and tumid; the rest 3 times broader than long. Furcal rami square, very short, with long terminal setæ.

Anterior antennæ 8-jointed, the proportional lengths being: $\frac{1.\ \ 2.\ \ 3.\ \ 4.\ \ 5.\ \ 6.\ \ 7.\ \ 8.}{16.\ 28.\ 2.\ 9.\ 12.\ 8.\ 4.\ 3.}$

Posterior antennæ, mandible, maxillipeds, and first 3 pairs and 5th pair of natatory legs as in *P. curticaudatus*. The 2-jointed inner branch of 4th pair natatory legs springs from middle of long basal joint at right angles; the 3 joints of outer branch being also at right angles to basal joint.

One specimen only, a female, was found in the general washings from dredged Invertebrata. The general appearance and the 4th pair of natatory legs clearly distinguish this species from the last described.

Hermannella arenicola, Brady.

Found in the general washings of dredged Invertebrata from the pearl banks.

Hermannella robusta, n. sp.—Plate XVII., figs. 1 to 8.

Length of female 1·1 millims.; male unknown.

A very robust species with comparatively short abdomen. Anterior antennæ 7-jointed; proportional lengths of joints: $\frac{1.\ \ 2.\ \ 3.\ \ 4.\ \ 5.\ \ 6.\ \ 7.}{16.\ 35.\ 5.\ 16.\ 8.\ 6.\ 4.}$

The posterior antenna has a short stout hook-like spine arising from the 3rd joint. Mandible and maxillipeds have a general resemblance to the corresponding organs in *Lichomolgus*. Both branches of 1st to 4th natatory legs are 3-jointed. The 5th legs are rudimentary. Abdomen with 4 segments; genital segment large and tumid, 4th joint longer than the 3rd; furcal rami about twice as long as broad, and slightly longer than the last abdominal segment.

This species is easily recognised by the robust body and short abdomen, which is less than a fourth of the length of the body, and by the short furca. Three females were found in the washings from Ceylon Invertebrates.

Hermannella serendibica, n. sp.—Plate XVII., figs. 9 to 11.

Length of female, 1·16 millims.; male unknown.

In general appearance more attenuated than *H. robusta*. Anterior antennæ 7-jointed; proportional length of joints: $\frac{1.\ \ 2.\ \ 3.\ \ 4.\ \ 5.\ \ 6.\ \ 7.}{8.\ 26.\ 6.\ 12.\ 9.\ 6.\ 4.}$

Posterior antennæ, mandible, maxillipeds and natatory legs similar to those of *H. robusta*. The 5th feet are more developed than in the previous species. Abdomen 4-jointed, rather less than half the length of the body. Genital segment large, much wider posteriorly than in front; 2nd, 3rd and 4th joints subequal in length and each about as long as broad. Furcal rami long and narrow, about 5 times longer than broad and equal to the combined lengths of the 3rd and 4th joints of the abdomen. Three females were found in washings from Gulf of Manaar sponges. This *Hermannella* is easily identified by its attenuated form, long abdomen, with the peculiar swelling of the genital segment, and long furca.

Hersiliodes leggii, n. sp.—Plate XVII., figs. 12 to 21.

Length of male 1·5 millims.; female unknown.

Anterior antennæ 7-jointed; the proportional lengths are: $\frac{1.\ \ 2.\ \ 3.\ \ 4.\ \ 5.\ \ 6.\ \ 7.}{11.\ 14.\ 7.\ 20.\ 13.\ 9.\ 12.}$

Posterior antenna 4-jointed, similar to that of other *Hersiliodes*. Mandible strong, with a well-developed biting part. Maxilla more developed than in *Lichomolgus*, and bearing a number of strong apical setæ. The first maxilliped has the terminal joint strongly toothed and also furnished with a setiferous digit. The second maxilliped well developed, in general appearance resembling that of other species of the genus.

Both branches of 1st to 4th natatory legs are 3-jointed. Fifth legs foliaceous, subquadrangular in shape, rather longer than broad, and furnished with 3 dagger-like spines and 1 seta. Abdomen 5-jointed, fully half as long as the body. Furcal rami short, about as broad as long.

One specimen in washings from Gulf of Manaar sponges. This species, which we name after Captain LEGGE, at present Inspector of the pearl banks, is easily recognised from any other member of the genus by the proportional lengths of the joints of the anterior antennæ and by the quadrangular 5th legs.

Hersiliodes tamilensis, n. sp.—Plate XVII., figs. 22 to 25.

Length, female 1·3 millims.; male unknown. In general appearance resembling the previous species. Anterior antennæ 7-jointed; proportional lengths of the joints: $\frac{1.\ \ 2.\ \ 3.\ \ 4.\ \ 5.\ \ 6.\ \ 7.}{10.\ 10.\ 5.\ 15.\ 10.\ 7.\ 11.}$

Posterior antennæ, mandible, maxilla, and 1st maxillipeds nearly as in *H. leggii*. Terminal joint of 2nd maxilliped armed with 2 moderately strong spines and 2 small setæ. Natatory legs 1 to 4 somewhat similar to those of *H. leggii*. Fifth legs long and narrow, about 3 times longer than broad, and armed with 3 dagger-like spines and 1 seta.

Abdomen 5-jointed, fully half as long as the body. Genital segment long and broad, widest near the middle; 2nd joint quadrangular in shape, about half as long as the genital segment; 3rd, 4th, and 5th joints shorter than broad, and in combined length equal to the 2nd joint. Furcal rami short and wide, about as broad as long.

In washings from Muttuvaratu pearl oysters.

The proportional lengths of the joints of the anterior antennæ, and the long and narrow 5th feet, distinguish this species from any of the others.

Hersiliodes dubia, n. sp.—Plate III., figs. 18 to 27.

Length, male 1·8 millims.; female unknown.

Cephalothorax quadrate in form, composed of 5 segments. Anterior antennæ 6-jointed, and all clothed with non-plumose setæ; the proportional lengths are as follows: $\frac{1.\ 2.\ 3.\ 4.\ 5.\ 6.}{8.\ 6.\ 5.\ 3.\ 4.\ 8.}$

Posterior antennæ 4-jointed, the basal joint equalling in size the 3 following.

Mandible with 2 horizontal plumose projections and 2 plumose setæ. Maxilla with 3 terminal spinous setæ, and 4 on the outer side, 2 of them plumose. First maxilliped 2-jointed, the apical joint terminating in a strong curved claw and a plumose spine on each side. Second maxilliped 2-jointed, the basal one with a rounded papilla; the hand angularly curved on outer side, terminating in a long rounded claw bluntly rounded at apex, and having on under side 3 spine-like setæ.

First 4 pairs of natatory legs 2-branched, each having 3 joints with the edges mostly clothed with fine hairs. Fifth pair each consist of a quadrate joint with 3 strong spines and a few hairs and setæ at base. Abdomen rather shorter than the cephalothorax, 5-jointed, the genital segment very large, nearly square, and having hooked posterior lateral terminations.

Furcal rami linear, about 4 times as long as broad, with a small spine on each outer side and terminating in 3 setæ of unequal lengths.

One specimen only, a male, was taken in the Suez Canal.

This species agrees, in most particulars, with Canu's *Hersiliodes.* Canu, however, gives 7 joints in the anterior antennæ, although his careful drawing of *H. pelseneeri* shows only 6 joints. It is evident that the species comprising the genus *Hersiliodes* undergo considerable changes in their various ecdyses, and in the absence of an adult female we can only provisionally place our species in this genus.

Family: ONCEIDÆ.

Oncea venusta, Philippi.

Oncea media, Giesbr.

Oncea minuta, Giesbr.

Oncea mediterranea, Claus.

All the above were generally distributed over the entire voyage. *O. media* was found only once about Ceylon, viz., at Mudalaikuli Paar. *O. mediterranea* occurred twice in Ceylon, viz., at Muttuvaratu Paar and at Talaivillu Paar. *O. venusta* was taken at 10 and *O. minuta* at 5 Ceylon stations.

Oncea subtilis, Giesbr.
Oncea notopus, Giesbr.
Oncea conifera, Giesbr.

Three rarer species. *O. subtilis* occurred at 3 Mediterranean stations; *O. notopus* between Port Said and Suez, and *O. conifera* in the Northern Indian Ocean.

Lubbockia squillimana, Claus.

Occurred at 4 stations in the Gulf of Suez and Red Sea, and once off Minikoi.

Family: CORYCÆIDÆ.

Corycæus venustus, Dana.

Eighteen species of the genus *Corycæus* are included in the collection. *C. venustus* was obtained in fair numbers throughout the entire voyage, occurring at 42 stations.

Corycæus rostratus, Claus.

Occurred at 5 Mediterranean stations.

Corycæus danæ, Giesbr.

Taken at 22 stations, from the Mediterranean onwards.

Corycæus furcifer, Claus.

Taken at 2 Mediterranean stations, twice in the Indian Ocean, and at 5 Ceylon stations.

Corycæus flaccus, Giesbr.

Occurred at 7 Mediterranean stations and once in the Indian Ocean.

Corycæus elongatus, Claus.

Taken once in the Mediterranean, twice in the Red Sea and once in the northern Indian Ocean.

Corycæus speciosus, Dana.

Generally distributed throughout the voyage, and taken at 5 Ceylon stations.

Corycæus lubbockii, Giesbr.

Found at 8 stations, in Mediterranean, Indian Ocean and 4 localities round Ceylon.

Corycæus carinatus, Giesbr.

Occurred 5 times, viz., Mediterranean, Gulf of Suez and Indian Ocean, off Minikoi and south of Cheval Paar, Ceylon.

Corycæus ovalis, Claus.

Taken at 11 stations in the Mediterranean, Red Sea and northern Indian Ocean.

Corycæus obtusus, Dana.

Corycæus gibbulus, Giesbr.

Corycæus longistilis, Dana.

Similar in range of distribution, occurring from Suez to Ceylon at 47, 41 and 16 stations respectively. *C. longistilis* however occurred only once about Ceylon, viz., south of Adam's Bridge, the others being generally represented round the island.

Corycæus concinnus, Dana.

First appeared in the Indian Ocean, where it occurred at 13 stations, and at 5 Ceylon localities.

Corycæus gracilicaudatus, Giesbr.

Similar in range to *C. concinnus*, but it first appeared in the Red Sea.

Corycæus robustus, Giesbr.

Taken once only, in the northern Indian Ocean.

Corycæus tenuis, Giesbr.

Occurred at 3 stations, viz., in the northern Indian Ocean, off Negombo, and at the Cheval Paar pearl banks.

Corycæus longicaudis, Dana.

One specimen was found at Muttuvaratu Paar, Ceylon.

Copilia mirabilis, Dana.

Found in the Mediterranean, Gulf of Suez, Red Sea, at 6 stations in the Indian Ocean, and once at Ceylon, south-east of Cheval Paar.

Sapphirina ovatolanceolata, Dana.

Ten species of the genus *Sapphirina* occur in the collection, the majority being represented at only 1 or 2 localities. *S. ovatolanceolata* was the most widely distributed, and occurred at 12 stations, extending from the Mediterranean to the Red Sea and Indian Ocean as far as Minikoi.

Sapphirina gastrica, Giesbr.

Occurred twice, viz., in the Red Sea, and again from Perim into the Indian Ocean.

Sapphirina ovalis, Dana.

One specimen was taken in the Indian Ocean after leaving Perim, and another south of Adam's Bridge, Ceylon.

Sapphirina nigromaculata, Claus.

Occurred at 6 Indian Ocean stations, and south of Cheval Paar, Ceylon.

Sapphirina metallina, Dana.

Sapphirina salpæ, Claus.

Sapphirina auronitens, Claus.

Sapphirina bicuspidata, Giesbr.

Sapphirina intestinata, Giesbr.

Sapphirina sinuicauda, Brady.

One or two specimens of each of the above were taken in the Indian Ocean, with the exception of *S. sinuicauda*, which was taken at Vankali Paar, Ceylon.

Family: ASTEROCHERIDÆ.

Asterocheres stimulans, Giesbr.

Asterocheres dentatus, Giesbr.

Asterocheres minutus, Claus.

Several specimens belonging to each of the above species were obtained in the general washings from Ceylon Invertebrates and also in washings from sponges collected in the Gulf of Manaar.

Asterocheres manaarensis, n. sp.—Plate XIX., figs. 11 to 20.

Length, female 0·78 millim.; male unknown.

Cephalothorax ovate, 6-jointed, the 5th joint very small. Abdomen 3-jointed; genital segment subquadrate, larger than the two following joints together.

Anterior antennæ 20-jointed, the relative lengths of the joints being as follows:—

1.	2.	3.	4.	5.	6.	7.	8.	9.	10.	11.	12.	13.	14.	15.	16.	17.	18.	19.	20.
12.	3.	2.	2.	2.	2.	2.	3.	2.	5.	7.	7.	7.	7.	8.	9.	13.	4.	7.	4.

The 17th joint has a long filament, the others profusely setose.

Posterior antennæ, maxilla, and maxillipeds similar to *Asteropontius typicus*.

Mandible consists of a long scythe-like spine, without biting teeth, and a 2-jointed palp, the smaller apical joint bearing two terminal plumose setæ.

Both branches of 1st pair of natatory legs 3-jointed; 1st joint of outer branch has a large posterior plumose spine; 3rd and 4th joints of inner branch are toothed on inner side. Inner branch of 4th pair 3-jointed, the apical joint terminating in a large serrated lanceolate spine; the inner side of the joints toothed. The 5th pair each consist of a ciliated oblong joint. Furca short and stout, broader than long. Two specimens, both females, were found in the washings from Gulf of Manaar sponges.

Asterocheres major, n. sp.—Plate XVIII., figs. 21 to 28.

Length, female 1·1 millim.; male 1 millim.

Body nearly circular in outline. Cephalothoracic segment large. Anterior antennæ 20-jointed ; proportional lengths of joints :—

1.	2.	3.	4.	5.	6.	7.	8.	9.	10.	11.	12.	13.	14.	15.	16.	17.	18.	19.	20.
12.	5.	4.	3.	3.	3.	3.	4.	4.	5.	4.	4.	5.	7.	7.	7.	10.	6.	4.	2.

Posterior antennæ, mandible and palp, maxilla, maxilliped, and natatory legs, 1st to 4th, nearly as in other *Asterocheres.* Fifth feet very narrow, about $3\frac{1}{2}$ times longer than broad, furnished with three apical setæ. Abdomen 3-jointed, about $\frac{1}{2}$ the length of the body, joints of moderate length, genital segment slightly longer than the 2nd joint, last joint about $\frac{3}{5}$ the length of the second. Furca very short, about as broad as long, and only $\frac{1}{4}$ the length of the last abdominal joint. The male is slightly smaller than the female, and has the anterior antenna only 17-jointed. The genital segment of the abdomen is slightly longer than the combined lengths of the next 2 joints.

A number of specimens in washings from material collected off Point de Galle. This species is easily recognised by its circular body and narrow abdomen.

Asterocheres minor, n. sp.—Plate XVIII., figs. 29 to 31.

Length, female 0·8 millim. ; male 0·7 millim.

In general appearance very like *Asterocheres major*, only much smaller.

Anterior antennæ 20-jointed ; proportional lengths of joints :—

1.	2.	3.	4.	5.	6.	7.	8.	9.	10.	11.	12.	13.	14.	15.	16.	17.	18.	19.	20.
10.	3.	3.	3.	2.	2.	2.	3.	4.	4.	3.	3.	4.	4.	5.	6.	8.	4.	5.	2.

Other appendages similar to *A. major*.

The distinguishing characters of this species are the difference in the proportional lengths of the joints of the anterior antennæ, the different proportional lengths of the abdominal joints and the furca, the latter being about $\frac{1}{2}$ the length of the last abdominal joint.

Several specimens in washings from Gulf of Manaar sponges.

Asteropontius, n. gen.

Cephalothorax roundly ovate, 5-jointed, the cephalic segment larger than the combined lengths of the 4 following segments. Anterior antennæ 18–19-jointed. Abdomen 3-jointed.

Outer branch of posterior antennæ 4-jointed, a small 1-jointed branch springing from the 1st joint. Maxilla 2-branched. Mandible long and narrow ; palp 1-jointed. Maxillipeds and natatory legs, 1st to 5th, as in *Asterocheres.*

Asteropontius typicus, n. sp.—Plate XIX., figs. 1 to 10.

Length, female 0·96 millim. ; male unknown.

Cephalothorax roundly ovate, about twice the length of abdomen ; genital segment as long as the other 2 abdominal joints combined; tumid in centre. Furca very short.

Anterior antennæ 19-jointed, all clothed with short setose spines; the 17th carries a long narrow filament. The proportional lengths of the joints are as follows:—

1.	2.	3.	4.	5.	6.	7.	8.	9.	10.	11.	12.	13.	14.	15.	16.	17.	18.	19.
12.	4.	3.	3.	3.	3.	3.	4.	3.	5.	7.	7.	7.	7.	7.	8.	9.	4.	6.

Mandible long, narrow, with 5 biting teeth at apex; palp 1-jointed, with long terminal plumose setæ. Maxilla 2-branched, the smaller one half the length and half the width of the larger branch, both bearing long terminal plumose setæ. Maxillipeds and 1st to 5th natatory legs as in *Asterocheres;* basal joint of outer branch of 1st pair has a broad lanceolate spine on apex of outer margin.

Several specimens, all females, were found in the washings from Gulf of Manaar sponges, and in the general washings of Invertebrates. The species bears a general resemblance to *Asterocheres*, but the 19-jointed antennæ and the 1-jointed mandible palp separate it therefrom.

Asteropontius attenuatus, n. sp.—Plate XVIII., figs. 11 to 20.

Length, female 0·92 millim.; male unknown.

Body attenuated, very narrow in front. Cephalothoracic segment triangular in outline, nearly twice as long as the combined lengths of the 1st, 2nd, and 3rd thoracic segments. Anterior antennæ 18-jointed, with a large sensory filament on the end of the 17th joint. Proportional lengths of the joints:—

1.	2.	3.	4.	5.	6.	7.	8.	9.	10.	11.	12.	13.	14.	15.	16.	17.	18.
11.	4.	2.	2.	2.	2.	2.	3.	7.	4.	7.	7.	7.	8.	8.	10.	12.	10.

Posterior antennæ, mandible, maxilla, maxillipeds, and 1st to 4th natatory legs nearly as in *Asteropontius typicus.* Fifth feet long and very narrow, about 6 times longer than broad, and furnished with 3 apical setæ. Abdomen 3-jointed. Genital segment longer than the combined length of the next 2 joints. Anterior portion tumid. Furcal rami short, about $2\frac{1}{2}$ times as long as broad, and equal to the length of the last abdominal joint.

Two specimens were found in washings from Ceylon Invertebrates.

This species is easily distinguished from *A. typicus* by its attenuate form and the long narrow 5th feet.

Collocheres giesbrechti, n. sp.—Plate XVIII., figs. 1 to 10.

Length, female 0·67 millim.; male unknown.

Body elongate, sub-ovate; cephalothoracic segment with a rounded forehead and about equal to twice the lengths of the 1st to 3rd thoracic segments combined. Anterior antennæ 20-jointed, with a sensory filament on the end of the 18th joint.

Proportional lengths of the joints:—

1.	2.	3.	4.	5.	6.	7.	8.	9.	10.	11.	12.	13.	14.	15.	16.	17.	18.	19.	20.
12.	3.	3.	3.	3.	3.	4.	3.	4.	3.	4.	7.	5.	7.	7.	8.	8.	9.	5.	9.

Posterior antennæ, mandible and palp, maxilla and maxillipeds and natatory legs nearly as in *C. gracilicauda*. Fifth feet 2-jointed, 2nd joint slightly curved, long and narrow, furnished with 2 sub-apical setæ on the outer margin, one sub-apical seta on the inner margin and one apical seta, on each side of which there is a distinct tooth-like projection of the foot. Abdomen narrow, 4-jointed. Genital segment longer than the combined lengths of the 2nd, 3rd and 4th joints. Furcal rami short and narrow, about $2\frac{1}{2}$ times longer than broad.

Two specimens in the washings from Ceylon Invertebrates.

This species is easily distinguished from the other members of the genus by the lengths of the joints of the anterior antennæ, the shape of the 5th feet and the furca.

We have much pleasure in naming the new *Collocheres* after Dr. GIESBRECHT, whose monograph on the Naples Copepoda belonging to this peculiar family has done much to simplify their study.

Scottocheres elongatus (T. and A. SCOTT).

Scottocheres longifurca, GIESBR.

Both found in washings from Ceylon dredged Invertebrates.

Lepeopsyllus, n. gen.

Body oval, thin and scale-like, composed of 4 segments. Abdomen 3-jointed and completely covered by the last thoracic segment. Furca completely covered or only partly covered by the same segment. The margin of the carapace is thickly lined with papilla-like prolongations, of irregular length, which probably impart strength to this region.

Siphon long, reaching to about the end of the last abdominal joint. Anterior antennæ 13-15-jointed. Outer branch of posterior antennæ 4-jointed; inner branch long and blade-like.

Mandible rudimentary, consisting of a long hair attached to a short slender basal joint; palp 2-jointed, the joints long and of about equal length, the outer one covered with minute hairs. Maxilla consists of 2 separate lobes attached to the ends of a long basal joint. Maxillipeds nearly as in the other Asterocheridæ.

Both branches of 1st to 3rd pairs of natatory legs 3-jointed; outer branch of 4th pair 3-jointed, the inner consisting of a minute knob with one hair; 5th pair each consist of a long curved hairy appendage. Furca divergent, long and narrow.

Lepeopsyllus typicus, n. sp.—Plate XIX., figs. 21 to 29.

Length, female 1·48 millims.; male unknown.

Anterior antennæ 15-jointed, the proportional lengths of the joints being as follows:

1.	2.	3.	4.	5.	6.	7.	8.	9.	10.	11.	12.	13.	14.	15.
26.	13.	18.	5.	4.	5.	4.	4.	4.	4.	4.	5.	3.	4.	1.

Joint 12 bears a long fine filament.

The other characters are the same as those of the genus. Furcal rami long and divergent, extending a little beyond the edge of the carapace.

One specimen, a female, was found in the Muttuvaratu pearl oyster washings. This species has a longer and less rounded body than the succeeding one, the only known species for which it could be mistaken. The jointing of the anterior antennæ also serves to distinguish it.

Lepeopsyllus ovalis, n. sp.—Plate XIX., figs. 30 to 33.

Length of female 1·4 millims. ; male unknown.

Carapace more rotund than in *L. typicus* but otherwise very similar. Anterior antennæ 13-jointed, the proportional lengths of the joints being as follows :—

1.	2.	3.	4.	5.	6.	7.	8.	9.	10.	11.	12.	13.
21.	10.	17.	5.	4.	7.	4.	4.	7.	5.	2.	4.	2.

The other appendages are practically the same as those of *L. typicus*. Furca are entirely covered by the carapace. Two specimens, both females, were found in the general washings from dredged Invertebrates.

Besides the difference in shape of the carapace, the jointing of the anterior antennæ serves to distinguish this species from *L. typicus*.

Doropontius, n. gen.

Body nearly circular ; cephalic and thoracic segments produced laterally into strong points. Abdomen of the female 3-jointed, anterior antennæ 17-jointed. Posterior antennæ as in *Asterocheres manaarensis*. Mandible, maxilla, maxillipeds and 1st–4th pairs of natatory legs as in *Asterocheres*. Fifth pair of natatory legs 2-jointed.

Doropontius denticornis, n. sp.—Plate XX., figs. 1 to 5.

Length, female 0·9 millim. ; male unknown.

The cephalic segment shield-shaped, forming about $\frac{3}{4}$ of the entire animal. Second and 3rd thoracic segments have each an obtuse lateral tooth. Abdomen short; genital segment about twice as broad as long, laterally excavated to form an upper and a lower tooth, the latter rounded posteriorly. The 2nd and 3rd segments together hardly equal in length to the 1st, and about twice as broad as long. Anterior antenna 17-jointed, the proportional lengths of the joints being as follows :—

1.	2.	3.	4.	5.	6.	7.	8.	9.	10.	11.	12.	13.	14.	15.	16.	17.
19.	6.	13.	5.	5.	1.	5.	6.	6.	7.	7.	7.	8.	10.	3.	6.	2.

The lower margin of the 4th joint is prolonged into a strong pointed tooth, and the 14th joint bears a long filament. Furcal rami quadrate, rather longer than broad.

A few specimens, all females, were found in washings from Gulf of Manaar sponges and in the general washings of Invertebrates. The pointed cephalic and thoracic segments, the anterior antennæ, and the 3-jointed abdomen are the characters which distinguish this genus and species.

Cletopontius, n. gen.

Body broadly ovate, the cephalic segment forming about $\frac{3}{4}$ of the entire body.

Abdomen 3-jointed. Inner branch of posterior antennæ 2-jointed. Mandible stylet-shaped, palp 1-jointed. Maxilla and maxillipeds as in *Asterocheres*. First, 2nd and 3rd pairs of natatory legs 2-branched, both branches 3-jointed; 4th pair composed of 1 branch only.

The characters of this genus do not agree in all respects with any of the known sub-families of the Asterocheridæ, and a new sub-family may therefore be required for its reception.

Cletopontius serratus, n. sp.—Plate XX., figs. 9 to 18.

Length, female 0·8 millim.; male unknown.

Lateral edges of 1st and 2nd thoracic segments bluntly serrated. Abdomen small, the genital segment being about equal in size to 16 of either of the 2 following joints,

Anterior antenna 18-jointed, the proportional lengths of the joints being as follows:—

1.	2.	3.	4.	5.	6.	7.	8.	9.	10.	11.	12.	13.	14.	15.	16.	17.	18.
28.	12.	7.	15.	6.	8.	10.	3.	6.	12.	10.	8.	8.	10.	10.	13.	14	3.

The 4th joint is faintly divided into 3, the 16th joint bears a long filament. Inner branch of posterior antenna 2-jointed; the apical joint less than $\frac{1}{2}$ the length of the basal joint.

The other characters as those of genus, which readily distinguish it. A few specimens, all female, were found in the general washings of dredged Invertebrates.

Bradypontius siphonatus, Giesbr.

Found in washings from Ceylon dredged material.

Artotrogus orbicularis, Boeck.

One specimen was in the general washings from Ceylon dredged Invertebrates.

Stephopontius, n. gen.

Body sub-quadrate, a strongly marked dividing line separating the cephalic segment from the thoracic joints; all have rounded margins.

Abdomen of female composed of 1 joint; that of male 3-jointed. Anterior antenna of female 6-jointed; the male antenna is 2-jointed, the apex forming in conjunction with the extremity of the basal joint what appears to be a strong clasping organ.

Posterior antenna 1-branched. Mandible stylet-shaped; palp 1-jointed. Maxilla represented by a stout plumose spine. Maxillipeds as in *Asterocheres*. First pair of natatory legs each composed of two 1-jointed branches, the outer branch very small; 2nd and 3rd pair 2-branched, both 2-jointed; 4th pair 1-branched, having 2 joints. In 5th pair each consists of a lamella.

Stephopontius typicus, n. sp.—Plate XX., figs. 19 to 31.

Length, female 6·7 millims.; male 8 millims.

Second thoracic segment in female has a terminal lateral appendage on each side; this is absent in male, which has a prolongation of the last thoracic segment on each side of the abdomen. The 1-jointed abdomen in female has a small protuberance on each side at the genital opening. Male abdomen 3-jointed, very small.

Anterior antenna of female 6-jointed, the proportional lengths being as follows:—

$$\frac{1.}{13.}\ \frac{2.\ \ 3.\ \ 4.\ \ 5.\ \ 6.}{16.\ \ 8.\ \ 8.\ \ 7.\ \ 16.}$$ The terminal joint bears a long filament.

Posterior antenna 4-jointed, the apical joint bearing a broad spine with wide trifid end. Other characters as in the genus. Furcal rami very small, spherical in male: knob-like in female. A number of specimens, both males and females, of this very striking form were found in the general washings from dredged Invertebrates. Its general appearance, the male anterior antennæ, and the 1st, 2nd and 5th natatory legs prevent its being mistaken for any other known species.

Family: ERGASILIDÆ.

Bomolochus scomberesocis, Kr.

One adult female with 2 larval forms attached to vulva was taken from the gills of *Caranx leptolepis* from Aripu, Ceylon.

Bomolochus unicirrus, Richiardi.

Several specimens, male and female, were found in the gill chambers of *Amphisile scutata*, Linn., from Ceylon.

Family: CALIGIDÆ.

Caligus dakari, Van Beneden.

Several specimens were taken from the mouth of *Arius venosus* caught in Palk Bay, Ceylon.

Caligus diaphanus, Nordmann.

Several were found about the mouth and attached to the dorsal fin of *Therapon puta* from Aripu, Ceylon.

Caligus benedeni, Bassett-Smith.

Found attached to the inner surface of operculum of *Sciæna diacanthus* from Palk Strait, Ceylon.

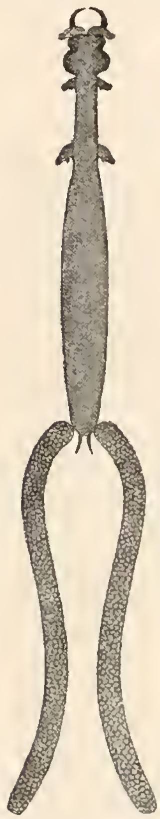

Fig. 1. *Chondracanthus cynoglottidis.*

Lepeophtheirus thompsoni, Baird.

Found associated with *Caligus dakari* in the mouth of *Arius venosus* from Palk Bay, Ceylon.

Family: CHONDRACANTHIDÆ.

Chondracanthus cornutus, Müller.

One only was taken from the gills of *Cynoglossus oligolepis*, from Ceylon.

Chondracanthus cynoglottidis, n. sp.—Text, fig. 1.

Length, female 4·65 millims. (excluding ovisacs); male unknown.

Head rounded, 2-lobed, as wide as the widest part of the body. Body constricted for about $\frac{1}{3}$ of its length, when it expands in width, again narrowing towards the posterior end, and terminating in short strong spines. Anterior antennæ unjointed, about 3 times as long as broad. Posterior antennæ consist of 2 gracefully curved spines. Two pairs of lateral prolongations (rudimentary appendages), having on under side of each a small rounded tubercle, spring from the constricted part of the body. A pair of long wide ovisacs, equalling in length the entire animal, are attached to the posterior end.

Specimens were found attached to the nasal cœcum in *Cynoglossus brachyrhynchus* and *C. brevirostris* by Mr. J. Johnstone, who obtained for us this series of 11 fish-parasites while examining the collection of Ceylon fishes in the Zoological Department of Liverpool University.

Family: LERNÆOPODIDÆ.

Brachiella thynni, Cuv.

Attached to gills of *Chirocentrus dorab*, from Palk Strait.

Brachiella merluccii, Bassett-Smith.

From grooves underneath the head of *Sciæna diacanthus* from Palk Strait.

Anchorella uncinata, Müller.

Found under head in the folds of operculum of *Gazza æquulæformis* from Palk Bay.

EXPLANATION OF PLATES.

PLATE I.

,, 23. ,, ,, ,, abdomen and furca. × 159.
,, 24. *Pseudodiaptomus aurivillii*, CLEVE, female, 5th natatory leg. × 159.
,, 25. ,, ,, male, 5th pair of natatory legs. × 159.
,, 26. ,, ,, ,, abdomen and furca. × 159.

PLATE III.

Fig. 1. *Sunaristes inopinata*, n. sp., female, from left side. × 80.
,, 2. ,, ,, ,, anterior antenna. × 156.
,, 3. ,, ,, ,, 1st natatory leg. × 90.
,, 4. ,, ,, ,, 2nd ,, × 120.
,, 5. ,, ,, ,, 4th ,, × 120.
,, 6. ,, ,, ,, last abdominal segment and furca. × 60.
,, 7. ,, ,, male, apical joints of anterior antenna. × 195.
,, 8. ,, ,, female, 5th natatory leg. × 390.
,, 9. *Sunaristes longipes*, n. sp., female, from left side. × 80.
,, 10. ,, ,, ,, 4th natatory leg. × 120.
,, 11. ,, ,, ,, last abdominal segments and furca. × 60.
,, 12. *Sunaristes curticaudata*, n. sp., female, from left side. × 80.
,, 13. ,, ,, ,, anterior antenna. × 111.
,, 14. ,, ,, ,, 2nd natatory leg. × 120.
,, 15. ,, ,, ,, 3rd ,, × 120.
,, 16. ,, ,, ,, 4th ,, × 120.
,, 17. ,, ,, ,, last abdominal segments and furca. × 90.
,, 18. *Hersiliodes dubia*, n. sp., male, from above. × 45.
,, 19. ,, ,, ,, anterior antenna. × 90.
,, 20. ,, ,, ,, posterior antenna. × 180.
,, 21. ,, ,, ,, mandible. × 260.
,, 22. ,, ,, ,, maxilla. × 260.
,, 23. ,, ,, ,, 1st maxilliped. × 260.
,, 24. ,, ,, ,, 2nd ,, × 90
,, 25. ,, ,, ,, 1st natatory leg. × 120.
,, 26. ,, ,, ,, 4th ,, × 120.
,, 27. ,, ,, ,, 5th ,, × 180.

PLATE IV.

Fig. 1. *Tegastes imthurni*, n. sp., female, from right side. × 106.
,, 2. ,, ,, another female, from left side. × 159.
,, 3. ,, ,, female, anterior antenna. × 195.
,, 4. ,, ,, ,, 2nd maxilliped. × 195.
,, 5. ,, ,, ,, 1st natatory leg. × 136.
,, 6. ,, ,, ,, 2nd ,, × 90.

Fig. 7. *Tegastes imthurni*, n. sp., female, 3rd natatory leg. × 60.

„ 8. „ „ „ 4th „ × 60.

„ 9. „ „ „ 5th „ × 60.

„ 10. *Tegastes donnani*, n. sp., female, from right side. × 159.

„ 11. „ „ „ anterior antenna. × 390.

„ 12. „ „ „ 5th natatory leg. × 90.

„ 13. *Tegastes twynami*, n. sp., female, from right side. × 106.

„ 14. „ „ „ anterior antenna. × 60.

„ 15. „ „ „ 2nd maxilliped. × 260.

„ 16. „ „ „ 5th natatory leg. × 181.

„ 17. *Tegastes chalmersi*, n. sp., female, from left side. × 159.

„ 18. „ „ „ anterior antenna. × 781.

„ 19. „ „ „ 2nd maxilliped. × 320.

„ 20. „ „ „ 1st natatory leg. × 500.

„ 21. „ „ „ 4th „ × 500.

„ 22. „ „ „ 5th „ × 500.

PLATE V.

Fig. 1. *Stenhelia brevicornis*, n. sp., female, from left side. × 106.

„ 2. „ „ „ anterior antenna. × 368.

„ 3. „ „ „ posterior antenna, inner branch. × 276.

„ 4. „ „ „ mandible and palp. × 276.

„ 5. „ „ „ 2nd maxilliped. × 368.

„ 6. „ „ „ 1st natatory leg. × 276.

„ 7. „ „ „ 4th „ × 221.

„ 8. „ „ „ 5th „ × 276.

„ 9. „ „ „ last abdominal segment and furca. × 159.

„ 10. *Stenhelia gracilicaudata*, n. sp., female, from left side. × 159.

„ 11. „ „ „ anterior antenna. × 276.

„ 12. „ „ „ 1st natatory leg. × 276.

„ 13. „ „ „ 4th „ × 276.

„ 14. „ „ „ 5th „ × 276.

„ 15. „ „ „ last abdominal segment and furca. × 159.

„ 16. *Stenhelia longicornis*, n. sp., female, from left side. × 106.

„ 17. „ „ „ anterior antenna. × 221.

„ 18. „ „ „ 1st natatory leg. × 221.

„ 19. „ „ „ 5th „ × 221.

„ 20. „ „ „ last abdominal segment and furca. × 104.

„ 21. „ „ male, 2nd natatory leg, inner branch. × 221.

„ 22. „ „ „ 5th „ „ × 221.

„ 23. *Ameira minor*, n. sp., female, from left side. × 159.

„ 24. „ „ „ anterior antenna. × 335.

„ 25. „ „ „ posterior antenna, inner branch. × 552.

„ 26. „ „ „ mandible and palp. × 552.

„ 27. „ „ „ 1st natatory leg. × 276.

„ 28. „ „ „ 5th „ × 335.

„ 29. „ „ „ last abdominal segment and furca. × 335.

PLATE VI.

Fig. 1. *Stenhelia perplexa*, n. sp., female, from left side. × 159.
,, 2. ,, ,, ,, anterior antenna. × 390.
,, 3. ,, ,, ,, 2nd maxilliped. × 530.
,, 4. ,, ,, ,, 1st natatory leg. × 260.
,, 5. ,, ,, ,, 4th ,, × 260.
,, 6. ,, ,, ,, 5th ,, × 260.
,, 7. ,, ,, ,, last abdominal segment and furca. × 260.
,, 8. *Stenhelia dentipes*, n. sp., female, from left side. × 159.
,, 9. ,, ,, ,, basal joints of anterior antenna. × 260.
,, 10. ,, ,, ,, 2nd maxilliped. × 781.
,, 11. ,, ,, ,, 1st natatory leg. × 390.
,, 12. ,, ,, ,, 4th ,, × 260.
,, 13. ,, ,, ,, 5th ,, × 390.
,, 14. ,, ,, ,, last abdominal segment and furca.
,, 15. *Ameira tenuipes*, n. sp., female, from left side. × 159.
,, 16. ,, ,, ,, anterior antenna. × 390.
,, 17. ,, ,, ,, posterior antenna, inner branch. × 390.
,, 18. ,, ,, ,, mandible and palp. × 390.
,, 19. ,, ,, ,, 1st natatory leg. × 390.
,, 20. ,, ,, ,, 5th ,, × 390.
,, 21. *Stenhelia minuta*, n. sp., female, from left side. × 159.
,, 22. ,, ,, ,, anterior antenna. × 260.
,, 23. ,, ,, ,, 1st natatory leg. × 390.
,, 24. ,, ,, ,, 5th ,, × 390.

PLATE VII.

Fig. 1. *Parastenhelia hornelli*, n. gen. et sp., female, from left side. × 106.
,, 2. ,, ,, ,, anterior antenna. × 260.
,, 3. ,, ,, ,, posterior antenna. × 260.
,, 4. ,, ,, ,, mandible and palp. × 390.
,, 5. ,, ,, ,, 2nd maxilliped. × 390.
,, 6. ,, ,, ,, 1st natatory leg. × 260.
,, 7. ,, ,, ,, 4th ,, × 195.
,, 8. ,, ,, ,, 5th ,, × 195.
,, 9. ,, ,, male, 2nd ,, × 260.
,, 10. ,, ,, ,, 5th ,, × 260.
,, 11. *Ceylonia aculeata*, n gen. et sp., female, from left side. × 106.
,, 12. ,, ,, ,, anterior antenna. × 390.
,, 13. ,, ,, ,, posterior antenna. × 390.
,, 14. ,, ,, ,, mandible and palp. × 390.
,, 15. ,, ,, ,, maxilla. × 260.
,, 16. ,, ,, ,, 1st maxilliped. × 260.
,, 17. ,, ,, ,, 2nd ,, × 780.
,, 18. ,, ,, ,, 1st natatory leg. × 260.
,, 19. ,, ,, ,, 4th ,, × 195.

Fig. 20. *Ceylonia aculeata*, n. gen. et sp., female, 5th natatory leg. × 195.
,, 21. ,, ,, ,, last abdominal segment and furca. × 90.
,, 22. ,, ,, male, 3rd natatory leg. × 195.
,, 23. ,, ,, ,, 5th ,, × 390.

PLATE VIII.

Fig. 1. *Laophonte hirsuta*, n. sp., female, from above. × 106.
,, 2. ,, ,, ,, anterior antenna. × 260.
,, 3. ,, ,, ,, posterior antenna, inner branch. × 395.
,, 4. ,, ,, ,, mandible and palp. × 395.
,, 5. ,, ,, ,, 2nd maxilliped. × 395.
,, 6. ,, ,, ,, 1st natatory leg. × 395.
,, 7. ,, ,, ,, 4th ,, × 395.
,, 8. ,, ,, ,, 5th ,, × 260.
,, 9. *Laophontella typica*, n. gen. et sp., female, from above. × 106.
,, 10. ,, ,, ,, from left side. × 106.
,, 11. ,, ,, ,, anterior antenna. × 395.
,, 12. ,, ,, ,, 2nd maxilliped. × 395.
,, 13. ,, ,, ,, 1st natatory leg. × 260.
,, 14. ,, ,, ,, 2nd ,, × 260.
,, 15. ,, ,, ,, 4th ,, × 260.
,, 16. ,, ,, ,, 5th ,, × 260.
,, 17. *Tetragoniceps dubia*, n. sp., female, from left side. × 106.
,, 18. ,, ,, ,, anterior antenna. × 260.
,, 19. ,, ,, ,, 2nd maxilliped. × 395.
,, 20. ,, ,, ,, 1st natatory leg. × 195.
,, 21. ,, ,, ,, 4th ,, × 195.
,, 22. ,, ,, ,, 5th ,, × 260.
,, 23. *Tetragoniceps minor*, n. sp., female, from left side. × 159.
,, 24. ,, ,, ,, anterior antenna. × 520.
,, 25. ,, ,, ,, 2nd maxilliped. × 780.
,, 26. ,, ,, ,, 1st natatory leg. × 260.
,, 27. ,, ,, ,, 5th ,, × 156.
,, 28. ,, ,, ,, last abdominal segment and furca. × 195.

PLATE IX.

Fig. 1. *Dactylophusia dentata*, n. sp., female, from left side. × 80.
,, 2. ,, ,, ,, anterior antenna. × 221.
,, 3. ,, ,, ,, posterior antenna, inner branch. × 221.
,, 4. ,, ,, ,, mandible palp. × 221.
,, 5. ,, ,, ,, 2nd maxilliped. × 221.
,, 6. ,, ,, ,, 1st natatory leg. × 184.
,, 7. ,, ,, ,, 5th ,, × 221.
,, 8. ,, ,, ,, last abdominal segment and furca. × 221.
,, 9. ,, ,, male, 2nd natatory leg, inner branch. × 221.
,, 10. ,, ,, ,, 5th ,, × 221.

Fig. 11. *Dactylophusia havelocki*, n. sp., female, from left side. × 80.
„ 12. „ „ „ anterior antenna. × 159.
„ 13. „ „ „ posterior antenna, inner branch. × 260.
„ 14. „ „ „ mandible palp. × 260.
„ 15. „ „ „ 2nd maxilliped. × 260.
„ 16. „ „ „ 1st natatory leg. × 195.
„ 17. „ „ „ 5th „ × 130.
„ 18. „ „ „ last abdominal segment and furca. × 130.
„ 19. *Dactylophusia hirsuta*, n. sp., female, from left side. × 80.
„ 20. „ „ „ anterior antenna. × 195.
„ 21. „ „ „ 2nd maxilliped. × 195.
„ 22. „ „ „ 1st natatoıy leg. × 156.
„ 23. „ „ „ 5th „ × 156.
„ 24 „ „ „ last abdominal segment and furca. × 111.
„ 25. *Dactylophusia ceylonica*, n. sp., female, from left side. × 64.
„ 26. „ „ „ anterior antenna. × 156.
„ 27. „ „ „ 2nd maxilliped. × 156.
„ 28. „ „ „ 1st natatory leg. × 156.
„ 29. „ „ „ 5th „ × 98.
„ 30. „ „ male, 1st „ inner branch. × 98.
„ 31. „ „ „ 2nd „ „ × 156.
„ 32. „ „ „ 5th „ „ × 130.

PLATE X.

Fig. 1. *Dactylophusia hamiltoni*, n. sp., female, from left side. × 80.
„ 2. „ „ „ anterior antenna. × 120.
„ 3. „ „ „ posterior „ × 181.
„ 4. „ „ „ 2nd maxilliped. × 260.
„ 5. „ „ „ 1st natatory leg. × 195.
„ 6. „ „ „ 5th „ × 195.
„ 7. „ „ „ last abdominal segment and furca. × 181.
„ 8. *Parastenhelia similis*, n. sp., female, from left side. × 106.
„ 9. „ „ „ anterior antenna. × 260.
„ 10. „ „ „ 2nd maxilliped. × 390.
„ 11. „ „ „ 1st natatory leg. × 260.
„ 12. „ „ „ 4th „ × 195.
„ 13. „ „ „ 5th „ × 260.
„ 14. „ „ „ last abdominal segments and furca. × 260.
„ 15. *Stenhelia knoxi*, n. sp., female, from left side. × 106.
„ 16. „ „ „ anterior antenna. × 390.
„ 17. „ „ „ 1st natatory leg. × 390.
„ 18. „ „ „ 5th „ × 195.
„ 19. *Dactylophusia robusta*, n. sp., female, from left side. × 159.
„ 20. „ „ „ anterior antenna. × 390.
„ 21. „ „ „ 2nd maxilliped. × 390.
„ 22. „ „ „ 1st natatory leg. × 260.
„ 23. „ „ „ 5th „ × 260.
„ 24. „ „ „ last abdominal segments and furca. × 260.

PLATE XI.

Fig. 1. *Dactylophusia laticaudata*, n. sp., female, from above. × 159.
„ 2. „ „ „ anterior antenna. × 260.
„ 3. „ „ „ posterior antenna, inner branch. × 260.
„ 4. „ „ „ mandible palp. × 260.
„ 5. „ „ „ 2nd maxilliped. × 260.
„ 6. „ „ „ 1st natatory leg. × 260.
„ 7. „ „ „ 4th „ × 260.
„ 8. „ „ „ 5th „ × 260.
„ 9. *Dactylophusia æmula*, n. sp., female, from above. × 159.
„ 10. „ „ „ anterior antenna. × 390.
„ 11. „ „ „ 1st natatory leg. × 260.
„ 12. „ „ „ 5th „ × 260.
„ 13. *Dactylophusia platysoma*, n. sp., female, from above. × 106.
„ 14. „ „ „ anterior antenna. × 390.
„ 15. „ „ „ 2nd maxilliped. × 390.
„ 16. „ „ „ 1st natatory leg. × 260.
„ 17. „ „ „ 4th „ × 260.
„ 18. „ „ „ 5th „ × 195.
„ 19. *Pseudothalestris imbricata*, Brady, female, from left side. × 159.
„ 20. „ „ „ anterior antenna. × 390.
„ 21. „ „ „ 2nd maxilliped. × 260.
„ 22. „ „ „ 1st natatory leg. × 195.
„ 23. „ „ „ 5th „ × 195.
„ 24. „ „ „ last abdominal segment and furca. × 395.

PLATE XII.

Fig. 1. *Porcellidium fimbriatum*, Claus, female, from above. × 106.
„ 2. „ „ „ anterior antenna. × 260.
„ 3. „ „ „ posterior antenna, inner branch. × 260.
„ 4. „ „ „ mandible and palp. × 195.
„ 5. „ „ „ 1st maxilliped. × 396.
„ 6. „ „ „ 2nd „ × 396.
„ 7. „ „ „ 1st natatory leg. × 260.
„ 8. „ „ „ 4th „ × 195.
„ 9. „ „ „ 5th „ × 195.
„ 10. „ „ „ abdomen and furca. × 180.
„ 11. *Porcellidium brevicaudatum*, n. sp., female, from above. × 106.
„ 12. „ „ „ anterior antenna. × 260.
„ 13. „ „ „ 5th natatory leg. × 260.
„ 14. „ „ „ abdomen and furca. × 195.
„ 15. *Porcellidium acuticaudatum*, n. sp., female, from above. × 106.
„ 16. „ „ „ anterior antenna. × 260.
„ 17. „ „ „ 5th natatory leg. × 195.
„ 18. „ „ „ abdomen and furca. × 195.
„ 19. *Porcellidium ravanæ*, n. sp., female, from above. × 106.

Fig. 20. *Porcellidium ravanæ*, n. sp., female, anterior antenna. × 260.
,, 21. ,, ,, ,, 5th natatory leg. × 195.
,, 22. ,, ,, ,, abdomen and furca. × 156.

PLATE XIII.

Fig. 1. *Peltidium ovale*, n. sp., female, from above. × 40.
,, 2. ,, ,, ,, anterior antenna. × 195.
,, 3. ,, ,, ,, 2nd maxilliped. × 95.
,, 4. ,, ,, ,, 1st natatory leg. × 95.
,, 5. ,, ,, ,, 4th ,, × 95.
,, 6. ,, ,, ,, 5th ,, × 95.
,, 7. *Peltidium angulatum*, n. sp., female, from above. × 53.
,, 8. ,, ,, ,, anterior antenna. × 195.
,, 9. ,, ,, ,, 2nd maxilliped. × 95.
,, 10. ,, ,, ,, 1st natatory leg. × 95.
,, 11. ,, ,, ,, 5th ,, × 195.
,, 12. *Peltidium speciosum*, n. sp., female, from above. × 53.
,, 13. ,, ,, ,, anterior antenna. × 195.
,, 14. ,, ,, ,, 2nd maxilliped. × 95.
,, 15. ,, ,, ,, 1st natatory leg. × 120.
,, 16. ,, ,, ,, 5th ,, × 195.
,, 17. ,, ,, ,, a smaller form, with thinner bands. × 64
,, 18. *Peltidium serratum*, n. sp., female, from above. × 40.
,, 19. ,, ,, ,, anterior antenna. × 195.
,, 20. ,, ,, ,, 2nd maxilliped. × 95.
,, 21. ,, ,, ,, 1st natatory leg. × 95.
,, 22. ,, ,, ,, 5th ,, × 95.
,, 23. *Peltidium perplexum*, n. sp., female, from above. × 40.
,, 24. ,, ,, ,, anterior antenna. × 156.
,, 25 ,, ,, ,, 2nd maxilliped. × 95.
,, 26. ,, ,, ,, 1st natatory leg. × 95.
,, 27. ,, ,, ,, 5th ,, × 195.

PLATE XIV.

Fig. 1. *Pseudanthessius maximus*, n. sp., female, from above. × 27.
,, 2. ,, ,, ,, anterior antenna. × 90.
,, 3. ,, ,, ,, posterior antenna. × 90.
,, 4. ,, ,, ,, mandible and palp. × 156.
,, 5. ,, ,, ,, 1st maxilliped. × 120.
,, 6. ,, ,, ,, 2nd ,, × 90.
,, 7. ,, ,, ,, 1st natatory leg. × 60.
,, 8. ,, ,, ,, 4th ,, × 90.
,, 9. ,, ,, ,, 5th ,, × 90.
,, 10. ,, ,, male, 2nd maxilliped. × 90.
,, 11. ,, ,, ,, abdomen and furca. × 30.
,, 12. *Pseudanthessius chelifer*, n. sp., female, from above. × 80.
,, 13. ,, ,, ,, anterior antenna. × 260.

Fig. 14. *Pseudanthessius chelifer*, n. sp., female, posterior antenna. × 156.
,, 15. ,, ,, ,, mandible and palp. × 260.
,, 16. ,, ,, ,, 1st maxilliped. × 260.
,, 17. ,, ,, ,, 2nd ,, × 260.
,, 18. ,, ,, ,, 4th natatory leg. × 156.
,, 19. *Pseudanthessius gracilis*, CLAUS, female, from above. × 80.
,, 20. ,, ,, ,, anterior antenna. × 260.
,, 21. ,, ,, ,, posterior ,, × 195.
,, 22. ,, ,, ,, 2nd maxilliped. × 180.
,, 23. ,, ,, ,, 4th natatory leg. × 195.
,, 24. *Pseudanthessius concinnus*, n. sp., female, from above. × 80.
,, 25. ,, ,, ,, anterior antenna. × 260.
,, 26. ,, ,, ,, mandible. × 260.
,, 27. ,, ,, ,, 1st maxilliped. × 395.
,, 28. ,, ,, ,, 2nd ,, × 395.
,, 29. ,, ,, ,, 1st natatory leg. × 195.
,, 30. ,, ,, ,, 4th ,, × 195.

PLATE XV.

Fig. 1. *Lichomolgus gracilis*, n. sp., female, from above. × 80.
,, 2. ,, ,, ,, anterior antenna. × 260.
,, 3. ,, ,, ,, posterior antenna. × 260.
,, 4. ,, ,, ,, mandible and palp. × 395.
,, 5. ,, ,, ,, 1st maxilliped. × 395.
,, 6. ,, ,, ,, 2nd ,, × 260.

It is with deep sorrow that I have to record the sudden death of my friend and fellow-worker, the senior author of this Report, just as his last sheets were passing through the press, and too late for any change to be made elsewhere in this volume. Mr. Isaac Thompson's many scientific friends, who have known and appreciated his work on the Copepoda, will share the feelings of regret which Mr. Andrew Scott, the joint-author, and I desire to express that this Report should have proved to be his last piece of scientific work.

COLONIAL GOVERNMENT
BY
THE ROYAL SOCIETY.

LONDON:
1904.

1077

CONTENTS OF PART II.

PEARL OYSTER REPORT.

SUPPLEMENTARY REPORTS.

PREFACE.

Part I. of this work was issued in November, 1903, and contained the following sections :—

(a) In the Pearl Oyster Report proper : (1) the Introduction ; (2) the Narrative ; (3) the Description of the Pearl Banks ; (4) Observations on the Sea ; and (5) Observations and Experiments on the Life-History and Habits of the Pearl Oyster ;

(b) In the series of Supplementary Reports : I., the Sea-bottoms ; II., the Marine Algæ ; III., the Gephyrea ; IV., the Polyplacophora ; V., the Holothurioidea ; VI., the Cephalochorda ; and VII., the Copepoda.

Along with that volume, I submitted to the Government of Ceylon a type-written section* dealing with practical recommendations as to the conduct of the inspections and fisheries, and as to the best means of conserving and exploiting the pearl banks. These recommendations, when revised and added to if necessary, as the result of further observation and experiments, will be given as the final section of the last volume of this Report.

In January, 1904, Mr. James Hornell was appointed Marine Biologist to the Ceylon Government, and soon after the further duties of Inspector of the Pearl Banks were added to his office. Facilities have now been given to him for carrying out the work, both experimental and executive, recommended in this Report, and he is at the present time engaged in testing the effects, under different conditions, of lifting oysters (both young and old) in bulk, by means of dredges. The transplantation of young oysters will also engage his attention, and the first results of his labours will probably be available for use before this Report is concluded.

In the present Part II., after a discussion of the past history of the principal "paars," Mr. Hornell and I give our account of the Anatomy of the Pearl Oyster, and that is followed by a notable section on the Parasites, contributed by Mr. Shipley and Mr. Hornell.

The Entozoa of the Pearl Oyster are of practical importance from two points of view : (1) because of their effect as parasites when present in sufficient numbers to

* This has since been printed by the Government of Ceylon as a 'Sessional Paper,' Colombo, 1904.

cause lesions in the body, and (2) because some of them provide the centres ot stimulation which give rise to pearl-production. The last is by far the more important, and at an early period of our work in Ceylon it engaged the attention of Mr. HORNELL and myself.

On the Cheval Paar, in March, 1902, we satisfied ourselves that the "orient" pearl, free in the tissues of the pearl oyster, is deposited around a cyst containing a Cestode larva, and preliminary notices to this effect were published in my Royal Institution lecture of March 27, 1903,* and at the Southport meeting of the British Association in September, 1903.

The Cestode larvæ were found in several stages, and the later ones, at least, clearly belonged to the genus *Tetrarhynchus*. Mr. HORNELL then found later Tetrarhynchid larvæ in the bodies of File fishes (*Balistes*) which, we were able to show, sometimes devour the pearl oysters. Finally, Mr. HORNELL'S discovery at Trincomalee in November, 1903, of an adult *Tetrarhynchus* in the intestine of a Sting-ray (*Tæniura melanospilos*, BLKR.), which had freshly-swallowed *Balistes* in its stomach, led us to suppose that the Cestode which passed its youngest stage in the pearl oyster became transferred as a later larva to the File-fish and attained maturity in the Sting-ray. This view was expressed tentatively in the Introduction to Part I. and more definitely in a letter to 'Nature' of November, 1903. Mr. SHIPLEY, however, who kindly consented to collaborate with Mr. HORNELL in working up these and the other parasites for the joint report which appears in this volume, from a further microscopic examination of the specimens sent home by Mr. HORNELL, has come to the conclusion that these various larvæ differ too much in their minute characters to be placed as stages in the one life-history. He regards them as separate animals, and although it is highly probable that the sequence of hosts—Pearl-oyster, File-fish, Sting-ray—will prove to be very much as was indicated in Part I., still the pearl-producing parasite has apparently not yet been traced through all its stages to the adult condition : further field-work still lies before Mr. HORNELL.

Our original statement that the nucleus in the case of the "orient" pearls is a Cestode larva holds good, and it is interesting to find that this observation has been independently corroborated by M. G. SEURAT, working alone in his laboratory at Rikitea, in the island of Mangareva (Gambier Archipelago). The oyster on which SEURAT worked was a *Meleagrina*, and the Cestode parasite he found is, according to GIARD,† an *Acrobothrium*, or some allied form. It is possible that some of our Ceylon Pearl Oyster parasites may also belong to the genus *Acrobothrium*, although the more advanced ones are certainly Tetrarhynchids.

It is probable that Mr. SHIPLEY and Mr. HORNELL will be able to contribute a further paper on these parasites in the last volume of this Report.

* See also 'Nature' for April 30, vol. LXVII., p. 620.

† 'Comptes Rendus Soc. Biol.,' Paris, Nov. 6, 1903, vol. LV., p. 1222.

The Supplementary Reports in the present Part call for no special remark. I am greatly indebted to my friends the authors for their kindness in helping me to make these contributions to our knowledge of the Biology of the Ceylonese Seas.

Mr. Andrew Scott asks me to state that *Ceylonia*, which was described as a new genus in the Report on the Copepoda (Part I., p. 265), is, he now considers, identical with Claus's genus *Jurinia* ('Die Copepoden-Fauna von Nizza,' 1866). As, however, the name *Jurinia* was pre-occupied when Claus used it, *Ceylonia* must stand as the name of the genus. Our species from the Indian Ocean (*C. aculeata*, Thomp. and Scott) is distinct from Claus's Mediterranean form, which now becomes *Ceylonia armata* (Claus).

The third volume will, so far as can be foreseen, be ready about the end of this year. It will contain Professor Dendy's Report upon the Sponges, part of which is in type, Professor J. Arthur Thomson's Alcyonaria, Mr. E. T. Browne's Medusæ, Mr. G. C. Bourne's Corals, Dr. Edith Pratt's Sarcophytons, Mr. A. Scott's Ostracoda, Mr. Farran's Nudibranchiata, and possibly some other papers on the remaining groups of Crustacea and Mollusca, along with further instalments of the Pearl Oyster Report by Mr. Hornell and myself.

A fourth volume early in 1905, containing accounts of the remaining groups of animals, articles on pearl-formation and on Mr. Hornell's recent inspections and our final Recommendations as to the conservation of the Banks, will, it is hoped, complete the Report.

REPORT ON THE PEARL OYSTER FISHERIES OF THE GULF OF MANAAR.—PART II.

HISTORY OF THE PRINCIPAL PEARL BANKS.

It has been shown in the Introduction to Part I. of this Report (p. 4) that the thirty-six fisheries of the nineteenth century took place on nine paars only out of the possible twenty-five to thirty, which is enough in itself to suggest that these banks are of very different values economically. In the section describing the physical features of the pearl banks of the Gulf of Manaar (Part I., p. 99), a classification of the ground was made into :—

(1.) Those paars, such as the Jagerboom, Kallatidel, Aripu, and Anaivelundan, which are at present practically worthless from an economic point of view.

(2.) Some, such as the Periya Paar, which might be used as valuable sources of supply of young brood oysters for transplantation, but cannot be relied upon to yield a fishery.

(3.) Those, such as the great Cheval Paar with its various sub-divisions, the North and South Modragams, the Periya Paar Kerrai, and the Muttuvaratu Paar, which are valuable and reliable grounds upon which most of the successful fisheries of the past century have taken place.

Other paars, such as those lying off Chilaw and Karativo, are less reliable, but may be valuable on occasions; and it must be borne in mind that the whole area is possible paar-ground which might at any time become productive, and consequently the periodic inspections should never be limited to the better known regions. But, as some account has already been given in Part I. of the leading physical and biological features of all the paars, it will suffice now to direct attention to the past history, so far as it can be ascertained, of those that are really of economic importance—especially those which have yielded fisheries and are shown in the accompanying table.

THE CEYLON PEARL FISHERIES from 1801 to 1904 inclusive, showing the Banks that were fished on each occasion. (Compiled from the Government Records at Colombo.)

* Captain DONNAN marks this fishery in his MS. chart as South Cheval Paar.
† Captain DONNAN marks this fishery in his MS. chart as North Cheval Paar.
‡ Recorded as "near the Isle of Cardieu, off Karativo Island."

The greatest of these, both in extent and in value, is the Cheval Paar with its outliers, the Periya Paar Kerrai to the north-west and the two Modragams to the south-east. Next in importance is the Muttuvaratu Paar, lying off Karativo Island;

and the others to be considered here, for different reasons, are the Periya Paar, Kondatchi Paar, Karativo Paar, the Dutch Modragam, and the Chilaw group.

The accompanying sketch-map (fig. 1) shows the approximate relative positions of these, the more important paars in the Gulf of Manaar. Charts showing the topography of the region on a larger scale were given in Part I.

Fig. 1. Sketch-map showing the principal pearl-oyster banks in the Gulf of Manaar. C., Chilaw Paar; Ch., Cheval Paar; K., Dutch Modragam and Karativo Paars; M., Modragam Paars; Mu., Muttuvaratu Paar; P., Periya Paar; P.K., Periya Paar Kerrai.

I. CHEVAL PAAR.*

The map published by BALDÆUS in 1672 shows, from the relative positions of prominent features of the shore-line, that the pearl banks then fished off Aripu correspond with the Cheval Paar of the present day. This establishes the permanence of the Cheval Paar in its general position and outline for over two centuries, and we have native records of important pearl banks in that region from much earlier times. No doubt, over-washes of sand have, from time to time, obliterated portions of the oyster-bearing ground, and at other times the scouring action of tides and storms may have extended the area of the hard "paar"; but notwithstanding these vicissitudes, we still have, as in early Sinhalese times, a group of more or less continuous banks

* For an account of the leading physical and biological characters of the Cheval Paar, see Part I., p. 100.

lying off Aripu, in the centre of the bight of Kondatchi, and yielding the most important fisheries now as they did in the days of the Tamil Queen Alliyarasani. The list of the fisheries given on p. 2 shows that the Cheval has given as many fisheries as those of all the other paars together.

There is some uncertainty in regard to the early records of the nineteenth century. The Cheval and Modragam banks are apparently sometimes entered as the Aripu paars or the paars off Aripu; the subdivisions, such as North Cheval, South-East Cheval, &c., have not a uniform nomenclature in the reports of different Inspectors, and the Government records do not agree in all respects with Captain DONNAN'S MSS. and charts to which we have had access. These discrepancies do not affect, however, any important points from which conclusions are drawn in this Report.

RECORD* OF THE CHEVAL PAAR.

Mar., 1802.—Whole Cheval covered with oysters 4 to 5 years old.

Oct., 1802.—Sample of 1668 oysters $5\frac{1}{2}$ to 6 years old lifted.

Mar., 1804.—Fishery (yielded 770,202 rupees).

,, 1805.—Oysters 5 to 6 years old on east side. Sample lifted.

,, 1806.—Fishery (yielded 412,842 rupees).

,, 1808.— ,, ,, 842,577 ,,

,, 1809.— ,, ,, 272,463 ,,

Oct., 1809.—Very few oysters on Aripu Paar and on Cheval, 6 fathoms. On South-east Cheval oysters 6 to 7 years old. On the North, 6 fathoms, 10 to 70 oysters at a dive. On the South, 7 fathoms, young oysters 2 years old. In 6 fathoms, on Koddai Paar (west end of South Cheval), oysters 1 year old. On the south-west, in 9 fathoms, oysters 3 years old.

Nov., 1810.—Oysters 2 to 4 years old of "Koddai" and "Cheval" kind. On South and South-west Cheval abundance of oysters 2 to 4 years old. On the north end, a very small spot, 5 to 6 years old. Sample lifted.

,, 1811.—Oysters 4 to 5 years old on East Cheval. A few 1 year old on the north-east side of the Aripu Paar. Abundant, 3 to 4 years old, on North-east Cheval. On West Cheval abundant oysters of "Kottapakku" variety. Pearls from 943 oysters valued at Rs. 8.93.

Mar., 1813.—On the South-east Cheval oysters 5 to 6 years old, in 6 fathoms, and a great proportion 6 to 7 years old, with many dead shells. The bank measures 2 × 2 miles and should be ready for fishing in Mar., 1814. On the East Cheval abundant oysters 6 years old. On the North-east Cheval, on a bank measuring 2 × 1 miles, abundant oysters 5 and 6 years old and

* Condensed from all the records at our disposal—Inspectors' reports and other papers by Captain DONNAN, Sir WILLIAM TWYNAM, and others, MSS. and charts in the Government Offices at Colombo, and other information obtained by Mr. HORNELL and myself.

some dead shells (supposed to be the same oysters as those found on the Periya Paar Kerrai in 1810).

Oct., 1813.—Samples lifted from Koddai Paar 6 and 7 years old, and from Kottapakku Paar 5, 6, and 7 years old, and from South-east and North-east Cheval 7 years old.

Mar., 1814.—Large fishery (yielded over 1,000,000 rupees to Government).

Oct., 1815.—Very few oysters, 1 year old, on Koddai Paar (centre of Cheval). On Kottapakku Paar (west of Cheval) oysters 6 years old, and some on North-east Cheval; both the latter recommended for fishery.

Mar., 1816.—All oysters dead. No fishery except a few from Kallatidel Paar. [Small fishery on Cheval and Modragam, *fide* VANE.]

,, 1820.—Oysters 4 years old fished (yielded 30,410 rupees).

,, 1821.—Remainder dead.

,, 1826.—Abundant oysters too young for pearls.

Oct., 1826.—5 year old oysters and smaller ones.

Mar., 1829.—Fishery on North-west Cheval (yielded 382,737 rupees).

,, 1830.— ,, South-east ,, ,, 222,564 ,,

Oct., 1830.—Sample lifted.

Mar., 1831.—Fishery on North-west Cheval (yielded 293,366 rupees).

Nov., 1834.—Oysters in 7 fathoms.

Mar., 1835.—Oysters 4 and $4\frac{1}{2}$ years old, recommended for fishing next March. Part of Cheval fished, along with Periya Paar Kerrai.

,, 1836.—Fishery on Central Cheval and Koddai Paar (South Cheval) (yielded over 160,000 rupees).

,, 1837.—Fishery on North Cheval (yielded 106,312 rupees).

Nov., 1840.—Oysters $1\frac{1}{2}$ to 3 years old.

,, 1851.— ,, 1 year old, on South-west Cheval, in a healthy state.

Mar., 1853.—Large bed of oysters on South-west Cheval (2×1 miles). Oysters "4 or 5 years old."

,, 1854.—Oysters on South-west Cheval healthy, but scattered and not very plentiful.

Nov., 1854.—Sample taken up from South-west Cheval and fishery recommended. Younger oysters $1\frac{1}{2}$ to $2\frac{1}{2}$ years old found to the west.

Mar., 1855.—South-west Cheval fished (yielded 109,220 rupees).

,, 1856.—Oysters on northern part remaining from last year said to be $5\frac{1}{2}$ years old. Oysters 3 years old to south.

,, 1857.—North-west Cheval fished (rather too young, over 32,000,000 oysters yielded only 203,633 rupees).

Nov., 1857.—Many dead shells.

Mar., 1858.—North-west Cheval fished (over 16,000,000 oysters yielded 241,200 rupees).

Nov., 1858.—Oysters 6 months old all over Cheval.

Mar., 1859.—North-west Cheval fished (3,000,000 oysters yielded 194,481 rupees). Oysters 2 years old on South-east Cheval. Oysters 1 year old on South-west Cheval.

Nov., 1860.—Abundant oysters 3 years old on South-west Cheval.

,, 1861.—Sample from South-east Cheval taken up and estimated at 5 years. Considered too young to fish next year [!].

Mar., 1862.—Oysters plentiful, but many dead shells to south.

Nov., 1862.—South-east Cheval inspected and sample lifted. Oysters fine and healthy looking and full grown. On the north-east the oysters lie thick and healthy, but are younger than on the south-east.

Mar., 1863.—South-east Cheval fished (over 11,000,000 yielded 510,178 rupees), oysters dying off. Oysters on South-west Cheval. Ground covered with large fishes (Ray) when fishery began.

Oct., 1863.—Sample lifted from South-west Cheval and fishery recommended for March next; many dead shells found. The oysters are of the same brood as those fished in March, 1863. No young oysters on any part of Cheval.

Mar., 1864.—All dead. Possibly some eaten by Rays, but the oysters were old.

Nov., 1865.—Bare of oysters.

Mar., 1866.—No oysters.

,, 1867.—Abundant young oysters (? "false-spat," *fide* HORNELL) attached to weed on grounds fished in 1858, 1859, and 1863, but only weed on fishing grounds of 1864 and 1859.

Dec., 1868.—Weed and oysters gone. No young ones. North and north-east much covered with sand. South-west and south (Koddai Paar) clear of sand, but covered with sponge.

Oct., 1869.—No oysters on usual grounds, but a patch 2 or 3 years old to eastward. Not enough to fish.

Mar., 1870. Oysters still there. 9 patches of young oysters 1 to 3 months old on Cheval. To west nothing but sand and rock.

April, 1871.—Two patches 1 year old on south-west and north-west. A few oysters 4 years old on patch found in 1869.

Mar., 1872.—Bed of oysters 2 to 3 years old from south-west to north-west. None on south-east.

,, 1873.—Oysters in same position as last year. Patch of young oysters a month or two old to extreme north-west.

Dec., 1873.—Oysters have begun to die off. Small fishery recommended for next March. Valuation Rs. 33.33 per thousand. Young oysters to north-west have all disappeared.

Mar., 1874.—North-west Cheval fished (yielded 101,199 rupees). Extensive deposit of young oysters on South-west and South-east Cheval, extending to south part of Modragam.

Mar., 1875.—Large bed of about 10,000,000 healthy oysters, 2 years old, on South-east Cheval. Smaller bed to east, believed to be of same age. On ground fished last year very few oysters and 40 per cent. dead shells.

„ 1876.—On South-east Cheval a few oysters scattered over a large area. Patch to the eastward now joined on. Very few dead shells. On West and North-west Cheval a very large number of small oysters 6 months old. Rock-fish [*Balistes*] eating the oysters.

Nov., 1876.—On South-east Cheval a bed of 3,000,000 oysters and some dead shells. Pearls valued at Rs. 26.70 per thousand. Oysters supposed to be 4 years old. Fishery recommended for next March. Young oysters on West and North-west Cheval still abundant.

Feb., 1877.—Oysters dying out.

Mar., 1877.—Fishery on East and South-east Cheval (yielded 184,591 rupees).

„ 1878.—Large bed, 3 × 1½ miles, of 3-year old oysters, thickly spread and firmly attached. Those on the south half are the oldest and should be fished first. To the south-east a small bed of oysters 9 months old. A small patch left over from fishery on East Cheval seemed healthy, and the pearls were more valuable than last year.

Nov., 1878.—Oysters still abundant, but not grown much.

„ 1879.—Bed of about 66,000,000 oysters 4½ years old, extending about 3 miles north-north-west and south-south-east, including the portions fished in 1831, 1835, 1855, 1857, 1858, 1859, 1874, and that which failed in 1864. These oysters seem to require another year. They are mixed with younger ones, probably from the patch found in 1878 to the south-east, which had disappeared. On the South-east Cheval 1 square mile was covered with oysters 3 months old, firmly attached. Samples from the south-east of the bed of older oysters were valued at Rs. 9.39 per thousand, and those from the north-west at Rs. 6.43. The south-east portion of this bed is recommended for fishing, as there are so many oysters.

Mar., 1880.—Fishery on North-west Cheval (over 35,000,000 oysters yielded only 200,152 rupees).

Dec., 1880.—On the North-west Cheval an extensive bed of 58,000,000 oysters 5½ years old. Valuation Rs. 21.37 per thousand. Immense numbers of young oysters, 3 months old, on bed fished last season, but the young oysters on the south-east, referred to in report of 1879, are dying off.

Mar., 1881.—Splendid fishery on North-west Cheval Paar (27,000,000 oysters yielded 599,533 rupees), but in lifting sample in February before the fishery the oysters were found to have thinned 40 per cent. since November.

Mar., 1882.—No oysters on banks off Aripu.

,, 1883.—No oysters.

,, 1884.—Oysters about 3 months old on East and West Cheval.

,, 1885.—East and West Cheval covered with a most extensive deposit of young oysters 18 months old. Shoals of Rays were seen, but have apparently done no damage.

,, 1886.—Large beds on east and west flourishing. Oysters $2\frac{1}{2}$ years old. On the east 202,000,000 and on the west 79,000,000. Loss since last inspection probably due to overcrowding. No damage seems due to Rays.

,, 1887.—Oysters $3\frac{1}{2}$ years old—healthy. On east side 195,000,000. On west side 38,000,000 and dead shells apparently destroyed by Rays. North-east Cheval fished (yielded 292,430 rupees).

Nov., 1887.—Extensive beds of oysters, 4 years old, all over. On west side the old oysters are covered with young ones 3 months old.

Feb., 1888.—Nearly all the old oysters gone from the bank. Possibly caused by currents. But found and fished to the east of the East Cheval (22,000,000 oysters yielded 804,247 rupees). West side stocked with young oysters.

Nov., 1888.—A few old oysters on the east. Young about 15 months old on west. Many dead shells.

,, 1889.—On the West Cheval a thick deposit of young oysters 3 months old. Those found in the same place in November, 1888, are all gone. None on the East Cheval.

,, 1890.—Four patches of oysters 15 months old on west and south.

Mar., 1892.—Bank bare of oysters.

,, 1893.—West side well stocked with oysters, 6 months old, in detached patches. A few small patches on north-east.

,, 1894.—Bare of oysters.

,, 1895.— ,, ,,

,, 1896.—Small patch of oysters, 6 months old, on north-west.

,, 1897.—Bare of oysters.

,, 1898.—A few small patches of oysters, 3 to 6 months old, on south-east.

,, 1899.—The few patches of young oysters found last year on East Cheval have entirely disappeared.

,, 1900.—Very extensive bed of oysters, 3 to 9 months old, on West Cheval 3 small patches of similar oysters on east side.

,, 1901.—Three detached beds on West Cheval. 2 detached beds, $1\frac{1}{2}$ to 2 years old, on East Cheval.

Oct., 1901.—Oysters in abundance, $1\frac{1}{2}$ to 3 years old, on both East and West Chevals, also spat up to 4 months old on North-east Cheval.

Mar., 1902.—Both old (3 years) and young (3 to 6 months) oysters on both East and West Chevals, and also some in the Central area.

Nov., 1902.—Both old (over 3 years) and young (6 to 18 months) oysters abundant on both East and West Chevals. Samples taken.

Mar., 1903.—Fishery on East Cheval (about 46,000,000 oysters, including Periya Paar Kerrai, yielded over 800,000 rupees).

Feb., 1904.—Mr. HORNELL estimated there were 35,000,000 of $4\frac{1}{2}$-year old oysters on the West Cheval. Also many young, about $2\frac{1}{2}$ years old.

Mar., 1904.—Fishery on West Cheval (over 41,000,000 oysters yielded over 1,000,000 rupees).

On looking over this record, although it is obvious that it is incomplete, that some gaps (*e.g.*, 1840 to 1851) occur, that some oysters are mentioned whose first appearance was not noted and others whose fate is not known, still it is possible, in most cases, to trace the history of events and to follow particular broods from year to year. One cannot but feel doubtful as to the accuracy of some of the ages assigned, especially in the case of the earlier records. If the oysters estimated at 5 to 6 years old in March, 1805, were those fished a year later, they must then have been unusually aged. Captain DONNAN considers that most oysters when fished are not more than 5 years old, and I am inclined to agree with him. If the 1805 oysters were really upwards of 5 years, a very serious risk was run in leaving them unfished; and the same remark applies in regard to the oysters estimated at 6 to 7 years in March, 1813, and fished in 1814. It is probable, looking through these and other records, that many beds of oysters have been lost in the past through delay in fishing. Inspectors and Administrators are no doubt tempted to wait by the thought that the older the oysters are the more valuable will be their pearls. An additional year of growth no doubt increases the value greatly, but the chances of death in that final year are also greatly increased. On the whole I am of opinion that 5-year old oysters should never be left unfished. It will be noticed that the reputed 6-year old oysters of October, 1815, apparently died that winter, that the 4-year old oysters of March, 1820, were dead before the following year, that oysters probably 4 years old in December, 1873, had begun to die off, that oysters supposed to be 4 years old in November, 1876, were dying 3 months later, and that the oysters fished on South-East Cheval in March, 1863 (which according to the estimate were 7 years! but I suspect this to be a mistake and that they were not more than 5 years) were dying off, while those of the same brood from the South-west Cheval were found to be all dead in March, 1864. I think it probable that these oysters of the 1863 fishery were those found "6 months old all over Cheval" in November, 1858, and were therefore about 5 years old when fished. If I am right in this estimate, then the "5 years" entered under November, 1861, must be a mistake for 3 years, and in that case the absurdity of the remark "considered too young to fish next year" disappears.

Considering the large number of broods of oysters that have succeeded one another on the Cheval Paar, the catastrophes have been singularly few, and this is important testimony to the reliability and relative safety of this region as a rearing ground, provided it is kept supplied with the necessary young oysters. Omitting those batches which probably died off from being left too long unfished, the only evidence we have of catastrophic disappearances is as follows :—

(1.) Young oysters attached to weed in March, 1867, gone in December, 1868. (Probably due to overwash of sand; but the young spat when attached to weed must always be very uncertain, and may simply have drifted out of the area when the weed rotted or was detached by the next monsoon. Mr. HORNELL has suggested that these were "false spat"—*Avicula vexillum.*)

(2.) The 2 to 3-year old oysters which were greatly diminished in number between March, 1875, and March, 1876. (Probably eaten by carnivorous fishes, such as *Balistes.*)

(3.) The extensive beds of oysters 4 years old in November, 1887, which had nearly all gone in February, but which are said to have been found further to the east during the fishery. (This was no doubt due to currents during the north-east monsoon,* as suggested by Sir WILLIAM TWYNAM.)

(4.) A few patches of small oysters found on East Cheval in 1898 had disappeared in 1899. (Small patches may easily be missed; or the ravages of a few *Trygon*-rays or a shoal of *Balistes* may so far reduce the patch that it is no longer recognisable by a few chance dives. I think it unlikely that muddy water caused by floods in the four rivers of the adjoining coast could, as suggested by Sir W. TWYNAM, produce a serious effect so far out at sea. The winter of 1898–9 was, however, an exceptional one, with heavy rains and strong currents.)

* This is corroborated by Captain DONNAN, who has kindly read the proofs of this section of the Report for me, and who writes (July 22nd, 1904): "I have no doubt whatever that a strong south-south-east current was the cause of the loss of the splendid bed of oysters on the Cheval in 1888. I noticed when I visited the bank in February to lift a sample and buoy off the bank, that the pieces of rock brought up by the divers were covered with byssus, and the divers said no shells, broken or whole, were to be found. I therefore concluded that the oysters must have been swept away by a current. I then asked the man in charge of the "Active," which was on the paar from November as a guard boat, if he had noticed any current after I left the banks in November, and he said, yes, in December when at anchor on the bank he found the current so strong to the south that he was afraid the guard-boat would drag her anchor, and he let go a second anchor—he estimated the current to be running at 4 knots and said it lasted a week. During my inspection of the bank in February, the divers brought up a *Pinna* shell with a number of old oysters on it, and so to try the effect of a current, I had the shell towed alongside the tug "Active," going at a speed of 4 knots. After about an hour's towing, and finding that none of the oysters had dropped off the shell, I had the speed increased to about 5 or 5½ knots, and in about half an hour's time all the oysters had dropped off, leaving their byssus on the *Pinna*; so after that experiment I had no doubt about a current being the cause of the loss of oysters from the Cheval."

None of these cases of disappearance ot oysters present any special difficulty or remain in mystery. All can be accounted for by natural causes which we know to be at work.

As the Cheval Paar is then, under most circumstances, so reliable as a rearing ground, it is important to consider the adequacy of the supply of spat. On looking over the history, we find that there is either direct record or indirect evidence of at least 26 fresh broods of oysters having arisen during the nineteenth century, as follows :—

Spat of 1801 (?).—Fished 1806.
,, 1805 or 1806.—(?) Fished 1809.
,, 1807.—Sampled 1811.
,, 1808.—Fished 1814.
,, 1810.—Fished 1816.
,, 1816.—Died 1821.
,, 1824 or 1825.—Fished 1829, 1830, and 1831.
,, 1831.—Fished 1835, 1836, and 1837.
,, 1838.—No record between 1840 and 1851.
,, 1850.—Fished 1855.
,, 1852.—Fished 1857 and 1858.
,, 1853.—Fished 1859.
,, 1858.—Fished 1863 ; remainder dead 1864.
,, 1867.—Spat on weed disappeared next year.
,, 1870.—Fished 1874.
,, 1873.—Fished 1877.
,, 1875.—Fished 1880 and 1881.
,, 1877.—(?) Fished also in 1881.
,, 1879. } Young oysters which died off.
,, 1880. }
,, 1883.—Fished 1887 and 1888.
,, 1887.—Young oysters which died off.
,, 1889.—No record of these.
,, 1892.—No record of these.
,, 1898.—Young oysters which died off.
,, 1899.—Fished 1903 and 1904.
[,, 1901.—Not yet fished.]

That 26 deposits of spat should have produced 25 fisheries must be considered a good record, and a strong testimony to the economic value and reliability of the bank. Several of the broods, such as that of 1899, have produced more than one fishery; and, on the other hand, some few broods evidently died off at an early age or have remained unrecorded. Although there have been so many fisheries, 25 in a century, and although it takes 4 or 5 years of oyster growth to produce a fishery, still it must not be supposed that the whole of the ground was almost continuously occupied by these successive broods of oysters. The area is so large and varied, and so small a space covered with spat is sufficient to produce later on a fishery, which itself may occupy only a small portion of the paar (see fig. 3), that there must often have been wide extents of ground uncovered. There is room on the Cheval Paar for many beds of oysters of several different ages to flourish simultaneously. It is probably a very rare occurrence for the whole region to be naturally covered by oysters young or old, and it is this that affords a valuable opportunity for artificial operations. If young oysters can be obtained from other less reliable paars, the rearing ground of the Cheval ought never in the future to be left unoccupied. As soon as possible after an area has been cleared by a fishery, it ought to be re-stocked by young oysters transplanted from the Periya or other outlying paars, so as to keep up, if possible, a constant series of broods coming to maturity in succession.

Fig. 2. Proposed culture areas recommended for the Cheval Paar and Periya Paar Kerrai.

In the following table the fisheries, since the beginning of the nineteenth century, have been assigned to their respective subdivisions of the Cheval, and it must be remembered that each of these is an area of at most perhaps a couple of square miles, capable of containing many millions of oysters and of yielding a profitable fishery. Yet several, if not most of these subdivisions, have lain either wholly or in part vacant in most years, and therefore, profitable as the Cheval Paar has been, there can be little doubt but that by such a system of cultivation as was outlined in Part I. of this Report, and will be elaborated in detail in the Final Recommendations, it could be rendered more profitable still. The diagram (fig. 2), planned by Mr. Hornell, shows the relative positions and names of the subdivisions referred to. These we would propose as culture areas, nearly all of which might be extended and improved by—

(1) Dredging up and removing injurious and competing organisms, and

(2) Laying down suitable clean hard materials such as broken tiles and stone, dead coral and shells as culch, to give a foothold to the oysters.

TABLE OF THE SUBDIVISIONS OF THE CHEVAL PAAR WHICH HAVE YIELDED FISHERIES.

The Nomenclature of the Subdivisions is that given in fig. 2.

		Totals.
Region undefined	1804, 1806, 1808, 1809, 1814, 1816, 1820	7
North Cheval	1833, 1835, 1887, 1903	4
North-east Cheval. . . .	1887, 1888, 1903	3

South Central Cheval . .	—	Nil

The localities of a number of the earlier fisheries of the Nineteenth Century (1828 to 1863) on the Cheval Paar and its extensions to north and south, the Periya Paar Kerrai and two Modragams, are shown on fig. 3. The exact positions of the fisheries before this time are not known with certainty. The next fishery after these dates (that of 1874) will be shown in a separate diagram, and a series of still later fisheries and inspections showing the distribution of oysters over the Cheval area will be discussed below. It will be noted from this diagram (fig. 3) how irregular and comparatively small the areas covered by a fishery usually are; and how wide extents of the paar may be left unoccupied by oysters. It is also clear from this figure that fisheries, and therefore beds of oysters, are by no means limited by the conventional

U-shaped outline of the Cheval Paar. The central embayment has evidently been sometimes occupied by oysters in the past just as it was when we dredged across it in February and in March, 1902. The position of the Periya Paar Kerrai as a northern extension of the East Cheval, and the practical continuity of the Modragams with the south central region are evident from both the plan of the ground and the distribution of the fisheries.

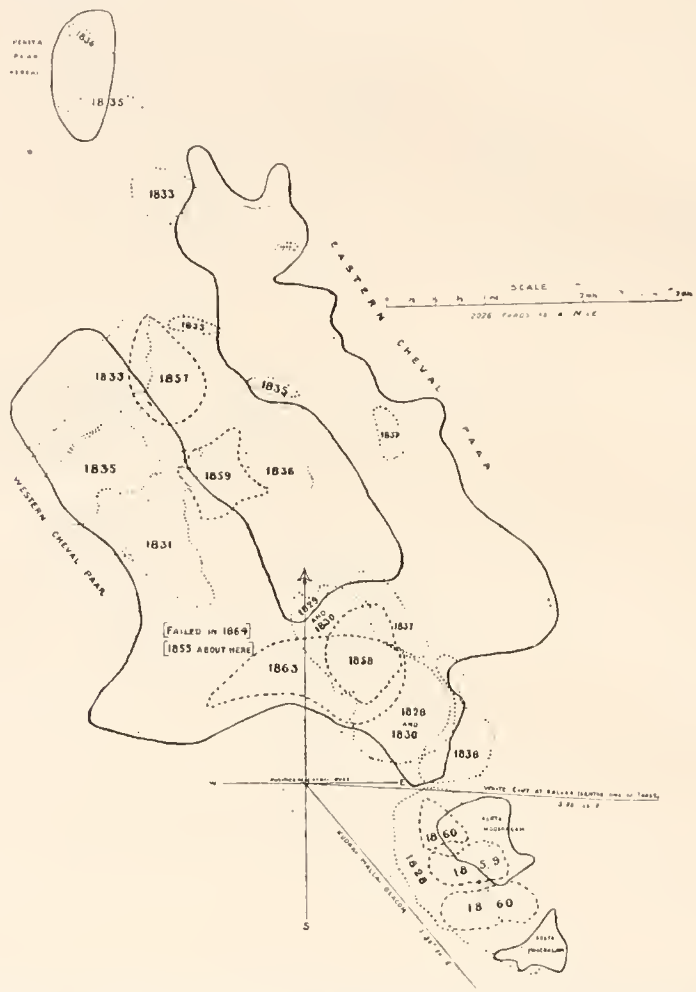

Fig. 3. Plan of the pearl fisheries, from 1828 to 1863, on the Cheval Paar, the Modragams, and the Periya Paar Kerrai.

The next fishery after 1863 is that of 1874, which took place on the North-west Cheval Paar, and as we have very complete records and charts showing the history of this bed of oysters, from the time when it was deposited as spat onwards to the fishery, these have been combined to form the diagram (fig. 4). This shows, by different lines, the condition during the five years 1870 to 1874, and may be taken as an example of the normal uneventful development of a small bed of oysters. It shows what are probably very usual features, viz. :—(1) that small isolated patches of spat either disappear (as in the case of those marked 1, 4, and 6) or expand and join (as in the case of 2, 3, and 5) to form eventually a continuous bed; (2) that if all goes well, as the oysters grow older they increase, for a time, their area of distribution, *e.g.*, we have the two beds of 1871 joining and expanding to form the much larger area of 1872, which again increases somewhat in 1873; (3) after a time, however, the oysters, now over 3 years old, begin to die off, and shrinkage of the bed

Fig. 4. History of one generation of pearl oysters on the West Cheval Paar—from the fall of "spat" in 1870 to the fishery of 1874.

takes place, so that the area fished in 1874 is considerably smaller than that occupied in 1873 or in 1872, and is no larger than the two beds of young oysters present in 1871. In accounting for such changes in the position and the extent of the bed, it is necessary to bear in mind (1) the very considerable powers of locomotion, especially of the young oyster, and (2) the damage done to a bed by both animate and inanimate foes. These have already been discussed in Part I. of this Report.

In order to illustrate more fully the irregular distribution of the oysters on the ground, the large areas that may remain unoccupied on a paar and the changes that take place during the development of a deposit of spat into a fishable bed of oysters, we shall now give a series of diagrams compiled from the MS. notes and plans of the periodic inspections deposited in the Master Attendant's Office at Colombo. They deal with the last 20 years, from March, 1884, and show (figs. 5 and 6) an extensive bed of young oysters which yielded fisheries in 1887 and 1888, various scattered deposits of young oysters (figs. 7 and 8) which apparently came to nothing, and finally (figs. 9 to 14) the detailed history of the extensive bed of young oysters which was first seen on the Western and Southern Cheval in March, 1900, afterwards spread on to the East, and eventually gave rise to the two recent very important fisheries, on the East Cheval in 1903 and on the West in 1904. Although these last oysters must all have been of much the same age, those on the East Cheval, and especially on the North-east, seem to have grown larger and looked older than the others. They were the first to be fished. Figs. 11 to 14 also show the rise and growth of the young oysters, now between 2 and 3 years old, which will probably provide a fishery in 1905 or 1906. In addition to the areas shown on the Eastern Cheval, they also occupy considerable parts of the South, Central, and Western. There are, as yet, no younger oysters in the district.

The first set of diagrams (figs. 5–8) shows the condition of the Cheval Paar at the inspections from March, 1884, to March, 1893. The continuous thick line represents the outline of the paar in each case. In fig. 5 the dotted area represents the part covered with oysters about 3 months old in March, 1884, and the area enclosed by a broken line shows the position of these same oysters in March, 1885. The shrinkage seen in the south-west corner becomes more marked in the following year.

In fig. 6 the dotted area is that occupied by $2\frac{1}{2}$-year old oysters in March, 1886, and the broken line shows the distribution of the same oysters in March, 1887 (then $3\frac{1}{2}$ years old). The oysters now formed two distinct beds, corresponding roughly with the East and West Cheval. These oysters were fished in March, 1887, and March, 1888, and, although so young, yielded a good return.

In fig. 7 the dotted areas on the Western Cheval represent two patches of young oysters, and that on the Eastern Cheval some scattered mature ones in November, 1888 (left over from the fishery in March): the broken line encloses an area covered with oysters 3 months old in November, 1889, while the four black patches show the parts covered with oysters 15 months old in November, 1890. None of these survived to March, 1892, when the bank was found quite bare of pearl oysters.

In fig. 8 the black areas show the extent of ground covered by young oysters, 6 to 9 months old, in March 1893. These scattered deposits came to nothing, as the bank was found to be bare of oysters at the inspections of 1894 and 1895.

The following six diagrams (figs. 9 to 14) show the distribution of oysters on the Cheval Paar during the period March, 1896, to April, 1903, as shown by the periodic inspections and the fishery of 1903. The conventional outline of the bank is shown as a continuous thick line. In fig. 9 the area with oblique lines was covered with oysters 6 months old in March, 1896, the small black areas were occupied with oysters 3 to 6 months old in March, 1898, and the areas enclosed by a dotted line (including an extent of about 5800 acres, occupying the greater part of the West and South Cheval) indicate young oysters at the inspection of March, 1900. These must have appeared as spat after the inspection of 1899, and are of interest as giving rise to the very important fisheries of 1903 and 1904. The bank was bare of oysters at the inspections of 1894, 1895, 1897, and 1899.

In fig. 10 the black areas show the distribution of oysters from $1\frac{1}{4}$ to $1\frac{3}{4}$ years old at the inspection of March, 1901, the dotted circles in this and subsequent figures showing the areas which were surveyed.

Fig. 5.

Fig. 6.

Fig. 7.

Fig. 8.

Figs. 5 to 8. Diagrams showing the distribution of oysters on the Cheval Paar at the inspections from March, 1884, to March, 1903. Scale about half an inch to one nautical mile.

Figs. 9 to 14, on p. 19, show a similar series of diagrams for the period March, 1896, to the end of the recent fishery in 1903.

Figs. 11, 12, 13, and 14 represent the condition of the paar at the inspections of March, 1902, November, 1902, February, 1903, and immediately after the fishery of 1903 respectively, the black areas showing the distribution of the same oysters as those shown in fig. 10, and the dotted areas showing the distribution of a new brood of young oysters, 3 to 6 months old, in March, 1902, and their condition at subsequent inspections. In fig. 13 the obliquely shaded areas represent continuations of the black areas outside the parts actually surveyed, which were only discovered by the divers at the fishery. In figs. 12, 13, and 14 the parts outside the dotted circles were not inspected. The Western Cheval was still covered with the oysters which have just been fished in March, 1904.

Fig. 14 is of interest as showing the very considerable area covered by fishable oysters (estimated at 22,000,000) which the divers had failed to clear in the fishery of 1903.

The history of the recent fishery (April, 1904) shows the reliable character of the Cheval Paar. Mr. Hornell, in February, found the three western beds of oysters in practically the same positions they occupied when we surveyed them with Captain Donnan in March, 1902. It is therefore only under some exceptional circumstances that any catastrophe happens to a bed of oysters on the Cheval.

The general conclusions we arrive at in regard to this ground are :—

1. That the Cheval Paar provides most favourable conditions for future fisheries, provided there be a sufficient deposit of spat.
2. That such deposits of spat are unfortunately of comparatively rare occurrence, and this accounts for most of the blank years in the history of the fisheries.
3. That consequently the need arises for transplanting young oysters from elsewhere on a large scale if such blank years on the Cheval Paar are to be avoided.

Consider, for example, the position of affairs at present and in the immediate future. The recent fishery (1904) has probably cleared the Cheval Paar of all fishable oysters, except what may still remain on the East Cheval from the fishery of 1903. The next oysters to come on are those on the West and parts of the South Cheval, which are now in their third year, and which will, if all goes well, yield a fishery in 1905 and, perhaps, also in 1906. There are no younger oysters in the Cheval district. There has been no fall of spat this year as yet, and the next possible time when it might occur will be about December. Taking the most favourable estimate, such oysters would not be fishable until March, 1908, but it may very possibly be that no deposit of spat will take place this year, and that consequently future fisheries, if left to unaided nature, may be still further delayed. There are, however, now plenty of oysters about 6 months old on the Periya Paar. They cover an area of about 10 square miles, and are probably sufficient to stock the Cheval Paar several times over. The past history of the Periya Paar justifies us in saying that there is

Fig. 9.

Fig. 10.

Fig. 11.

Fig. 12.

Fig. 13.

Fig. 14.

practically no chance of these young oysters coming to maturity where they are. If these are transplanted to the Cheval banks at the earliest opportunity and in sufficient quantities—for such work to be successful must be done on a large scale—they ought to be in their fourth year by March, 1907, and would probably yield fisheries then and in 1908. Our aim should be to have a constant succession of broods maturing on the Cheval, so as to give a continuous series of fisheries, and if sufficient spat does not fall naturally, these broods must be brought from elsewhere.

II. MODRAGAM PAARS (NORTH AND SOUTH).

Fig. 3, on p. 14, shows the close relation between the two little Modragam paars and the great Cheval region. An account of the leading physical and biological characters will be found in Part I., p. 105. The fishery record is as follows :—

1804.—Fished along with the Cheval Paar.
Oct., 1804.—Oysters 5 years old on a bank of small extent.
Mar., 1805.—Small bed of oysters 6 years old. Sample of 1987 oysters lifted. To the south of the bank was found a patch of "Kottapakku" oysters, 3 to 4 years old, and another patch of same age and kind to the north-east. Also a patch of Cheval oysters, 3 to 4 years old.
1806.—Fished along with the Cheval Paar.
1808.— ,, ,, ,, ,, ,,
1809.— ,, ,, ,, ,, ,,
Nov., 1811.—Only a few oysters.
Mar., 1813.—Very few young oysters.
1814.—Fished along with the Cheval Paar.
1816.— ,, ,, ,, ,, ,,
,, 1820.—Oysters 7 years old. Fished along with the Cheval Paar.
,, 1826.—"Great quantity of large oysters."
,, 1827.—"Plenty old oysters in 5 fathoms."
,, 1828.—South-east Modragam fished (yielded 305,234 rupees).
,, 1836.—Fished (6,000,000 oysters yielded 58,624 rupees).
,, 1856.—Oysters in great abundance on west of Modragam, 1 to 8 years old.
Nov., 1856.—Great abundance of oysters, mostly 4 years old.
Mar., 1857.—Oysters in abundance in large clusters, 3 to 5 years old.
Nov., 1858.—Sample of 12,000 lifted.
Mar., 1859.—North paar fished; oysters probably 4 to $4\frac{1}{2}$ years old (over 6,000,000 yielded 287,678 rupees).
,, 1860.—Remainder on north, 5 years old (800,000 oysters yielded 87,269 rupees), and younger ones, 4 years old, on south fished (nearly 3,000,000 oysters yielded 279,547 rupees).

Nov., 1860.—Oysters 8 to 12 months old.

,, 1861.—No oysters on the south-east portion. On the south and on the northern edge, abundance of healthy oysters, 2 to 3 years old. On the North Modragam, healthy oysters $5\frac{1}{2}$ years old.

Mar., 1862.—Oysters 3 to 4 years old, very healthy and abundant, covering 1 square mile; thickest on south part. Should be fishable in 1863.

Nov., 1862.—Millions of oysters 2 to $2\frac{1}{2}$ years old.

1863.—Oysters have totally disappeared. [Probably eaten by Rays.]

Mar., 1864.—No young oysters.

,, 1867.—No oysters.

,, 1868.—To the west and south-west of the bank there is much weed covered with young oysters.

Nov., 1868.—No oysters.

,, 1869.— ,,

Mar., 1870.— ,,

,, 1871.— ,,

,, 1872.—On South-east Modragam a small patch, 9 to 12 months old.

,, 1873.—Oysters have disappeared.

,, 1875.—Two beds of oysters, 2 years old, healthy and numerous on the north and south paars.

,, 1876.—The south bed almost disappeared and the north bed thinned. No dead shells.

Nov., 1876.—200,000 oysters fishable in March, 1877.

Mar., 1877.—North Modragam fished (yielded 4420 rupees).

Nov., 1879.—No oysters.

Mar., 1883.— ,,

,, 1885.—Oysters plentiful, 18 months old; Rays feeding on them.

,, 1886.—Two separate beds, 25,000,000 on north, 14,000,000 on south, oysters $2\frac{1}{2}$ years old; on the south bed mixed with some a year younger. Apparently no loss from Rays yet.

,, 1887.—Serious loss of oysters; north fished at once (yielded 103,664 rupees); south contained too many young oysters mixed with the old.

Nov., 1887.—Some oysters remaining.

Feb., 1888.—3,000,000 on north; 2,000,000 on south, mixed with some 1 year younger. Both banks fished, along with Cheval Paar.

Nov., 1888.—Very few old; no young.

,, 1889.—None.

Mar., 1893.—No oysters.

,, 1899.— ,,

,, 1900.—Small patch of young oysters.

,, 1901.—Two insignificant patches.

Mar., 1902.—North covered with young oysters; south has one bed of young and some of 3 years old.

April, 1903.—Some oysters present in clusters on the sand, and singly adhering to rock.

Mar., 1904.—Large quantities of $2\frac{1}{2}$-year-old oysters on both banks.

It is obvious, in looking over such a record as the above, that it is an incomplete history, and that, in the absence of certain data, we are unable to re-construct a perfect picture of the sequence of events. Still certain beds of oysters can be traced in successive years as follows:—

No doubt the 5 and 6-year old oysters recorded in 1804 and 1805 were those fished in 1806; and the spots of 3 to 4 years old found in 1805 were those fished in 1808 and 1809. But it remains doubtful when the oysters fished in 1814 made their appearance. Those fished in 1816 are very probably the young oysters noted in 1813; and it may be remarked that what may seem comparatively few when young, and small, and closely packed, will, if they live and spread out, be sufficiently numerous when large to form a respectable fishery. It may have been some of these same oysters that formed the 7-year old fishery of 1820. We have no data in regard to the oysters fished in 1828 and in 1836, and after that comes a gap of 20 years during which there are no records. During 1856 and 1857 oysters of all ages were apparently found in abundance, although, in the absence of any history, it may be permissible to doubt whether any were really 8 years old. It is also curious that the older oysters found during these two years and the following one were not fished. In November, 1858, a sample of 12,000 was lifted, and the oysters on the north bank, then estimated at 4 to $4\frac{1}{2}$ years old, were fished to the number of over 6,000,000. The following year what were left on the north bank, amounting to under 800,000 oysters, were fished along with nearly 3,000,000 younger ones from the South-east Modragam. The latter are referred to as 3 years old, but, judging from the high price obtained, it seems unlikely that they were so young.

Young oysters were found on the bank the following November, and again in November, 1861; and in March, 1862, the prospects for a fishery the following year were good. In November younger oysters were also seen "in millions," but in 1863 the oysters had "totally disappeared." This catastrophe occurred during the north-east monsoon, so it was probably not due to any exceptional disturbance of the ground, and from the remarks made by Twynam and Donnan in their Fishery Inspection Report of November, 1863, to the effect that the appearance of the shells brought up showed that they had been destroyed by some animals preying on them, it is very probable that the loss of this bed of oysters was due to an incursion of Rays. Sir W. Twynam thinks, however, that they were also injured by the heavy floods of 1862–63.

From this time there is a blank till 1875, when beds of 2-year-old oysters were found, which yielded the small fishery on the North Modragam in 1877. In 1868, and again in 1872, quite young oysters were seen in the neighbourhood of the Modragams, but these came to nothing. Deposits of spat on weeds must always, in the nature of things, be of very uncertain value. A little extra wind or current in a particular week may drift the weeds with their precious burden on to unsuitable ground or out of the pearl-bank district.

Even if the weeds remain till they rot or the young oysters leave them, the exact nature of the bottom, and the presence of culch or suitable hard objects, may determine whether the spat will be overwhelmed in shifting sand or will start a fresh bed of oysters. No special causes, then, are required to account for the disappearance of weed and spat in its younger stages.

After the fishery of 1877 comes an interval of 10 years, the next fishery being in 1887. That must not be taken as implying that during that time the ground was in any way changed in its nature or unsuitable for oyster growth. Two things are necessary for a successful bed of oysters: first, the suitable ground, and, secondly, a supply of spat; and if an area has been fished out, as the North Modragam was in 1877, and no other adult oysters are present in the neighbourhood, it is easy to understand that no spat will be forthcoming, and that suitable ground may, if left to unaided nature, lie unoccupied for a series of years until, through some accident of winds and tides, or the slow migration of parent oysters, a deposit of spat is again brought into the region. This must have happened in the Modragams in the summer or autumn of 1883, as in March, 1885, oysters 18 months old were found plentiful, but being devastated by Rays. They were still fairly abundant the following year, but in 1887 the loss of oysters was becoming so serious that the north bank was fished at once and yielded nearly 9,000,000, which brought in over 100,000 rupees. In the following year, 1888, the few millions that remained on both banks were fished. On this as on several other occasions difficulties, delay, and loss of oysters were caused by the mixture of fishable old with much younger ones. This is, perhaps, inseparable from the method of fishing by means of native divers, but it is probable that if the oysters were dredged up in bulk, old and young together, from a steamer, most of the young could be separated rapidly by hand on board and thrown back before leaving the "paar" without excessive work, undue delay, or much sacrifice of the young oysters. The prospects of a fishery next year are good.

III. PERIYA PAAR KERRAI.

The relation of this small northern paar to the great Cheval district is seen in fig. 3, on p. 14, and its leading physical and biological characters will be found noted in Part I. at p. 108. The fishery record is as follows:—

Mar., 1802.—Oysters 4 to 5 years old.

Oct., 1802.— ,, $4\frac{1}{2}$ to $5\frac{1}{2}$ years old, many dead shells.

Mar., 1804.—Fishery.

Mar., 1805.—Dead shells.
Oct., 1809.—Young oysters, 2 years old.
Nov., 1810.—Abundant oysters, $1\frac{1}{2}$ to 3 years.
,, 1811.—Oysters present.
Mar., 1813.— ,, 2 to 3 years old.
Nov., 1815.— ,, 6 and $6\frac{1}{2}$ years old—to be fished.
,, 1816.— ,, all dead—no fishery.
,, 1820.— ,, 4 years old.
,, 1821.— ,, dead.
Oct., 1828.—Small patch of good oysters.
Mar., 1832.—Oysters present.
,, 1833.—Fishery (yielded 320,896 rupees).
,, 1835.— ,, (16,000,000 oysters yielded 403,460 rupees).
,, 1836.— ,, (3,000,000 ,, 40,158 ,,
,, 1870.—Two patches of young oysters.
,, 1871.—No oysters.
,, 1876.— ,,
,, 1886.—Two small patches, 3 to 6 months old.
Nov., 1887.—Small patch of oysters about 2 years old.
Mar., 1893.—No oysters.
,, 1899.— ,,
,, 1901.—On south-west 7,000,000 oysters 1 to 2 years old.
,, 1902.—Many oysters about 3 years old.
,, 1903.—Fishery (1,500,000 oysters yielded 32,861 rupees).
,, 1904.—Oysters left last year now gone.

This bank, as might be expected from a northerly extension of the North-east Cheval, although of small size is quite a profitable and reliable paar. It has yielded 5 fisheries that are recorded and one at least, that of 1815–1816, has evidently been lost through the oysters being left too long unfished.

Those of 1820, again, should probably have been fished that year. During the 100 years of our record we have evidence of at least 8 deposits of spat on this bank, but there may well have been more, as this little paar did not until recently receive such close attention as its gigantic neighbour, the Cheval. The patch of hard bottom forming the paar appears to vary considerably in extent and shape from time to time, as the diagram (fig. 15) shows. The variations are, no doubt, due to movements of the sand, and any losses of oysters that have occurred are probably due to that cause or to the incursions of large Rays (Trygonidæ). In March, 1902, we found 3-year-old oysters in quantities which Captain Donnan estimated at over 21,000,000.

In November, 1902, the fishable oysters were estimated at 8,000,000, and in February, 1903, Captain Legge put the figure at a little under 7,000,000.

At the actual fishery, a month later, only 1,473,297 oysters were lifted, but this small number was due in part, at least, to the fact that the great depth (9 fathoms as compared with 6 fathoms on the Cheval) caused the collapse of several divers and discouraged the others, so that it was found impracticable to work longer on the bank. The marked decrease in the number of oysters during 1902 was undoubtedly due to large Rays. Mr. HORNELL found samples of crushed oysters and many broken shells and characteristically comminuted fragments, which he has sent to me, and which I agree are the result of the action of the tooth plates of large Elasmobranchs such as *Trygon uarnak* and its allies.

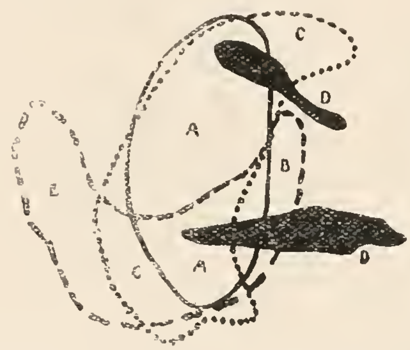

Fig. 15. Plan of the Periya Paar Kerrai. The whole line surrounding A shows the area as inspected in 1882, the dashed line round B shows the paar in 1884, the dotted line round C shows the condition in 1886, while the two black patches indicate the parts fished in 1835 and 1836.

IV. KONDATCHI PAAR.

This is a part of the Cheval group, and evidently forms an extension of the southern end of the East Cheval. Although only one fishery is recorded from this paar, that of 1801, oysters have several times been fished or traced extending to the eastward from the southern part of the Cheval paar in the direction of the Kondatchi. Consequently it is quite possible that a bed might mature and a fishery might take place on this just as on any other part of the Cheval region.

No detailed record of the history is necessary, but it may be added that when we examined this bank in March, 1902, it had about 5,750,000 oysters. These were much reduced in November, 1902, and had nearly all gone by March, 1903, and it seems probable that the destruction in this case may be due to the great numbers of large Star-fishes, and especially of *Pentaceros*, present on the bank.

V. PERIYA PAAR.

This lies outside the other paars in the Cheval district, about 18 miles from land and close to the top of the bank that runs steeply down into deep water. An account of the leading physical and biological features was given in Part I., at pp. 76 and 110. The remarkable fishery record is as follows :—

Mar., 1813.—Oysters 2 years old, in clusters, sticking to small detached rocks.
Nov., 1863.—Young oysters, 6 months old, on piece of ground 3 × 2 miles.
Mar., 1864.—Oysters about 12 months old appearing to be same as last year, but 2 miles further west.

Mar., 1878.—On the Kottapakku paar, where oysters were found in 1802 (extension of Periya to south-east), found 3,500,000 oysters, but there were 13 per cent. dead shells. They were of the "Kottapakku" variety.

Nov., 1878.—Oysters dying on Kottapakku Paar. Pearls valued at Rs. 17.29 per 1000. Small fishery suggested for March.

Mar., 1879.—Bank fished (yielded 95,694 rupees).

Feb., 1880.—Abundance of young oysters.

Mar., 1882.—No oysters on the bank.

April, 1883.—Neighbourhood of ground fished in 1879 thickly covered with young oysters 6 to 9 months old.

Mar., 1884.—Oysters still on bank, mixed with others 3 months old.

,, 1885.—Older oysters gone and very few of the younger remaining.

,, 1886.—No oysters on the bank.

Nov., 1887.—Abundance of young oysters 2 to 3 months old.

,, 1888.—Oysters of last year gone and new lot come, 3 to 6 months old.

,, 1889.—Oysters of last year gone; a few patches present, 3 months old.

Mar., 1892.—No oysters on bank.

,, 1893.—Abundance of oysters 6 months old.

,, 1894.—No oysters on bank.

,, 1895.— ,, ,, ,,

,, 1896.—Abundance of young oysters 3 to 6 months old.

,, 1897.—No oysters present.

,, 1898.— ,, ,, ,,

,, 1899.—Abundance of oysters 3 to 6 months old.

,, 1900.—Abundance of oysters 3 to 6 months old; none of last year's remaining.

,, 1901.—Oysters present, 12 to 18 months old, but not so numerous as in preceding year.

,, 1902.—Young oysters very abundant, 2 to 3 months old. Only a few patches of older oysters (2 to $2\frac{1}{2}$ years) remaining.

Nov., 1902.—All the oysters gone.

April, 1903.—Some oyster spat seen on Sargassum weed.

Mar., 1904.—Bank of 5 × 2 miles covered with young oysters (3 months old) from end to end.

This is an extraordinary history. In 100 years there has only been one small fishery, that of 1879, and yet the Periya Paar probably receives more deposits of spat than any of the other banks. Since 1880 the bank has been naturally re-stocked with young oysters at least 12 times without yielding a fishery. The destruction and the reproduction are both, in this case, on an enormous scale. As this bank was dealt with fully in the Narrative (p. 76) in Part I., I need only say here (1) that the destruction of the successive broods of young oysters seems to be due to the configuration of the ground and its exposure to the south-west monsoon, and (2) that the constant production of fresh spat renders possible the transplantation of young pearl-oysters in enormous quantities from the Periya Paar to other safer grounds further inshore, such as parts of the Cheval district.

VI. DUTCH MODRAGAM PAAR.

This paar, notwithstanding its name, lies at a considerable distance from the better known North and South Modragams. It is about 10 miles to the south-west, and on the other hand is only about a mile to the north of Karativo Paar. It clearly belongs to the Karativo and Muttuvaratu group rather than to the Cheval and Modragam series of paars. It has been described in Part I., at p. 111.

This is a disappointing but at the same time a promising bank. It has apparently not yielded a fishery in British times, and yet it has, on various occasions, been found covered with oysters both young and old (over 3 years). It has a rough hard bottom, suitable for affording good attachment, and it evidently receives deposits of spat, *e.g.*, one in the summer of 1899 and one in the summer of 1902. Consequently, notwithstanding its poor record in the past, I see no reason why it should not at any time yield fisheries like those of the neighbouring Karativo and Muttuvaratu Paars.

It is only of the last few years that we have detailed records; but these, as given below, will serve as a sample to indicate the nature and prospects of the bank.

Recent History of the Dutch Modragam Paar.

April, 1899.—No oysters.

Mar., 1900.—386 acres covered with young oysters 3 to 12 months old (*fide* Donnan).

,, 1901.—Two small detached beds of oysters from $1\frac{1}{2}$ to 2 years old, 1,750,000, rapidly disappearing since last year; about 51 acres of ground covered by these oysters (*fide* Donnan).

April, 1902.—A small bed of 387,500 square yards (= 80 acres) bearing oysters of 2 to $2\frac{1}{2}$ years old (*fide* Donnan).

Nov., 1902.—Oysters were present which, though apparently not over 2 years old, must have been $2\frac{1}{2}$ to 3 years of age. They were mixed with quantities of young, from 6 to 8 months old.

Feb., 1903.—At the place where Mr. Hornell made an examination in a diving dress, very many pearl oysters lay thickly spread on the bottom, very similar in appearance and size to those of Muttuvaratu; age apparently $3\frac{1}{2}$ years, with considerable numbers of younger and smaller ones.

Mar., 1904.—Oysters plentiful ; apparently the majority are not more than 2 to $2\frac{1}{2}$ years old. These represent the young spat which was noted as abundant in November, 1902 ; their growth has been at the expense of the older ones that were present in 1902, and which have been smothered or killed out by the competition of the more vigorous and numerous young.

VII. KARATIVO PAAR.

A short account of the characters of this paar will be found at p. 113 in Part I. Its fishery record is as follows :—

Nov., 1829.—Oysters 5 years old.

Mar., 1832.—Fishery (yielded 45,810 rupees).

1863.—Found nothing.

Mar., 1864.—A few oysters 12 months old ; do not look healthy.

,, 1867.—Only a few scattered oysters.

,, 1868.—To the south-west, weed covered with young oysters.

,, 1870.—Patches of weed covered with young oysters.

,, 1871.—No oysters.

,, 1875.— ,,

,, 1882.— ,,

,, 1883.— ,,

,, 1886.—4,000,000 oysters, 18 months old, on the fishing ground of 1832 ; 1,500,000, 3 years old, thinly spread, and 8 per cent. dead.

May, 1887.—Oysters apparently all gone from fishing ground of 1832 ; young oysters present, not enough for fishing.

Nov., 1889.—3,000,000 of the oysters found in 1886 ; small fishery held at once.

Mar., 1890.—Some fished with fishery at Muttuvaratu.

Nov., 1890.—Most of the oysters had died out.

Mar., 1891.—Remaining oysters (200,243) fished with fishery at Muttuvaratu.

,, 1893.—No oysters.

,, 1899.— ,,

Mar., 1900.—Bare of oysters.

,, 1901.—" A fairly large bed of oysters (234 acres) of from 6 to 12 months old"—number estimated* 30,000,000.

April, 1902.—25,330,000 oysters, from $1\frac{1}{2}$ to 2 years old, occupied a bank having an estimated area of 1,570,850 square yards (= 324 acres).

Nov., 1902.—Not inspected.

Mar., 1903.—Mr. Hornell's inspection by means of diving apparatus showed that the oysters present in April, 1902, had practically all disappeared.

,, 1904.—Old oysters all gone. Some younger (2 years old) have appeared.

* But little importance can be attached to numerical estimates of oysters at this age, and Mr. Hornell advises that such estimates should not be made use of except in the case of banks of mature oysters.

If we include "the paar near the Isle of Cardieu, off Karativo Island," as recorded in 1832, we have four fisheries in all—the other three being of more recent date (1889–91). A great gap, however, exists in the records—from 1832 to 1863—so it is possible that this, like the neighbouring Muttuvaratu Paar, was lost sight of or neglected for some time.

It is evident that spat has appeared on the bank from time to time—three times between 1864 and 1870—and in all probability the area is as good for rearing as the Muttuvaratu Paar, and as likely to yield fisheries. I attach no importance to spat "on weed" disappearing. At that stage it is too uncertain and too much at the mercy of the winds and waves to be regarded as more than a *possible* source of supply. Besides if the weed be carried away from one paar it may drift on to another, and so is not necessarily lost, although it may be lost sight of.

The oysters fished in November, 1889, must have been those that were 18 months old in 1886, and if so, the observation of May, 1887, that the oysters were gone from the fishing ground of 1832 must have been erroneous, unless it be that the oysters shifted their ground, were temporarily lost, and were found again in 1889.

A large deposit of young oysters must have appeared in the summer and autumn of 1900. It was surveyed in March, 1901, and again in April, 1902, when it occupied a still larger area. This increase in area may have been due to spreading of the oysters, or more likely to differences in the areas examined at the two inspections. It is seldom that successive inspection areas closely agree in position—it being practically impossible to place the inspection vessel on the same bearings at successive inspections.

In the following spring, however, Mr. Hornell's inspection showed that these oysters had nearly all gone, and in March, 1904, the bank was practically bare again. If there is no mistake in the locality, and the oysters have not been shifted to some adjoining ground, this is a disappointing case of a bed which ought to have yielded a good fishery, failing after it seemed to be well established. This paar, it must be remembered, is just on the edge of the deep water, exposed to currents, and therefore in a somewhat precarious condition. The loss of these oysters was very probably due to monsoon currents in the summer and autumn of 1902.

VIII. MUTTUVARATU PAAR.

An account of the leading physical and biological characters of this important bank was given in Part I., at p. 114. The fishery record is as follows:—

Dec., 1820.—Oysters, 1 year old, on rock—very thick.
Mar., 1826.—Quantities of large oysters.
,, 1827.—Plenty of old oysters.

* * * * * * *

,, 1886.—27,000,000 oysters 18 months old.

Nov., 1887.—49,000,000 3-year-old oysters firm on rocky ground.

Dec., 1888.—Oysters have not suffered. Sample lifted 4 years old—fishery recommended.

Mar., 1889.—39,000,000 oysters fished. Oysters were young (yielded 498,377 rupees)—small thick "Kottapakku" variety.

Nov., 1889.—Still a large number (30,000,000).

Mar., 1890.—Over 33,000,000 oysters fished (yielded over 300,000 rupees)—much mixed in size; plenty of small pearls.

Nov., 1890.—Oysters still there in quantity.

Mar., 1891.—Over 44,000,000 oysters fished (yielded over 900,000 rupees)—much mixed, but for the most part full-grown, rich in pearl; rapidly dying off—many putrid and of offensive smell when brought to the Kottus.

,, 1893.—No oysters.

,, 1895.— ,,

,, 1896.—127 dives showed oysters 3 to 6 months old. 499 dives were unproductive—bare rock.

,, 1897.—260 dives gave bare rock; 410 showed the presence of young oysters, about 1 year old, estimated at 72,000,000.

,, 1898.—Oysters, 2 to 2½ years old, reported from 278 dives; 429 reported bare rock.

,, 1899.—The bank is again practically clear of oysters. All but total disappearance. Probably due to ravages of large Rays.

,, 1900.—Abundance of young 3 to 9 months old.

,, 1901.—Abundance of young 18 months old; 178,000,000. Large area on north-west side of southern portion has been completely cleared since last year.

,, 1902.—Oysters still present in enormous abundance; 277,000,000.

Nov., 1902.—Considerable reduction in number, and appearance stunted; many yellow individuals present.

Mar., 1903.—Still very numerous, about 125 to the square yard in places.

,, 1904.—Some old still remain, but dying off rapidly. Considerable numbers of younger ones, about 1 year old, now present.

The history of the Muttuvaratu Paar is interesting because of the great gap from 1827 to 1886, during the greater part of which period the bank had apparently been lost sight of. In 1820, 1826, and 1827 there are entries of quantities of old oysters on the rocky bottom,* but there are no records of a fishery until after Captain DONNAN

* Captain DONNAN, however, writes to me that he thinks it probable that these early inspections were on HAMILTON'S Muttuvaratu Paar, which lies between 2 and 3 miles to the north-east of the true Muttuvaratu; in which case we have no record of the true paar from the time of the Portuguese until DONNAN re-discovered it in 1860 or 1861.

re-discovered* the bank about 1860, and watched it carefully after his appointment as Inspector in 1863. And yet there is reason to believe that it was known to the natives, and that there may have been native fisheries there in early times, extending even to the period of the Portuguese occupation. JOHANN JACOB SAAR (1662), in describing the capture of Manaar by the Dutch, referred to one important pearl bank at 3 miles' and another at 10 miles' distance from Manaar. These miles, being Dutch, are from $3\frac{1}{2}$ to 4 times as long as English, and consequently these two banks were respectively from 10 to 12 and from 36 to 40 miles to the south—distances which correspond with the positions of the Cheval and Muttuvaratu paars. The Muttuvaratu Paar is 3 miles in length and covers the ground between 36 and 39 miles from Manaar. It is unlikely that so much importance should have been attached to this bank by the Portuguese and the Dutch unless it had yielded fisheries.

When Captain DONNAN inspected the bank in 1886, it had what was estimated at 27,000,000 of oysters in their second year. There must have been many more. When inspected in November, 1887, a still larger estimate was made (still much under the mark), and this excellent bed of oysters yielded eventually the three very profitable fisheries of 1889, 1890, and 1891, during which in all about 117,000,000 of

* The story of this discovery is so interesting that I add it here in Captain DONNAN'S own words. He told it to me on the pearl banks in 1902, and I have now got him to write it out, and I quote from his letter of July 11th, 1904:—"My first visit to the Muttuvaratu Paar was, as far as I can remember, in November, 1860, or in March, 1861. I was then in command of the s.s. 'Pearl,' and was on a visit to the pearl banks under the direction of Captain PRITCHARD, Master Attendant at Colombo and then Acting Superintendent of the Pearl Fishery. PRITCHARD gave the chart of the banks to me and told me to anchor on each bank according to the bearings, but on getting on the chart bearings of the banks off Karativo I found we were off the bank of soundings, and that the chart was unreliable. I therefore suggested to PRITCHARD that I should go down south of Dutch Bay again and start afresh, steering north and keeping in 8 fathoms water, and stopping every quarter of a mile or so and sending down a diver. PRITCHARD thought that was a good idea and told me to carry it out, which I did. After a great many stops and dives of 'Chippie Illai' (no oysters) at last the diver reported oysters, so I anchored and sent out the boats to inspect, the result being a find of a bed of full-grown oysters mostly all dead and very few found alive. This bank would no doubt have yielded a good fishery if it had been discovered a year sooner. I made a note of the position of the bank, and when I became Inspector of Pearl Banks I determined to visit that spot every two or three years, as I imagined that the spot where oysters had matured would be a likely spot for them to come on again, but it was not until 1886 that I was rewarded for my perseverance by finding a large bank of young oysters which yielded three fisheries in succession.

"When the oysters were approaching maturity, I looked up STEUART'S book to see if he had any record of a bank in that neighbourhood, and I found that in the Dutch time a native of Calpantine had given information of a bank, named Muttwartu Paar, some 8 miles north-west of Calpantine Flagstaff. There was no information as to the position of the flagstaff, but I imagined that the bank referred to might possibly be the one I had discovered. I thereupon consulted the Adigar of Manaar as to the meaning of the word Muttwartu, and he replied that the proper name must be Muttuvaratu Paar, which means the bank where the pearls come, so I then decided that the bank I had discovered should bear that name.

"It is, I think, very probable that my Muttuvaratu Paar is the same as the one referred to in the Dutch records, and in that case my discovery was only a re-discovery of an old bank that had been lost for ages."

oysters were lifted. These fisheries show well how pearl oysters increase in value as they get old, the last one (1891) when the oysters were rich in pearl being much the most remunerative, and in fact being the only fishery since 1814 that has brought in nearly 1,000,000 of rupees. But the record also shows the risk there is in trying for the enhanced value by delaying the fishery once the oysters are over 5 years of age. In 1891 this bed must have been 6 years old, and they are described as rapidly dying off, many being already dead and putrid.

The next deposit of young oysters on the Muttuvaratu, found in March, 1896 disappeared* in 1898–99 (a winter of exceptionally heavy rains and storms); and a fresh population made its appearance a year later and has been recorded at all the inspections since. In March, 1902, it was estimated by Captain DONNAN at the enormous figure of 277,000,000. This number has probably been greatly reduced since by disease and the ravages of enemies, and it is doubtful whether sufficient will survive to yield a fishery next year when these oysters will be over 5 years of age.

The adult oysters of the Muttuvaratu Paar are of small size and have a peculiarly stunted appearance. They are infested with parasites, and also seem liable to a diseased condition in which the mantle and other tissues become of a yellow colour. In April, 1903, over 11 per cent. of the oysters examined were affected with this disease. The Muttuvaratu, like the Karativo and the Dutch Modragam, seems excellently adapted for the deposit of spat, but less reliable than the Cheval as a rearing ground.

IX. CHILAW PAARS.

There are several paars, large and small, in the neighbourhood of Chilaw, which have been described in Part I. (pp. 117, 118). The following record covers several of these :—

Mar., 1802.—Oysters 5 years old. On Jokkenpiddi, 4½ and 4 years old.

,, 1803.—Jokkenpiddi fished (yielded 163,154 rupees).

Oct., 1804.—Nothing on Jokkenpiddi.

Nov., 1812.—On the Jokkenpiddi Paar, oysters 4 and 5 years old, with young ones attached, estimated to be fished in 1815. On Karkopanni Paar, abundant oysters 2 to 3 years old, and to the north, some of 4 to 5 years. On the Chilaw Paar a small bank of oysters 4, 5, and 6 years old, half of them dead.

Nov., 1814.—On Karkopanni the oysters are thin and scattered, upwards of 6 years old, and there are many dead shells—to be fished in March. On Jokkenpiddi, only dead shells. On the Chilaw Paar nothing but rock and dead shells.

* Captain DONNAN informs me that it was his report on this disappearance which caused Sir E. WALKER, then Acting Governor, to write to the Secretary of State asking for an expert enquiry into the condition of the pearl banks, and so gave rise to the present investigation.

Mar., 1815.—Small fishery on Karkopanni (yielded 5842 rupees).

Dec., 1820.—On the Jokkenpiddi, a few oysters 2 years old. On the Karugugalie Paar a large bed of oysters 1 to $1\frac{1}{2}$ years old.

April, 1871.—No oysters.

,, 1875.—On Jokkenpiddi, a small patch. On Chilaw Paar, a large bed 6 months old.

,, 1876.—Still some oysters; doubtful if they are enough for fishery.

Nov., 1876.—On Chilaw Paar, 500,000 oysters 2 years old. On Jokkenpiddi, 250,000, 3 years old.

April, 1878.—On the south part of the Jokkenpiddi Paar there is a bed of oysters of "Kottapakku" variety, 4 years old. The others seen on Jokkenpiddi in 1876 are nearly all gone. Those on the Chilaw Paar are nearly all gone.

Nov., 1878.—Oysters on Jokkenpiddi all gone.

April, 1882.—On Chilaw and Karkopanni, beds of 2-year-old oysters.

,, 1883.—Last year's oysters still exist and thrive.

,, 1884.—Oysters dying off fast. Small fishery held on Chilaw Paar (yielded 17,153 rupees).

Nov., 1884.—Small fishery off Chilaw, and on Karkopanni.

April, 1885.—Three beds of young oysters 6 months old.

Dec., 1888.—Only one patch found in 1885 remains; oysters very few and scattered.

Nov., 1889.—Not inspected.

April, 1899.—No oysters.

Mar., 1901.— ,,

April, 1902.—Chilaw Paar had a bed of young oysters, 6 to 9 months old, covering about 1,120,000 square yards. Jokkenpiddi had many young oysters 3 months old.

Mar., 1903.—Not inspected.

Mar., 1904.—Oysters over 2 years old still present.

From the early Sinhalese records it seems probable that the banks off Chilaw were much more productive in ancient times than they have been during the last century. Chilaw seems, in fact, to have been formerly as important a fishery centre as Chilavaturai. The Sinhalese poem, 'Kovul Sandésaya,' written about the middle of the fifteenth century, refers to the pearl-lined shore of Chilaw in such a manner as to suggest that this locality was the centre of the Southern, or Sinhalese, pearl fisheries. In Portuguese and Dutch times its fame seems to have been eclipsed by that of the more northerly banks worked from the settlement at Manaar; but as the Chilaw region is still productive, and yielded at least three fisheries in the nineteenth century, it is possible that beds of oysters may have remained undiscovered and unfished. The record shows great gaps—from 1820 to 1871 and again from 1888 to

1899—so that probably the history looks less favourable than the reality may have been.

The fishery in 1803 was on the Jokkenpiddi Paar, and that in 1815 was on the Karkopanni, so that the fishery of 1884 was the only one on the Chilaw Paar proper—all were small fisheries. On the whole the record is uneventful, there have been no great successes and no marked catastrophes. There are no new conclusions to draw, but the banks may still be of value. There seems no reason why a bed of oysters should not mature on occasions, and parts of the Chilaw region will at least serve from time to time to supply a stock of young oysters to the Cheval or other paars that require replenishing.

Pearl fishing fleet at work on the Cheval Paar.

CONCLUSIONS.

This examination of the records of the principal pearl banks has served to emphasise some of the conclusions that were put forward in Part I. of this Report. In tracing the history of the different beds of oysters, in considering how the paars differ from one another and in trying to find the causes of such catastrophes as have occurred, we are brought to see :—

(1.) That man can do comparatively little to mitigate the severity of such influences as tell against the life and prosperity of the pearl oyster. He may possibly, if it be thought wise, to some extent diminish the ravages of certain carnivorous fishes, and he may by dredging the banks improve their condition and remove competing organisms. and also thin out beds that are overcrowded, but he is powerless against the invasion of microscopic parasites and of sand over-washes caused by monsoons, storms and tidal currents;

(2.) That much can be done, however, to preserve and make the best of what oysters we have, by careful inspections, by judicious transplantations and by speedy fisheries undertaken at the right moment.

Inspections should be as accurate, as frequent and as extensive as possible. They should extend beyond the conventional limits of the known paars and aim at exploiting new areas. It must be remembered that the greater part of the shallow shelf that forms the Ceylon side of the Gulf of Manaar out to the 10-fathom or 12-fathom line is potential "paar ground" and that new deposits of spat might be found any day on almost any part of it. It is impossible, of course, to inspect the whole area in detail every year, but it is important that lines of observations should be run across at least the more likely parts, and that could readily be done by means of a series of dredgings from a small steamer. The inspections should give early intelligence as to (*a*) new deposits of young oysters which might possibly require to be transplanted to safer ground, and (*b*) the necessity for a speedy fishery in order to save some threatened bed of adult oysters from being totally lost.

The necessity for transplantation has already been pointed out in Part I. It will suffice now to state that transplanting is the only means by which (*a*) many beds of young oysters can be saved from almost certain destruction, and (*b*) large areas of suitable ground can be supplied with a sufficient oyster population.

The relative efficiency of different methods of transplanting and also of speedy fishing by means of dredges or trawls—to be used in emergencies, when a bed of oysters might be lost if left unfished—are matters upon which Mr. Hornell, as Inspector of the Pearl Banks, is now experimenting, and it is hoped that in our recommendations which will conclude the final Part of this Report we may be able to incorporate results obtained from his present experiences.

Finally, there are prospects of good fisheries both next year and in 1906 on the Modragams and several divisions of the Cheval Paar—possibly also on the Muttuvaratu and the Dutch Modragam in the latter year. The results in 1907 and the immediately succeeding years will, so far as we can now see, depend upon whether large measures of transplantation are adopted without delay.

ANATOMY OF THE PEARL OYSTER.

(*Margaritifera vulgaris*, Schum.).

[With NINE PLATES.]

The Anatomy of the Ceylon Pearl Oyster has never been adequately investigated. L. G. Seurat, in his little book 'L'Huître Perlière,'* gives a short account of the structure of one of the large pearl oysters of the Pacific, *Meleagrina margaritifera*, and makes a few remarks upon the shell and some of the organs of the much smaller Ceylon pearl oyster (then known as *M. fucata*). Several writers on Molluscan morphology have described special points in our animal—or closely related species. For example, Grobben† gives some information as to the heart, Pelseneer‡ as to the branchiæ and nervous system, Ridewood§ discusses the gill structure in *Avicula argentea* and various species of *Meleagrina*, and Thurston|| gives a few figures and a brief description.

The works of Garner, Rawitz, Thiele and Biedermann all contain useful information bearing more or less on our subject. H. L. Jameson¶ has recently written on the identity and distribution of the mother-of-pearl oysters and has determined that the Ceylon form commonly known as *Avicula fucata* is in all probability the *Perlamater vulgaris* of Schumacher, belonging to the modern genus *Margaritifera*, and must therefore be known as *Margaritifera vulgaris*, Schum.

In the following account of the anatomy of the Ceylon pearl oyster, while the aim has been to give a fairly complete description of all parts of the body, those organs have been treated most fully which are of greatest importance in connection with the operations of the pearl fisheries and of the oyster culture. And, as in biological work generally Structure should never, if possible, be dissociated from Function, what information could be given in regard to the uses of the parts has been supplied when discussing the anatomy.

I have included as much as possible from our field-notes in regard to the habits and actions of the living animal as seen in our experimental tanks, since it is a rare event

for the naturalist to have such an animal as this alive under observation. It will be noticed that certain of our figures—drawn by Mr. HORNELL—are taken from the living animal. Some of the photographs are his, others are my own.

Our pearl oyster and a number of allied "mother-of-pearl" shell-fish belong to the family AVICULIDÆ, which RIDEWOOD has recently shown to be more nearly allied to the PECTINIDÆ (scallops) and SPONDYLIDÆ, in gill structure, than to the OSTREIDÆ (the true oysters). They are therefore placed in the order ELEUTHERORHABDA, characterised by the relative freedom of the gill filaments (see description below), while the OSTREIDÆ and PINNIDÆ are placed in the group EULAMELLIBRANCHIATA. The order Pseudolamellibranchiata, in which the pearl oysters and their allies were formerly placed, has thus been abolished.

The general characters of the AVICULIDÆ (pearl oysters and their allies) are as follows:—

The shell is usually inequivalve, the dorsal margin straight, often very long and forming anterior and posterior wings or "auricles," the lateral teeth of the hinge-line are much prolonged and may be inconspicuous, the minute structure of the shell is "cellular"; the mantle lobes are not fused, siphons are absent; the foot is moderately long, tongue-shaped, with a well-developed byssus gland; the posterior adductor muscle is very large and nearly central, the anterior adductor is usually absent. The gills may or may not fuse in part with the mantle, gill lamellæ plicate and heterorhabdid, with both descending and ascending filaments which are held in position to their neighbours by "ciliated discs" placed at intervals along the filaments.

These and other important points in structure will be more fully described and explained in the pages below and are shown in some of the figures on the plates.

SHELL.

The bivalve shell of the Ceylon pearl oyster, *Margaritifera vulgaris*, SCHUM. (= *Avicula fucata*, GOULD), is inequivalve, the left valve being deeper or more convex externally than the right. Each valve is more or less rounded in outline, with a flattened dorsal edge ending in projecting wings or "auricles" in front and behind (Plate I., figs. 2, 3, 4). The dorso-ventral and antero-posterior diameters are much the same, and in a 4-year old specimen measuring 9·5 centims. in length (dorso-ventrally) the breadth (antero-posterior) is 9 centims. Two shells, both 8·5 centims. long, measured respectively 7 centims. and 8 centims. in breadth. Plate I., fig. 5, shows an unusually narrow form. Other variations in the shape of the shell are shown on the plates—Plate I., fig. 4 is an unusually straight and fig. 6 an unusually oblique form. In handling some thousands and seeing some millions of these shells, as we have done, one cannot but be struck by the great variation in form and markings. Probably some of the supposed species of *Margaritifera* are merely varieties of the Ceylon form.

The shell is very thin, about 1·5 millims. over the greater part of its extent, and is lined by an exceedingly brilliant layer of nacre or mother-of-pearl. The outside of the shell is usually marked by 6 or 8 radial bands of dark red or reddish-brown on a pale yellowish ground. These colours are brightest and best seen in young specimens, as in the older shell they become dulled and obscured on the outside by incrustations and growths (Plate II., fig. 2). They are, however, usually visible even in large specimens on the inside of the valve on the ventral margin (see fig. 1). The outer surface in the young shell is also marked by concentric ridges or projecting imbricating lamellæ, which grow out at intervals to form spatulate or finger-like processes (Plate VII., fig. 14), which may be over 12 millims. in length. These are sometimes seen in the old shell (Plate I., fig. 2). The layer of nacre ends from 10 millims. to 15 millims. back from the free edge of the shell (Plate I., fig. 4), and at that point the shell in a well-grown specimen is about 1 millim. in thickness. From this the shell thickens gradually towards the dorsal edge, reaching an average of 2 millims. at about the point of greatest convexity of the valve.

In thick shells it may be as much as 3 millims. at this point, and an examination of the section shows that this increased thickness is due entirely to the nacre, which may be 2 millims., while the prismatic layer is only 1 millim. Over the greater part of the shell these two layers are of equal thickness, say from 0·5 millim. to 1 millim. each. On the anterior ear of the shell, forming the side of the byssal notch, there is a thickening of the shell up to about 5 millims.; and at the hinge, in the mid-dorsal line, another local increase may reach to 8 millims.

At the ventral edge the shell beyond the lining of nacre gradually decreases in thickness, and in a rapidly growing shell the free edge is flexible and horny in consistence, being composed of periostracum and a thin layer of prismatic shell still imperfectly calcified. Two shells from Kondatchi Paar (17th November, 1902), measuring 7 centims. in length, have this delicate margin, free from nacre, extending up to 2 centims. in width, not including the processes at the edge (Plate I., fig. 3).

On Plate I., figs. 1 and 2 show the contrast between an unusually smooth and an unusually imbricated shell; figs. 3 and 4 show variations in the development of the nacre and the margin, and figs. 5 and 6 marked differences in the shape of the shell. The "auricles" and the byssal notch also vary much in their development, as may be seen from the figures.

The hinge line is a narrow ridge running along the greater part of the straight dorsal edge and in contact with its fellow of the other valve, but not conspicuously cut up into projecting teeth. Much elongated, narrow, ridge-like lateral teeth are present. Outside the middle third of its length is the large black elastic ligament (see Plate I., fig. 4). It may measure in an adult shell about 20 millims. in length and 5 millims. in breadth. The ligament serves to open the shell, and so is antagonistic to the adductor muscle. Alongside the ligament and extending from the hinge line upwards to the umbo (the most prominent point of the valve, placed in front of the ligament near the anterior end of the dorsal edge) is a sloping area of roughened shell, marked with close-placed lines of growth. This area (Plate I., fig. 4) becomes much more extensive, and less vertical in its slope, because of an increased thickening of the hinge, in old shells, and its condition is a good guide to the age after the shell has ceased to grow actively in length and breadth.

The shell is composed of three layers, outer, middle, and inner. The very thin outer layer is the uncalcified, cuticular "periostracum," an extremely delicate horny layer which allows the colour of the layer below to show through, and which becomes worn off in old shells. At the free margin of the shell the periostracum is very thin and transparent, extends beyond the calcareous matter, and is reflected to join the surface of the ectoderm cells of the mantle-edge in the longitudinal groove where it is secreted. The periostracum is seen in several parts of the section represented in Plate VIII., fig. 1, and also as a detached film in the groove on the mantle-edge in Plate VIII., fig. 2, *Per. ostr.*

The middle or "prismatic" layer of the shell shows what CARPENTER called, in *Pinna*, a "cellular" structure being formed of calcareous prisms or columns running transversely to the surface, and appearing as polygons in section (Plate VII., figs. 14 to 18, and Plate VIII., fig. 1).

The carbonate of lime is laid down in an organic matrix of conchiolin, and is found in the adult pearl oyster to be in the form of the mineral aragonite. The prismatic layer is deposited by the mantle epithelium near the free edge, just behind the margin which forms the periostracum; and many such layers of prisms may be formed successively, each new one inside the last, as the shell grows. At the free edge of the shell and on the imbricating ridges these films may separate and stand out as in the section shown on Plate VIII., fig. 1. The red and brown coloration of the shell is in this layer, certain of the prisms being charged with pigment, as shown in fig. 18 on Plate VII. Various stages in the decalcification of the prisms is shown in fig. 19. Complete decalcification reduces a section to a honey-comb-like network of conchiolin (as shown in Plate VII., fig. 17), which is continuous with the very similar organic periostracum lying over it.

The inner layer is the "nacre," formed of numerous delicate lamellæ of the organic matrix conchiolin, and calcareous matter. It is transparent under the microscope, allowing the "cellular" structure of the prismatic layer to show through it clearly (see Plate VII., fig. 15), and is almost structureless, having merely a fine granular appearance (Plate VII., fig. 21) in surface view under a high power. The layers of which it is formed show as a series of very closely placed contour lines (Plate VII., fig. 20). The most conspicuous feature of the nacre is the beautiful iridescence, an interference phenomenon due to the diffraction of light by the irregular free edges of the numerous delicate lamellæ, alternately calcareous and organic, of which the layer is formed. The iridescence in the case of the Ceylon shell is singularly brilliant, but the nacre is too thin to be of much value in the arts.

The markings on the interior of the shell (Plate IV.) consist of :—

(1) The large adductor impression sub-centrally placed and occupying from one-third to one-half the diameter of the shell; and

(2) The pallial line and scars caused by the insertion of the pallial muscles, which are fan-shaped bundles formed of fibres radiating outwards from small insertions placed along the pallial line. These insertion scars vary considerably both in number and in form. Usually there are from 12 to 15 between the umbonal region, where they begin anteriorly, and the antero-ventral end of the adductor, with 3 between the dorsal tip of the latter and the hinge line (see Plate IV., figs. 2 to 6). Besides these, which are distinct scars, there is an extremely narrow and practically continuous insertion band confluent with the posterior and ventral edge of the adductor scar. This band leaves no separate impress upon the nacreous surface of the valve, its scar, like that of the retractor muscle of the same side, being merged with that of the adductor (see Plate IV., fig. 1). Figs. 2 to 6 show five variations in the distribution of the insertion scars of the pallial muscles, while fig. 1 is the typical arrangement of the muscles as seen on removal of the valve.

As to the size of the Ceylon pearl oyster shell at different ages, we believe from our observations on different grounds that there may be very considerable variations according as the conditions are favourable or the reverse. It is difficult to get well-established dates fixing the ages, but the following figures may be useful as giving some indication.*

A pearl oyster in the Master Attendant's Office at Colombo, labelled by Captain DONNAN as being $2\frac{1}{2}$ years old, measures $3 \times 2\frac{3}{4}$ inches.

The average of the oldest pearl oyster from the Muttuvaratu Paar in March, 1902, also considered by Captain DONNAN to be $2\frac{1}{2}$ years old, is $2\frac{1}{4} \times 2$ inches.

A 1-year-old oyster, from the samples in the Master Attendant's Office, measures $2\frac{1}{8} \times 2$ inches.

Some natural-size drawings made by Dr. ONDAATJE many years ago, at Colombo, show the following sizes :—

1-year-old measures	. . . .	2×2 inches.
2 ,, ,, ,,	. . . .	$3 \times 2\frac{3}{4}$,,
3 ,, ,, ,,	. . . .	$3\frac{1}{2} \times 3$,,

Mr. HORNELL is now measuring very large numbers of shells, and is determining more accurately than has yet been done the average growth year by year, and the results of his observations will appear in the final volume.

* See also the measurements and weights given in "Observations and Experiments on the Life-History and Habits of the Pearl Oyster," in Part I. of this Report, p. 136.

GENERAL ANATOMY.

Before describing the different systems of the body in detail, it may be well to refer to a few of the figures on the plates, which give some idea of the general structure and arrangement of the soft parts of the animal inside the shell.

Fig. 3 on Plate II. shows the left side of the animal when one valve of the shell has been removed; the dorsal surface is above and the anterior end to the left. In the centre is seen the single great adductor muscle (white) with the heart and viscera above it, the sickle-shaped gills (dark) curving round the lower central surface of the muscle, and the foot (at the base of the gills) with its byssus fibres projecting anteriorly (to the left). The mouth is above the byssus, and the anus on the ventro-posterior edge of the muscle where the anal funnel can be seen projecting (right-hand side of figure).

The three widely gaping specimens seen in fig. 5, A, B, C, show the adductor muscle in the middle crossing from valve to valve, the gills in the form of two lamellæ on each side and a mantle lobe or pallium lining each valve of the shell. The pigmented mantle-edge, studded with little papillæ or tentacles, is well seen in the left-hand specimen (A).

The diagrammatic dissections shown in figs. 1 and 2 on Plate VI. give the chief systems of the body in their relative positions. Fig. 1 shows mainly the course of the alimentary canal from the mouth (*O*) to the stomach (*St.*) and through the various parts of the intestine to the anus (at *An.f.*). Fig. 2 shows, in addition, the heart (*Au.* and *V.*) and the principal blood-vessels. The lettering of these figures in the Explanation of Plates will supply further information.

Finally, the series of sections through different parts of the body, given in Plate V., show the relations of gills to mantle lobes, of gills to foot, of adductor muscle to viscera, of stomach to liver, of intestine to heart, and so on. They need not be described here in detail, as a full account of each is given in the Explanation of the Plates.

PALLIUM OR MANTLE.

The integument or outer part of the body-wall forms two great lateral flaps, the right and left pallial or mantle lobes which line the valves of the shell and wall-in the pallial cavity—the space, freely open to the water when the shell gapes, into which the foot and the gills project (see the top row of sections on Plate V.). The two pallial lobes are separated anteriorly, ventrally, and posteriorly, but become continuous dorsally underneath the hinge-line of the shell. The free edge of the lobes is thickened, pigmented, and fringed with short branched tentacles (see Plate III., figs. 6 to 10). This pallial edge of the mantle is attached some little distance inside the margin of the shell, and the nacre stops short where the mantle is attached (see Plate II., fig. 6, where the mantle has been drawn back at one point to show the nacre), and that is the point to which the mantle is retracted in preserved specimens, leaving the non-nacreous part of the valve exposed (see also text-fig. 1, where the pigmented mantle edge is drawn up on the left side of the figure to show the nacre).

The mantle has the same general structure as in other better-known Lamellibranchs, such as the European oyster, *Ostrea edulis*. It is composed mainly of connective-tissue traversed by muscular bundles and numerous blood spaces, and covered on both

Fig. 1. Dissection of pearl oyster from the right side, showing the stomach and digestive gland, the gills, foot and byssus, pigmented pallial margin, and a cyst-pearl *in situ* at the top left-hand corner; natural size, from a photograph by Mr. HORNELL.

outer and inner faces by a layer of epithelial cells, the ectoderm (Plate VIII., fig. 2). The epithelium on the outer surface, next to the nacreous layer of the shell, is secretory, while on the inner free surface, facing the pallial cavity, the ectoderm is ciliated (Plate VIII., fig. 2, *i.ep.*). The centre and dorsal part of each pallial lobe is adherent to the rest of the body and thus envelops the viscera (Plate V., fig. 10, *Pall.*), while the ventral and marginal parts hang down freely like a flap or curtain, so as to form the side walls of the pallial cavity (see various sections on Plate V.).

Further details of the minute structure of the mantle are seen in fig. 2 on Plate VIII. The marginal and velar processes, the deep periostracal groove, the blood spaces, the glands, the muscles, and the nerves are all evident. The character of the epithelium in different parts is shown in the more highly magnified side figures:—A. shows the tall epithelium which secretes the prismatic layer; B. is the much lower general surface which deposits nacre; C. shows the ciliated internal surface; D. and E. the side and end of the marginal groove, with glands and high epithelium for the secretion of the periostracum.

Each pallial lobe may be divided into three parts, a central, a distal or muscular, and the marginal mantle-edge. The central pallial area extends from the mid-dorsal line to the pallial line (Plate IV., fig. 1), where the shell is marked with muscle scars. This part of the pallial lobe is perforated by the insertions of the adductor (*Add.*), the retractor (*Ret.*), the levator (*Lev.p.*, *Lev.a.*), and the pallial muscles. In a healthy condition of the living pearl oyster, the tissues of this part of the mantle are soft and mucoid in consistence, and opalescent white in colour. After hardening in alcohol this tissue becomes brittle, and has a semi-prismatic fracture which is very characteristic. All varieties of pearls—cyst, ampullar, and muscle pearls—may form within its substance. Text-fig. 1, p. 43, shows a cyst-pearl *in situ* close to the dorsal extremity of the adductor muscle.

The distal or muscular area is translucent, and is capable of considerable contraction by its muscles, and distention by the influx of blood into the large sinuses it contains. It is formed of a thick layer of loose connective-tissue traversed by nerves and blood-spaces, and by the radiating fan-like bundles of the pallial muscles (Plate VI., figs. 1 and 14, *Ret.Pall.*). This region is highly sensitive and irritable, and so contractile that we found it difficult to introduce even minute foreign bodies between the mantle-lobe and the shell in our experiments on artificial pearl-production.

The marginal region or mantle-edge is chiefly a muscular thickening which ends in two thin membranous folds with pigmented papillate edges (Plate II., figs. 3, 5, A, and text-fig. 1). The outer of these, bearing digitate papillæ, is in the same plane as the inner surface of the shell and forms the true pallial edge (Plate V., fig. 1, *Mg.Pall.*). The inner, which bears flattened palmate papillæ, and may be called the pallial veil or velum, projects inwards at right angles from the mantle-edge (Plate V., fig. 1, *Vel.*), so that the veil of the one pallial lobe stretches towards that of the other (Plate II., fig. 5, A). In life the free edges of the two veils are usually in contact along the median line of the body, except at two spots where they gape. One of these, the inhalent aperture, is somewhere about the middle of the ventral surface; while the other, the exhalent, is at the posterior end, opposite the opening of the anal funnel and supra-branchial chamber. The former is not a permanently localised or specialised opening, its position and its size and shape vary considerably from time to time, so that any part of the ventral edge may form temporarily the inhalent gap through which the main in-flowing current passes. The exhalent aperture, on the contrary, is definitely localised and specialised. In outline it is broadly ovoid or almost circular (Plate III., fig. 10). Its broad rounded lower (ventral) margin is immediately dorsal to the pallial fold, an inwardly directed gutter-like fold of the velar margin that meets the tip of the ctenidium (see Plate VI., figs. 1, 2, &c., *Pall.f.*).

In 3 to 4-year old oysters the velum has a breadth of fully $\frac{1}{4}$ inch on the ventral aspect where it is most fully developed. Here, too, the marginal processes are largest, and are of two kinds, long and short, several of the latter usually alternating with the singly placed longer (Plate III., fig. 6). Diversity of form in the larger ones is great, no two being quite alike, but most of them are doubly trifid, the summit of the papilla being first divided into 3 stout branches, each of which again divides into 3 digitate twigs; occasionally a twin process is seen (fig. 7). The extremities of the twigs bear minute (? sensory) processes formed of groups of epithelial cells.

In a healthy expanded oyster, where the papillate edges of the velum meet, these large papillæ interdigitate (Plate III., fig. 10). The short papillæ, which are placed between, are simpler, and digitate in form.

Along the posterior edge of the body, *i.e.*, from the pallial fold upwards to the posterior end of the hinge, the larger papillæ of the veil become greatly reduced in size and simpler in form until, in the region of the posterior "auricle" of the shell, they approach in character those of the pallial margin. The same reduction in size is also seen in the velar processes within the anterior auricle.

The pallial margin consists of a conspicuously pigmented papillate free inner edge and an outer fold, which is continuous with, and is covered by, the film of periostracum which folds over the free edge of the valve (Plate VIII., fig. 2, *Mg.Pall.* and *Per.Ostr.*). The whole of the free margin is drawn out into very delicate and very sensitive elongate digitate processes of two sizes, long and short (Plate III., fig. 8). In young specimens, 1 year old, the tips of the longer papillæ bear asymmetrically disposed secondary projections, sometimes simple, sometimes very abbreviated. In older individuals—2 years old and upwards—these longer papillæ become further elongated and conspicuously fimbriated (Plate III., fig. 9). They can be seen, when alive, swaying and bending gracefully about as if the tip were a tactile organ on watch, feeling first in one direction, then in another. These finger-like processes are especially well developed in the region of the exhalent aperture—some, a full $\frac{1}{4}$ inch in length, projecting even beyond the velar papillæ, which latter are here turned outwards in the same plane as the mantle lobe. The long processes stand singly, separated from one another by from 2 to 11 short and usually simple digitate papillæ closely set (Plate III., fig. 8). The appearance of the surface of a papilla in section is shown in Plate VIII., fig. 2, at *Mg.Pall.*

The Ciliated Pallial Path.—The whole of the inner surface of the pallial lobes is ciliated, but, at the ventral truncate edge of the labial palps, a specially marked ciliated path begins which, curving at once outwards and downwards, passes to the base of the velum, parallel with which it runs until it reaches the anterior wall of the pallial fold, where it passes over the velar edge by means of a slight folding of the latter (*Pall.f.*, Plate VI., fig. 14). The cilia of this pathway are in continuous action from before backwards, by which means the unsuitable particles collected by the gills and sent forward to and rejected by the palps are conveyed away and passed out from this pallial fold (Plate VI., figs. 1, 15, &c., *Pall.f.*).

When coming under the influence of the strong excurrent flow from the gills, the smaller particles are frequently propelled to a considerable distance from the oyster—a provision to ensure that they do not again become a source of annoyance and loss of energy to the animal. This provision for thus disposing of unsuitable particles is especially useful when the water is disturbed and laden with sand or mud. Under such circumstances the oyster feeds slowly, rejecting nearly everything that comes. When, as happened sometimes in our tanks at the Galle Marine Laboratory, the in-flowing water was laden with decaying vegetable *débris* in great quantity, or when mud was present, the palps accumulated the particles till they had enough to form a small bolus. This while forming was revolved constantly by the palpar surfaces. When large enough, a twist seemed to be given to it whereby it passed from the palps to the anterior end of the pallial ciliated path, along which it advanced rapidly, and was shot out in a few seconds. In the course of a few hours it has been noticed, when the tank water remained still, that a conical pile of ejecta more than $\frac{1}{4}$ inch high accumulated on the ground just behind the oyster (Plate VI., fig. 14, *Pel.*).

Pigmentation.—The free pallial margin together with the velum is in most cases deeply pigmented (Plate II., figs. 3, 6), usually in black, grey, and shades of yellows and browns, mostly chestnut brown, though orange is also frequent. The pigmentation is usually in the form of large alternate blotches which give a certain appearance of regularity to the colouring; but the exact pattern varies much. It is noticeable, however, that there is considerable difference in the degree of pigmentation in oysters from quite shallow water and in those from depths of 6 to 10 fathoms. The latter have the colouring mainly confined to the velum and the pallial margin, whereas in the former the pigment may extend widely over the general inner face of the mantle. We find that orange and chestnut tints are much more frequent amongst the pearl oysters of Trincomalee Harbour, which live in shallows averaging from 6 to 18 inches at low tide, than amongst those from the deeper banks in the Gulf of Manaar. The gills also are more frequently and more extensively pigmented at Trincomalee than amongst individuals from deeper water.

THE FOOT AND BYSSAL ORGAN.

The Foot is a highly mobile tongue-shaped organ capable of great elongation and contraction. It arises from the anterior region of the visceral mass nearly midway between the mouth and the intestinal lobe and has the anterior extremities of the branchiæ flanking it on either side (Plate VI., fig. 1). The greater part of its bulk is composed of networks of muscle fibres running in various directions, thus ensuring a wide range of movement, and is so extensively penetrated by blood spaces that the organ is highly cavernous. When these spaces are rendered turgid through an influx of blood, the foot becomes erected and is then quite three times as long as in the completely contracted, non-turgid state. In the latter condition it has the form of a slender elongated cone tapering gently from a wide base to a pointed apex (Plate III., fig. 13). The dorsal and ventral surfaces are clearly distinguishable, the former convex in section; the latter, which is grooved longitudinally, is also convex in section when in a state of contraction (Plate III., fig. 21). It becomes flattened in the distal third when the organ is extended (fig. 20). In oysters of 2 years of age and upwards the dorsal surface and the sides of the foot are usually so thickly covered with dark chestnut pigment speckles as to appear quite brown. The speckles become less numerous on the lower parts of the sides as they approach the prominent white edges of the ventral or pedal groove, while the floor of the locomotor or anterior part of the pedal groove is usually pigmented similarly to the exposed part of the foot. Occasionally the pigment is purplish-brown, dark drab, or even dark orange.

The foot in 3-year-old oysters is capable of extension to over $1\frac{1}{2}$ inches when fully turgid; in contraction the length is $\frac{1}{2}$ inch or even less. In an older oyster it may be extended to over 2 inches. Oysters 6 to 9 months old can extend the foot to a length of 1 inch, contracting it to about $\frac{1}{3}$ of an inch.

A deep pouch-like pit, the byssus gland or organ, is lodged at the proximal end of the foot upon the ventral aspect. The wide mouth of the pit (Plate III, figs. 13, 14, 15, 22, &c.) is a little way anterior to the junction of the foot with the visceral mass, while the pouch itself penetrates deeply backwards and slightly downwards into the central portion of the visceral mass (Plate VI., fig. 2). The axis of the mouth of the byssal gland coincides with the longitudinal axis of the foot. The byssal gland lodges the common "root" of a bundle of stout, laterally-flattened, bronze-green fibres, the byssus, which by means of a discoid attachment at the distal extremity of each fibre anchors the pearl oysters to rocks and other objects (Plate III., figs. 16, 22, 22, 23). The anterior edge of the mouth of the byssal gland passes into a groove, the pedal groove, extending medially along the whole of the remaining length of the ventral surface of the foot (Plate III., fig. 20, and Plate VIII., figs. 3 and 4).

The pedal groove comprises two regions functionally distinct, a distal or locomotor and a proximal or secretory. Both are, indeed, lined with a layer of secreting glands, but while this layer is of great thickness in the proximal region, in the distal it is thin, and the secretion is of a different character (Plate VIII., figs. 3, 4). When the foot is contracted, the edges of all parts of the pedal groove are approximated.

The hinder or secretory part of the groove has two regions, an anterior part which is cup-shaped when in use, and a hinder which is nearly always tubular through the approximation of the lips of the groove. The anterior cup-shaped part is about mid-way between the base and the tip of the foot, and may be termed the "disc-pit." The tubular byssal groove connects this with the byssal gland. Figs. 3 and 4, on Plate VIII., represent the structure of the foot as seen in transverse section; both show the numerous muscle bundles, longitudinal, circular, and oblique; fig. 3 has the open locomotor pedal groove ventrally, and fig. 4 the closed byssal groove which becomes an open canal further out.

Functions of the Foot.—The functions of the foot are threefold: the distal ventral surface subserves locomotion; the median and posterior parts effect attachment by means of the secretion of the byssal fibres; lastly, on account of the general mobility of the organ, and probably its sensory nature, the tip is of great use in cleaning the gills and mantle from intrusive particles that cannot otherwise be got rid of.

Locomotion.—As has been explained in this Report, Part I., the pearl oyster is capable of travelling short distances when it is freed from the byssal cable which attaches it to some foreign body. When separated either by the byssus being wrenched away, as may happen in diving operations or in dredging for transplantation, or by its own action in sloughing the root of the byssus, it soon, under favourable conditions, extends the foot as far beyond the shell as possible and begins to travel. The tip of the foot circles round, bending first in one direction and then in another, till it meets a body suitable for crawling upon. Then the groove immediately behind the tip opens (see Plate III., figs. 18 and 19) and is flattened against the surface selected, whereupon progression takes place by alternate extension and contraction, as seen in the crawling action of the typical gastropod foot. Only that part of the pedal groove anterior to the disc-pit takes part in the locomotion, an action therefore strictly limited to the distal third of the organ.

Cleansing.—As to the use of the foot in freeing the gills, palps, and mantle from intrusive bodies, it can be seen through the partly open valves of a living oyster that the point is pushed between the gill plates, and over the inner surface of the mantle, gently stroking the surface and insinuating itself into the crevices, thus freeing the parts from any foreign bodies—accumulations of *débris*, &c.—that might cause inconvenience. It is frequently on the move in this manner; when at rest, it lies shortened up, with the tip turned to the left, and tucked downwards between the left gill and the mantle. In one pearl oyster, in which Mr. HORNELL had broken a hole in the umbonal region of the valve, the mantle beneath being also pierced, the foot was seen feeling gently round the edges of the wound and working off particles of dirt that had gathered. The tongue-like tip was passed occasionally *through* the wound in the mantle and projected somewhat, at one time well beyond the hole in the valve. The tip also freed the wound from dirt lying between the mantle and the valve.

Attachment by the Byssus.—When a pearl oyster finds a place to re-attach to, subsequent to sloughing a former byssus, it uses the locomotor region of the tip as a suctorial organ to hold its body in position, while at the same time the disc-cup expands and its edges press against the attachment surface, and the edges of the byssal groove are tightly closed against one another. While in this position, the byssal gland pours forth through the byssal groove a quantity of a fluid secretion which has the property of coagulating and hardening upon contact with sea-water. This secretion sets in a remarkably short time, and usually after the foot has remained pressed to the contact surface for between 3 and 5 minutes, it is withdrawn and then reveals the presence of a pale yellow, elastic strand stretching from the mouth of the byssal gland to the point where it is attached by an oval disc, which is a model of the cavity of the disc-pit. During the withdrawal of the foot the edges of the byssal groove open to permit of the newly-formed byssal fibre passing out. Under favourable conditions this operation is performed again and again, until at last from 50 to 70 fibres are formed, constituting a wonderfully strong cable of attachment. In 3-year-old oysters the byssus is so strong that the twist and wrench necessary to break it off requires a distinct effort. The divers dislike fishing pearl oysters which are attached individually to rocky surfaces, as the effort of wrenching them off reduces the result of the day's work both by taking longer time and also because of the weariness induced by the hardness of the work. After a few days' fishing on a rocky bank the divers' hands become painfully lacerated unless they take the precaution, as many do now, of using roughly made gloves. From the age of 4 to 5 years the strength of the byssus decreases, rendering the older oysters more easy of detachment.

Structure of the Byssus.—On examining a sloughed byssus we find that the individual fibres arise from an ovate, laterally compressed "root" (Plate III., fig. 23; sometimes it is forked with laterally spreading groups of fibres), the surface whereof is corrugated or laminated in correspondence with the parallel folding or grooving, which is characteristic of the inner surface of the walls of the byssal gland (Plate VIII., fig. 5). This mass can be resolved into branched or pennate fibres, the twigs of which penetrate between the lamellæ of the gland and come into close relation with the surrounding muscle bundles. Each byssus fibre, outside the body, is distinctly flattened laterally, and can be readily frayed into a number of longitudinal fibrils. Each terminates distally in an oval disc by which attachment is made to rocks, old oysters, and other suitable bodies. The fibres are of a lustrous deep bronze-green colour, growing paler as they enter the root. When first formed, however, they are pale yellow, gradually becoming of the characteristic green tint in the course of the ensuing 48 hours.

The byssus is markedly elastic and very tough, and the disc is so firmly attached that if sufficient tension is applied either the substance to which the disc adheres gives way or the strands themselves break. It is a most rare occurrence for the "root" to be torn out—a fact that is of the greatest importance in the cultivation by transplantation of the pearl oyster, as otherwise the pearl oysters dredged for transplantation would be so injured during the operation that death would ensue in the majority of cases. As it is, the wrenching off of pearl oysters is found in practice to induce no ill effects. An hour afterwards, under favourable and natural conditions, the pearl oyster begins to slough the root of the ruptured byssus and may, indeed, actually make re-attachment by means of a new byssus within this period.

The approximated ends of the two retractor muscles are attached to the hinder end of the byssal gland (Plate III., fig. 24, *Ret.*). The structure of the byssus gland, as seen in section, is shown in fig. 5 on Plate VIII. It is divided into two halves, placed right and left, and each formed of parallel layers of glands opening into narrow folds, in which the secretion forms long, and in places convoluted, threads. The byssus fibre is a compound structure formed by the union of a number of these threads of secretion. The figure shows a few of the narrow folds from one side only, the glands, the convoluted threads of secretion and the close relation with groups of muscle fibres on the periphery of the organ.

THE MUSCULATURE.

The pearl oyster is monomyary, possessing a single adductor (the posterior), the largest and most important muscle in the body. The other muscles present are:—one pair of retractors of the foot, two pairs of weak pedal levator muscles (superior retractors), the orbicular retractor muscle of the mantle (pallial muscles), the intrinsic muscles of the foot and visceral mass, the branchial bands, and the heart or cardiac muscle (which will be discussed under the vascular system below).

The Adductor Muscle of the shell (*Add.*, Plate VI., fig. 1) stretches transversely across the body from valve to valve. It is a massive bundle, wedge-shaped in section, and slightly curved (Plate II., figs. 3, 4). The narrow end points upwards and lies immediately behind the ventricle of the heart. The terminal part of the rectum runs in the middle line along the posterior surface (Plate VI., fig. 1, *Int.* 3).

As the concavity of the muscle faces upwards and forwards, the wider ventral end, which is rounded, is turned anteriorly. Its anterior margin marks, approximately, the centre of each valve, while the dorsal and posterior apex lies a short distance in front of the posterior sinus in the margin of the shell. Thus, as the lower end of the adductor stretches from side to side in the widest region of the body, the fibres decrease in length as they approach the dorsal and posterior extremity, where the extent of the muscle is less by half than at the anterior and ventral end.

The muscle is not homogeneous; two distinct regions are obvious. The one, a narrow tendinous strip made up of white glistening fibres, forms the posterior border (*Add.'*, Plate VI., fig. 1, and sections on Plate V.); the other, broad and massive, of colourless, semi-translucent fibres, occupies the remainder of the mass. Under the microscope, the fibres of the latter are finer when teased up, and have an appearance which has been described as striation, but is by no means distinct;* those of the former are about two to three times as thick, more fleshy and quite smooth.

The substance of this muscle is permeated with lacunar spaces, penetrating into and among the loosely compacted bundles of fibres. The blood supply is derived from the posterior pallial arteries which arise from the terminal branches of the posterior aorta and pass outwards to the mantle sunk within the substance of the tendinous portion of the adductor (*Art.p.p.*, Plate VII., fig. 4).

The power exerted by the adductor in bringing the two valves together by its contraction is very considerable, and the action is very rapid. Sir WILLIAM TWYNAM

* Very much less obvious than the striation of the corresponding fibres in, for example, *Pecten opercularis*.

relates ('Report on Ceylon Pearl Fisheries,' p. 6, 1900) how at the fishery of 1891, after the oysters had been landed and had lain in heaps in the Kottu for some time, one gaping individual had still strength enough left to snap at and seize a hungry sparrow which incautiously attempted to feed upon it. The oyster held on so tightly that all the efforts of the trapped bird to escape were vain, and the strangely assorted pair are now to be seen in Sir WILLIAM TWYNAM's museum at Jaffna. Similarly, Mr. HORNELL reports that an oyster lying in the Kottu during the last fishery (1903) captured a mouse (now in the possession of the Lieutenant-Governor the Honourable Mr. E. IM THURN); and that he himself saw the foot of that agile animal, an inquisitive mongoose, caught by an oyster which resisted all the efforts made to dislodge it for nearly five minutes.

Although the pearl oyster has not the power of moving rapidly through the water or over the sea-bottom after the fashion of *Lima* and of some species of *Pecten*, by the violent expulsion of water caused by a sudden closure of the valves, still it can eject a jet of water with some force to a distance of 9 to 12 inches, as can be seen when living oysters are watched in shallow vessels of water. This forcible ejection is evidently useful in dislodging any small animals and other particles that may have gained access to the branchial chamber.

The Retractors of the foot are a pair of symmetrically disposed muscles lying in the horizontal plane of the body. They originate (*Ret.*, Plate III., figs. 24, 25) in the walls of the byssal gland and, then diverging, pass backwards in V-like manner, to be inserted, one into the right valve, the other into the left, within the concavity of the adductor scar (compare *Ret.* on Plate IV., fig. 1, with other figures on same plate). Neither retractor impresses a separate scar upon the nacre, the posterior edge of the retractor impression blending indistinguishably with the anterior edge of that of the adductor.

In its anterior portion each retractor is sub-cylindrical, flattening to an oval, in section, at the place of insertion. There is no decussation of the fibres of the two bundles at their junction anteriorly.

The Levators of the foot are four, two anterior and two posterior. Each of the anterior pair (*Lev.a.*, Plate III., fig. 26) has its insertion at the apex or inmost point of the umbonal recess of its respective valve—a point directly dorsal to the mouth region. From this place the fibres pass vertically downwards, on either side of the mouth, spreading laterally, fan-like, as they go. The external lateral fibres eventually blend with the muscular sheath on the sides of the viscero-pedal mass, while the inner or anterior fibres pass into the root of the foot.

The left anterior levator is considerably stronger than its neighbour, a specially strong cord of fibres passing on the inner side to the dorsal aspect of the root of the foot. By the contraction of this cord the foot is drawn over to the left side, which is its normal position when in a state of rest. The explanation of this asymmetrical arrangement is seen in the fact that the left valve is much deeper and consequently more roomy than the right, and so the foot is more easily accommodated on that side of the body (as shown in Plate II., fig. 6).

The posterior pedal levators (*Lev.p.*, Plate III., fig. 26) are two short insignificant bundles which originate high up in the fibres of the anterior levators, exactly on the level of the mouth. Thence their course is backwards and upwards through the visceral mass to an attachment to the valves behind the scar of the corresponding anterior levator, but on a slightly lower plane. The whole course of each posterior levator in an adult oyster is less than one-quarter of an inch—from $\frac{3}{16}''$ to $\frac{1}{4}''$. The contraction of the anterior levators causes the foot to be retracted and raised dorsally; the coincident shortening of the posterior levators introduces a drag towards the rear. No protractor muscles are present, turgescence of the venous pedal spaces effecting, in the main, the protrusion of the foot when muscular relaxation takes place.

The Intrinsic Muscles of the foot and viscera are diffuse rather than in masses. Those of the foot form a muscular enveloping sheath or interlacing net of considerable thickness and complexity. It is formed of several ill-defined layers and scattered bundles, shown in transverse section on Plate VIII., figs. 3 and 4. A number of the internal bundles run in the main longitudinally along the foot, some fibres run circularly, there are groups diverging radially, and in some parts the fibres interlace in various directions.

In the visceral mass proper, small transverse muscle bundles pass from side to side, binding its tissues together and providing a framework, slight though it be, wherein ramify the tubules of the digestive gland and of the gonads. These transverse intrinsic bundles are somewhat spindle-shaped, each end narrowing to a tendinous insertion attached to the fibrous connective-tissue ensheathing the visceral mass.

Of other intrinsic muscles the most important are the branchial, one of which, in the form of a flat band of muscle fibres, runs within each ctenidial axis from end to end, close to the dorsal edge, along with a large nerve. These bands have the effect of retractor muscles, shortening the gills and withdrawing their posterior extremities, an action assisted by other muscle fibres which radiate, fan-like, from a point just in front of the anterior margin of the adductor. There are also muscle bundles running longitudinally down each side of the principal filaments (Plate VIII., fig. 13, *m.b.*).

The Pallial Muscles (*Ret.pall.*, Plate VI., fig. 14) are all retractors, and together constitute the orbicular muscle of the mantle. They are a series of fan-shaped muscles, radiating outwards to the mantle edge from a number (15 to 18) of insertion centres of various sizes, arranged circularly, and which together form the well-marked pallial line of scars that runs parallel with the margin of the shell, upon the inner surface of each valve (Plate IV., figs. 1 to 6). The fibres lie entirely within the layer of loose connective-tissue, that is between the inner and outer epithelial surfaces of the free portion of the mantle. Their ultimate ramifications form an anastomosing network, the branches diverging and reuniting in the complex manner seen in Plate VII., fig. 13. The bundles in some cases surround the branches of the pallial nerves.

With the exception of the heart, and the somewhat indistinct appearance of striation in the larger portion of the adductor, the muscle fibres throughout the body are non-striped.

THE ALIMENTARY CANAL.

As the œsophagus and the stomach, together with two-thirds of the intestine, lie within the viscero-pedal mass (see Plate VI., fig. 1), the surrounding tissues, first those of the superficially placed gonad and then of the more deeply lying digestive gland have to be carefully picked away before the relative positions and the course of the parts can be traced. Hardened material is easier to manipulate than fresh ; and the best method is to kill the animal by immersion in a 5-per cent. aqueous solution of formol, and to keep it therein till the day prior to dissection, when it should be removed from the shell and soaked in several changes of fresh water to remove most of the formol.

Two projecting horizontal lips conceal the aperture of the mouth (*O.*, Plate VI., fig. 1). Each is smooth on both outer and inner surfaces, and is produced laterally at each extremity into a labial palp, the upper lip passing right and left into the right and left dorsal palps, and the lower into the corresponding ventral palps (*Pa.*, in various sections on Plate V.). The palps are smooth on the surfaces turned away from the mouth, but are closely grooved on the opposed faces which bound the entrance to the mouth. The mouth thus guarded lies at the base of the deep cleft formed by the approximation of these lips. It is a large, slit-like depression placed transversely between the anterior levator muscles of the foot. Each of the two corners or angles of the mouth is produced laterally to merge imperceptibly into the palpar gutter that marks the line of junction of the dorsal and ventral palps of that side. In this way a long shallow ciliated gutter leads up to each angle of the mouth from between the palps.

The oral cavity rapidly contracts inwards to the narrower width of the œsophagus (*Oe.*, Plate VI., fig. 1), which is a short, straight, ciliated tube, dorso-ventrally compressed, continued posteriorly along the median line and in the same plane as the mouth. Its hinder end opens into the anterior end of the stomach, slightly below the level of the roof.

The form of the stomach (*St.*, Plate VI., fig. 1) is ovoid, the long axis lying horizontally, with the narrow end directed anteriorly and slightly upwards. It is unsymmetrically placed, encroaching greatly upon the left portion of the visceral mass—so much so that three-fourths of its capacious chamber lies to the left of the median plane. Except at the extreme left, and for a small space on the roof, it is enveloped by the digestive gland.

Folds and depressions diversify the walls and floor of the stomach and break them up into definite areas. The most conspicuous is a slightly projecting vertical fold which arises from the posterior wall and from the hinder part of the floor, marking out the hinder or cardiac moiety of the stomach into a right and a left chamber. This postero-ventral fold (*P.v.f.*, Plate VI., fig. 7) dies away before reaching the roof, which, in marked contrast to the rugose floor, is smooth and unbroken, except for a small but well-marked median depression or pit at the junction of the anterior with the median third. The wide bipartite opening into the intestine and intestinal cæcum (*Int.ap.*, Plate VI., fig. 7) marks the hinder end of the floor of the left chamber, which may therefore be named the intestinal or pyloric chamber. In size it slightly exceeds the right or cæcal chamber, the former being appreciably deeper, and being as wide as it is deep, whereas the height of the latter is twice as great as its breadth (Plate VI., fig. 4). Anterior to where the postero-ventral fold dies away midway along the floor, a peculiar flattened and obliquely sloping plate (*Pl.d.*, Plate VI., fig. 7), facing backwards, upwards, and to the right, occupies a sub-central position; and branching channels radiate forwards on its surface, connected possibly with the distribution of the digestive fluid. To the right of this area, which may be named the dendritic plate, is a ridge with accompanying furrow, running forwards and upwards to the antero-lateral bile-duct, while to the left is a shallow, wide pre-intestinal depression (*P.i.dep.*, Plate VI., fig. 7). A deep, rugose, sub-œsophageal pit (*S.œ.p.*) is well marked anterior to the dendritic plate, and high up on the right lateral wall the postero-lateral furrow leads from the postero-lateral duct towards the intestinal aperture. On the left side, a stout antero-lateral fold lies between the pre-intestinal depression and the sub-œsophageal pit.

The digestive gland, or "liver" (*D.gl.*, Plate VI., fig. 1), as already noted, surrounds the stomach except at small areas upon the extreme dorsal and right lateral aspects. Under healthy conditions it is of large size and of a characteristic deep sage-green colour. It is made up of dense clusters of secreting alveoli (Plate IX., fig. 3), which open into ductules and thence into the larger ducts, which lead into the stomach. There are eleven of these terminal ducts, namely :—

a. The *antero-lateral duct* (*D.a.l.*, Plate VI., fig. 6), opening high up on the right side, and posterior to the right of the sub-œsophageal pit.

b. The *postero-lateral duct* (*D.p.l.*, fig. 6), opening at the same level and on the same side, within the posterior third of the stomach. Several large ductules open at its very end (as is the case with *a* and several of the others), and, as the latter is wide, some of these tributary apertures are visible from within the stomach. This duct ramifies within the upper and posterior region of the digestive gland.

c. The *postero-ventral duct* (*D.p.v.*, fig. 7) opens in the floor of the posterior third, also upon the right side. It comes from the posterior and ventral parts of the gland.

d. Anterior to the last named are the *three sub-central ducts* (*D.s.c.*, fig. 7), the inmost one being of large size.

e. *Two pre-intestinal ducts* open within the pre-intestinal depression and drain the left ventral portion of the gland.

f. Below the œsophageal aperture the openings of three small *sub-œsophageal ducts* (*D.s.œ.*, fig. 7) can be readily made out, bringing the secretion of the anterior and lower portion of the glandular organ.

To see the openings of these ducts, divide the stomach horizontally along the mid-lateral plane and syringe out the contents. Then *a* and *b* will be seen upon the right side of the roof (see fig. 6), the remainder upon the ventral half (fig. 7). The course of the larger ducts can also be traced for some distance by picking away the glandular tissue around the stomach (see also figs. 8 and 9).

Lining the greater portion of the gastric cavity, dipping into depressions and rising over the folds, a gelatinous layer (corresponding to the "flèche tricuspide" of some other molluscs) invests the epithelial lining. It is colourless and transparent; and in section is seen, under the microscope, to be a cuticular laminated structure in close relation with the underlying epithelium. In freshly caught, healthy individuals, the distal end of the crystalline style is invariably seen protruding into the stomach from the circular and larger anterior portion of the intestinal aperture.

The intestine may be divided into three sections of approximately equal length, namely: (*a*) The descending portion; (*b*) the ascending portion; and (*c*) the rectum (see Plate VI., fig. 1).

(*a*) The first or descending section of the intestine (*Int.* 1) passes ventrally, with a slight inclination to the rear, into and through the posterior part of the visceral mass, which is here composed of the tubules of the gonad. Its course then lies behind the base of the byssal gland and between the converging bundles of the two pedal retractor muscles. At this point it changes its direction and curves forwards and downwards to the prominent antero-ventral corner of the visceral mass which marks the point of its junction with the ascending branch (*Int.*, 2).

A longitudinal fold projects inwards from the anterior and one from the posterior wall of the descending intestine. As these folds are *vis-à-vis* and to one side of the median axis of the tube, they divide it into two unequal longitudinal chambers, or rather gutters, that to the left being the larger (Plate VI., fig. 10, *a*). The two folds are low and little prominent for a short distance from the stomach; little by little they reach further across the cavity till in the middle and lower thirds their apices broaden and close together, so as to form two distinct tubes. The broader of the two is circular in section at all points; the smaller, except at the beginning, is irregular in sectional outline and appears rather as a narrow and deep gutter along the side of the broad cylindrical left portion (Plate VI., fig. 10, *b*).

The narrow tube usually contains a train of partially digested food matter, while under healthy conditions the larger cavity is completely filled with a clear gelatinous solid cylinder, the crystalline style, a gently tapering, pliant and slightly elastic rod. The right-hand tube, in spite of its insignificant diameter, is the true intestine, the wider left being the sheath of the crystalline style, which here, as in *Ostrea*, *Pecten*, *Cardium* and *Mya*, is imperfectly separated from the anterior portion of intestine, with which it communicates by a longitudinal cleft. The function of the crystalline style is still doubtful. Among more modern views, while Möbius, Haseloff, and Hazay have argued that it represents a reserve food supply, Barrois, Pelseneer, and others believe it to function as a lubricant to obviate the danger of sharp fragments, taken in with the food, causing damage to the delicate lining of the intestine. The upper end of the style certainly projects into the stomach, and as it wastes, the hinder part is continuously being pushed upwards to compensate for the loss. According to Barrois, sand and shell fragments are invested by the viscous waste of the style, and so made bolus-like are moved along the intestine more freely and without inflicting injury upon the walls.

Margaritifera vulgaris is, however, capable of exercising a certain degree of selection in feeding, and sand grains are seldom seen in any numbers within the alimentary canal. And yet the crystalline style is always present in healthy individuals containing a fair amount of food material in the intestine, as, for example, all the individuals examined in Trincomalee harbour in October, 1902, and upon the Pearl Banks during the 1903 fishery. But out of 43 oysters examined at Galle during June, July, and August, while in a state of semi-starvation, having been kept for ten days and upwards in water containing little suitable food matter, five only showed a crystalline style. The alimentary canal of the whole number contained an extremely small amount of food, and the visceral mass was notably shrunken.

Still it must be remembered that small sand grains and sharp-pointed sponge-spicules and diatoms are here and there to be met with in the stomach contents, and in these cases the suggested gelatinous investment by the style would be useful. Moreover, the cohesion of particles into a bolus capable of traversing the intestine more readily, brought about by the investment, would, no doubt, also be useful.

A valvular folding of the intestinal ridges gives entrance to the ascending region of the intestine (*Int.*, 2, Plate VI., fig. 1), which, however, before turning on an upward course, curves backwards along the base of the visceral mass to the left of and parallel with the lower or forwardly directed portion of the descending intestine. At the posterior extremity of the ventral surface of the visceral mass the two intestinal divisions intersect, the ascending section crossing to the right. The intestinal loop (*Int.lp.*, Plate VI., fig. 3) thus formed in the floor of the visceral mass is the visceral loop. From the point of intersection the ascending intestine turns sharply upwards, running parallel with and closely adjacent to the upper part of the descending intestine, the course of the latter lying a little forward and to the left. The portion of the ascending intestine forming the second limb of the visceral loop is small in diameter and somewhat compressed. The anterior fold of the descending intestine is continued into it as a somewhat undulating and irregular dorsal ridge dying off midway along.

At the point where this division of the intestine assumes a dorsal course, an increase takes place in the diameter, concurrent with the appearance of a great longitudinal fold, the *typhlosole* (Plate VI., figs. 3 and 11, *Ty.*) projecting inwards. At its start, this typhlosole projects from the anterior wall, but almost at once curves over to the posterior side of the tube, thence running vertically upwards without further change of course. Longitudinal and somewhat oblique furrows channel the surface, and as it expands greatly above the line of attachment to the intestinal wall, its bulk largely fills the cavity of the intestine. In transverse section, the lumen is seen to be reduced to an attenuate long-horned crescent (Plate VI., fig. 5). As it approaches the level of the floor of the stomach, the typhlosole thins down rapidly to a low ridge, and the intestine itself then curves posteriorly in the direction of the heart (Plate VI., fig. 1). This change in direction and thinning down of the typhlosole indicate the commencement of the rectum (*Int.*3, Plate VI., fig. 1), which is not marked by any other definite sign.

From the right-angled curve made by the intestine posterior to the stomach, the rectum runs posteriorly, through the upper part of the pericardium. Beyond this it begins to curve ventrally, and passes round the posterior aspect of the adductor muscle in the median line, ending in an erectile ear-like process bearing the anus (Plate VI., fig. 1), and situated opposite the exhalent orifice of the mantle.

The rectal typhlosole, though well-marked as a semi-cylindrical ridge (Plate VI., fig. 12, *Ty.*), never rises much above the semi-diameter of the tube. It runs along the intestinal floor while in the cardiac region, and when the rectum courses behind the adductor muscle it becomes a median fold on the anterior wall.

Where the first portion of the rectum passes through the narrow upper part of the pericardium, it has the ventricle attached to its lower surface (Plate VI., fig. 1) with an anterior aorta running forwards and upwards to the left, and a posterior aorta passing backwards posteriorly and ventrally to pursue a course parallel with the rectum (see also Plate VII., fig. 2). From the point where it passes from the cardiac region, the rectum and the accompanying aorta are overlaid with a considerable thickness of spongy lacunar tissue (Plate IX., fig. 6). The bulk thus attained renders the course of this division of the intestine conspicuous as a massive semi-cylindrical vertical ridge descending the posterior surface of the adductor in the median line. This rectal ridge (*R.r.*, Plate VI., fig. 15) is frequently pigmented with splashes of black and opaque white pigments—occasionally it is suffused more or less extensively with orange. Figs. 6 and 7 on Plate IX. show the range in height and shape of the rectal ridge, and fig. 8 gives the character of the tall ciliated epithelium of the rectum.

The anal process (*An.f.*, Plate VI., fig. 3) is a comparatively large, slightly curved, erectile, ear-shaped organ facing ventrally. It stands out at right angles to the last section of the rectum, and the tip is directed posteriorly, while the margins tend to be somewhat in-curved. The anal aperture (*an.*) is situated at the base, on the ventral aspect. Fæcal matter is expelled periodically in string-like masses, which, caught up by the steady exhalent current, are swept out through the mantle orifice and carried some little distance clear of the animal (Plate VI., fig. 14, *Pel.*).

The form of the anal process is likely to prove of diagnostic importance in the characterization of species when a revision of the genus *Margaritifera* and allied forms is undertaken upon the basis of a study of the soft parts. The variations in the shells of *M. vulgaris*, which our plates exhibit, show that such characters alone are insufficient for an accurate differentiation of some species.

The one living *M. margaritifera*, LINN. ("Black-lip"), which we had an opportunity of examining in Ceylon had an anal process wholly different from that of *M. vulgaris*, being pinnatifid palmate, with five lobes (Plate III., fig. 5).

In a third species, small and much flattened, which appears to be closely related to the Shark's Bay shell, this process is simple, as in *M. vulgaris*, but is broader in proportion, and with a rounded obtuse free termination, whereas in the latter it is longer and more lanceolate, with an acuminate tip (see Plate III., figs. 1 and 3). But probable variations in the soft parts must also be considered.

The histology of the wall of the alimentary canal is shown in figs. 8, 9, and 10, on Plate IX. The tube is lined by ciliated columnar epithelium throughout, and presents no features that call for special detailed description. The columnar cells on some parts of the wall are enormously taller than on other parts (see fig. 9), so as to form great pads projecting into the lumen. The ciliated epithelium of the stomach is continued for some distance along the larger ducts of the digestive gland (fig. 2).

The cæca of the digestive gland are seen cut in various directions in figs. 1 and 2 on Plate IX. In a transverse section the exterior of the cæcum is circular, but the lumen is frequently quadrangular (fig. 4) because of the unequal size of the gland cells. The organ agrees in detailed structure (see Plate IX., figs. 1 to 4) with that of other better-known Lamellibranchs, such as the common oyster.

THE BRANCHIÆ.

Between the slightly opened valves of a living pearl oyster the four sickle-shaped branchiæ or gills, delicately fluted and usually more or less edged and dappled with shades of grey and drab, are easily seen (Plate II., fig. 5). The free edges curve outwards from the base of the foot (Plate II., figs. 3 and 4), and, keeping a little inside of and parallel with the mantle edge, extend to a point just ventral to the exhalent orifice, where they narrow to a well-defined combined tip (fig. 3).

Of these four gills, two belong to each side of the body (*Br.*, Plate V., fig. 3), and each such lateral pair (Plate VIII., fig. 6) constitutes morphologically one ctenidium —so that one fold or "gill" is a hemi-ctenidium. The ctenidium consists of a vascular basis or axis upon which are inserted at right angles along its whole length two rows of long delicate branchial filaments, hollow outgrowths of the axis. As the axis extends from the ventral border of the palps anteriorly along the front edge of the visceral mass, nephridium and adductor muscle, and curves round ventrally and posteriorly to a point opposite the anus, with its convexity first forwards and then downwards, it follows that these branchial filaments must be directed in the upper or oral region forwards, and in the lower or ventral downwards—in all cases towards the nearest margin of the valve.

The outwardly directed parallel filaments of each series are folded upon themselves, so that they become deeply V-shaped. The folding in each case is away from the common centre or axis, the external filament turning outwards and the internal inwards. Consequently, each branchial plate, formed of the doubled filaments, consists of two lamellæ—the direct and the reflected—which enclose between them a narrow inter-lamellar space (see Plate V., fig. 4)—where the outer lamella of the external hemi-ctenidium is the reflected, and the inner (that which is attached to the vascular axis) is the direct—the converse being the case with the internal hemi-ctenidium where the outer lamella is the direct one: the two direct lamellæ face one another.

Immediately behind the visceral mass the edges of the reflected lamellæ of the inner gills (*a.g.f.*, Plate VIII., fig. 7) of the two sides join loosely in the middle line, so as to show in a transverse section the form of two capital W's, imperfectly joined, thus—WW (Plate V., fig. 9, *Br.*). The free outer edge also adheres somewhat, under normal conditions, to the adjacent mantle by a thickened rim; but both the median and the lateral concrescing surfaces are readily separated with a little pressure, and it can scarcely be said that there is permanent fusion.

Histological examination of these places shows that the union is by means of very long and perfect ciliary junctions (Plate VIII., figs. 8, 9, 10), closely resembling in the appearance both of cells and cilia the ciliated discs of the filaments. At the extreme ventral edge of the median junction of the inner gills there is a very narrow but quite definite organic connection (Plate VIII., fig. 9, *org.*) which must be ruptured when the gills are pressed apart. At these ciliated junctions the epithelial cells are cubical or low columnar, with a distinct seam or margin from which the very regular stiff cilia project (figs. 9 and 10).

The common base (*ct.a.*, Plate VIII., fig. 6) of each ctenidium is a vascular attached ridge reaching from the anterior end of the gills, overlapped slightly by the bases of the palps, to a point near the anterior end of the adductor, thence running as a free axis to the posterior or distal extremity. It is seen in both conditions in sections on Plate V., attached in fig. 4 and free in fig. 9. Within the axis lie two great blood-vessels, the afferent and the efferent branchials. The former (*Br.aff.*, Plate VIII., fig. 8), which conducts the blood from the venous sinuses to the gills for purification, lies internal and dorsal to the latter (in Plate VIII., fig. 8, it appears as a tube above the efferent vessel, *Br.eff.*).

Hollow outgrowths, the inter-lamellar junctions, containing branches from the afferent vessels, convey blood from the axial trunk to the base of the reflected lamella. Thence the blood enters certain of the individual filaments, flowing outwards to the free margin, where it passes over into the direct filaments and so returns inwards to the branchial axis, where it joins the efferent vessel by openings along each side. The branchial afferent vessels and the band-shaped inter-lamellar junctions (Plate VIII., figs. 8 and 12) are comparatively few, and each serves a group of 10 or 12 of the reflected filaments. On the other hand, each direct filament has its own aperture into the efferent vessel.

The filaments composing a lamella are not placed in one plane. On the contrary, the lamella is pleated or plicated regularly at right angles to its base, so as to have alternating shallow channels and rounded ridges (Plate VIII., fig. 12). The number of filaments constituting a plica varies from 10 to 12. The transverse section of the gills given in fig. 12 on Plate VIII. shows how the ridges are formed by the plication of the filaments. At the bottom of each channel there is a specially large and modified filament (Plate VIII., figs. 12 and 13, *p.f.*) with a great development of skeletal chitin and some muscle bundles. These are known as the principal filaments, and they have the inter-lamellar junctions attached to them and alone receive afferent branchial vessels. The aërated blood passes from the gills by the ordinary filaments.

Neighbouring filaments are joined by continuous organic union mainly at the lower and the upper ends of the reflected filaments, where there are longitudinally-running blood vessels. Elsewhere the filaments are joined chiefly by the interlocking stiff cilia of the large ciliated discs which occur at intervals (Plate VIII., fig. 11, *c.d.*) throughout their length. In many places, however, groups of two or three or more filaments (see figs. 16, 17) are united by true organic junctions which occur alongside the ciliated discs, as Ridewood* suggested might possibly be the case. Fig. 16 shows four filaments united, I have found several examples of six, and in one specimen the whole twelve filaments of a plica were joined by continuous tissue. The concrescence is not always at the internal edge of the filaments, but may be about the middle, and in one case I found two unions between two neighbouring filaments leaving an ovate ciliated gap. But all such examples of true organic union are comparatively few and exceptional, and we certainly do not have in this gill the continuous solid inter-filamentar junctions which are found in the less simple gills of the Eulamellibranchiata (such as *Venus*, *Cardium*, *Mya* and *Anodonta*).

The frequency and arrangement of the ciliated discs is seen in fig. 11, representing a longitudinal section along several adjacent filaments, and a transverse section at the level of these junctions is seen in fig. 16. The epithelial cells bearing these special stiff cilia project beyond the general surface, and are of cubical or low columnar form.

The gill of the pearl oyster is thus what Pelseneer termed "Pseudolamellibranch," the lamellæ being plicated and connected by inter-lamellar vascular junctions, while the individual filaments are mainly united by the interlocking of the ciliated discs.

In transverse section the filament has a bluntly wedge-shaped outline, the narrower end being internal. The structure of an ordinary filament, where free from junctions,

* 'Phil. Trans.,' vol. 195, B, p. 155.

and more highly magnified, is shown in fig. 14. The epithelium on the surface is ectoderm, and this varies in height in certain parts, and is ciliated along special tracts, the chief of which are the frontal and the lateral (Plate VIII., figs. 13, 14). Underneath the epithelium of the gill filament is a thin layer of connective-tissue strengthened by chitinous thickenings. These skeletal thickenings take on a special development in the principal filament lying in the angle between two ridges (Plate VIII., fig. 13). Connective-tissue septa do not occur in the interior of the ordinary filaments, but at the level of the ciliated junctions the modified filaments which bear the discs may have their lumen largely obliterated by an unusual development of connective-tissue (fig. 15). Further details can be seen in the figures.

Apart from the special action of modified cilia in forming an interlocking junction, the normal function of the ordinary cilia on the branchiæ is to create the all-important current of water which enters the pallial chamber and passes over and through the branchial lamellæ, so as (1) to aërate the blood flowing in the filaments, and (2) to convey food particles to the mouth. The respiratory current is apparently due to the normal rhythmic lashing of the cilia on the large cells at the edges of the filaments; while the collection or rejection of particles in the water seems to be the result ot special action stimulated apparently by the irritation. Particles arrested by the branchial filter are caught up by the nearest cilia, which by local reversed lashing carry them outwards to the free ventral edge of the lamella. Here they are guided by the cilia of a pathway running along the branchial margin and are propelled forwards and upwards to the anterior end of the gill, where they come under the influence of the palps, to be accepted as food or rejected and conveyed to the exterior by the pallial ciliated band. On Plate VI., fig. 13 shows the ciliated paths, upon and between the gills, by which particles can approach the palpal gutters (*b.*) leading to the mouth (*a.*); and fig. 14 shows the track (*Pall.cil.b.*) along the mantle edge by which excreta pass to the exterior at the pallial fold (*Pall.f.*).

THE VASCULAR SYSTEM.

In common with all typical Lamellibranchs, *Margaritifera vulgaris* has a circulatory system consisting of a heart and a series of arteries, whence by means of irregular ill-defined spaces, the lacunæ, between and among the tissues and organs the blood flows into larger and usually well-defined thin-walled cavities, the venous sinuses. The bulk of the blood then circulates through the gills prior to being returned to the heart, but a portion passes direct from certain sinuses in the mantle. Of these vessels the arteries alone have definitely cellular walls, those of the sinuses being of connective-tissue.

The heart is contained in a thin-walled transparent sac, the pericardium (*Per.*, Plate VII., fig. 2), occupying nearly all of the posterior region of the body, the space bounded in front by the posterior limit of the viscero-pedal mass and behind by the upper part of the adductor. While in front the pericardium is in contact wholly with the viscero-pedal mass, its floor is formed of the wide median communication between the right and left nephridia; posteriorly the pericardial wall is entirely free and coincident with the body-wall and forms the anterior and dorsal boundary of the adductor embayment of the supra-branchial chamber, and laterally its walls are also partially free.

Dorsally the walls gradually approach, and close to the apex are perforated by the rectum; so narrowed, however, is the portion of the pericardium above the latter that it appears in sagittal sections rather as a tubular connection uniting the lateral portions of the main pericardial chamber—the supra-rectal pericardial arch (*Per.ar.*, Plate VII., fig. 1). This part of the wall is separated from the dorsal or hinge portion of the body-wall only by some loose connective-tissue.

Anteriorly there arises on either side from each ventral corner a wide sleeve-shaped prolongation directed forwards, so that the two appear to clasp the viscero-pedal mass. These are the two reno-pericardial canals (*Rn.per.*, Plate VII., fig. 1) each of which opens anteriorly by a horizontal slit (*Rn.per.'*, Plate VII., fig. 8) into one of the nephridia close to the external renal orifice.

The heart largely fills the pericardial space and is clearly distinguished through the thin pericardial wall. It consists of a dorsally situated median ventricle (*v.*, figs. 1 and 2) and two lateral auricles (*au.*, fig. 1)—dark-walled and symmetric—lying ventral to the ventricle. The auricles are liver-coloured bodies with puckered walls, roughly triangular in form when viewed from behind. The apex of each is attached separately to its respective corner of the base of the ventricle. The two are connected medially by the junction of their inner corners, while thin sheets or partitions of connective-tissue anchor their bases to the floor of the pericardium immediately over the inter-nephridial passage. The walls are largely thickened by the presence of numerous accessory excretory glands—the pericardial glands—to which is due also their distinctive dark-brown hue (see p. 65 below for details of these glands).

An efferent blood-vessel from the gills enters each auricle at the outer angle of the base. The auricular cavities inter-communicate through the basal junction and are reduced in capacity by inward projections of the walls.

The lips of the auriculo-ventricular apertures project inwards and form simple yet effective valves preventing the reflux of blood into the auricles during the ventricular systole. The ventricle is elongated, of a pale yellowish-white tint; the walls are thick and muscular, and the cavity is further reduced by numerous muscular trabeculæ crossing in various directions. As Grobben first pointed out, this ventricle does not surround the rectum, as is so usual in Lamellibranchs, but its dorsal extremity is intimately fused with the lower surface of the rectum. The muscle fibres in the wall of the heart are distinctly striated (Plate IX., fig. 12).

Anteriorly and posteriorly the dorsal ends of the ventricle pass into the anterior and posterior aortæ respectively. The latter (*Ao.p.*, Plate VII., fig. 2), the smaller of the two, passes backwards into the tissue surrounding the exposed part of the rectum and runs therein parallel with the latter to a point slightly above the anus (about $\frac{1}{8}$ inch in $2\frac{1}{2}$-year-old specimens). Here it changes its course, turning forwards into the hinder tendinous portion of the adductor muscle and immediately divides into two branches (Plate VII., figs. 4 and 5). One of these turns to the right, passing through the muscle parallel to and a little beneath its surface. Just before reaching the insertion of the muscle it turns abruptly at right angles and passes into the mantle—as the right posterior pallial artery (*Art.p.p.*, Plate VII., figs. 4 and 5). Its neighbour on the left—the left posterior pallial artery (*Art.p.p.'*)—passes under the rectum and into the tendinous part of the adductor, emerging and entering the left mantle lobe in a similar manner to the right branch.

Each of these arteries after entering the mantle runs forward along its junction with the adductor till opposite the paired pallial sense organ (*S.o.*, Plate VII., fig. 5). Curving forwards each then runs out to the inwardly projecting tongue of the mantle edge opposite the posterior gill tips. Here an anterior and a posterior branch are given off which run forwards and backwards respectively within the thickened pallial margin, parallel to and just beneath the pallial gutter.

The anterior branch meets a similar branch from the anterior pallial artery, the two so fused being the common pallial artery (Plate VI., fig. 2, *Art.c.p.*).

The anterior aorta (*Ao.A.*, Plate VI., fig. 2) passes forwards from the heart, above and to the left of the rectum, and then bends to the right and runs above and to the right of the stomach and œsophagus.

Of the many branches given off by this arterial trunk, by far the most important and largest is the first, the unpaired visceral artery (*Art.vis.*, Plate VI., fig. 2). This branches off immediately after the dorsal aorta crosses the rectum. It is rather wider than the continuation of the aorta. Turning ventrally, it penetrates the central portion of the viscero-pedal mass, crossing in its course to the left of the descending intestine and then giving off branches into the gonad and to the intestines.

Returning to the dorsal aorta, we find it supplying numerous arteries to right and left—and downwards—the chief of these being the hepato-pedal artery (*Art.h.p.*, Plate VI, fig. 2), given off just above the junction of the œsophagus with the stomach. Then branches are given off to the right and left labial palps, and beyond the mouth the aorta ends in two diverging branches—the right and left anterior pallial arteries (*Art.a.p.*), which pass ventrally within the mantle edge to fuse with the posterior pallial arteries as the common pallial artery (*Art.c.p.*).

The hepato-pedal artery, like the visceral, passes downwards to supply the viscero-pedal mass. Level with the floor of the stomach it bifurcates, the anterior branch going forwards to the foot as the pedal artery, the posterior branch—the hepatic artery—turning back to traverse the digestive gland. From the pedal a branch goes forwards and bifurcates to form twigs going right and left to the palps.

The blood stream, carried by the ultimate ramifications of the arteries, passes into the lacunæ—irregular spaces between the tissues—whence it drains into larger cavities, the venous sinuses, which conduct directly to the heart (from the mantle) or indirectly by the intermediation of the gills.

The blood is colourless, and contains nucleated corpuscles, which are shown in some of the figures of the blood spaces in the gills (Plate VIII., figs. 11, 13).

THE EXCRETORY SYSTEM.

The renal excretory system consists of the paired nephridia and possibly of the numerous small pericardial glands projecting from the walls of the auricles. The nephridia consist of two large symmetrical pouch-like sacs lying one on either side of the hinder half of the viscero-pedal mass. Each opens into the pericardium by a wide duct and to the exterior by a minute pore, and they intercommunicate by a wide channel beneath the auricles. In outline each is roughly triangular, the apex passing into the channel under the auricles, while the elongated base looks outwards and forwards, coinciding with the base of the anterior third of the gill of that side, and thus conforming to the inclination of the gill.

The outer wall of the nephridium (*Neph.*, Plate VII., fig. 8) is thin and membranous; it is fused with the body-wall, as is also the most anterior portion of the inner wall, namely, that strip extending from the base of the gill to the viscero-pedal mass; from this line it runs back, overlying and in contact with the hinder part of the gonad, gradually narrowing as it approaches the auricle.

The external renal aperture (*Rn.o.*, Plate VII., fig. 8) is a minute oval opening furnished with a sphincter muscle. It opens immediately below the genital aperture, within an inconspicuous lipped slit, the urino-genital vestibule (Plate VII., figs. 10 and 12), placed at the junction of the inner plate of the inner gill with the visceral mass, at a point about mid-way between the ventral border of the latter and the base of the foot.

Each nephridium consists of a glandular and of a non-glandular portion. By separating the right and left ctenidia and reflecting each, the glandular region (*Neph.'*, Plate V., fig. 4) is seen as a narrow, elongated, coloured strip—yellow, or pale brown, or even dark dull red—bordering the anterior part of the inner base of each gill. It consists of spongy tissue, occupying the anterior angle formed by the meeting of the inner and outer walls of the organ, and the secretion passes from the cavernous chambers of the glandular region directly into the spacious cavity of the main or non-glandular portion. The spongy renal tissue shows, when magnified, branching tubes and septa formed of irregularly cubical cells much vacuolated and with very distinct nuclei (Plate IX., fig. 15).

The passage (*Np.con.*, Plate VII., fig. 8) connecting the right and left nephridia lies beneath the auricles. It is a wide tunnel with thin membranous walls, bounded behind by the lower part of the pericardium, while in front its wall lies against the visceral mass, and below it fuses with the body-wall and so forms part of the roof of the adductor embayment of the supra-branchial chamber.

The reno-pericardial tubes (*Rn.per.*, Plate VII., fig. 8) are a pair of wide lateral prolongations of the pre-cardiac part of the pericardium, thin-walled and membranous, and directed forwards. Each gradually narrows towards the anterior end, where it opens into the non-glandular part of the nephridium of its own side. The aperture is a curved slit, with the concavity facing towards the ventral aspect (*Rn.per.'*). It has but one lip, the tube opening at a very acute angle. It is situated upon the inner wall of the nephridium, immediately to the rear of the external renal aperture. Usually, but not invariably, a small area around is rendered conspicuous by flecks of brown pigment.

Compared with the total bulk of the body, the size of the nephridial system is small, especially when we bear in mind the comparatively great size of this organ in some other Lamellibranchs, such as *Anodonta* and *Cardium*. There are, however, also the accessory pericardial glands, described by GROBBEN,* possessing an excretory function, situated on the walls of the auricles and on the neighbouring part of the pericardial wall; and it is the dark-brown colouring of these glands which renders the auricles most conspicuous objects in the dissection of the pearl oyster (see Plate VI., fig. 1). These glandular outgrowths increase largely the secretory area, as the auricular walls are thrown into numerous pouches, which are of a spongy structure, with deep folds of the inner surface dipping down into the blood stream. The epithelium shows large cubical, rounded or ovate cells packed with concretions and granules (Plate IX., fig. 13). The lower or auricular end of the pericardium is also glandular, and has its epithelium thrown into folds formed of granular vacuolated cells (Plate IX., fig. 14) of the same character as those of the nephridium. The secretion from all these pericardial glands passes by the wide reno-pericardial ducts into the nephridia, and thence gains the exterior by the renal aperture.

THE NERVOUS SYSTEM AND SENSE ORGANS.

The nervous system of the pearl oyster is of the ordinary Lamellibranch character, and is very similar to that of *Mytilus edulis*, the common mussel. The bi-laterally symmetrical central nervous system has 3 pairs of ganglia: (1) the cerebral ganglia at the sides of the œsophagus (Plate VI., fig. 15, *Cer.g.*), (2) the pedals conjoined to form a single ganglion (fig. 16, *Ped.g.*) at the base of the foot, and (3) a pair of large visceral or parieto-splanchnic ganglia (fig. 15, *Par.sp.g.*) lying upon the anterior surface of the adductor. These are connected as follows:—

Stout paired nerves, the cerebro-visceral connectives (*C.v.con.*), link the cerebral with the parieto-splanchnic ganglia (fig. 15), while a pair of similar cords—cerebro-pedal connectives (*C.p.con.*)—joins the cerebral with the pedal nerve mass (fig. 16).

* 'Arbeit. Zool. Instit. Wien,' Bd. VII., 1888.

The cerebral ganglia are pre-oral or supra-œsophageal in position, and a nerve cord or commissure, passing over the œsophagus, connects the two cerebral ganglia; while a single stout transverse cord—the visceral commissure—joins the two parieto-splanchnic ganglia (fig. 18).

The cerebro-visceral connectives surpass all the other commissural nerves in length. Taking their rise at the posterior end of the cerebral ganglion, each passes backwards and downwards, buried within the visceral mass, till it emerges opposite the upper angle of the base of the foot. Then it passes ventrally, overlaid by the renal sinus, whose course it follows till, entering the tissue at the base ot the gills, it turns slightly forwards—still passing ventrally—and ends in its respective parieto-splanchnic ganglion (fig. 15).

In addition to the supra-œsophageal cerebral commissures and to the connectives passing to the pedal and parieto-splanchnic ganglia respectively, the cerebral ganglion of each side gives off anteriorly a stout nerve—the anterior common pallial. This passes forwards, bifurcating almost immediately. The outer branch (the external pallial nerve) courses along the pallial edge, meeting and anastomosing with the corresponding external pallial branch of the posterior common pallial trunk. The labial palps and the otocysts are also innervated from the cerebral ganglia.

The cerebro-pedal connectives arise from the posterior and outer sides of the cerebral ganglia, and run downwards within the visceral mass and just behind the levator muscles of the foot to the pedal ganglion. They lie close together in their course, and about midway each gives off a nerve, passing posteriorly into the visceral mass.

The double nature of the pedal mass is distinctly seen in sections (Plate IX., figs. 16 and 16A). Three principal nerves arise from the pedal ganglion to innervate the foot and byssal gland (Plate VI., fig. 16). One, the dorsal (or superior) pedal nerve, given off from the upper anterior part, passes along the dorsal region of the foot to the tip of this organ, throwing off twigs as it goes. Its terminal portion innervates the locomotor or crawling portion of the foot. The second, the ventral (or inferior) pedal nerve, arises immediately below the last described, passes forwards and downwards and supplies the byssal groove and disc-pit. The byssal nerve is the third offshoot from the pedal ganglion; it comes away from the ventral end and passes direct to the byssal gland, dividing into numerous branches.

Each of the visceral or parieto-splanchnic ganglia receives from above the stout cerebro-visceral connective, the two ganglia being themselves united by a single transverse visceral commissure. In addition to these connecting nerves, each ganglion gives off two stout distributory nerves (Plate VI., fig. 18)—an anterior lateral (the branchial, *n.br.*) and a posterior (the pallial, *n.pal.*). Each branchial nerve leaves the ganglion at the anterior lateral corner, turns down at once into the base of the gills, and then passes backwards to the posterior tips following the course of the afferent vessel. The posterior common pallial nerves emerge from the posterior end of the visceral ganglia; from the base of each a stout nerve (fig. 18, *n.s.o.*) passes straight back, parallel with its neighbour and midway between the median line and the margin of the adductor, till it reaches the pigmented pallial sense organ of its respective side—a little anterior to the anus.

After giving off the last-named nerves, the common pallial trunk passes backwards and outwards, bifurcating almost immediately; the external branch, the larger, is the external pallial nerve and straightway bends outwards and passes into the mantle; the inner branch pursues a more median course, but in turn it soon divides. The outer of the resultant nerves becomes the median pallial nerve; the inner the internal pallial nerve, the latter being the weakest of these three pallial trunks. By the ramifying of these three nerves in the muscular and marginal regions of the mantle, and by their anastomoses with a corresponding series of inner, outer, and median branches given off by the anterior common pallial trunks from the cerebral ganglion, a complex network of nerves termed the pallial plexus is formed. A somewhat similar arrangement of the pallial arteries is found—the marginal pallial artery having, like these pallial nerves, a double origin.

In the case of the nerves, we find the external pallial, as indicated by the name, passes directly to the margin along which it runs, branching as it goes; the median takes a parallel but more internal course, and anastomoses freely with its fellow outside, while the third or inner branch passes forwards along the line of insertion of the pallial retractors, branches being given off which meet and anastomose with others from the median. On tracing these three nerves forwards we find that they join the corresponding series arising from the anterior common pallial trunk.

Sense-Organs.

Specialized sense-organs are few and of low type in the pearl oyster, the only structures that can come under this head being the otocysts, the osphradia, and the pallial or abdominal organs of Thiele. The latter are a pair of slightly asymmetrical laterally compressed tubercles lying upon the ventral surface of the adductor muscle, one on either side, a little anterior to the anus. In each the long axis lies transverse to the greater axis of the body. Dark pigment renders them conspicuous, and the one to the right is distinctly the larger. It is also situated slightly further back than its neighbour. In sections these sensory papillæ are seen to be covered with epithelium which contains specialized sense-cells. Plate IX., fig. 17A, shows the tip of one of these sensory papillæ. They are innervated by a special nerve from the visceral ganglion, possibly derived from the cerebral, close to the posterior pallial nerve (Plate VI., fig. 17, *n.s.o.*). The function of these organs is probably olfactory or of such a (?) tactile nature as to test the quality of the water passing over the gills, or to be stimulated by particles it contains.

The otocyst, at the pedal mass, has numerous otoconia, and is supplied from the cerebral ganglion. The osphradium is an area bounded by a well-marked projection close to the parieto-splanchnic ganglion at the origin of the branchial nerve. It has a small ganglionic mass lying at its base (Plate IX., fig. 18), and its nerve is cerebral in origin.

There are probably sensory cells in the ciliated epithelium on the grooved and corrugated oral surfaces of the labial palps (Plate IX., fig. 11); but the sense of touch seems to be localized chiefly in the margin of the mantle, and more especially in the filiform and digitate processes of the velum. These latter are extremely sensitive to touch, and the longer processes of the anterior and of the ventral margin have compound digitate apices; it is upon these multiple terminations (Plate IX., figs. 19, 20) that the chief sensory epithelial cells are disposed. The long processes of the posterior part of the mantle edge are of a different form. They are cylindrical filiform organs beset on all sides with short spinulate branches towards the tip (Plate III., fig. 9). Those on the margin of the temporary exhalent aperture are notably developed, and in life sway and sinuously bend in snake-like motion unceasingly. In sections they show a delicate columnar epithelium which is no doubt sensory.

Little can be said definitely regarding the sense of sight, although we have some evidence of the function being performed to a certain extent. Thus from the observations described in Part I., it is clear that there is a marked sensibility to light and shadow—a sensibility which may be termed dermatoptic, as it resides in the surface layer of certain regions. When the tanks were well lighted during the day, the shadow of a hand passing over was frequently followed by the immediate closing of the oyster's valves, and conversely after dusk they showed a similar but more accentuated re-action when stimulated by a bright light. Especially is this the case when surprised during a promenade, when having slipped their byssal cables they crawl along in search of a new resting place. At such times, or when forming new byssal threads, they appear extremely sensitive; they cease operations immediately and remain passive, with valves closed, as long as the irritation is continued. This photoscopic or dermatoptic sensibility can be located only in the soft parts turned towards the light—the edges of the mantle and the surface of the foot, when the latter is protruded—and there we invariably find patches of more or less deeply pigmented epithelial cells.

THE REPRODUCTIVE ORGANS.

The sexes are separate in *Margaritifera vulgaris*, and, as is shown by the experiments detailed on p. 125 in Part I., remain the same from season to season, *i.e.*, each individual is permanently either male or female throughout life.

The gonads (*Go.*, Plate VI., fig. 1) are paired but asymmetrical. The pair together forms a thick envelope covering the stomach, liver and first two sections of the intestine, and thus constitutes the greater part of the outside of the proximal portion of the viscero-pedal mass (Plate IX., fig. 1). Yet although the gonads envelop the viscera of this region, they do not hide the byssal gland, which, lying excentrically, comes in contact with the body-wall on the right; and when the viscero-pedal mass is viewed from this aspect (Plate VI., fig. 2), the byssal gland is seen as a broad band reaching from the base of the foot backwards to the right retractor muscle. This band has the appearance of dividing the right gonad into a dorsal larger part and a ventral smaller (Plate VI., fig. 15), a division more apparent than real, as the two parts are continuous to the left of the byssal gland. No portion of the reproductive glands extends into the foot proper, or into the mantle as in the case of *Mytilus*.

When mature, the male and the female gonads are practically indistinguishable from one another to the naked eye. Both are usually pale creamy yellow in colour; the male, in some cases, rather paler than the female. The male, too, is rather less bulky than the female; this, however, is no guide to the sex, as the bulk will in that case approximate to that of a partially developed female.

The gonads, testes or ovaries as the case may be, consist of branched tubuli, whereon cluster myriads of saccate cæca, the alveoli (Plate IX., figs. 21, 22). In these arise, by proliferation from the germinal epithelium of the walls, spermatozoa or ova, according to the sex. The accumulated ripened products filling these alveoli and tubuli are then passed on into three trunks, which converge into a single main vessel just within the external genital aperture (Plate VII., fig. 11). This opens immediately dorsal to the renal aperture of the same side, and, indeed, the vestibule into which they both open is really a deep cleft whereof the V-shaped bottom merges imperceptibly into the primary genital duct.

The spermatozoa (Plate IX., fig. 22A) are excessively minute and of the typical form. The head is comparatively large, clear, and highly refractile, ovate in outline; while the long flagellum, proceeding from its more rounded end, is from nine to twelve times the length of the head.

The ovarian ova (Plate IX., fig. 21), measuring 16 μ by 8 μ, are more or less polygonal in form, by reason of mutual pressure, while within the alveoli and tubuli of the female gonad; but when shed they become of a laterally compressed pyriform, or ovate, shape. The former is most characteristic—the narrow short stalk marking what was originally the place of attachment to the germinal epithelium. When fertilization takes place, the stalk functions as a micropyle. The vitelline membrane enclosing the coarsely-granular vitellus is thin. The nucleus is large, oval in outline, very clear, and but lightly granular, in length and in breadth exceeding the half length and the half breadth of the entire ovum. A nucleolus is also present, very conspicuously situated within the nucleus, close to its periphery. The more detailed characters of the ovum and the fertilization and early embryology will be discussed in a future Part of the Report in connection with the Life-History of the Pearl Oyster.

Ret.', impression of retractor muscle.
Ret.ins., insertion of retractor muscle.
Ret.pall., pallial retractor muscle.
Rn.o., renal orifice.
Rn.per., reno-pericardial canal.
Rn.per.', aperture of last.
Rn.s., renal sinus.
R.r., rectal ridge.
Sn.add.lat., lateral adductor sinus.
Sn.m., median sinus.
Sn.tr., transverse sinus.
S.o., pallial sense organ.
S.œ.p., sub-œsophageal pit.
St., stomach.
St. 1, intestinal or pyloric chamber of stomach.
St. 2, right or cæcal chamber of stomach.
Ty., typhlosole.
V., ventricle.
Vel., velum of mantle.
Vel.pr., velar processes.
V.l., visceral lobe.
V.m., visceral mass.

PLATE I.

Fig. 1. Right valve of a specimen of the Ceylon pearl oyster (*Margaritifera vulgaris*) from Kondatchi Paar, showing an unusually smooth and rounded form; nat. size. This seems very similar to the "Shark's Bay shell," described by JAMESON as *M. carchariarum.*

,, 2. Right valve of another specimen of the same species brought up in the same haul from Kondatchi Paar, to illustrate variation in the shell; nat. size.

,, 3. Inside of right valve of an unusually wide specimen from Kondatchi Paar, showing a broad margin devoid of nacre and very large auricles; nat. size.

,, 4. Inside of left valve of a more normal shell, from Cheval Paar, showing well-developed nacre and a group of small pearls near the anterior auricle; nat. size.

,, 5. Outside of left valve of an unusually straight and narrow specimen, from Cheval Paar, the surface covered with Polyzoa and other organisms; nat. size.

,, 6. Outside of left valve of an unusually oblique specimen from Cheval Paar, the surface largely covered with adhering organisms; nat. size.

(Figs. 1 and 2 from drawings by Mr. J. HORNELL; figs. 3 to 6 from photographs by W. A. H.)

PLATE II.

Figs. 1 and 2 show photographs (W. A. H.) of the inside and outside of the valve of a normally developed pearl oyster, showing form, markings and nacre; slightly reduced.

Fig. 3. From a photograph (J. H.) of the animal after removal of the left valve, showing foot and byssus, mantle, gills, adductor muscle, &c.; nat. size.

,, 4. From a photograph (J. H.) of pearl oysters from (A) Muttuvaratu Paar and (B) East Cheval Paar, of the same age (3 years to $3\frac{1}{2}$ years) to show the marked difference in growth; nat. size.

,, 5. From a photograph (J. H.) of three pearl oysters seen edgeways, to show adductor muscle and mantle lobes; nat. size.

,, 6. From a photograph (J. H.) of a pearl oyster with the right valve removed and dissected to show the adductor muscle, foot, &c.; nat. size.

PLATE III.

Figs. 1 to 5 show differences in the soft parts of three species of "pearl oysters."

Fig. 1. Anal funnel of *Margaritifera* sp. (?)—a small, flat, dark brown species, A in ventral and B in lateral view; enlarged; *a.*, anus.

,, 2. Ventral part of visceral mass of same species from the side; nat. size.

,, 3. Anal funnel of *M. vulgaris* (SCHUM.), A in ventral and B in lateral view; enlarged; *a.*, anus.

Fig. 4. Ventral part of visceral mass of same species, from the side, showing the visceral lobe (*v.l.*) more prominent and more distinctly separated than in fig. 2; nat. size.

,, 5. Palmate anal funnel of *M. margaritifera* (Linn.); enlarged.

,, 6. Marginal processes from ventral part of velum; *s.h.*, sensory tufts on tips of branches.

,, 7. Similar processes from another individual.

,, 8. Simpler processes of the pallial edge—typical forms.

,, 9. Some variations in the longer processes of the pallial edge; *a*, from near exhalent orifice; *b*, *c*, *d*, common forms; *e*, bifurcate form, unusual—all these processes × 4.

,, 10. Semi-diagrammatic view of posterior aspect of living pearl oyster, showing the usual circular appearance of exhalent orifice; enlarged; *My.pall.*, edge of mantle lobe; *Pall.f.*, pallial fold; *Vel.pr.*, velar processes interdigitating.

,, 11. An abnormal anal funnel, the tip being bifurcate (compare fig. 3, A); enlarged.

,, 12. An abnormal foot (from South-east Cheval), the tip being bifurcate. The lateral branch is non-functional, its groove having no connection with the byssal gutter and pit (compare fig. 18).

,, 13. Dissection showing foot (ventral surface) lying at rest within the mantle cavity; three byssal fibres are present; nat. size.

,, 14. Lateral view of the foot at rest; nat. size.

,, 15. Foot extended in the act of secreting a new byssal fibre; the locomotor region and the byssal disc-pit are pressed against the rock *a*; *By.p.*, byssus pore.

,, 16. Foot retracted from rock to reveal the new byssal fibre; *By.d.p.*, the disc-pit in which the attachment disc of the fibre was moulded—the lips have partially closed.

,, 17. Diagram showing the relative positions of the parts during and after the secretion of a byssal fibre.

,, 18. Ventral surface of foot when, the old byssus having been cast off, the animal is crawling with tip of foot searching for a new place of attachment.

,, 19. The same as seen through a glass plate over which the animal is crawling by means of its flattened locomotor region; *By.p.*, byssus pore; *By.d.p.*, byssus disc-pit; *By.t.*, byssus groove; *Ped.loc.*, distal locomotor region.

,, 20. The same when attached by byssus, and elongated for the purpose of forming a fourth byssal fibre (compare with fig. 15).

,, 21. Semi-diagrammatic transverse sections through foot; *a* and *b*, through the distal locomotor region; *c* and *d*, through the proximal secretory region; *x*, locomotor surface; *By.t.*, byssal groove; the shaded part is secretory, the unshaded part mainly muscular (compare figs. 3 and 4 on Plate VIII.). All these figures of foot are about natural size.

,, 22. Sagittal section through foot and byssal organ; *By.*, byssus; *By.p.'*, pleated surface of byssal gland; *By.p.gl.*, glandular tissue of byssal gland; *By.t*, byssal groove; *My.*, muscular tissue of foot; *Ped.loc.*, locomotor distal third of foot.

,, 23. The byssus: A, an entire byssus which was sloughed off by the oyster, showing the numerous fibres uniting in a common root lodged in the byssal pouch; B, one side of root of same byssus enlarged; C, reverse side of same root, showing furrows and ridges in dendritic form moulded in the pleated surface of the byssal gland—the two sides of the root diverge in some cases to form two separate masses of rootlets; D, distal end of byssal fibre, showing the disc of attachment, *a*.

,, 24. Antero-ventral view of visceral mass, looking towards pericardium to show relative positions of the retractor and adductor muscles; nat. size.

,, 25. Dissection from right side to show the course of the retractor muscle from its origin (*Ret.*) in the shell to its insertion (*Or.*) at the base of the foot. The visceral mass is shaded dark. The right mantle lobe is cut away along line *a*; nat. size.

,, 26. Dissection to show the course of the anterior (*Lev.a.*) and the posterior (*Lev.p.*) levator muscles, and the manner of their attachment to the base of the foot (F.).

PLATE IV.

Fig. 1. Outer surface of the mantle, as seen from left side on removal of valve, to show the number and arrangement of the insertions of the pallial muscles; nat. size. *Add.*, adductor muscle; *Ret.*, retractor muscle; *Lev.a.* and *Lev.p.*, anterior and posterior levators.

Figs. 2 to 6. Drawings of the interior of five pearl-oyster valves to show the variations in the arrangement and number of the scars produced by the insertion of the pallial muscles; nat. size. *Lev.a.* and *Lev.p.* indicate the scars of the anterior and posterior levators of the foot.

PLATE V.

Showing a series of sections across the body at different levels; slightly enlarged. D, dorsal; V, ventral; R, right, and L, left side of body.

Figs. 1 to 8. Vertical transverse sections in series from before backwards.

Fig. 1. Through œsophagus (*Oe.*); anterior end of byssal pouch (*By.p.*); palps (*Pa.*); anterior and posterior levator muscles (*Lev.a.*, *Lev.p.*); gonad (*Go.*); mantle lobe (*Pall.'*, *Pall.''*); pallial edge (*Mg.Pall.*); and velum (*Vel.*).

,, 2. Through anterior part of stomach (*St.*), parallel with last, showing also digestive gland (*D.gl.*) and hepato-pedal artery (*Art.h.p.*).

,, 3. Parallel with last, through lower part of byssal pouch with byssus-root (*By.r.*); antero-dorsal tip of nephridial sac (*Neph.*); end of intestinal loop (*Int.lp.*); and obliquely through branchiæ (*Br.*).

,, 4. A little posterior to last, showing postero-ventral hepatic duct opening into stomach (*St.*); glandular part of nephridium (*Neph.'*); sections through intestinal loop (*Int.lp.*); and anterior ends of the two retractors (*Ret.*) joining on posterior wall of byssal gland.

,, 5. Through posterior end of stomach (*St.*), showing intestine (*Int.* 1) leaving stomach, the two retractor muscles (*Ret.*) converging towards byssal pouch; nephridial sacs (*Neph.*) at their widest; Adductor muscle (*Add.'*), &c.

,, 6. In vertical plane immediately behind stomach, along ascending intestine (*Int.* 2), two portions of adductor (*Add.'* and *Add.''*); visceral artery (*Art. vis.*) descending through gonad, &c.

,, 7. Through the auricles (*Au.*) and posterior end of visceral mass with rectum (*Int.* 3); insertion of retractors (*Ret.*); pericardium (*Per.*); median venous sinus (*Sn.m.*); and lateral adductor sinuses (*Sn.add.lat.'*).

,, 8. Through ventricle (*V.*) and rectum (*Int.* 3), upper and posterior part of auricles (*Au.*), pericardial arch (*Per.ar.*), anterior aorta (*Ao.a.*), branches of median sinus (*Sn.m.'*), &c.

,, 9. Oblique dorso-ventral section through middle of visceral mass, adductor muscle, &c., as before.

Figs. 10 to 14. Horizontal sections at different levels, working downwards.

Fig. 10. At level of stomach (*St.*), showing anterior levators (*Lev.a.*) in transverse section, palps (*Pa.*), supra-cardial part of rectum (*Int.* 3), pericardial arch (*Per.ar.*), and an arrow entering anterior aorta cut obliquely.

,, 11. At level of ventricle (*V.*) and dorsal part of foot (*F.*), showing 3 sections of the intestine (*Int.* 1, 2, 3), palps (*Pa.*), &c.

,, 12. At level of auricles (*Au.*), showing auriculo-ventricular apertures, rectal ridge (*R.r.*) on posterior face of adductor, &c.

,, 13. Through middle of foot, showing origin of retractors (*Ret.*), inter-auricular communication, &c.

,, 14 Through byssal gland and root of byssus (*By.r.*), showing course of retractor muscles to insertion (*Ret.ins.*), &c.

PLATE VI.

Fig. 1. General anatomy of the pearl oyster as seen in sagittal section. The alimentary canal is slightly diagrammatic, as the limbs of the visceral loop do not lie in one plane, and neither the descending nor the ascending parts of the intestine are exactly in the median plane, and consequently would not occur in the one section. The size is that of a $2\frac{1}{2}$-year-old oyster. For the explanation of the reference letters, see list on p. 70.

" 2. Dissection (semi-diagrammatic in parts) in same position as last figure, to show the principal arteries, see explanation of reference letters on p. 70.

" 3. Dissection of the alimentary canal; nat. size.

" 4. Transverse vertical section through dorsal part of visceral mass, passing through posterior part of stomach to show the two parts separated by the postero-ventral fold (*P.v.f.*) and the intestinal aperature (*Int.ap.*); enlarged.

" 5. Horizontal section through visceral mass at base of the byssal gland, showing the retractor muscle fibres (*Fib.ret.*) inserted into the wall of the folded byssal gland (*F.by.p.*); *Go.*, gonad; *Art.*, arteries; *Int.* 1 and 2, descending and ascending parts of intestine; enlarged.

" 6. Stomach bisected horizontally; roof viewed from below, to show the opening of the œsophagus (*œ.*) and ducts; enlarged. Stomach wall in solid black.

" 7. Floor of same stomach viewed from above, to show dendritic plate (*Pl.d.*) and the various openings; enlarged.

" 8. Diagrammatic longitudinal vertical section of the stomach to the right of the median line, to show ducts entering; enlarged.

" 9. Diagrammatic longitudinal vertical section of the stomach to the left of the median line, to show ducts entering; enlarged.

" 10. Outline of cavity of first or descending part of intestine: *a*, cæcum of crystalline style; *b*, intestinal cavity proper; enlarged.

" 11. Portion of second or ascending part of intestine, opened to show the typhlosole (*Ty.*); enlarged.

" 12. Transverse section through rectal ridge, on posterior surface of adductor muscle, to show rectum (*a*) with its typhlosole (*Ty.*); *c*, loose connective tissue; *b*, posterior aorta (see also Plate IX., figs. 6 and 7); enlarged.

" 13. Diagram to show the ciliated paths leading from the gills by the palpar gutters (*b*) to the mouth (*a*); *d*, channel between base of external gill and mantle; *e*, at junction of external with internal gills; *f*, at junction of internal gills; *h*, along crest of external gill; *i*, along crest of internal gill. The paths diverge, converge, and join as shown.

" 14. Dissection to show the course of the ciliated track (*Pall.cil.b.'*) from labial palp (*Pa.*) along base of velum to pallial fold (*Pall.f.*), opposite posterior tips of gills. *Ret.pall.*, pallial retractor muscles; *Pel.*, particles ejected; nat. size.

" 15. Dissection from the right side, with right pallial lobe and right ctenidium removed, in order to show the course of the cerebro-visceral connective (*C.v.con.*); nat. size.

" 16. Diagram of the pedal ganglion (*Ped.g.*) and its connections and nerves; nat. size.

" 17. Posterior surface of adductor muscle (*Add.*), showing the parieto-splanchnic ganglia (*Par.sp.g.*) and their nerves; *n.br.*, branchial nerve; *n.pal.*, pallial nerves; *n.s.o.*, nerve to sense-organ (*S.o.*); nat. size.

" 18. Ventral aspect of adductor muscle and visceral mass (*v.m.*), to show the nerves given off by the parieto-splanchnic ganglia; nat. size. Lettering as in last figure.

PLATE VII.

Fig. 1. Diagram of the heart and pericardium, seen from behind; enlarged.

" 2. The same from right side. Lettering for both figures:—

Au., auricle; *V.*, ventricle; *Per.*, pericardium; *Rn.per.*, reno-pericardial canal; *Np.con.*, channel connecting nephridia; *Per.ar.*, pericardial arch; *Int.* 3, rectum; *Ao.a.*, anterior aorta; *Ao.p.*, posterior aorta.

Fig. 3. Dissection of dorsal surface of visceral mass, seen from above, enlarged; to show branches of anterior aorta (*Ao.a.*).

„ 4. Semi-diagrammatic vertical section through rectal ridge and adductor muscle, to show posterior aorta (*Ao.p.*) branching into right and left posterior pallial arteries (*art.p.p.*); enlarged.

„ 5. Course of the posterior pallial arteries from their origin in the posterior aorta close to the anal funnel (*An.f.*) out to the pallial margin; nat. size.

„ 6. Plan of the venous sinuses on the ventral and posterior aspects of the adductor muscle; enlarged. For lettering see p. 70.

„ 7. Plan of the same from the dorsal aspect, enlarged; showing especially the main and branch branchial afferent vessels (*Br.aff.*) to the gills. *Rn.s.*, renal sinus.

„ 8. Diagrammatic representation of the nephridial system and its relations to the pericardium. The arrows show the reno-pericardial canal (*Rn.per.'*) and the external renal aperture (*Rn.o.*).

„ 9. Enlarged view of the external renal aperture (*Rn.o.*) and of the reno-pericardial opening (*Rn.per.'*).

„ 10. Opening of the urino-genital vestibule at the junction of base of ctenidium (*ct.*) with the wall of the visceral mass (*v.m.*); enlarged.

„ 11. Transverse section through the urino-genital opening, showing the emergence of the genital duct; enlarged.

„ 12. More enlarged view of the urino-genital opening; *a.*, genital aperture.

„ 13. Anastomosis of the muscle fibres of the pallial muscles. × 40.

„ 14. A thin process from the growing margin of the shell, to show the "cellular" structure of the conchiolin in which the calcareous matter is laid down. × 40.

„ 15. Margin of the shell showing the same structure. × 40.

„ 16. Some prisms from a thick section of the prismatic layer. × 50.

„ 17. Part of a section of the prismatic layer decalcified to show the conchiolin framework. × 100.

„ 18. Part of a section of the prismatic layer showing the ends of the prisms and the distribution of pigment, × 50. A. shows one prism more magnified containing granular pigment.

„ 19. A, B, C, stages in the decalcification of prisms, × 100; D, the conchiolin framework; E, part of conchiolin more highly magnified to show layers of deposition.

„ 20. The nacre in surface view showing contour lines, × 300; A, more enlarged.

„ 21. Another part showing the granular appearance sometimes seen. × 300.

„ 22. Decalcified nacre, looking like a very much crumpled and folded membrane. × 300.

PLATE VIII.

Fig. 1. Section through the margin of decalcified shell to show the successively formed layers of prismatic material separating at the free edge. × 50.

„ 2. Section of the mantle lobe showing the marginal and velar processes. × 50.

A, B, C, D and E show the character of the epithelium, &c., at the points indicated, more highly magnified. × 500.

„ 3. Transverse section of the foot in the distal locomotor part. × 50.

„ 4. „ „ „ „ region of the byssal groove. × 50.

„ 5. Transverse section of part of the byssus gland, showing the secretion lying in the lamellar ducts. × 50.

„ 6. Dissection of posterior part of left ctenidium (the outer and inner gills of the left side). × 2.

„ 7. Diagrammatic transverse section across the two ctenidia, to show the median ciliated junction (*M.c.j.*) between the two inner gills and the lateral ciliated junctions (*L.c.j.*) between the outer gills and the mantle lobe. × 2.

Fig. 8. Transverse section through the left mantle lobe and both ctenidia, to show their relations and the extent of the median (*M.c.j.*) and lateral (*L.c.j.*) ciliated junctions. × 15.

,, 9. The median ciliated junction between the inner lamellæ of the inner gills; *org.*, slight organic connection. × 400.

,, 10. The lateral ciliated junction between the outer lamella of the outer gill (*g.f.*) and the mantle lobe (*Pall.*) × 400.

,, 11. Longitudinal section along the gill filaments, to show the ciliated discs (*c.d.*). × 50.

,, 12. Horizontal section across the two ctenidia (four "gills," *o.g.* and *i.g.*), to show the plication, the interlamellar junctions (*i.l.j.*), and the principal filaments (*p.f.*). × 50.

,, 13. Small part of such a horizontal section more highly magnified, to show a principal filament (*p.f.*), several ordinary filaments (*g.f.*), and an interlamellar junction (*i.l.j.*). × 400.

,, 14. An ordinary gill filament in transverse section, to show cilia, &c. × 500.

,, 15. Transverse section of a filament at the level of a ciliated disc (*c.d.*). × 500.

,, 16. Section showing filaments joined by organic union at the level of the ciliated discs. *a* is an ordinary filament free; *b* is a filament with a ciliated junction; *c*, *d*, *e* show ciliated and organic junctions together; *f* shows a ciliated junction alone. × 400.

,, 17. Another group of two filaments showing organic union. × 400.

PLATE IX.

Fig. 1. Section through visceral mass, to show stomach (*St.*), cæca and ducts of digestive gland (*D.gl.*), gonad (*Go.*), &c. *P.* shows an encysted Cestode larva. × 20.

,, 2. Another section of the stomach and digestive gland more highly magnified. × 50.

,, 3. Duct of digestive gland terminating in cæca. × 50.

,, 4. Transverse section of cæcum of digestive gland. × 400.

,, 5. Transverse section of pallial muscle bundle enclosing branch of pallial nerve (*n.*). × 400.

,, 6. Transverse section of rectal ridge (*R.r.*), showing rectum (*Int.*3), posterior aorta (*Ao.p.*), and loose connective-tissue. × 50.

,, 7. Section across another part of rectal ridge further back. × 50.

,, 8. Part of transverse section of rectum more highly magnified, to show epithelium. × 400.

,, 9. Part of wall of stomach highly magnified, to show epithelium. × 400.

,, 10. Transverse section of intestine near the loop, to show irregular typhlosole. × 50.

,, 11. Section across labial palps. × 50.

,, 12. Part of wall of heart, to show striped muscle fibres of the ventricle. × 400.

,, 13. Part of wall of auricle, to show gland cells. × 400.

,, 14. Section through ventral end of pericardium, to show pericardial glands. × 50. A, a part more highly magnified. × 400.

,, 15. Section from glandular part of nephridium, to show renal cells. × 400.

,, 16. Transverse section of pedal ganglionic mass. × 50.

,, 16A. Another section showing junction of cerebro-pedal connectives. × 50.

,, 17. Pallial sense-organ. × 50. A, the apex more highly magnified. × 400.

,, 18. Section showing parieto-splanchnic ganglion and osphradium. × 50.

,, 19. Sensory papilla on pallial tentacle. × 500.

,, 20. Tip of velar papilla. × 500.

,, 21. Section through female gonad, to show developing ova. × 400.

,, 22. Section through male gonad, to show tubules filled with developing spermatozoa. × 100. A, part of a cæcum more highly magnified. × 400.

THE PARASITES OF THE PEARL OYSTER.

BY

ARTHUR E. SHIPLEY, M.A., F.R.S.,
FELLOW AND TUTOR OF CHRIST'S COLLEGE, CAMBRIDGE,

AND

JAMES HORNELL, F.L.S.,
MARINE BIOLOGIST TO THE CEYLON GOVERNMENT AND INSPECTOR OF PEARL BANKS.

[WITH FOUR PLATES.]

INTRODUCTION.

THE history of the formation of pearls in European mussels around the Cercaria of Trematodes is recorded in the papers of GARNER (1871), GIARD (1897), DUBOIS (1901) and others, and it has recently been re-told in more detail by Dr. H. LYSTER JAMESON.* The main part of Dr. JAMESON'S own observation was directed to the *Leucithodendrium* (*Distomum*) *somateriæ* (LEVINSEN) of the eider-duck (*Somateria mollissima*, LINN.) and of a scoter (*Oedemia nigra*, L.), the sporocyst of which he states is found in *Tapes decussatus*, GMEL., and in the cockle, *Cardium edule*, L., whilst the tailless Cercaria infests the mussel, *Mytilus edulis*, and is the centre round which the small lustreless pearls of that mollusc are formed. It has been pointed out since that two points are still left in an unsettled condition by JAMESON'S paper, viz. (1) the exact mode of origin of the epithelial sac around the parasite which secretes the pearl, and (2) the supposed transference of the parasite from the cockle to the mussel.

With regard to the history of the relationship of internal parasites to the pearls formed in the Ceylon pearl oyster, *Margaritifera vulgaris*, SCHUM.—not a true oyster but a member of the AVICULIDÆ, and so allied to the mussel, *Mytilus edulis*—we quote two short paragraphs from Professor HERDMAN'S Introduction to the first volume of this Report:—

> "To Dr. KELAART (1857 to 1859) belongs the honour of having first connected the formation of pearls in the Ceylon oyster with the presence of vermean parasites. It is true that Filippi, seven years before, in 1852, showed that the Trematode *Distomum duplicatum* was the cause of pearl formation in the fresh-water mussel *Anodonta*, and KÜCHENMEISTER (1856), MÖBIUS (1857),

* 'P. Zool. Soc.,' London, 1902, p. 140.

and others extended the discovery to other pearl-producing oysters, and to other parasites; but it is possible that KELAART knew nothing of these papers, and that he made his discovery in regard to the Ceylon oysters quite independently. He (and the Swiss Zoologist, HUMBERT, who was with him at a pearl fishery) found '*in addition to the Filaria and Circaria, three other parasitical worms infesting the viscera and other parts of the pearl oyster. We both agree that these worms play an important part in the formation of pearls; and it may yet be found possible to infect oysters in other beds with these worms, and thus increase the quantity of these gems.*' Thus we have KELAART, in 1859, definitely stating the possibility, in the case of the Ceylon pearl oyster, of infecting other beds with the larvæ of the pearl-producing Platyhelminthian parasites in order to increase the quantity of pearls.

"THURSTON, in 1894, confirmed KELAART'S observation, finding in the tissues and also in the alimentary canal of the Ceylon oyster, '*larvæ of some Platyhelminthian* (*flat worm*).' He figures ('Madras Mus. Bull.,' I., Plate II., fig. 1) a section showing two of the parasites encysted between the alimentary canal and generative tubes. Here the matter rested so far as the Ceylon pearl oyster was concerned."

KELAART'S work has been till recently somewhat neglected, and we therefore give in a note* the whole paragraph which deals with parasites from his last Report.†

The large number of oysters dissected during the fifteen months of Dr. HERDMAN'S and Mr. HORNELL'S expedition enable us now to furnish what is probably a fairly exhaustive list of the Entozoa of the pearl oyster, seven in number. They comprise one Cestode (*Tetrarhynchus unionifactor*, n. sp.), three Trematodes (*Muttua margaritiferæ*, n. sp., *Musalia herdmani*, n. sp., *Aspidogaster margaritiferæ*, n. sp.) and three Nematodes, *Ascaris meleagrinæ*, n. sp., *Cheiracanthus uncinatus*, and an unidentified species of *Oxyuris*.

* "I have not in this paper detailed some very interesting discoveries made since my last Report, on the Anatomy and Physiology of the Pearl Oyster, believing that they are better fitted for a treatise on the subject than to be embodied in a Report to the Ceylon Government, which must necessarily be written in popular form. However, as this Report may, like the preceding ones, fall into the hands of scientific men, I shall merely mention here that Monsieur HUMBERT, a Swiss zoologist, has, by his own microscopic observations at the last pearl fishery, corroborated all I have stated about the ovaria or genital glands and their contents; and that he has discovered, in addition to the Filaria and Circaria, three other parasitical worms infesting the viscera and other parts of the pearl oyster. We both agree that these worms play an important part in the formation of pearls; and it may yet be found possible to infect oysters in other beds with these worms, and thus increase the quantity of these gems. The nucleus of an American pearl, drawn by MÖBIUS, is nearly of the same form as the Circaria found in the pearl oysters of Ceylon. It will be curious to ascertain if the oysters in the Tinnevelly banks have the same species of worms as those found in the oysters on the banks at Arripo."

† Reprinted in the 'Proceedings of the Madras Government Revenue Department,' 17th February, 1864.

The ectoparasites of the pearl oyster consist principally of shell-boring animals which tunnel more or less extensively into the nacreous portion of the valves. Of these, the only one whose depredations are of economic importance is the boring sponge *Cliona margaritiferæ*, DENDY. The other two, the Polychæte worm *Leucodore* sp., and the Lamellibranch mollusc *Lithodomus* sp. (date-shell), are never so numerous as to constitute a serious danger to the oyster population of the pearl banks.

I. CESTODES OF THE PEARL OYSTER.

I. CESTODE LARVÆ IN THE PEARL OYSTER, *Margaritifera vulgaris*, SCHUM.

The cestode larvæ of the pearl oyster pass through several stages in the tissues of the host, that is if they escape being entombed within the centre of a pearl. Economically these unpleasant little creatures are of supreme importance to the Ceylon pearl fishery, as their presence in the oyster causes the formation of the finest quality of pearl and those with the highest lustre.

These larvæ first attracted attention during the second cruise* of the "Lady Havelock," on March 6th, 1902, and the following days, when numbers of the early globular stage were dissected out from the livers of oysters dredged from the West Cheval Paar. Subsequently, during the investigation carried out at the Galle Biological Laboratory, a second and more advanced stage of a *Tetrarhynchus* larva was found in the same animal. Details of the morphology and histology were then worked out, and the relationship which the larvæ bear to pearl formation was investigated.

It is usual for a *Tetrarhynchus* to enter its first host as an embryo enclosed in an egg-shell. As VAULLEGEARD† says, "L'œuf doit être avalé par un animal marin ; il ne se développe que si cet être lui fournit un milieu convenable, mais les Tetrarhynques paraissent peu tenir à une espèce ;" the drawings made by one of us (Plate I., fig. 1) of a free-swimming larva taken in the plankton at the north end of the Muttuvaratu Paar seems to point to the fact that the embryo of the pearl-forming parasites may leave the egg-shell before entering their first host, and this must be so if the organisms in question are truly the young of the *Tetrarhynchus;* this point, however, requires corroboration.

The earlier and more globular-shaped of the two stages met with in the pearl oyster is by far the more numerous, as may naturally be expected. It accounts for all save one per cent. of the total cases found. The liver, the gills (Plate I., figs. 3 and 4), and the connective tissue of the mantle (Plate I., fig. 2) are the organs chiefly favoured ; the muscles are practically free, while the gonads yield comparatively few.

* See "Narrative," this Report, Part I., p. 70.

† 'Mem. Soc. Normandie,' XIX., 1897 to 1899, p. 353.

In the liver and in the base of the gills they usually reach the greatest size; in the gill-filaments, where they occasionally abound, they seldom attain other than minute dimensions. Each is enveloped in a tough, elastic, and fibrous capsule of spherical form, derived from the adjacent connective-tissue cells (Plate I., figs. 5, 6, and 8). The capsules of those found in the liver and gill-bases are specially thick and strong, and slightly opalescent. In extreme cases the fibrous capsule has a thickness equal to fully half the diameter of the enclosed parasite (Plate I., fig. 5 *a*, and fig. 8 *a* and *b*).

The minute larvæ encapsuled in the gill-filaments—and these are easy of observation because of the transparency of the capsule membrane (Plate I., figs. 5 and 8)—may be seen occasionally to rotate slowly within their prison. The body is subglobular and remains so, even after considerable increase in size. The oldest larvæ however tend gradually to assume an elongated cylindrical form, with a pointed protrusible head, a denticulated collar, and a long oval body, foreshadowing the change to the rarer second or hooded larval phase (Plate I., figs. 12 and 13).

The larva in this stage closely resembles one of those figured in a paper by Professor GIARD on "L'Origine Parasitaire des Perles."* It was observed by Monsieur SEURAT, who not unnaturally mistook it for *Amphistoma*.

In the globular stage, whether minute or comparatively large, the structure differs but in details. Thus the body consists of two regions, an anterior, the smaller, and a large bladder-like posterior division. The former measures approximately but one-third of the total diameter. Viewed *en face*, this region has the appearance of a broad convexly-annular sucker, with a wide central orifice, wherefrom protrudes slightly the rounded summit of a low eminence (Plate I., fig. 9).

The saccate hinder portion of the body is thin-walled and filled with granular contents wherein rounded refractile corpuscles lie scattered abundantly, especially in the peripheral layer (Plate I., figs. 12 and 13). Under slight pressure, as first seen, it exhibited a striking resemblance to a tiny Trematode, or it might be mistaken for a large Gregarine.

When freed from its investing membranes, the larva progresses slowly by means of the alternate elongation and contraction of the body, the low central anterior eminence assisting by protrusion and retraction. The anterior region is clear and slightly tinged with yellow; the hinder is colourless and granular.

The cephalic "sucker" is in reality a head-sheath, the low median eminence within being a proboscis-like head rudiment, the scolex-rudiment (Plate I., fig. 6). When the latter is retracted—the normal condition when at rest within the cyst capsule—it lies sunk within the sheath, separated from it by a deep and narrow encircling groove. Under the influence of slight pressure, the head is seen (Plate I., fig. 11) to be shot out in the form of a blunt cone, the head groove being temporarily obliterated. The muscular walls of this cephalic apparatus, sheath as well as head,

* 'C. R. Soc. Biol.,' LV., 1903, p. 1222.

are highly developed, and consist of two series, one running longitudinally, the other in a circular manner.

The cuticle of the head and its groove is smooth ; that of the sheath is ornamented with a multitude of closely set minute shagreen-like points, resembling in shape denticles from the skin of *Scyllium* ; the central point having a tiny basal projection on either side (Plate I., figs. 10 and 11, Plate II., fig. 18).

The hinder portion of this larva is the morphological equivalent of the "bladder" of the Cysticercus stage of *Tænia*, differing however in that the contents, in lieu of being fluid, are composed of a loose connective-tissue parenchyma, in which are distributed the rounded refractile bodies already referred to. These effervesce upon the application of acid, and by this test, taken together with the similarity in appearance, they are shown to be calcareous corpuscles identical with those so widely met with among the Cestoda.

Ensheathing the body parenchyma are two muscular layers of similar arrangement to those of the head, but of extremely feeble development. These in turn are overlaid by a cuticle of peculiar appearance. In the parenchyma ramify the tubules of the vascular system.

The connective-tissue framework of the cortical region of the parenchyma is rather denser than it is in the centre. In the former, accumulating at the periphery, lie the majority of the calcareous corpuscles. Of these, while some are nearly spherical, the greater number are slightly reniform, or else obscurely compound, double, or even roughly trifoliate, shallow depressions marking some out into two or even three distinct areas (Plate II., figs. 16 and 17). With pressure, they can be broken into irregular sharp-edged fragments, just as a glass ball shatters under a blow.

The traces of a distinct and fine capsule around many of the corpuscles, which can be detected in the living tissue, is probably the remains of the cells in which the concretions arise (Plate II., fig. 17).

A closely woven network of anastomosing tubules of exceeding delicacy, suffused with the palest of pink tints, is also to be seen in the cortical parenchyma. Such represents a generalised and rudimentary excretory system which becomes specialized in succeeding stages (Plate I., fig. 12).

In the peripheral region just under the cuticle are occasionally to be made out large clear-walled cells filled with colourless transparent globules; probably these are the "bladder-cells" which ooze through the cuticular tubules under pressure.

When a living larva is examined microscopically, the body behind the denticulated hinder portion of the head-sheath shows a distinct appearance of being clothed in a densely ciliated envelope. So distinct is the appearance, that time after time references to the "ciliated surface" of these larvæ appear in the earlier notes made on the steamer "Lady Havelock." Never however were these cilia seen in motion, and this suspicious circumstance led to a more minute scrutiny, which revealed that the appearance is due to an optical illusion. In reality the apparently ciliated layer is an extremely delicate semi-mucilaginous external cuticular layer—the *epicuticle* as we may perhaps term it—deriving its deceptive appearance of ciliation from numerous closely-set vertical tubuli (Plate I., fig. 15). Underlying this is the thin true cuticle, perforated with pores corresponding in position and continuous with the tubules of the epicuticle. In consistence it is elastic, firm, and strong.

When one of these larvæ is being examined alive under pressure, after some time, as activity and vitality decrease, the epicuticle begins to disintegrate, delicate bladder-like cells filled with clear, colourless, oil-like globules ooze through the tubules from the sub-cuticular tissues, the mucilaginous epicuticle disappears concurrently, apparently dissolving, so that after the lapse of a few minutes the larva shows but the merest traces of this investment. The body appears then to be bounded externally by the firm and very thin true cuticle, a multitude of free thin-walled sacs full of oil-globules clustering cloud-like around the larva (Plate I., fig. 15).

In the elongated Balanoglossus-like older individuals belonging to this first larval stage, the head rudiment becomes longer and more proboscis-like; its bulk increases more rapidly than its sheath, which tends to assume a collar-like form (Plate I., figs. 12 and 13). At this stage, movements become more active, and the larva, facilitated by its more vermean form, crawls restlessly about when freed from its capsule. Histologically, the tissues show no further differentiation.

The larvæ we have described correspond so closely with the figures of those found by Monsieur SEURAT given in Professor GIARD'S article mentioned above, that we think there is little doubt that they are at least generically the same. Professor GIARD identifies these as belonging to the family Monobothria of VAN BENEDEN'S Order Pseudophyllidea. If Professor GIARD'S identification be correct, then our larvæ also belong to this family. We have, however, found a larval stage of an undoubted *Tetrarhynchus* living in the pearl oyster, and it is not impossible, though it seems improbable, that this stage is but a later one of such of the larvæ described above as escape entombment in a pearl.

This second stage, or larval *Tetrarhynchus*, shows a great advance on the larva described above. In length it measures from 4·5 millims. to 5·5 millims., and has a sagittate outline. The body, covered with a sculptured cuticle, is sub-cylindrical, decreasing slightly in diameter at the extreme posterior extremity (Plate II., fig. 19).

The anterior end is sub-conical, furnished laterally with two hood-like lappets, which are laid back ear-like, one on either side, when the creature is quiescent. They function as organs both of progression and of adhesion. Two muscular cup-shaped depressions occur in each, constituting two pairs of simple suckers (Plate II., fig. 22). When at rest, these suckers are not apparent; but as the lappets sweep forwards, either as swimming or locomotor organs, or as organs of prehension and attachment, the pits or suckers become conspicuous and comparatively deep. The lappets are extremely mobile, changing form continuously.

The short caudal region, slightly less in diameter than the rest of the body, terminates bluntly and is armed over the posterior moiety with stiff cilia-like hairs (Plate II., fig. 20).

The internal structure of the body is obscured by the massing of innumerable calcareous corpuscles in the cortical region. No details of the excretory system could be made out, save the presence of the main longitudinal trunks, and of a well developed terminal contractile vesicle opening to the exterior at the posterior extremity (Plate II., figs. 19 and 20), and a few loops in the head (Plate II., fig. 21).

Conspicuous within the second quarter of the body lie the four great proboscis-sacs. Each proboscis passes forwards to its point of emergence between the cephalic suckers (Plate II., fig. 22). One of their hooks is shown in Plate II., fig. 23.

The cuticle possesses a certain surface ornamentation, consisting of tiny mammillations or tubercles, irregularly disposed (Plate II., fig. 20), except upon the caudal portion, where the markings assume a meandering Greek pattern of graceful and intricate curves. The latter are possibly the expression of a post-mortem shrinkage, they were not observed in all cases, and are exaggerated in our figure.

II. Cestodes in the File or Trigger Fishes.

In looking for the second host of the pearl oyster parasites, it was natural to examine the species of *Balistes*, the Trigger or File fishes. It has been asserted, and also contradicted, that these fishes feed largely on pearl oysters and other molluscs. We have, however, confirmed the truth of the statement, having on many occasions found pearl oyster shells in the stomachs of *Balistes* taken on the banks. The presence in the body of both *B. mitis* and *B. stellatus* of numerous Tetrarhynchid cysts led to the hope that a further stage in the life history of the parasite upon which jewellers are so greatly dependent had been discovered. A more minute examination however, renders the connexion between the parasites of the pearl oyster and those of the file fish a doubtful one.

We have found so far in the *Balistes* two *Tetrarhynchi* belonging in our opinion to two distinct species, and these we have named *Tetrarhynchus balistidis* and *T. pinnæ* respectively. The latter is ensheathed in a large bladder-like vesicle, four or five times the length of the scolex, and perhaps twice as broad, the whole somewhat resembling a Lima-bean. The other form, *T. balistidis*, is also ensheathed in a vesicle. but of somewhat different form ; it has, for instance, little space between the inner and outer wall, and is simply a double membrane closely applied to the head of the scolex. It does not arise from the extreme end of the scolex, and so envelop the whole scolex, but it arises a little way behind the head and is folded forward as a woman might turn a short cape over her head. The result is that in this second form the scolex projects behind the vesicle (Plate II., fig. 24), whilst in the first the vesicle projects behind the scolex (Plate II., figs. 31 and 32).

Macerated specimens and sections show that the teeth of these two *Tetrarhynchi* are very different in shape, size and number. In *T. balistidis* the teeth are few in number, slightly curved or hooked, with a well pronounced broad base (Plate II., figs. 33 and 35). Seen in optical section, there are but two teeth visible in a transverse row, and probably each transverse ring of teeth consists of but four to six of these structures (Plate II., fig. 34). The teeth of *T. pinnæ* are, on the other hand, exceptionally numerous. They arise in two hemicircles, and the centre of each hemicircle lies posterior to the free ends. The right and left hemicircles alternate, as is seen in Plate II., fig. 37. The teeth are so numerous that the oblique \\// shape in which they are arranged is not evident when the teeth are themselves examined. Then only a forest of fine blades is seen like the clashing swords of an army acclaiming an Emperor, but if the lens be focussed on to the bases from which the teeth originate the orderly arrangement, as of soldiers drawn up in rank, becomes apparent. The teeth of this form differ from the stout teeth of *T. balistidis* not only in their number, but in their size and shape. They are smaller and far more delicate in outline, and are shaped like a Malay kriss (Plate II., fig. 36). At the proximal end is a small haft or handle, which probably represents the portion embedded in the flesh.

T. balistidis occurs encysted in the liver, and beneath the peritoneum of the spotted file or trigger fishes (*Balistes stellatus* and *B. mitis*). Its length is about 12 millims. to 13 millims., and its breadth 1·5 millims. to 2 millims. It consists of a rounded triangular head and an elongated, melon-seed-shaped body. The head is enveloped in a protective sheath—like an amnion—but remaining open at a median pore (Plate II., fig. 24). The hooked introverts and their muscular sheathes are all confined to the head, and are enveloped in the sheath. Traces of the bothria or suckers are visible. The body is quite free from the sheath and in no part surrounded by it. Both body and head are crowded with calcareous corpuscles.

What we take to be a later stage of *T. balistidis* also occurs beneath the peritoneum of *Balistes mitis* and *B. stellatus*. This stage is represented by the squarish head of a *Tetrarhynchus* with the introverts protruding and the bothria well marked (Plate II., fig. 25). This form has thrown off its body and its amnion, in fact the whole vesicle has disappeared. It shows distinct signs of 4 bothria, such as exist in *Tetrarhynchus bisulcatus*, LINTON. The introverts and their muscular sacs lie one on either side of the level of the bothria. The small papilla or protuberance at the posterior end indicates the beginning of the body or string of proglottides of the adult.

We have thus in *Balistes mitis* and *B. stellatus* in all probability two stages of the species *T. balistidis*.

T. pinnæ lies in more definite cysts formed by the pathological growth of the tissues of its host, and from which they can be easily shelled. The cysts are elongated oval or sausage-shaped, whitish or brownish-yellow in colour, and some

10 millims. to 15 millims. in length (Plate II., figs. 28, 29, and 30). The larva with the cyst is covered by a thin cuticle, beneath which lie some poorly developed circular and longitudinal muscular fibres (Plate II., fig. 38). The body of the vesicle is very fluid, consisting of a highly vacuolated parenchyma. In the parenchymatous cells numerous oil drops and calcareous bodies lie.

Finally we have a very small *Tetrarhynchus* found amongst the spiral valves of the intestine of a sting-ray, *Tæniura melanospilos*, BLKR., kindly identified for us by Mr. G. A. BOULENGER of the British Museum (Plate IV., figs. 67, 70, 71, and 72). In the stomach of this fish, known locally as the "Pulli-thirikkai," two entire and quite unmutilated *Balistes* were found. Dr. VON LINSTOW has kindly furnished us with a diagnosis of this *Tetrarhynchus*, which he has named *T. minimus*, and this we subjoin in the systematic part dealing with the Cestoda (p. 89).

Amongst the specimens of *Tetrarhynchus minimus* found in the *Tæniura* was a single example of *Polypocephalus*, a genus established by BRAUN* for some specimens he described from the stomach of *Rhinobatis granulatus*, CUV.

We have now dealt with the following forms :—

A. In the pearl oyster, *Margaritifera vulgaris*, SCHUM.—

(i.) Small Cestode larvæ in various tissues, some of these form the nuclei of pearls. These correspond very closely with the larvæ found by Monsieur SEURAT, and identified by Professor GIARD as belonging to the family Monobothria.

(ii.) Older larvæ, of the genus *Tetrarhynchus*, in more than one stage, the most mature and the most abundant of which have no sign or trace of a vesicle, the introverts protruded and probably functional, the muscular sacs of the introverts reaching back to the middle of the body, a well developed excretory system with a terminal pore, the posterior end of the body spinous, with sinuous markings, and the rest of the body covered with low warts (Plate II., fig. 20).

B. In the file or trigger fishes, *Balistes mitis*, *B. undulatus*, and *B. stellatus*—

(iii.) *Tetrarhynchus balistidis*, n. sp., whose head is closely enveloped in a vesicle which does not enclose the body, the teeth on the introvert are large and few in number, 4 to 6 in a horizontal ring (Plate II., fig. 24); a later stage of this form, like it encysted in the sub-peritoneal tissue, is represented by a squarish head with 4 bothria (Plate II., figs. 25 and 26). This stage has quite freed itself from vesicle and "body," but is provided posteriorly with a papilla or protuberance, from which the proglottides will probably arise.

(iv.) *Tetrarhynchus pinnæ*, n. sp., enveloped in a large vesicle swollen with

* 'Arbeit. Inst. Würtzburg,' IV., 1877–78, p. 297.

aqueous parenchyma. The vesicle covers the whole head and such body as exists, and in relation to the scolex recalls the Cysticercus stage of *Tænia*. The oval cysts lie embedded in the sub-peritoneal tissues. The introverts of this form have enormous numbers of weak hooks which arise from shaped bases. There are but 2 bothria (Plate II., figs. 28, 29, 30, 31, 32, 36, 37, 38).

(v.) *Tetrarhynchus minimus*, v. LINS., from the spiral valve of the intestine of *Tæniura melanospilos*, BLKR., a fish which eats *Balistes* (Plate IV., figs. 67, 70, 71, 72).

C. In the sea—

(vi.) A planarian-like larva, which in the structure of its calcareous corpuscles and its cuticle recalls the embryonic forms described above.

What is the relationship of these six forms?

To begin with the last, the planarian-like larva found swimming by lateral undulations—for it is unciliated—certainly resembles the youngest forms found in the pearl oyster. The indications of the invaginated head and the presence of calcareous corpuscles strengthen the resemblance. On the other hand, we as yet know of no other Tetrarhynchid which has a free-swimming larva. *Tetrarhynchi* make their way into their first host as embryos still encased in egg-shells. The Bothriocephalidæ have however free-swimming larvæ, but these swim by cilia. On the whole, we think it probable that this larva is the first stage in the life-history of the pearl-forming organism, but until it has been observed to enter the *Margaritifera vulgaris*, and until a more minute examination by sections proves the precise nature of the larva, it would be unwise to be dogmatic.

The young larvæ within the oyster have a two-fold fate, (i) either they become the nuclei around which their own sarcophagus is secreted, or—but this is most improbable—(ii) they may grow into the older *Tetrarhynchus* larvæ. The first have no further interest for their race. They perish but to form "pearls of great price" for which men risk their lives, and, as dried-up mummies set in a costly sheath, they serve to deck the crowns of kings and the necks of fair women. Had Cleopatra, when she dissolved her Orient pearl in vinegar, examined the residue with a lens instead of drinking it, she would doubtless have found a shrivelled, dried-up particle, the mummy of a tape-worm larva, around which the pearl had been deposited.

The *Tetrarhynchi* found in the pearl oyster seem to lack but reproductive organs to be adults. The following features in these forms are of importance in considering their alleged relationship with the encysted forms found in the *Balistes*:—the presence of the 2 lappets, each sheltering 2 bothria; the absence of any kind of vesicle; the position of the muscular sheaths into which the introverts can be withdrawn, the posterior end of these lies about half-way along the body; the warty markings on the skin; and the ciliated posterior end of the body.

None of these features are reproduced in either of the *Tetrarhynchi* encysted in the tissues of the *Balistes*. The more advanced larvæ from the pearl oyster have arrived at a later stage in development than the larvæ found in the *Balistes*, and, unlike them, seem to belong to that group of the Tetrarhynchidæ which form no vesicle. The teeth on the introvert differ in all respects from those of the *Tetrarhynchi* of the *Balistes* and from another *Tetrarhynchus* sp. found in *Trygon walga*. Those of the two species from the *Balistes* differ in nearly every detail. It would be rash to make a dogmatic statement as to the future fate of the *Tetrarhynchus* of the pearl oyster. The trigger or file fishes (*Balistes*), known to the Tamil fishermen as the Kilathi, have by our own observation been proved guilty of feeding largely on pearl oysters. Fragments of pearl oysters are frequently found in their stomachs, and altogether they seem to be the most likely host for the further development of the oyster parasite. We do not, however, think that it is at present clear that they are the second or final host.

Like the pearl oysters, the infested file fishes are by no means confined to the oyster banks in the Gulf of Manaar. Our Ceylon Expedition took them at Trincomalee and again at Galle; at the latter place one was taken so infested with young *Tetrarhynchi* that the mass of their cysts equalled in bulk the whole of the stomach and intestine. A second point is that the form with the large vesicle, *T. pinnæ*, was also found in the tissues of a large *Pinna* sp., a mollusc more widely distributed around Ceylon than *Margaritifera vulgaris*.

The nature of the teeth and their arrangement in *T. minimus* argues against any relationship between the pearl oyster parasite and the small *Tetrarhynchus* found in *Tæniura melanospilos*, and this want of relationship is corroborated by its very minute size. At present the final host of the pearl-forming Cestode does not seem to be *Tæniura melanospilos*. Still the adult *Tetrarhynchi* live almost exclusively in the alimentary canal of Elasmobranchs. Other members of this order which were found in the neighbourhood of the pearl fisheries were *Pteroplatea micrura*, Bl. and Schn., and *Trygon walga*, Müll. and Heull, *T. uarnak* (Forsk.) and *T. sephen* (Forsk.). The last two species were taken by Thurston in the Gulf of Manaar. Day also records *T. marginatus*, Blyth, *T. bleekeri*, Blyth, *T. hennettri*, Müll. and Heull, *T. kuhlii*, Müll. and Heull, *T. lumbricata*, Bl. and Schn., *T. zugei*, Müll. and Heull, from the Indian and Indo-Malayan seas. Probably one of these is the host of the final stages of the two Tetrarhynchid metacestoid larvæ found in the *Balistes*, which they certainly eat, and possibly also of the pearl-forming larvæ of the *Margaritifera vulgaris*. Linton* has described a number of *Tetrarhynchi* from various species of *Trygon*. These are *Tetrarhynchus* (*Rhynchobothrium*) *hispidus*, *T.* (*Rh.*) *longispinis*, *T.* (*Rh.*) *tenuispinis*, and *T.* (*Rh.*) *wagneri*, *T. tenuis*,† and *T. robustus*

* 'U.S. Commission of Fish and Fisheries. Commissioner's Report,' Part XV., 1887. Washington, 1891.

† The *T. lintoni* of Vaullegeard.

from *Trygon centrura*. DIESING* has also described *T.* (*Rh.*) *rubromaculatus* from *Trygon pastinaca*, and *T.* (*Rh.*) *heteromerus* from *Trygon brucco*, but the Trygons from the seas around Ceylon have yet to be investigated for their Cestode parasites. None of these *Tetrarhynchi* hitherto described from Trygons sufficiently resemble the forms described in this Memoir to warrant any claim to relationship.

SYSTEMATIC DESCRIPTION.

The following is an attempt to draw up the systematic characters of the three Tetrarhynchids described above, but it must not be forgotten that these characters are taken from larval forms. Although the later stages of the larvæ obviously approximate to the adult condition, the characterisation of a species from a larval form is always open to objection.

Cestodes from Pearl Oyster.

1.—**Tetrarhynchus unionifactor**, n. sp., Plate II., figs. 19 and 20.

Well advanced larva, about 6·5 millims. to 7 millims. in length. Head with two lappets at the bottom of each two bothria. Introverts with teeth spirally arranged, teeth shaped as in figure, uniform in shape and size. Surface of body covered with low warts except the hindermost end, where the last thirtieth of the total body length was ornamented with coiling markings, perhaps post-mortem wrinkling. The posterior half of this region bears stiff cilia. The sacs of the introverts stretch throughout the anterior half of the body. There is no trace of vesicle.

Habitat :—In the tissues of the pearl oyster. *Margaritifera vulgaris*, SCHUM., from the Gulf of Manaar, Ceylon.

Cestodes from File or Trigger Fish.

The three Cestodes hitherto recorded from the genus *Balistes*, and they are all from *Balistes capriscus*, L., are :—

(i.) *Rhynchobothrium paleaceum*, RUD., which in a larval state is found in *Mullus barbatus*, L., and is a synonym of *Tetrabothriorhynchus migratorius*, DIES.† According to VON LINSTOW'S 'Compendium der Helminthologie' this species is figured in OLSSON'S "Entozoa, iakttagna hos Scandinaviska hafsfiskar."‡ In the explanation to the Plate, however, the Cestode is simply called a *Tetrarhynchus* without specific name.

* 'S.-B. Ak. Wien,' XLVIII.

† 'DIESING 'Systema Helminthum,' p. 573, and 'Rev. d. Cephal. Param.,' 'S.-B. Ak. Wien,' XLVIII., p. 294.

‡ 'Lund. Univ. Ars-skr.,' 1886 (IV.), Plate II., figs. 35, 36, 37.

(ii.) *Tetrarhynchus balistes-caprisci*, Wag.* Two figures are given of a *Tetrarhynchus* from *B. capriscus*, but there is no diagnosis of the species, and the figures are hardly sufficient for purposes of precise determination.

(iii.) *Cestoscolex capriscus*, Parona, is mentioned in a list given in 'Res Ligusticæ,' II. "Vermi Parasiti in Animali della Liguria,"† but no description and no figures are given.

From the above brief résumé of the literature of the subject it seems impossible to identify the specimens at our disposal with any of those mentioned by previous writers. We have therefore made a fresh start and described the two species from *Balistes* as new.

2.—**Tetrarhynchus balistidis**, n. sp., Plate II., fig. 24.

Well advanced metacestoid larva, still retaining the body, 12 millims. to 13 millims. in length. Head triangular, enveloped by a closely wrapping vesicle which leaves the body free. Body crowded with calcareous corpuscles. Teeth of introvert few, only 4 or 6 in a transverse row, strongly hooked. Introvert sheathes confined to the head and not entering the body, which, it seems, is after a certain time thrown off (*cf.* fig. 25) with the vesicle. Apparently 4 lappets.

Habitat:—The metacestoid stage or cysticercoid occurs in the sub-peritoneal tissues of *Balistes stellatus* and *B. mitis* from Ceylon.

3.—**Tetrarhynchus pinnæ**, n. sp., Plate II., figs. 31 and 32 and 38.

The advanced larva or metacestoid is enclosed in a large vesicle, which not only covers the head, but the entire body, and is much larger than the body, 1 millim. to 15 millims. long. The teeth on the introvert are very numerous and arranged in oblique lines. Each tooth is slender, very slightly hooked, and is shaped like a Malay kriss. The proboscis sheaths extend nearly to the posterior end of the scolex. Two lappets.

Habitat:—The metacestoid larva lives in cysts in the tissues around the alimentary canal of *Balistes stellatus* and *B. mitis*, the younger larvæ probably in a *Pinna* sp. from Ceylon.

Cestodes from Sting-Ray.

4.—**Tetrarhynchus minimus**, n. sp., von Linstow.—Plate IV.,‡ figs. 67, 70, 71, 72.

Length 3·7 millims., the last proglottis measures 1·6 millims. in length and 0·39 millim. in breadth. The body consists of about 6 proglottides. The scolex or head bears on its anterior third 4 roundish projections directed backwards; these

‡ Plates III. and IV. have, by mistake, been lettered 3 and 4 in Arabic.

are the proboscis sheathes from which the proboscides are protruded (Plate IV., figs. 71 and 72). The projections bear very minute, closely packed hooks, from their apices the proboscides protrude, and these bear larger hooks at wider intervals. There is a regular gradation in the size of the proboscis hooks which is shown in Plate IV., fig. 67. The part of the proboscis which is retracted is arranged in a wavy fashion. The reproductive pore is lateral on the posterior third of each proglottis, but for the most part, only immature proglottides were present. The ova are thin-shelled, spherical, with a diameter of 0·0039 millim. This is the smallest of all species of *Tetrarhynchus*.

Habitat:—The folds of the spiral valve of the intestine of *Tæniura melanospilos*, Blkr., taken off Ceylon, at Trincomalee.

The very peculiar and regular arrangement of the teeth, and the gradation in their size and shape is a remarkable feature in the *Tetrarhynchus* from the *Tæniura*. These features seem to separate it off both from the *Tetrarhynchi* of the pearl oyster and from those of the file fish, and to bring us to the conclusion that these forms which seemed at first as if they might be stages in one life-history are really independent species, and that our knowledge of the life-cycle of the parasite which causes the formation of pearls is still incomplete.

II. TREMATODES OF THE PEARL OYSTER.

Three species of Trematodes inhabit the pearl oyster, all of them in an immature condition. They all appear to be new species and we have called them *Muttua margaritiferæ*, *Musalia herdmani*, and *Aspidogaster margaritiferæ* respectively.

1.—**Muttua margaritiferæ**, n. gen. and n. sp.—Plate III., figs. 53, 54, 55, 56 and 57.

Minute, 0·9 millim. to 0·75 millim. in length. Lanceolate shape, slightly narrower anteriorly, both ends bluntly rounded. Cuticle covered with minute pointed scales which extend over posterior end. Suckers almost equal in size, the posterior lies behind the middle of the body. No prepharynx. Pharynx medium in size, no œsophagus, the links of the alimentary canal extend to the vesicle of the excretory system, *i.e.*, almost to the posterior end of the body. Excretory vesicle large, transversely placed and somewhat basin shaped, the coils of the excretory tubules are very marked on each side of the pharynx. Genital pore to the right of the posterior sucker. The vagina is plicated, the penis is large. The cercaria stage has two black eye-spots, one on each side of the pharynx. The characters of the species are those of the genus.

Habitat:—The cercaria stage inhabits the pearl oyster, *Margaritifera vulgaris*, Schum. It is usually found in the gills, and is most frequently met with in those oysters which live on a rocky substratum, such as those of the Muttuvaratu Paar.

Of the three Trematodes associated with the pearl oyster, this is the only one found in any abundance; the other two species are so rare that no more than some half-dozen individuals have been met with during the course of the present investigation.

The local distribution of *M. margaritiferæ* is noteworthy. Its Cercariæ swarm in the stunted pearl oysters of the Muttuvaratu Paar; but in those from the Eastern Cheval they are very rare. Rocky ground predominates in the former locality, sand in the latter. As a consequence the molluscan, annelidan and fish constituents of the fauna show considerable divergence, and this, in turn, influences the numbers of the two unknown animals which lodge respectively the sporocyst and the adult form of this Trematode, and thus produces the erratic local distribution noted.

These Cercarian larvæ are usually found in the gills of the pearl oyster; there they occur frequently in considerable numbers. In a fragment of gill-lamella from a Muttuvaratu individual, made up of 12 filaments, as many as 6 of these Trematodes were found. To a much smaller degree they infest the mantle. In the other organs they seldom appear.

Their abundance is strangely variable even in oysters from the same "paar." In those from the Muttuvaratu, the majority contain from 20 to 40 each; occasional individuals are, however, found infested by an extremely limited number, and in a few instances there is a total absence of the parasite. On the other hand, in the large well-grown oysters from the Eastern Cheval, during the past eighteen months it was exceptional to find even a single one.

To give an account of the life-history of the Trematode and to discover the hosts of the other stages in its life-cycle, it will be needful to anchor on the Muttuvaratu Paar for a sufficiently long period to permit of an exhaustive examination of the principal organisms that live there in association with the oysters. A lengthy visit to this particular paar is also required in order to determine whether this Trematode has any importance as a pearl-inducing factor, although, so far as present evidence goes, it is strongly against such a presumption—every one of the dozen cyst-pearls obtained from this bank which have been decalcified has yielded a Cestode larva as nucleus.

The stage of *Muttua margaritiferæ*, which is met with in the pearl oyster, is a quiescent Cercarian form of an advanced character, the alimentary canal and the copulatory organs being fully developed. What appear to be testes are also present, but no trace of ovary was detected.

The larva lies coiled or, rather, doubled upon itself (Plate III., fig. 54) within a thin membranous adventitious capsule. It frequently changes position, rotating slowly within its prison.

When liberated by the rupture of the investing sac, the body is seen to be gracefully lanceolate in outline when viewed from either the dorsal or the ventral aspect. Anteriorly it is somewhat truncate, posteriorly it narrows rapidly, ending in a blunt rounded angle (Plate III., fig. 55). In length it is remarkably uniform, 0·75 millim. to 0·9 millim. covering all the individuals measured.

The two suckers are equal in diameter, that of each equal to one-third of the width of the body at its widest part. The posterior or ventral sucker (*v.s.*) is placed just behind the middle point in the longitudinal axis, its anterior margin approximately coinciding with this point. The muscular structure of the suckers presents no unusual feature.

Transverse rows of minute spines, closely and regularly disposed, beset the cuticle. The points are directed backwards, and as a rule they alternate in position with those of the row in front. The rows encircle the body, and, being arranged with perfect regularity, they impart a distinct appearance of annulation. There are about 150 or more of these encircling rows (Plate III., fig. 57, *c.s.*).

Two black eye-spots are conspicuous, even when the larva is viewed within its capsule (Plate III., figs. 54 and 55, *e*). One lies on either side, close to the junction of the oral sucker with the muscular pharynx. The diameter of each eye is equal to the width of two of the transverse rows of cuticular spines.

A wide aperture in the centre of the oral sucker opens into its capacious funnel-shaped cavity, a chamber continually varying in size. The mouth lies at the base of this funnel, whence a short buccal passage leads directly into the muscular pharynx (*ph.*), elliptical in optical section. There is practically no œsophagus, and the two long tubular digestive cæca (*d.c.*) arise close to the pharynx. Each of these, as it passes backwards, curves outwards till it approaches close to the lateral margin, thereafter pursuing a nearly straight posterior course. The cæca terminate at a point close to the anterior border of the excretory vesicle (*c.v.*). They are never distended with food material, as happens in the case of the succeeding species; little is to be seen save a number of rather large clear globules. All the organs are, indeed, remarkably clear and free from the massing of opaque granules so frequent in many Cercariæ and which is so marked a feature of the species next to be described.

The excretory system consists of two tubular lateral trunks extending the whole length of the body. Anteriorly, in the pharyngeal region, they are much convoluted; posteriorly they empty into a capacious median vesicle which communicates with the exterior by means of a narrow funnel-shaped pore at the hinder end. The excretory vesicle varies considerably in form; sometimes, as when the larva is lying within its capsule, it is broadly ovate, the narrow end directed posteriorly (Plate III., fig. 54, *c.v.*); at other times, when the worm is crawling about after liberation, the vesicle shortens and widens, and appears as a broad transverse chamber, roughly triangular in outline, the base directed forwards (Plate III., fig. 55, *c.v.*). The epithelial cells lining its interior are very conspicuous; they consist of very large cells, markedly convex on the free surface.

Two paired glands, which appear to be the male gonads, are present. They are situated laterally, one on either flank of the ventral sucker. Each is an elongated sac, broader behind than in front, and full of densely packed cells containing numerous clear globule-like bodies. No ovary can be traced.

Both of the copulatory organs are present and well developed. They open side by side to the immediate right of the ventral sucker at about the level of its centre. That of the male consists of a great cylindrical penis-sheath (*p.sh.*) lying, in great part, posterior to the ventral sucker. It contains a well-defined seminal vesicle (*s.v.*) at the posterior end together with the rudiments of the penis itself. The distal portion of the sheath is somewhat narrowed to form a distinct neck.

The female organ, the vagina, lies to the right, alongside and parallel with the penis-sheath. The walls are thrown into a number of circular folds or pleats—wide grooves, concave in section, alternating with sharp-angled encompassing projecting folds—that give it much the appearance of a broadly spindle-shaped Chinese lantern. No trace of uterus can be made out.

The encysted cercariæ of this Trematode resemble those figured and described by JAMESON in some features, but differ from them in other particulars, which indeed exclude it from the sub-family Brachycoelinæ to which *Leucithodendrium* belongs, *e.g.*, the two branches of the alimentary canal extend far beyond the ventral sucker, and indeed reach almost to the hinder end of the body.

It is difficult to establish a new genus upon a form which is not yet adult, but after going through the twelve sub-families into which LOOSS* has split up the Distomidæ we cannot bring our specimens into line with any of them. Some of their characters appear in one sub-family and some in another, but the totality of characters does not appear in any one of them. Owing to the immaturity, several of the chief features of the adult anatomy, such as the disposition of the uterus, could not be made out.

The increasing difficulty of coining names hitherto unoccupied has induced us to fall back on Tamil, and we suggest the name *Muttua* (Muttu means a pearl) for the genus. This will recall the particular paar (Muttuvaratu) where it occurs in the greatest abundance.

2.—**Musalia herdmani**, n. gen. and n. sp.—Plate III., fig. 51, and Plate IV., figs. 58, 59, and 65.

Skin smooth, without denticles. Pharynx rather smaller than oral sucker. Ventral sucker very large and protrusible; its diameter, as compared with that of the oral, is as 7 : 3. Œsophagus very short, a median backward pouch projects between the origin of the two limbs of the alimentary canal. The latter are long and reach back to the end of the body. The reproductive openings lie between the ventral sucker and the oral, but nearer the latter. The testes lie behind the ventral sucker and are inclined at an angle one to another, the ovary lies behind them. Excretory bladder small and triangular.

Habitat:—The larval encysted stage is found in *Margaritifera vulgaris*, SCHUM., encapsuled in the muscles, the mantle, and the foot.

* 'Zool. Jahrb. Syst.,' XII., 1899, p. 522.

This species is exceedingly rare in the pearl oyster. Four individuals only have been found, two from oysters hailing from the Periya Paar Kerrai, and a like number from the Muttuvaratu. Both of the former were found in the muscular pallial region in front of the base of the foot (Plate IV., fig. 65) in separate oysters. Of the others, one lay in the floor of the visceral mass, the other in the posterior ventral region of the mantle.

As in *Muttua margaritiferæ*, the stage met with had the outward form and the rudiments at least of all the organs of the adult individual. The specimens found were, however, not sexually mature, and being in an encysted condition must be considered as a Cercaria. Their length when in a normal non-contracted condition is $\frac{1}{8}$ of an inch (3 millims.). They are of an elongated narrow lanceolate shape, with a ratio of length to breadth of about 6 to 1 (Plate IV., figs. 58 and 59).

The cuticle is perfectly smooth, without denticles or ornamentation of any description.

The suckers are of greatly disproportionate size, the ventral rather more than twice the diameter of the oral (ratio of 7 : 3). The former (*v.s.*) is rendered further conspicuous by being pedunculate, rising boss-like from just behind the centre of the body. The peduncle is rather longer than half the diameter of the sucker (Plate IV., fig. 58). It has a large degree of mobility.

When *in situ*, and also when freed from its capsule, to the naked eye the worm appears of a pale pink tinge; under a low power of the microscope this is resolved into a dark yellow coloration confined to the œsophagus and wide digestive cæca of the alimentary canal. The only other colour present, when viewed by transmitted light, is the black of the narrow excretory trunks.

The mouth is situated at the bottom of the funnel-shaped cavity of the oral sucker (Plate IV., fig. 59, *o.s.*). It opens almost immediately into the short muscular pharynx (*ph.*). A rather wide aperture admits in turn to a peculiar saccate, subglobular œsophagus (*œ.*) which gives off laterally and dorsally a branch on either side. These pass outwards, at right angles, for a short distance, then, turning posteriorly, they are continued as very wide blind sacs, the digestive cæca (*d.c.*) as far as the anterior border of the excretory vesicle (*e.v.*). A great mass of yellow granules distends both œsophagus and digestive cæca, imparting a characteristic deep yellow hue to the digestive system. By reason of their great bulk these organs occupy the major portion of the body of this worm—a condition contrasting notably with the transparent and practically empty state of the alimentary canal in *Muttua margaritiferæ*.

The main trunks of the excretory system (*ex.tr.*) are two narrow tubes, black by reflected light, coursing backwards in sinuous manner from the pharyngeal region, one on either side. Posteriorly they empty into the slender pyriform excretory vesicle (*e.v.*), transparent and contractile. The products of excretion pass to the exterior by a terminal excretory pore (*ex.p.*).

It is probable that this species is protogynous, for while the testes are as yet empty, the ovary is densely packed with granular tissue. In the present resting condition the former organs appear as two paired ovoid sacs, clear, and with no distinguishable contents. They lie immediately posterior to the ventral sucker. Behind the left testis lies the globular ovary, opaque with the mass of its crowded granular contents.

The copulatory organs lie near the anterior end of the body. They open side by side just behind the œsophageal dilatation. The penis-sheath (*p.sh.*) has a nearly median position; the vagina lies a little to the left. The former is cylindrical, showing the rudiment of a seminal vesicle (*s.v.*). The vagina is slightly curved and appears to have glandular walls. The uterus (*ut.*) is barely distinguishable in pressure preparations as a long, transparent coiled tube running from the base of the vagina backwards to connect with the ovary. Vasa deferentia are not to be made out.

In many respects this larval form conforms to the characters of Looss' sub-family PHILOPHTHALMINÆ.* It is a larval form, so that the difference in size is immaterial. More important is the fact that the testes in the new species are, roughly speaking, on a level, not one behind the other, and that they are before, and not behind the ovary, as they are in the Philophthalminæ. The members of this family live, according to Looss, "An geschützten Stellen der Körperoberfläche bei Vögeln."

Until we have succeeded in tracing the life-history of this form, it would be unwise to dogmatize as to its systematic position. We have, however, little doubt that it is a new genus; and we have named it after Musali, the district of which the pearl fishery coast is part. The Adigar of Musali is the native official responsible for all details when a fishery camp is being organized. The present holder of the office, Mr. V. VRASPILLAI, typifies everything that is best in the headman system in vogue in Ceylon.

3. **Aspidogaster margaritiferæ**, n. sp.—Plate IV., figs. 60, 61, 62, 66, 68, 69.

Length in immature specimens 6 millims., colour brown ochre dorsally, but the foot has a beautiful rose-red hue. Four rows of alveoli or suckers on the foot arranged alternately; the number of alveoli is not precisely known, it probably increases with age, but there are something like 20 in the outer rows and 18 in the two median rows. A number of "tube-feet" project from the area between the outer rows and the middle rows and between the two central rows. There are none on the outer side of the outer rows.

Habitat.—Pericardial cavity of *Margaritifera vulgaris*, SCHUM. Taken at the Cheval Paar, Ceylon.

Three specimens of this Trematode, closely related to *Aspidogaster conchicola*, were found within the pericardial chambers of pearl oysters from the south and south-east

* 'Zool. Jahrb. Syst.,' XII., 1899, p. 586.

areas of the Cheval Paar. They were pinkish red to the naked eye, and of comparatively large size, quite ¼ inch (6 millims.) when extended. From its distinctive habitat, we may appropriately apply the name *margaritiferæ* to this species.

The body is composed of two distinct regions, an anterior neck-like portion, slender and cylindrical, bearing oral sucker and mouth at the free extremity, and a posterior stout region which spreads laterally, on the ventral aspect, into a broad, oblong, pedal disc, armed with rows of numerous sucker-pits and short, digitate tube-feet (Plate III., figs. 49 and 50, and Plate IV., figs. 61 and 66). The dorsum is minutely wrinkled or annulated transversely (Plate IV., fig. 62).

The oral suctorial apparatus (*o.s.*) is not of the definite rosette form typical of *Distomum;* it appears as a transverse slit bounded by thin mobile lips. The lips divaricate when about to make adhesion, as in the manner characteristic of an ordinary lipped sucker.

Careful examination during life showed the pedal disc (*p.d.*) to possess a wonderfully complex structure. The surface is excavated into numerous cup-shaped hemispherical pits, associated with which are numbers of small tube feet of remarkable characteristics. Both series are arranged with perfect regularity. The shallow pits or suckers (*s.p.*) are disposed in four longitudinal rows, the individual pits of one row alternating with those of the adjoining, an economy of space which permits the accommodation of the largest possible number of pits (Plate IV., figs. 60 and 61). The mouth of each sucker-pit is simple, bordered by a membranous edge containing muscular elements. When the animal is detached from its hold, the apertures are frequently seen to close by an approximation of the muscular margin. In most cases the edges meet in a tri-radiate manner; in others the lips close upon a single slit, the axis of this being at right angles to the adjacent margin of the pedal disc (Plate IV., fig. 62).

The tube-feet project from the angles between the sucker-pits, forming therefore three double ranks of feet disposed in zig-zag pattern (Plate III., fig. 52, Plate IV., figs. 61, 66, and 68). There are none along the margin of the pedal disc. They are hollow, thin-walled, and tubular, capable of great extension and of complete retraction by inversion, in manner similar to the eversion and retraction of the proboscides of *Tetrarhynchus.* They are hollow erectile organs of the simplest structure, possessing the power of extension in an extraordinary degree. When fully extended, they assume the form of slender cylinders tapering very gradually to an acuminate apex (Plate III., fig. 52, Plate IV., fig. 68). Partially retracted, they exhibit a closely annulated or wrinkled appearance, reminding one of the annulation of an earthworm, the anterior extremity of which they greatly resemble. When drawn in more fully, they show as low truncate pillars or stumps.

The alimentary canal is median and unbranched, ending blindly near the posterior end of the body. The mouth, situated at the base of the oral sucker-slit, leads into a short narrow buccal canal opening into the strongly muscular pharynx (*ph.*) oblong in optical section. Immediately behind this is a thin-walled vesicle representing the œsophagus. From this issues the long unbranched, thick-walled digestive cæcum (*d.c.*).

The excretory system is more highly specialized than in the two Distomids already described. As in them, it consists of a lateral trunk system opening behind into a contractile vesicle. In place, however, of arising in the pharyngeal region and passing backwards direct to the contractile vesicle, each trunk is doubled and consists of a proximal and a distal section. The proximal, which receives numerous branch feeders in its course, arises in the posterior portion of the body, close to the termination of the digestive cæcum. Thence it runs forwards to the anterior end of the pharynx, where it loops and turns upon itself, passing backwards over nearly the same course as it came. As it goes it coils around the primary or proximal portion. Both divisions are richly ciliated, a current is observable passing forwards in the cavity of the proximal limb, towards the hinder end in the other, or the distal limb. Another (third) tube or band is very faintly visible running longitudinally. Possibly it is a sexual duct.

The only specimen which could be spared to the knife was immature. There is a median aperture just between the pharynx and the anterior end of the foot. The penis is well-marked, the testis is single and so is the ovary, both lie in a mass of parenchyma which is separated above from the mass in which the alimentary canal lies, and below from the foot by two sheets of muscles. No vitellaria, uterus, or LAURER'S canal were distinguishable.

A pale smoky yellow tint suffuses the entire body, saving in the tissues lying dorsal to the tube-feet, where a warm brick-red tint is distinctive. The tube-feet appear to be colourless.

When one of these *Aspidogasters* is extracted alive from the pericardium, it exhibits an active and restless disposition, crawling freely about in a watch-glass. Its habit when thus isolated is to attach itself firmly by the suckers of the pedal disc and to wave the long neck-like anterior region from side to side, upwards and downwards, after the manner of a leech scenting or searching for prey, swaying to the extreme right, back almost to the posterior end of the body, then swiftly swinging round it repeats the search upon the left side, then forwards and above (Plate IV., figs. 61 and 69).

The manner of progression resembles that of a leech. Making adhesion over the whole of its ventral sucking disc, the mouth rises from the surface to which it has till now adhered; the neck stretches forwards, lengthening to the utmost, it curves downwards, the lips part, and the oral sucker makes a fresh adhesion (Plate IV., figs. 69). The posterior portion of the body is next drawn forwards, the anterior suckers of the disc remaining fixed the while; then, where the posterior region is well shortened, the whole of the ventral disc is freed and drawn along to the point where the oral sucker is fixed, when the disc re-attaches first at the anterior end and then posteriorly. Thus the animal moves one step forwards and is brought back to the attitude it had at the beginning.

In BRONN'S Trematoda, BRAUN enumerates four species of *Aspidogaster*, viz., *A. conchicola*, v. BAER, *A. limacoides*, DIESING, *A. insignis*, LEDIZ, and *A. macdonaldi*, MONT. In his recent revision of the family Aspidobothridæ, NICKERSON* places the third of these, *A. insignis*, in the genus *Cotylaspis*, thus reducing the number of species of *Aspidogaster* to three. Of these three our species is most clearly allied to *A. macdonaldi*, inasmuch as these two species, and these two species alone, are provided with the remarkable "tentacles" or "tube-feet" which project between the suckers of the foot. It however differs from this species in the following particulars:—(i.) MACDONALD'S specimens were tallowy in colour, while ours are of an ochreous brown with a deep, rose-pink foot; (ii.) MACDONALD'S specimens were $\frac{1}{8}$ inch to $\frac{1}{10}$ inch in length, ours are $\frac{1}{4}$ inch long; (iii.) MACDONALD mentions "cæca" in the intestine of *A. macdonaldi*, ours have a simple alimentary canal, possibly MACDONALD has made a mistake in this respect; (iv.) MACDONALD records some 180 tentacles and some 120 alveoli or suckers, the numbers in our specimens are fewer; (v.) MACDONALD found his specimens "creeping about in the respiratory siphon of a large *Melo*, or melon-shell, in Shark Bay, Western Australia," our specimens occurred in the pericardial chamber of *Margaritifera vulgaris*, SCHUM., on the Cheval Paar, Ceylon.

At the end of his paper NICKERSON raises the question as to whether MACDONALD'S species does not deserve generic rank. If it does it carries our species with it. The chief generic character would be the possession of the tentacles or "tube-feet." At present, and until more specimens have been investigated and until we know more of the life-history, it seems wise to regard these forms as well-marked species of *Aspidogaster*.

III. NEMATODES OF THE PEARL OYSTER, AND OF THE FILE FISH.

The only previous record of a Nematode from the pearl oyster that we have been able to find is in a list by Dr. L. ÖRLEY of the Nematodes in the British Museum,† where the name appears of *Ascaris meleagrina*, KOLLAR, from the pearl oyster. VINCENZ KOLLAR wrote almost exclusively on insects, and we were unable to trace any reference to this Nematode in such of his writings as we have been able to inspect. We therefore applied to Mr. C. D. SHERBORN for help. Together with Professor F. JEFFREY BELL, he very kindly made an inspection of ÖRLEY'S MS.,

* 'Zool. Jahrb. Syst.,' XV., 1901 to 1902, p. 597, NICKERSON makes no mention of *A. vallei*, STORS, described in a Memoir I have not seen, from the œsophagus and stomach of *Thalassochelys caretta* (M. STOSSICH, 'Appunti di Elmintologia').

† 'Ann. Nat. Hist.,' IX., 5th Series, 1882, p. 310.

where the name KOLLAR occurs, but when this was compared with W. BAIRD'S copy of GRAY'S Catalogue, a note in BAIRD'S handwriting was found containing the words *Ascaris meleagrina*, KELAART. There seems little doubt that ÖRLEY miscopied KOLLAR for KELAART. We have not, however, been able to find any diagnosis in the reports of KELAART, or any figure of this animal which would enable us to recognize the species, and so it seems that the name is a *nomen nudum*.

Three species of Nematoda, representing as many genera, *Oxyuris*, *Ascaris*, and *Cheiracanthus*, were found in the pearl oysters on this expedition.

The *Oxyuris* was met with but twice, and both specimens were unfortunately lost. They measured barely $\frac{1}{8}$ inch in length. They were found in the intestine of the pearl oyster. The other two species were found encysted in the tissues of the pearl oyster. These were kindly examined for us by Dr. VON LINSTOW, who identifies one as new. The specimens which reached England, and which were submitted to him, were both larvæ. Dr. VON LINSTOW has been good enough to give us the following descriptions :—

Ascaris meleagrinæ, n. sp.—Plate III., figs. 42 and 43.

The greatest length is 29 millims., the breadth is 0·55 millim. On the anterior end there are 3 lips, of these the dorsal one is round, with 2 large papillæ directed forward ; on the anterior edge a row of small teeth or projections occur, and between the 3 chief lips lie 3 secondary and much less prominent lips. The cuticle is regularly ringed. The œsophagus is $\frac{1}{8\cdot13}$ of the total length, and the conically pointed tail is $\frac{1}{116}$ of the same. A pair of anal glands occurs in the end of the alimentary canal.

Habitat :—The larva in the tissues of the pearl oyster *Margaritifera vulgaris*, SCHUM., the adult in the intestine of the file fishes *Balistes mitis* and *B. stellatus*.

This Ascarid is usually found within the gonad of the pearl oyster, less frequently within the tissues of the mantle, in all cases in an encysted condition. It appeared, in life, transparent and slightly yellowish to the naked eye. Under the microscope, the intestine is seen to be a brownish-yellow tint. The surface of the body is distinctly and closely annulated.

In the pearl oyster, its primary host, this Nematode does not attain sexual maturity, remaining encysted and immature so long as this host lives. The mature stage is reached only after the pearl oyster, happening to be devoured by one of the oyster-eating species of file fishes—usually *Balistes mitis* or *B. stellatus*—suffers digestion within the stomach of the fish. Being thus set free, the Ascarid finds its way into the intestine and attains there eventually a notably larger size than when in its primary host, the pearl oyster.

Statistics and Details.—Out of 24 pearl oysters, 3 to $3\frac{1}{2}$ years old, from the Periya Paar Kerrai, dissected on 7th November, 1902, as many as 10 contained 1 each of this Ascarid. The cysts were lodged chiefly in the gonad in the immediate vicinity of the stomach, most to one or other side, a few above the roof of this organ. One individual was found beneath the mouth in the substance of the labial palps.

Out of a further lot of 16 dissected on 7th November, 1902, and coming from North-east Cheval Paar, 5 contained this species of Nematode. As many as 5 of these worms were found in one individual; 3 were within the gonad, a fourth was contained in a large cyst in the palpar region of the mantle close to the pallial line.

In a second pearl oyster, 2 Nematodes were found in the gonad. A third and fourth each had one encysted in the same region, while in a fifth the Nematode cyst was in the mantle.

On 14th November, 1902, 43 pearl oysters from South-west Cheval yielded but 3 individuals harbouring this parasite, found in each case in the gonad. In another lot, one individual had one of these Ascarids in a cyst in the antero-ventral region of the mantle.

On 5th November, none were found in 30 oysters from South-east Cheval, and on 6th November, none in 15 oysters from the same.

On 11th November, two out of 20 dissected oysters from North-west Cheval yielded each 1 Nematode from the gonad.

On 12 November, 20 oysters from West Cheval gave but one, which contained this parasite. It was encysted within the wall of the stomach.

On 15th and 16th November, none were found in 61 pearl oysters from South-east Cheval.

On the 18th and 20th November, none were yielded by the dissection of 55 individuals from the Dutch Modragam and Muttuvaratu Paars.

On 3rd and 4th February, 1903, 5 individuals out of 83 dissected oysters from South-east Cheval showed 1 Nematode each in the gonad.

On 8th and 13th February, 1903, 3 oysters only were infected out of a lot of 120 dissected from North-east Cheval, in each case the cyst was within the gonad.

Of 15 oysters dissected on 11th February, 1903, from Periya Paar Kerrai, 1 only yielded an Ascarid, found in the usual position.

On 12th February, 1903, 32 oysters from the North Cheval contained no trace of this worm.

Of a total of 534 pearl oysters dissected specially in search for Nematodes, 30 individuals yielded specimens of this species.

The cysts were usually of distinct pyriform outline, flattened laterally. Occasionally the form was irregular.

Cheiracanthus uncinatus, Molin.—Plate III., figs. 41, 44, 45, 46, 47, and 48.

Echinocephalus uncinatus, Molin, 'Denk. Ak. Wien,' XIX., 1861, 2nd Abth., p. 311.

This Nematode was also in a larval state. The specimens averaged 12·8 millims. in length and 0·43 millim. in breadth. The cuticle is swollen. On the thickened head end are 6 rows of about 50 hooks about 0·031 millim. long. The head-lappets are rounded behind and abut on one another in the lateral line. There are 6 lips on the head. The œsophagus is $\frac{1}{45}$ of the entire length, and the conically pointed tail end is $\frac{1}{54}$ of the total length. Four tubes lie beneath the anterior end of the œsophagus; these are 2·05 millims. in length, and, as is characteristic for the genus *Cheiracanthus*, these are shorter than the œsophagus and show externally a layer of spiral muscles. The larvæ were found encysted in the adductor muscle.

The adult of these forms is in all probability the *Cheiracanthus uncinatus*, described and figured by Molin under the name *Echinocephalus uncinatus*. It is found in the alimentary canal of *Trygon pastinaca* and of *Trygon brucco*.

This second Nematode infesting the pearl oyster is a robust species, readily distinguishable at sight from the Ascarid, by its comparative shortness and the subglobular enlargement of the cephalic extremity, which is armed with 6 concentric rings of backwardly-directed spines (Plate III., figs. 41, 44, 45). This globular cephalic inflation is characteristic, but at times it appears in a deflated condition, as shown in Plate III., fig. 45, when the form becomes that of a truncated cone.

To the naked eye it appears when lying in its cyst of a faint pinkish tint, under magnification the alimentary canal is seen to be of a dirty pale-yellow hue. The colourless transparent tissue lining the body wall has a distinct areolar appearance, due to the presence of large saccate cells. The body is smooth, with no trace of annulation.

This Nematode favours exclusively as its habitat the substance of the adductor muscle, lying coiled up therein in an ovoid cyst. Plate III., fig. 47, shows some of the usual regions in the muscle where it is found. Its occurrence is strictly limited to this particular organ, but occasionally it would appear to become freed from its envelope and to leave the muscle, as instances occurred of this species being entombed in the nacreous lining of the shell. In several cases the covering film of nacre obscured scarcely anything of the outer form of the worm's body, the globular head and curved and pointed tail being especially conspicuous.

Later stages have been found by one of us in the trigger fishes *Balistes mitis* and *B. stellatus*, both pearl oyster-eating species, as proved by the presence of the shell fragments in the stomach.

This spinous-headed Nematode is found both in the alimentary canal and in the visceral cavity of *Balistes*. In the latter case, where it is much the more frequently found, it burrows in the peritoneal membranes and adjacent connective-tissue. Judging from this habitat, it would appear to use its spine-armed cephalic extremity as a burrowing organ.

It is most probable that the adult also lives in some species of *Trygon* which are known to feed on file fish, and also on pearl oysters.

Statistics and Details.—In all the cases noted below the Nematode was found in the adductor muscle—one Nematode in each case (Plate III., fig. 47).

Thus in all 41 individuals had the adductor muscle infested by this Nematode out of a total of 542 pearl oysters dissected specially in search of this parasite. In one of those of February 4th, the worm lay upon the surface of the muscle on the ventral aspect. In only one instance were two Nematodes found in the same muscle—never a greater number.

In the intestine of *Tæniura melanospilos* was found a fragment of a Nematode which was undeterminable, and a number of the species *Ascaris pastinacæ*, Rud., which inhabits also *Trygon pastinaca*, Cuv.

EXPLANATION OF THE PLATES.

PLATE I.

Fig. 1. Planarian-like free-living organism, possibly the larva of a species of Cestode, taken in the plankton on Muttuvaratu Paar, 19th November, 1902. It is most probably of the same species as the encysted larvæ found so abundantly in the pearl oysters of the paar named. Actual length when elongated, 0·37 millim. The rudiment of what may be the proboscis is already apparent. *a–h*, show various specimens in various attitudes; *c.c.*, calcareous corpuscles; *cut.*, the thick mucilaginous cuticular layer; *Pr.*, possible rudiment of a proboscis.

,, 2. Three fragments *a*, *b*, and *c* of the distal or marginal region of the mantle of a pearl oyster, showing Cestode cysts scattered in the intermuscular connective-tissue. Natural size. *Mg.Pall.*, pallial margin; *Mg.vel.*, velar margin; *T.cy.*, Cestode cysts.

,, 3. A Cestode cyst (*cy.*) in an interlamellar junction at the base of a branchia. × 3 diameters.

,, 4. Fragment of a branchia of a pearl oyster showing encysted larval Cestode (*cy.*). × 12 diameters.

,, 5. *a.* Nucleus of a "fine" pearl from the posterior ear region of a Cheval Paar oyster. The proboscis sheath and the central pit within which the proboscis is retracted are clearly shown. *k.* A "fine" pearl, showing distinct resemblance in outer form with the characteristic appearance of a Cestode larva (see fig. 5, *i*), viewed anteriorly; *c*, the same viewed laterally; *d* and *e*, natural size of the same. *i.* Outline of a young Cestode larva for comparison with the preceding. *f.* An elongated pearl, also having resemblance in outline to a Tetrarhynchid larva. *h.* Natural size of same. *l.* A lenticular pearl having an equatorial band of brown prismatic pearl-substance.

,, 6. Section through an encysted larva of about the same shape as that represented in fig. 4. The rostrum or proboscis (*a*) is still retracted in the body.

,, 7. *a* and *b*, two of the later larval stages of the Cestode met with, in encysted condition, in the tissues of the pearl oyster. Compare with fig. 13. × 80 diameters.

,, 8. A. A partially calcified Cestode cyst from the muscular pallial region of a 3-year old oyster from the Muttuvaratu Paar. The larva was dead and slightly changed in outline—partial disintegration having taken place. In colour it was dirty yellow. In the outer layers (*b*) of the cyst capsule a deposit of lime salts had begun. B. Another cyst. *b.* The outer layers of cyst; *c.* Nucleus, obtained by decalcification, of a fine pearl from the muscular pallial region of a pearl oyster from the Cheval Paar. C. Nucleus of another "fine" pearl from the ventral pallial region of a pearl oyster from the same locality as before; *d.* a few calcareous corpuscles seen within the larva as solution brought the character of the nucleus into view. D. The innermost of the membranous laminæ left after solution of the corresponding pearl coats; *c*, a dead Cestode larva forming the actual nucleus; a ball-shaped calcification within the Cestode larva is seen. (Weight 195 milligrs.)

,, 9. Very young Cestode larva extracted from a thick-walled cyst in the mantle of a pearl oyster. × 50 diameters. (NOTE.—The outer layer is *very faintly* seen under a low power, and has an appearance closely resembling ciliation. The distal limit is not so strongly marked as shown here, see fig. 10.) *c.c.*, calcareous corpuscles; *Pr.*, proboscis; *Pr.sh.*, proboscis sheath.

,, 10. Young Cestode larva extracted from a cyst within the mantle of a pearl oyster. It shows the minute denticulation of the proboscis collar. × 25 diameters.

,, 11. The same, seen under slight pressure, whereby the proboscis, *Pr.*, has been evaginated forcibly. *Pr.sh.*, proboscis sheath. × 25 diameters.

Fig. 12. Another larva of the same stage, seen under slighter pressure, and higher magnification. × 40 diameters. The vertically striated mucilaginous cuticle is clearly shown, together with a network of anastomosing vessels. *Cut.*, cuticle; *Ex.p.*, excretory pore.

,, 13. Shows the beginning of the change from a spherical to an elongated form of body. Taken from a cyst from the viscero-pedal mass of the pearl oyster.

,, 14. Portion of same larva seen in optical section at region of proboscis collar, showing a fragment of the anastomosing network of vessels and the large bladder-like cells full of clear globules, lying beneath the dermal layer (semi-diagrammatic). The calcareous corpuscles are omitted for the sake of clearness. *Den.*, denticles; *Par.*, sub-dermal bladder-like cells; *Pr.sh.*, proboscis sheath; *Ves.*, anastomosing vessels.

,, 15. *a.* Optical section of body-wall of a Cestode larva from the pearl oyster, showing the normal appearance. *b.* Final stage, when, under continual pressure, the mucilaginous cuticular layer has disintegrated, its place being taken by one or two layers of the bladder-like cells, which thus come to invest the body of the larva. *c.* The same as *a* under slight pressure; an invasion of the delicate cuticular layer by bladder-like cells full of clear globules is in progress.

PLATE II.

Fig. 16. Forms of the calcareous corpuscles found in the larvæ of *Tetrarhynchus unionifactor.*

,, 17. The same, enclosed in the cells that secrete them.

,, 18. Form of denticles which ornament the proboscis collar of the early larva of *Tetrarhynchus unionifactor.*

,, 19. The oldest larval stage of *Tetrarhynchus unionifactor* met with in the tissues of the pearl oyster. *Arm. cil.*, armature of stiff cilia around excretory pore; *cs.*, one of the two pairs of cephalic suckers; *Ex.o.*, external orifice of excretory system; *Pr.*, protractile proboscides; *Tr.ex.*, lateral trunks of excretory system.

,, 20. Surface view of the posterior extremity of the same individual on an enlarged scale.
a. Shows the warted pattern of the whole surface of the body, except at the extreme posterior extremity, where, as shown (*b*), the surface marking becomes sinuous; other letters as in fig. 19.

,, 21. A loop of the excretory network in the cephalic region of the same individual.

,, 22. Anterior extremity of an individual of the same stage as that depicted in fig. 19 seen under greater magnification. *Pr.sh.*, sheath of proboscis; *Ret.m.*, retractor muscle of proboscis.

,, 23. One of the hooklets from a proboscis.

,, 24. A larval form of *Tetrarhynchus balistidis* from the liver of a *Balistes*, sp. × 16 diameters. *C.c.*, calcareous corpuscles; *Tr.ex.*, excretory trunks. The natural size is shown by the small figure to the right.

,, 25. Sub-spherical larva of *Tetrarhynchus balistidis* found in oval and in rounded cysts beneath the peritoneum of *Balistes*, sp.; *Pr.pro.*, proboscis protruded.

,, 26. A slightly older example of the same.

,, 27. Natural size of a cyst of *T. balistidis* from abdominal cavity of a *Balistes*, sp.

,, 28. Cyst from peritoneum of *Balistes*, nat. size, containing *T. pinnæ.*

,, 29. The larval *T. pinnæ* freed from cyst membrane. Nat. size.

Figs. 30, 31, 32. The same, under higher magnification. *C.c.*, calcareous corpuscles; *Cy. mem.*, cyst membrane; *Pr.ret.*, proboscides retracted; *Sc.*, scolex.

Fig. 33. Teeth of *T. balistidis*, isolated by maceration and highly magnified.

,, 34. Teeth of *T. balistidis in situ* on the introvert.

,, 35. More teeth of *T. balistidis* for comparison with fig. 36.

Fig. 36. A single tooth of *T. pinnæ*.

„ 37. A portion of the introverts of *T. pinnæ*, showing the oblique rows with enormous numbers of weak teeth.

„ 38. A section through the head, cut in two places, and showing the four proboscides and the bladder, with widely separated walls, of *T. pinnæ*, magnified to the same extent as figs. 39 and 40.

„ 39. A section through the head, cut twice, and the bladder of *T. balistidis* showing the four introverts, magnified to the same extent as fig. 38.

„ 40. A section through the same, showing the junction of the head with the inner wall of the bladder.

PLATE III. (3 on Plate).

Fig. 41. Head end of *Cheiracanthus uncinatus*. *gl.*, glands; *int.*, intestine; *l.*, lip; *œ.*, œsophagus.

„ 42. Tail end of *Ascaris meleagrinæ*. *a.gl.*, anal glands; *int.*, intestine.

„ 43. Head of *Ascaris meleagrinæ*, seen from above.

„ 44. Head end of *Cheiracanthus uncinatus*, inflated. × 30.

„ 45. The same collapsed.

„ 46. The whole worm, *Cheiracanthus uncinatus*. × 6.

„ 47. Diagrams showing usual position of *Cheiracanthus uncinatus* within the adductor muscle. Natural size.

„ 48. Posterior extremity of *Cheiracanthus uncinatus*. × 30.

„ 49. Ventro-lateral view of *Aspidogaster margaritiferæ*. In this specimen the tube feet were all retracted. The natural size is shown by the small figure on the right.

„ 50. Side view of the same with extended tube feet. The natural size is shown by the small figure on the right.

„ 51. Views of spirit specimens of *Musalia herdmani*, magnified.

„ 52. Transverse section through the suckers and tube feet of *A. margaritiferæ*, highly magnified.

„ 53. Cercaria of *Muttua margaritiferæ* within its cyst capsule. Extracted from the branchial tissue of a pearl oyster. × 30.

„ 54. The same under greater magnification. × 10. Lettering as in fig. 55.

„ 55. The same larva freed from its capsule, and under slight pressure. × 90. *c.s.*, cuticular spines; *e.v.*, excretory vesicle; *d.c.*, digestive cæca; *e.*, eye-spots; *ex.p.*, excretory pore; *p.sh.*, penis sheath; *ph.*, pharynx; *s.v.*, seminal vesicle; *v.s.*, ventral sucker.

„ 56. Penis sheath of same larva.

„ 57. Anterior extremity of same larva. × 240. *c.s.*, cuticular spines; *e.*, eye; *ex.t.*, excretory tubules.

PLATE IV. (4 on Plate).

Fig. 58. *Musalia herdmani*, immature specimen from the mantle of a pearl oyster. Natural appearance fully extended. Letters as in fig. 59.

„ 59. The same shortened and broadened under pressure. Life size on right. *e.v.*, excretory vesicle; *d.c.*, digestive cæca; *ex.p.*, excretory pore; *ex.t.*, excretory trunks; *œ.p.*, œsophageal pouch; *o.s.*, oral sucker; *ov.*, ovary; *ph.*, pharynx; *p.sh.*, penis sheath; *t.*, testis; *v.*, vagina; *v.s.*, ventral sucker.

„ 60. *Aspidogaster margaritiferæ*; adult from the pericardial chamber of a pearl oyster, seen ventro-laterally. The tube feet are retracted. *dig.c.*, digestive cæcum; *ex.t.*, double excretory trunks; *o.s.*, oral sucker; *p.d.*, pedal disc; *ph.*, pharynx; *s.p.*, sucker pits.

Fig. 61. The same seen from the ventral aspect while crawling over a glass plate. The dotted outlines *a* and *b* show the leech-like mobility of the anterior region of the body in attitudes assumed frequently when the worm is restless. *t.f.*, tube feet. The other letters as in fig. 60.

,, 62. View of the posterior extremity of the same, from above, showing the sucker-pits (*s.p.*) closed by the approximation of their lips. The fine transverse wrinkling characteristic of the dorsum of the trunk is also shown in the figure.

,, 63. Ciliated ectoparasite from gills of pearl oyster with paired trilobed eyes.

,, 64. Another characteristic appearance of the same. A contractile vacuole is seen posteriorly and two triradiate eye-spots anteriorly.

,, 65. Diagram of pearl oyster to show at *a* the position of the cyst enclosing *Musalia herdmani*, in the tissues of the pearl oyster. $\times \frac{1}{2}$.

,, 66. A portion of the pedal disc seen when an *Aspidogaster margaritiferæ* is detached from its hold and turned upon its back. The edges of the disc then recurve inwards to varying degrees.

,, 67. Highly magnified view of the end of a proboscis of *Tetrarhynchus minimus*, showing the various sized hooks and their arrangement.

,, 68. Tube feet of *Aspidogaster margaritiferæ* in various states of extension and retraction.

,, 69. *a*, *b*, *c*, successive attitudes assumed by *A. margaritiferæ* during progression. *d*, another view of the same when about to change position.

,, 70. Head of *Tetrarhynchus minimus*.

,, 71. Optical section of the same.

,, 72. *Tetrarhynchus minimus*, showing proglottides.

NOTE.—Owing to an error in the lithographer's office, Plates III. and IV. have been printed as 3 and 4, in Arabic numerals.

PARASITES OF THE PEARL OYSTER

REPORT

ON THE

HYDROIDA

COLLECTED BY

PROFESSOR HERDMAN, AT CEYLON, IN 1902.

BY

LAURA R. THORNELY.

[WITH PLATES I. TO III. AND TEXT-FIGURES.]

INTRODUCTORY.

THIS collection of Hydroids from Ceylon comprises 43 species, of which 13 are now described as new to science, and one of these requires the formation of a new genus. A few specimens are too small in quantity to have more than a generic name assigned to them.

Our knowledge of the Hydroid fauna of Indian seas* is mainly due to ARMSTRONG, who described a few species from the Bay of Bengal, two of which are represented in our series; to ALLMAN, who worked out a small collection sent home by Mr. HOLDSWORTH from Ceylon in 1874, containing two of our most striking species; and to HINCKS, who described a small collection made by Dr. JOHN ANDERSON in the Mergui Archipelago in 1889, two species of which we have.

But the faunas of Australia and the East Indies are evidently similar in many of their species, and we have several of those described by BALE and VON LENDENFELD. It is also clear that some of our species have a wide distribution over the globe, as we find in our Ceylon list *Plumularia setacea* and *Cuspidella costata*, both British species, and the former recorded from North America, Australia, and New Zealand, while the latter has been found in North America.

* See List of Literature, p. 125.

Most of the specimens in this collection were dredged by Professor HERDMAN during the cruise of the "Lady Havelock" round Ceylon in February and March, 1902, but some were also obtained by the native divers from the pearl banks, or were picked off the experimental cages in which pearl oysters were kept suspended from the ship.

It is probable that the Ceylon fauna contains many more species of Hydroid Zoophytes, some of which are unknown to science, since there are many small specimens and fragments in the collection which are not large enough or complete enough to be described, but which evidently do not agree with the characters of any known species.

The following is a list of the species described in this Report. Those marked with a star are, I believe, additions to the recorded fauna of the Indian seas :—

ATHECATA.

**Corydendrium chevalense*, n. sp.
Bougainvillia, sp.
**Eudendrium pusillum*, von Lendenfeld.
**Podocoryne denhami*, n. sp.
**Clavactinia gallensis*, n. gen. & sp.
**Tubularia gracilis*, von Lendenfeld.

THECAPHORA.

Halecium, sp.
**H. flexile*, Allman.
**Clytia geniculata*, n. sp.
**Obelia hyalina*, Clarke.
**O. australis*, von Lendenfeld.
O. andersoni, Hincks.
Campanularia juncea, Allman.
**C. corrugata*, n. sp.
**Hebella calcarata* (A. Agassiz).
**Lafoea serrata*, Clarke.
**Cuspidella costata*, Hincks.
**Sertularia gracilis*, Hassall.
**S. ligulata*, n. sp.
**S. fissa*, n. sp.
**S. tenuis*, Bale.
**S. loculosa*, Busk.
**S. rugosissima*, n. sp.
**Diphasia mutulata* (Busk).
Sertularella, sp.
Thuiaria, sp.
**T. palans*, n. sp.
**Desmocyphus palkensis*, n. sp.
**Synthecium orthogonia* (Busk).
Pasythea hexodon, Busk.
Idia pristis, Lamouroux.
**Plumularia setacea*, Ellis.
**P. buskii*, Bale.
**Monostaechas quadridens* (McCrady).
**Antennella gracilis*, Allman.
A. allmani, Armstrong.
**Aglaophenia perforata*, Allman.
**A. phœnicea*, Busk.
Halicornaria insignis, Allman.
H. setosa, Armstrong.
**Lytocarpus hornelli*, n. sp.
**L. fasciculatus*, n. sp.
**L. plumosus*, n. sp.

This list shows in all thirty-two species added to the list for the Indian seas in addition to seven previously known and four left specifically undetermined.

HYDROIDA.

Sub-order I.: ATHECATA.

Family: TURRIDÆ.

Corydendrium chevalense, n. sp.—Plate I., fig. 4.

Trophosome.—Colony reaching the height of $\frac{1}{2}$ an inch, with a simple or branched stem of a pale straw colour, slightly wrinkled, but never ringed. Branches lying alongside the stem for a short distance near their origin, then diverging; very much twisted and entangled (see Plate I., fig. 4). Hydranths varying in size, those on unbranched stems the largest, with about 18 tentacles scattered on the upper $\frac{2}{3}$ of their length.

Gonosome.—Medusiform gonophores on short peduncles, springing singly or 2 or 3 near one another, often 2 opposite, on both sides of the stem, between the origin of the branches and the hydranth.

Locality:—On *Pecten* shells and on sea-weeds from the Cheval Paar, Gulf of Manaar, 6 to 8 fathoms.

From indications in the gonophores, which vary much in their stages of development on the same specimen, the manubrium appears to be four-lipped, the radiating canals four, and the tentacles many. The form of the medusa of *Corydendrium* has not yet been traced, and the one species, *C. parasiticum*, Cavolini, has now remained so long imperfectly known that it seems doubtful whether its description will ever be completed. In the meantime it seems better to place the present species here rather than to form a new genus or to place it with *Turris*, only known as an unbranched form.

The fully developed trophosome of *Turris* has, however, not yet been seen. If, therefore, the further development of the present gonophores should lead to their identification with those of *Turris*, as appears possible, then this species will require to be transferred to that genus, the definition of which will be altered so as to include simple *or branched* forms.

Family: BOUGAINVILLIDÆ.

Bougainvillia, sp.

This is not recognisable as any known species, and there is not sufficient material to enable me to describe it fully as a new species. One peculiarity of the form is that the branches have frequently blunt-ended tendrils growing from them.

Locality:—Found growing among colonies of a Campanularian (*Obelia australis*) from the Cheval Paar, Gulf of Manaar, 6 to 8 fathoms.

FAMILY: EUDENDRIIDÆ.

Eudendrium pusillum, VON LENDENFELD (17).—Plate I., fig. 5.

From their mode of growth, smooth stems and the colour of the zooids, and also from the position of the gonophores, I believe the present Ceylon specimens to belong to this species. Many of the colonies are only half an inch in height, but some are larger than has yet been described for *E. pusillum*, reaching $1\frac{1}{4}$ inches. The main stem is of a very dark brown, annulated at its origin and with a few rings occurring here and there, up the stem. The branches are alternate, ringed above their origin, and the ramuli which terminate in hydranths bearing gonophores are ringed or wrinkled throughout. These last are not so long as the ordinary ramuli, their hydranths never lose all the tentacles, although they become atrophied. There are only female gonophores present. The hydranths have about 26 tentacles each. As this species has not been figured before, I show it on Plate I., fig. 5.

Locality:—This species, previously known from Port Jackson, Australia, occurred on the experimental pearl-oyster cages hung over the side of the ship at Cheval Paar, in the Gulf of Manaar, in April, 1902.

FAMILY: HYDRACTINIIDÆ.

Podocoryne denhami, n. sp.—Plate I., fig. 6.

TROPHOSOME.—Basal crust beset with numerous tall, stout, linear, reddish spines. Hydranths white, with about 24 tentacles on the barren ones and only 4 or 5 on those bearing gonophores, and these latter are also considerably smaller.

GONOSOME.—A pair of large and globose gonophores to each hydranth.

Locality:—Growing on a *Murex* shell containing a Pagurid dredged in Palk Strait.

This species resembles *Podocoryne areolata* (ALDER) in general appearance of the hydranths, the spines and the gonophores, as figured by HINCKS, but the tentacles are far more numerous on the larger hydranths of the colony, and the gonophores when separated from the colony are found to be borne on hydranths in place of being sessile on the common base, as at first sight they appear to be.

At Professor HERDMAN'S suggestion, this interesting new species from the north of Ceylon is named in honour of Mr. E. B. DENHAM, C.C.S., Assistant Government Agent in the Manaar district, near where the specimen was obtained.

Clavactinia, n. gen.

TROPHOSOME.—Hydranths claviform, sessile, with filiform tentacles forming several verticils below the base of a conical proboscis; borne on an expanded crust.

GONOSOME.—Sporosacs borne on blastostyles which rise directly from the crust between the hydranths.

This genus differs from *Hydractinia* in having several verticils of tentacles (see Plate I., fig. 3), and in not having globular clusters of thread-cells in place of tentacles on the blastostyle.

Clavactinia gallensis, n. sp.—Plate I., fig. 3.

Trophosome.—Colonies an inch square, or more, having a yellowish crust spotted with minute dark red spines, and with larger ridged spines of the same colour placed at intervals. Hydranths opaque white with about 14 tentacles surrounding the upper portion of the body.

Gonosome.—Sporosacs borne on very short-stemmed blastostyles, 5 or 6 on each, almost round in shape and showing about 5 divisions.

Locality:—Growing on gastropod shells belonging to *Eburna* and *Neritina;* dredged in Galle Bay, 2 fathoms.

There are no spiral zooids on these colonies, which have, with their spinous crusts, so much the appearance of a *Hydractinia*. The blastostyles are very short, and the sporosacs on them are in various stages of development. The *Eburna* shells are covered with the colonies, many of them not fully grown; these shells contained the living animal at the time they were taken. On the *Neritina* shell the hydranths and gonophores cover the crust much more fully, but the hydranths are smaller and have their tentacles so contracted as to appear almost capitate.

Family: TUBULARIIDÆ.

Tubularia gracilis, von Lendenfeld (17).

From the general resemblance and the large number of gonophores, borne on erect peduncles, I am inclined to consider that the present specimens belong to this Australian species, although when more material is at hand for examination, further details may appear which will require their separation as a distinct form. The stems are unbranched, entangled with others at their bases by their rhizomes. They are smooth, like von Lendenfeld's specimens of *T. gracilis*, for the most part, but are occasionally ringed at the base and here and there up the stem. The largest are only $\frac{3}{4}$ of an inch in height, but as the zooids vary a good deal in general size, the stems may possibly grow to the usual height of *T. gracilis* under favourable circumstances. The hydranths are slightly smaller than those of *T. gracilis*, the largest present being only about $\frac{2}{10}$ of an inch across the tentacles and $\frac{1}{10}$ of an inch in total height. They are reddish in colour when living, and the gonophores are greenish-yellow. The gonophores are borne on short, branched peduncles, and are present in various stages of development. The most fully developed have 4 lobes, and show a division of their sides by 4 longitudinal grooves. A hydranth carries about 9 peduncles with about 30 gonophores on each.

Locality:—This species, previously known only from Port Jackson, Australia, was found growing on the fibre of the "coir" baskets containing experimental pearl oysters suspended from a buoy in Galle Bay during June, 1902.

SUB-ORDER II.: THECAPHORA.

FAMILY: HALECIIDÆ.

Halecium, sp.

There are only a few fragments of this interesting looking species with very widely expanded hydrothecæ. It looks somewhat like *Diplocyathus*, ALLMAN (4), but is without the nematophore-like cup characteristic of that genus.

Locality:—North of Cheval Paar, 7 to 10 fathoms.

Halecium flexile, ALLMAN (4).

Several young colonies, only $\frac{1}{2}$ an inch in height, were found growing on the oyster cages suspended from the side of the ship at Cheval Paar, in the Gulf of Manaar.

These colonies may seem too small to be referred to this species with certainty, but they are evidently young, only here and there show the beginning of a fascicled stem and have no gonophores present. The hydranths are very large and very much swollen below the base of the tentacles. The specimens are beautifully preserved, showing the details of internal structure clearly. The hydrophores do not stand away from the internode so much as is shown in ALLMAN'S figures, but the shallow annulation of the internodes is the same.

Locality:—This species was previously recorded from near Marion Island and from Patagonia; and the present specimens were found on oyster cages at the Cheval Paar, in the Gulf of Manaar.

FAMILY: CAMPANULARIIDÆ.

Clytia geniculata, n. sp.—Plate III., figs. 4, 4A.

TROPHOSOME.—Colony $\frac{3}{5}$ of an inch in height. Stem bending slightly to right and left, a hydrotheca on a ringed pedicel at each flexure, which has a decided knee-like bend (Plate III., fig. 4). Stem monosiphonic, branched sparingly, a branch either taking the place of a hydrotheca or being given off from the hydrothecal pedicel near its base. Hydrothecæ on long or short pedicels, ringed throughout, or only above and below, with from 5 to 20 rings; large and deep (fig. 4), with long 2-spined teeth, and very compressible.

GONOSOME.—Gonothecæ cylindrical above, narrowing rapidly downwards, on short, ringed stalks (fig. 4A), about 5 rings, and with a very short neck and wide rim to the aperture, situated near the base of the pedicels of the hydrothecæ and containing medusoid gonophores, the most advanced of which show 4 rudimentary tentacles.

Locality:—Growing on oyster cages suspended over the side of the ship, between February 15 and March 10, on the north-east Cheval Paar, Gulf of Manaar.

The peculiar mode of branching is the most striking feature of this form (Plate III., fig. 4), one pedicel bearing a hydrotheca gives off another from its side which starts with a knee-like bend and then runs up almost parallel with the first; another is given off from this one again on the opposite side from the first, and so on alternately, sometimes for nine times in succession, with no other form of branching. A more complicated form of growth is seen when two branches are given off almost opposite each other, or when the branches divide again.

The sides of the hydrotheca are so compressible that the form of the teeth, in these preserved specimens, cannot be seen satisfactorily. They are folded over as in BALE's figure of *Campanularia bispinosa* (12), and so are probably arranged in pairs as in that species.

Obelia hyalina, CLARKE (13).

A few fragments, probably of this form, previously found north of Goblos Island, were found growing on oyster cages hung from the ship, between February 15 and March 10, on the north-east of the Cheval Paar.

Obelia australis, VON LENDENFELD (17).

A few fragments of this form, previously found in New Zealand, were growing on oyster cages hung from the ship, between February 15 and March 10, on the north-east of the Cheval Paar.

Obelia andersoni, HINCKS (14).

These specimens have rather more rings on the pedicels of the hydrothecæ and teeth on the hydrotheca margin than HINCKS gives. He does not mention the height of the colonies, nor whether they are branched. Our specimens are $\frac{1}{4}$ of an inch in height, and they branch occasionally, in which case there is always a hydrotheca in the axil. The shape of the hydrothecæ, which HINCKS lays most stress on in his diagnosis of the species, corresponds with these specimens. The line represented in HINCKS' figures running round the hydrotheca, near the base, is only to indicate the beginning of the cylindrical portion, I believe; it is not visible in our specimens. This is a most delicately beautiful little species.

Locality:—Previously known from the Mergui Archipelago, it now occurs growing on oyster cages hung over from the ship, between February 15 and March 10, on the north-east Cheval Paar.

Campanularia juncea, ALLMAN (1).—Plate I., figs. 1 to 1B.

The specimens of this form in the present collection agree with ALLMAN's description for the most part, but our colonies reach a height of 18 inches instead of only 12, while gonothecæ are present, and in some cases an operculum on the hydrotheca—both structures previously unknown. Moreover, our colonies do not show the division of the stem into internodes which ALLMAN describes and figures. Still, this is such a striking form that there can be no doubt about the identification.

There are two kinds of gonothecæ borne on separate colonies, which are thus of distinct sexes. They are placed beneath hydrothecæ on the stems and branches, and turn downwards at about the same angle that the hydrothecæ stand upwards. The male gonotheca (Plate I., fig. 1) is cylindrical, with a wrinkled outline and rounded top, about $\frac{1}{3}$ as long again as the hydrotheca; while the female (Plate I., fig. 1A) is truncated above, with a marginal rim and a boss to one side of the upper surface, and is broader and not so long as the first. They both have the same coarse, granular texture as the hydrothecæ.

Fig. 1. *Campanularia juncea*—showing expanded zooid, and hydrotheca with operculum. Magnified.

In a few specimens of about 2 inches in height, the details of the zooid (text-fig. 1), its 34 tentacles, its base resting on a floor above the base of the hydrotheca, &c., are quite visible, and in these can be seen distinct opercula with 4 valves (Plate I., fig. 1B). A trace here and there of what may be broken portions are the only indications of the operculum in the rest of the material, which is composed of larger colonies (text-figs. 2, 3), opaque and older looking in comparison with these small fresh bits. If the specimens with opercula are not to be regarded as a different species from those without, which I have not the least inclination to believe, then the genus *Thyroscyphus*, ALLMAN (3), founded for species having a 4-valved operculum, must either be given up or the present species must be removed to that genus. I prefer the former course; and it seems probable that the opercula are only present in the young condition and become lost in older colonies.

For a Campanularian this is a remarkable species on account of its great size and coarse habit, and its marked resemblance to a Sertularian (text-figs. 2, 3). It grows in great profusion over some parts of the pearl banks, and is said to be characteristic of the East Cheval Paar, where, in the Inspector's reports, the great masses sometimes brought up by the divers are alluded to as "heather." Text-fig. 2 shows the species in the fresh living state, and fig. 3 shows older coarser tufts, largely dead, such as form the "heather" of the diver.

Locality:—Generally distributed round the coast of Ceylon, but especially large and abundant on some parts of the pearl banks in the Gulf of Manaar.

Campanularia corrugata, n. sp.—Plate I., fig. 2.

TROPHOSOME.—Stems of varying length rise from a creeping stolon, both being thick and wrinkled, but without rings. Hydrothecæ about $\frac{1}{10}$ of an inch in height usually, but varying in size with age; cylindrical, the same width all their length; transversely ringed more or less, sometimes with as many as 8 rings; the aperture obliquely sloped with an everted even rim which is often reduplicated, while sometimes a complete new hydrotheca rises out of the old one, its stem passing through this, and standing at varying heights above it (Plate I., fig. 2). Zooid with about 20 tentacles. Gonosome not present.

Locality:—Found creeping over shells and zoophytes, north of Cheval Paar, 7 to 10 fathoms.

This species has very much the appearance of *Campanularia grandis*, Allman (1),

Fig. 2. *Campanularia juncea*—well-grown but living. This and fig. 3 are about $\frac{1}{3}$ natural size.

Fig. 3. *Campanularia juncea*—old coarse tufts ("heather"), mostly dead.

but has no node below the hydrotheca, although there are sometimes one or two joints, and it does not narrow towards the margin. It has apparently a tendency to completely reduplicate itself, a habit I have only seen described in the case of *Clytia poterium*, L. Ag. (8). The older hydrotheca has always lost its zooid when this happens, and also its corrugated sides, and looks old and worn.

Hebella calcarata (A. Agassiz) (9).

This species, previously known from Woods Holl, on the east coast of North America, was found creeping over Sertularians from the Gulf of Manaar.

Family: LAFOËIDÆ.

Lafoea serrata, Clarke (13).

A few colonies of this delicate little form were found creeping over Sertularians from the Gulf of Manaar. Previously known from Cuba.

Cuspidella costata, Hincks (15).

One or two broken fragments of this distinctive form were found creeping over a Sertularian from the Gulf of Manaar. The species was previously known from both sides of the North Atlantic—Woods Holl and Britain.

Family: SERTULARIIDÆ.

Sertularia gracilis, Hassall—Plate II., fig. 3.

Our Ceylon specimens correspond with Hincks' (15) description of this form in all its parts, but are much more attenuated than his figures represent, both in stem and hydrotheca, so that they have quite a different appearance (see Plate II., fig. 3). Many of the hydrothecæ have reduplicated margins, which adds length to them; also in the preserved specimens the operculum often stands open and adds further to the appearance of length. The species is known from both shores of the North Atlantic (Britain and North America).

Locality:—Galle and onwards up the West Coast of Ceylon, deep water; attached to Algæ, &c.

Sertularia ligulata, n. sp.—Plate II., figs. 1 to 1b.

Trophosome.—Colony about $1\frac{1}{4}$ inches in height in the largest specimens, with simple or sparingly branched stems. Branches mostly given off from one side of the stem, either two or three near together, or widely separated and few (Plate II., fig. 1). They are narrowest at their junction with the stem below a pair of hydrothecæ, are smooth near the base, and have an oblique joint below their lowest pair of hydrothecæ (Plate II., fig. 1a). Both stem and branches usually end in tendrils terminated by large flat disks which adhere to foreign objects (fig. 1a).

Hydrothecæ always in opposite pairs, one pair to an internode. They touch each other for $\frac{2}{3}$ of their length in front and are widely separated behind; the free portion is abruptly divergent, so as to leave a fold across the front of the cell; orifice bilabiate.

A good length of internode is seen below the hydrothecæ, and, usually, a joint just above a pair of hydrothecæ. A peculiar process like a little tongue or strap (hence the name I give this species) protrudes from the orifice above the zooid, and is sometimes contracted within the hydrotheca (fig. 1a).

Gonosome.—Gonothecæ resemble closely those of *Sertularia complexa*, Clarke (13), barrel-shaped and rugose, borne on the stems singly below hydrothecæ (fig. 1b).

Locality :—Found growing on stems of other Hydroids and on the experimental oyster cages in the Gulf of Manaar.

I have seen no account or figure of anything corresponding with the peculiar tongue-like process described above, except in Hincks' description (16) of the contents of the nematophores of some Plumularians. In *Diplocyathus*, Allman (4), and *Hypophyxis*, Allman (4), we have other forms of Hydroids outside the Plumulariidæ which show nematophores, but in the present species there is no containing receptacle for this process apart from the hydrotheca itself. The process appears to reach from the centre of the stem and proceeds along the upper bent portion of the hydrotheca.

The orifice of this species is bilabiate, the upper surface slightly peaked, but when the operculum is open it often appears to be even-rimmed and hooded.

Sertularia fissa, n. sp.—Plate II., figs. 2 to 2f.

Trophosome.—Colony a tangled mass of loose, straggling, rather coarse, brown stems, about 3 inches in height, dichotomously branched (Plate II., fig. 2); both stem and branches bearing hydrothecæ, in opposite pairs widely separated from one another (figs. 2d and 2f). Branches given off from before and behind a pair of hydrothecæ, not from their sides; occasionally two branches coalesce, and there are two pairs of hydrothecæ found back to back (see figs. 2d, e, f). Hydrothecæ adherent for $\frac{2}{3}$ of their length, free above, and diverging at right angles with the stem. They touch each other in front (fig. 2a), on the upper pairs, on the branches; but are separated below, and are widely apart at the back (fig. 2b). Margin with an upper and 2 lateral teeth, often reduplicated, and having an operculum.

Gonosome.—Gonothecæ borne on stem and branches, attached just below a hydrotheca (fig. 2c) by a short pedicel, and turned abruptly up to lie along the branches. They are about 3 times the length of the hydrothecæ, oval, with a short, broad neck and even rim, and strongly ribbed.

Locality :—Found on worm tubes from off Galle, off Mount Lavinia, off Kaltura, and on the Cheval Paar, depths of from 6 to 30 fathoms.

Sertularia tenuis, Bale (11).—Plate II., fig. 5.

The present specimens agree with Bale's figures and description of the unbranched form of *Sertularia tenuis* in size and shape of the hydrothecæ—there are no gonothecæ. These colonies show the margin of the hydrothecæ often reduplicated, and there is a bivalved operculum. There is one colony which may be mentioned as possibly only an abnormality in this species. It has a branch which proceeds from one of a pair of the hydrothecæ of the stem (see fig. 5), a feature of the genus *Thecocladium*, ALLMAN (2), with which genus, however, this species has nothing else in common. The species is known from Williamstown, Australia.

Locality :—The Ceylon specimens were attached to worm tubes, shells, algæ, &c., from the Cheval Paar, Gulf of Manaar.

Sertularia loculosa, BUSK (10).

These specimens correspond with the description of the unbranched form in BALE'S catalogue, they are rather shorter and have no gonothecæ present.

Locality :—This species, previously known from Australia, was found north of the Cheval Paar, 7 to 10 fathoms, growing on the calcareous alga *Halimeda*.

Sertularia rugosissima, n. sp.—Plate II., fig. 4.

Stems simple, rather less than $\frac{1}{2}$ an inch in height, of a bright brown colour. Hydrothecæ, one pair to an internode, corrugated for the upper $\frac{3}{4}$ of their length (fig. 4). They touch in front, excepting the lower ones on the stem, and are separated behind, and are free and divergent at right angles for $\frac{1}{2}$ their length. They have two lateral teeth and are closed by a bivalve operculum.

Gonosome not present.

This is a neat, minute form, quite half as small as *Sertularia pumila*, and is the only Sertularian with opposite annulated hydrothecæ.

Locality :—Found creeping over algæ from the Gulf of Manaar.

Diphasia mutulata (BUSK), **(10).**—Plate II., figs. 6 to 6B.

This form corresponds entirely with BUSK'S descriptions. The pieces are only about an inch in height, and are unbranched and bear male gonothecæ (Plate II., fig. 6). On some specimens the hydrothecæ are smaller and less prominent than on others, and sometimes subalternate (fig. 6B), and the gonothecæ on these have only a few spines near the top and are of smaller size. This form is shown on Plate II., fig. 6A. The species has been found at Torres Strait and Port Molle, Australia.

Locality :—Our specimens were growing on stems of *Lytocarpus*, &c., at several localities : off Galle ; Station I., off Negombo ; and in the Gulf of Manaar.

Sertularella, sp.

A fragment of a *Sertularella* was found on the Cheval Paar, Gulf of Manaar.

Thuiaria, sp.

TROPHOSOME.—Stems branched, about $\frac{3}{4}$ of an inch in height, not fascicled, having two, alternate, hydrothecæ to an internode on the unbranched portion of the stem, and where there is a branch, one hydrotheca is present also in its axil. Branches alternate, with a joint shortly above their origin.

Hydrothecæ alternate, well separated, except near the tops of branches, where they slightly overlap one another, and are more oval in shape. Margin with two teeth. No gonothecæ present.

There is such a small piece of this, that although the characters do not agree with those of any known species of *Thuiaria*, still I do not feel justified in describing it as a new form.

Locality :—Gulf of Manaar.

Thuiaria palans, n. sp.—Plate III., figs. 5, 5A.

TROPHOSOME.—Stem of a bright brown colour, branched, with a joint just below the origin of each branch. Branches alternate, long and straggling. Hydrothecæ two or three to an internode on the stem, four or five on the branches, adherent up to quite near the top, when they become free and divergent; margins reduplicated and with two lateral teeth.

There is only one broken piece of this form $2\frac{1}{2}$ inches in height, but it seems so distinct from all previously described species that I feel bound to describe it as new, and I believe the above characters will determine it.

Locality :—Palk Bay, 7 fathoms.

Desmocyphus palkensis, n. sp.—Plate II., figs. 7 to 7B.

TROPHOSOME.—Hydrocaulus $2\frac{1}{2}$ inches in height, with a dark brown stem, pinnately branched; the pinnæ paler in colour, alternate, one to an internode, with a straight and an oblique joint shortly above their point of origin.

Hydrothecæ alternate on the stem and separated from each other by its width (Plate II., fig. 7), adnate for $\frac{2}{3}$ of their length, one in the axil of each pinna and one on either side of the internode above; on the pinnæ they are opposite, a pair to each internode (fig. 7A), adnate for $\frac{2}{3}$ of their length in front, free and divergent above, with two lateral teeth and an operculum.

GONOSOME.—Gonothecæ borne on short stems below the hydrothecæ on the stem, oval, strongly ringed, with a wide neck (fig. 7B).

Locality :—Palk Bay, 7 fathoms.

These specimens are broken off above and below, but have the appearance of being nearly complete. They resemble *Desmocyphus longitheca*, ALLMAN (**3**), in some respects, but the hydrothecæ on the stem are never opposite and adnate to one another and the specimens are $1\frac{1}{2}$ inches taller.

Synthecium orthogonia (BUSK) (**10**).

A few of the hydrothecæ on these specimens are subalternate.

Locality :—The species is known from Port Jackson. Our Ceylon specimens were found on the experimental oyster cages on the Cheval Paar, Gulf of Manaar.

Pasythea hexodon, Busk (10).

There are some unbranched colonies of this species with from four to ten hydrothecæ in a set, and with one or two gonothecæ.

The species is known from Australia. Our specimens were found growing on stems of *Halicornaria insignis*, &c., on the north of Cheval Paar, Gulf of Manaar.

FAMILY: IDIIDÆ.

Idia pristis, Lamouroux.

The largest piece of these specimens is broken off at the top, and is $3\frac{1}{2}$ inches in height. Gonothecæ are present.

This species is known from Torres Strait, Bahia, and the Persian Gulf. Our Ceylon specimens were on worm tubes, &c., from off Galle, and onwards up the west coast to Mount Lavinia and Kaltura, and also in the Gulf of Manaar.

FAMILY: PLUMULARIIDÆ.

Plumularia setacea, Ellis.

A good many colonies of this species were found, and gonothecæ are present.

It was previously known from Australia, Messina, North America, and Britain.

Locality:—Our Ceylon specimens were attached to worm tubes, &c., from the north end of Cheval Paar, 7 to 10 fathoms, and elsewhere in the Gulf of Manaar.

Plumularia buskii, Bale (11).

There are a few colonies only of this form, about 1 inch in height, and without gonothecæ, but otherwise following Bale's description, excepting that, in some cases, a few of the lower pinnæ on the stems are opposite instead of alternate, an arrangement that has been described in the case of *Plumularia cornucopia*, Hincks (16).

The species is only known from Australia. Our Ceylon specimens were found in the Gulf of Manaar.

Monostæchas quadridens (McCrady) (18).

The specimens of this form are about the size of those first described when Allman founded the genus; half an inch is the height of the largest colony.

The species is known from Pacific reef, Barbadoes, and the North Atlantic.

Locality:—North of Cheval Paar, 7 to 10 fathoms, Gulf of Manaar.

Antennella gracilis, Allman (3).

These specimens agree with the description of *Antennella gracilis* in all respects but size, and are probably from their position young colonies. They are about $\frac{1}{4}$ inch instead of 1 inch in height. In the details of stems, hydrothecæ and nematophores they agree. The hydrothecæ are not quite cylindrical, narrowing downwards slightly.

There are a few gonothecæ, which is important, as these have not been observed before in the genus *Antennella*. They are identical in position and shape with those of *Monostæchas quadridens*, ALLMAN (3), and have the two nematophores at their base. These colonies resemble the branches of *M. quadridens* exactly, but are on a smaller scale.

This species was known previously only from the West Indies, between Cuba and Florida. Our Ceylon specimens were found growing on the experimental oyster cages on the Cheval Paar, Gulf of Manaar.

Antennella allmani, ARMSTRONG (7).

There is very little of this form. The lateral nematophores are very long, and the hydrothecæ have everted rims, as figured by ARMSTRONG (7).

This is an Indian Ocean species which was dredged off Galle and onwards up the west coast of Ceylon.

Aglaophenia perforata, ALLMAN (2).

In the absence of corbulæ, I cannot be quite sure of the identity of this species, of which a quantity was found growing over Amphipod tubes. It differs from ALLMAN'S description in being rather larger, colonies reaching the height of half instead of only quarter of an inch, and in the number of marginal teeth on the hydrothecæ not exceeding ten. There is a nematophore at the base of each pinna and one below, on the same internode of the stem as the pinna, which is not described by ALLMAN. ALLMAN'S specimens were from the St. Vincent Islands. The Ceylon specimens were found growing on masses of Amphipod tubes and on small pearl oysters in the experimental oyster cages in the Gulf of Manaar.

Aglaophenia phœnicea, BUSK (10).

There are a few colonies of this form growing over worm tubes from the north end of the Cheval Paar, 7 to 10 fathoms. It was previously known only from Torres Strait.

Halicornaria insignis, ALLMAN (1)—(Text-fig. 4).

The species described under this name by ALLMAN was 9 inches in height, unbranched, with a stout, monosiphonic stem, of a dark brown colour; the hydrocladia paler in colour; two, opposite, hydrocladia to an internode; hydrothecæ winged and toothed, with a long, curved, mesial nematophore, and two lateral nematophores taller than the hydrothecæ.

The present specimens correspond exactly with this description, but that the colonies are of far greater height, one reaching a size of $15\frac{1}{4}$ inches, spreading from the base in a beautiful fern-like way (see text-fig. 4), and that they are covered with gonothecæ.

There is also one colony of about 9 inches in height, exactly corresponding with

ALLMAN's description, except for the addition of the gonothecæ. This colony and the larger colonies evidently belong to the same species, so that I do not hesitate to call

Fig. 4. *Halicornaria insignis.* About ¼ natural size.

them all *Halicornaria insignis*, and to add the description of the gonosome, previously unknown.

The gonothecæ resemble those of *H. bipinnata*, ALLMAN (1). They are of the same colour as the hydrothecæ, obconic in form, one side more convex than the other, truncated above, and attached below, by a short stem, to the hydrocladia below its lowest hydrotheca. As the hydrocladia are opposite and closely set, the gonothecæ form a thick double row up the stems.

There are some specimens of the little bivalve mollusc *Avicula* (*Margaritifera*) *zebra*, REEVE, attached to these colonies, and so coloured and banded as to present the appearance of being part of the Zoophyte.

Locality :—Pearl banks, Gulf of Manaar.

Halicornaria setosa, ARMSTRONG (7).

The specimen from off Kaltura differs from the others very much in appearance, owing to the pinnæ being less fasciculated and twice as long, but this does not seem a sufficient reason for making a new species, unless, when more material has been examined, other special characteristics are found.

Locality :—Off Mount Lavinia and Kaltura, and on the Cheval Paar, Gulf of Manaar.

Lytocarpus (?) hornelli, n. sp.—Plate III., figs. 1 to 1B.

Trophosome.—Colony slender, 16 inches to 18 inches in height, with long, straggling branched stems (fig. 1). Stem and branches polysiphonic, of the same thickness, and dark brown colour. Branches alternate usually, but occasionally several given off near together and from one side of a stem. Branchlets carrying hydrocladia about $\frac{1}{10}$ of an inch in length, arranged in loose, bottle-brush form on the branches, having monosiphonic stems, an oblique joint some little way from their bases, and, below that, transverse joints which make long and short internodes to the base.

Cauline nematophores form a line up the central fascicle of the main stem and branches.

Hydrocladia are of a pale straw colour, not closely set; they branch alternately from the upper side of the branchlets, one from each internode, and there is one nematophore on each internode above this which is long and tubular and bends in the opposite direction to the hydrocladia.

Near the base of each hydrocladia there is a solitary nematophore; then follow hydrothecæ, closely set, separated by transverse joints. They are beautifully transparent and elegant, with an even, outwardly curved rim, and are about twice as deep as they are wide, having no anterior fold (fig. 1A).

The mesial nematophore reaches about halfway up the hydrotheca, is adnate below, tubular and diverging outwards above, with two orifices. The lateral nematophores are tubular, adnate to the hydrotheca below its rim and rising about as much above it. The intrathecal ridge is very near the base of the hydrotheca and reaches more than halfway across it.

Between each branchlet on the upper portion of the stem is a string of nematophores in threes, sometimes as many as twelve sets in a line (fig. 1B).

Gonosome not present.

Locality:—Off Mount Lavinia and Kaltura; also Station I., off Negombo.

Lytocarpus fasciculatus, n. sp.—Plate III., figs. 3 to 3B.

Trophosome.—Colony, stems fascicled, thick, of a pale brown colour; giving off, at intervals of about an inch, alternate branches, less thick, but fascicled like the stem, and of the same colour (fig. 3). These are about $2\frac{3}{4}$ inches in length, and carry closely set hydrocladia, about $\frac{6}{10}$ of an inch long, of a paler colour than the stems, branching alternately and pointing forwards and outwards, with a short cauline nematophore between each.

Hydrothecæ (fig. 3A) closely set, deep, with a crenate margin and a central tooth, the sides sloping upwards from the tooth, and backwards, and being free from the stem for a short distance from the top. Mesial nematophore short, barely half as long as the hydrotheca, free and spout-like for a third of its length. Lateral nematophores short and broad, not reaching to the top of the hydrotheca.

Intrathecal ridge very low down, reaching about half-way across the hydrotheca.

Phylactocarps (fig. 3B) of the same length as the hydrocladia, occurring at intervals up the branches among these, a hydrotheca at the base, succeeding internodes being alternately barren or with a spine which has a large flattened gonotheca at its base. The spines all turn to the same side.

Locality :—Off Galle and onwards up the west coast to Kaltura and Mount Lavinia.

There are only pieces broken from the tops of colonies of this form, and they appear to belong to a large species. In some respects they resemble *Lytocarpus secundus*, but the branches are not so closely set on the stems and have not such a one-sided mode of growth, and are about $\frac{1}{2}$ an inch longer, $\frac{6}{10}$ of an inch instead of $\frac{2}{10}$. Also the phylactocarps in *L. secundus* are only half as long as the hydrocladia, while here they are as long, and the hydrotheca at their base is not described as being present in *L. secundus*.

Lytocarpus plumosus, n. sp.—Plate III., figs. 2 to 2B.

Trophosome.—Colony about 2 inches in height, unbranched, plumose (fig. 2); the stem monosiphonic, of a dark brown colour. Hydrocladia closely set, $\frac{4}{10}$ of an inch in length, pale yellow, given off alternately to right and left from the front of the stems, one to each internode, which carries besides two cauline nematophores, one at the base of the hydrocladia and one below it. Hydrothecæ (fig. 2A) fairly deep, narrowing downwards from the rim, which is toothed, one small tooth in front and two on either side. Mesial nematophores about the height of the hydrothecæ, free and spout-like near the top. Intrathecal ridge sloping upwards, from low down posteriorly to about opposite the middle of the nematophore.

Phylactocarps (fig. 2B) scattered up the stems, about half as long as the hydrocladia. They have one hydrotheca at the base of each and spines, branching to either side alternately, above it.

Gonosome.—Gonothecæ at the bases of the spines, one to each.

Locality :—Growing on worm tubes from the Gulf of Manaar.

REPORT

ON THE

POLYCLAD TURBELLARIA

COLLECTED BY

PROFESSOR HERDMAN, AT CEYLON, IN 1902.

BY

FRANK FORTESCUE LAIDLAW, B.A. CANTAB.

[WITH ONE PLATE.]

THE seas lying about the island of Ceylon appear to support a particularly rich Planarian fauna. Although a greater number of species have already been described from these waters than from any other part of the world, the Mediterranean Sea alone excepted, I have not been able to identify any of the species mentioned below with any already described from them.

A large collection was made by SCHMARDA,* who describes no fewer than twenty-nine species from the Ceylon seas, whilst nineteen others are recorded by Dr. COLLINGWOOD.† Coloured figures carefully executed are available for all these species, so that I believe I have not overlooked any identities. Unfortunately neither of these writers was able to give sufficient account of the internal anatomy of the species they described, consequently the generic determination of their species is often a matter of uncertainty, and hence it is not possible at present to compare the general characters of this fauna with that of other parts of the world.

LANG‡ apparently makes no additions to the list; and since the publication of

* 'Neue wirbellose Thiere, beobachtet und gesammelt auf einer Reise um die Erde 1853 bis 1857,' I Band, "Turbellarien, Rotatorien und Anneliden," I. Hälfte, Leipzig, 1859.

† 'Trans. Linnean Society,' 2nd Series, Zoology, vol. I., p. 83, Plates XVII.–XIX. Three species, *Planaria aurea*, *Penula fulva* and *Penula alba*, are omitted by Dr. COLLINGWOOD from his account of KELAART'S species. See KELAART, 'Journ. Ceylon Branch Roy. Asiat. Soc.,' 1856–1858, pp. 134–139.

‡ 'Fauna und Flora des Golfes von Neapel,' XI., Polycladen, 1884.

LANG's monograph I can find no further records, save of *Cestoplana ceylanica* added by myself.*

Three of the species described below were collected in Ceylon by Mr. GARDINER in 1899. He has been good enough to permit me to incorporate my account of them with that of the species with which Professor HERDMAN has kindly entrusted me.

Paraplanocera aurora, LAIDLAW.

Paraplanocera aurora, LAIDLAW, 'P.Z.S.,' 1903, vol. II., Part I., p. 102, Plate IX., fig. 1.

One specimen which agrees in every respect with the type specimen from Zanzibar, save that it is nearly twice as large, being about 30 millims. in length, whilst Mr. CROSSLAND's specimen was only 15 millims. long. The Ceylon specimen was found at Station XVI., on the Periya Paar, in the Gulf of Manaar, at a depth of 9 fathoms.

Woodworthia, n. gen.

Closely allied to *Idioplana*. Body rounded, no notch on the anterior margin. A complete series of marginal eye-spots present. Prostate provided with a duct which joins the vesicular duct at the base of the penis. Female aperture separated from male; vagina of great length, having a bilaterally symmetrical accessory vesicle.

Woodworthia insignis, n. sp.—Plate, figs. 1 and 9.

One specimen, pearl banks, Gulf of Manaar.

Measurements.—Length, about 25 millims.; breadth, about 22 millims. Buccal opening sub-median. Male aperture about 4 millims. from hind end of body; female aperture about 0·5 millim. behind male. Tentacles 5 millims. apart.

Coloration.—In the spirit specimen an uniform whitish brown, in the living creature probably white. Scattered irregularly over the whole dorsal surface are numerous minute black dots of pigment.

Eye-spots.—These are grouped in a dense cluster at the foot of each tentacle, over the brain, and round the margin of the body. The spots over the brain are few in number and rather widely scattered. Those on the margin are very minute and are irregularly arranged; on the front part of the margin they may be two or three rows deep.

Body-wall.—The epidermis, both on the ventral and on the dorsal sides, contains numerous long, rather slender rhabdites, those on the dorsal side being nearly half as long again as those on the ventral side.

The basement membrane is remarkably thick. The muscles of the body-wall consist on the dorsal side of a longitudinal layer next the basement membrane, followed by diagonal fibres, and on their inner side a circular layer. On the ventral

* LAIDLAW, in GARDINER's 'Fauna and Geography of the Maldive and Laccadive Archipelagoes,' vol. I., Part III., p. 302, fig. 72.

side there is, in addition to these, an inner diagonal layer, and, lastly, an inner longitudinal layer.

Gut.—The pharynx is large and folded, of the type usually found in Planoceroids. The gut branches are very numerous and anastomose freely. The cells forming the epithelium appear to have broken away, in most cases, from the gut-wall, and to have rounded themselves into little spheres which lie free in the lumen. This is possibly due to some delay in fixing the tissues after the specimen was taken from the dredge.

Genital Apparatus.—The ovaries are dorsal; the testes cannot be distinguished in my sections, although the ends of the vasa deferentia are crowded with spermatozoa. The relations of the rather complicated terminal parts of the genital ducts will be rendered more easily comprehensible by a reference to the accompanying Plate, fig. 9.

Terminal Male Organs.—The small conical penis (*pe.*), which is unarmed, projects into the antrum masculinum (*a.m.*), which is a simple chamber lined with what appears to be a secreting, non-ciliated epithelium. Into the base of the penis run two ducts: one, that lying more dorsally, conveying secretion from a small muscular prostate gland (*pr.*), the other, the more ventral of the two, runs backwards and downwards for some distance to widen into a vesicula seminalis (*v.s.*). This latter duct is lined with ciliated epithelium and has rather thick muscular walls. It widens quite gradually into the vesicula, which receives on its dorsal side, some way behind its anterior end, the two vasa deferentia (*v.d.*), which, as they approach the vesicula, become endowed with muscular walls, composed, as in the case of the vesicula and its duct, of circular fibres.

The prostate duct is very short and enters the prostate immediately after it passes out of the penis. The interior of the prostate is divided into three longitudinal chambers (see Plate, fig. 1) by the folding of its secretory wall, outside which is a thick layer of circular muscle fibres traversed by a few radial and longitudinal strands.

Female Terminal Ducts.—The vagina is chiefly remarkable for its extreme length. The antrum (*a.f.*) is small, it opens vertically upwards. From it the vagina (*va.*) runs straight forward close to the dorsal body-wall. It consists here of a tube of rather narrow diameter, lined with ciliated epithelium, and surrounded by a few circular muscle-fibres. It continues forward until it has passed right beyond the level of the male organs. Its diameter then increases and it bends downwards and forwards for some distance, then turns upwards, receiving the secretion of the large shell glands (*sh.gl.*) at this level. Finally, near the dorsal body-wall, it turns sharply backwards, running parallel to the first part of its course and at about the same level with it, so that the two parts often lie side by side. At a level considerably in front of the extreme front end of the male apparatus the backwardly-directed part of the vagina receives the common duct running into it from the two uteri (*c.d.*). This duct is rather longer than is usual. The backward course of the vagina is continued until the level of the antrum femininum is almost reached. The structure of this part is similar to that of its first part. Finally it ends by opening in the middle line into a large crescentic accessory vesicle (*acc.ves.*), whose "horns," lying one on either side of the middle line, are directed forward. The two halves of the accessory vesicle end in large, rather rounded lobes (*l.*). Its walls are composed of an active secretory epithelium which is at first columnar, but becomes more cubical in the lobes. These lobes contain a quantity of thick spongy secretion. In this secretion mass lie a large number of remarkable spindle-shaped bodies which vary considerably in size, and stain very deeply. They are shown in fig. 1, on the Plate. Each of these bodies lies in a small clear cavity which is spherical in shape. In the sections it is, of course, seen as a clear round patch, in which the dark-stained spindle-shaped body lies equatorially. The nature of these bodies is quite unknown to me, and the state of preservation of the tissues in the single specimen prevents a more detailed description. I am inclined to conjecture, however, that they may be spermatophores. In one or two cases the clear space surrounding them seems to be occupied by a gelatinous lightly-staining substance (x, in fig. 1, on Plate).

The most striking features of the genital apparatus of this species are (i) the great length of the vagina and (ii) the shape of the accessory vesicle, which is, roughly speaking, bilaterally symmetrical. The first of these peculiarities is paralleled in *Idioplana australiensis*, a species described by WOODWORTH.* This species also resembles that under discussion in the following respects:—Distribution of the eye-spots, coloration, and structure of the terminal parts of the male ducts. Consequently we may conclude that the two are closely related.

Idioplana, however, differs from *Woodworthia* in shape, in possessing a peculiar notch on the anterior margin, and in the fact that the prostatic duct and the vesicular duct open to the exterior almost independently of one another.

Woodworthia, on the other hand, possesses an accessory vesicle which is bilaterally symmetrical. These differences are sufficient to warrant a generic separation of the two forms.

Stylochus ceylanicus, n. sp.

Three specimens from Cheval Paar.

Measurement (of largest specimen).—Length, about 47 millims.; breadth, 27 millims. Genital aperture 4 millims. from hinder end of body. Tentacles 4 millims. apart. Buccal opening sub-central.

Coloration.—Judging from the preserved specimens, this must be, on the dorsal surface, a dull yellow covered with very numerous small ill-defined black spots which are absent in the area lying just over the brain. Ventral surface plain yellowish-white.

Eye-spots.—Numerous spots lie close together about the base of either tentacle;

* WOODWORTH, 'Bull. Mus. Harvard,' vol. XXXII., No. 4, p. 63, Plate XXXII., figs 2–5, 1898.

there are a number of scattered eye-spots about equal in size to those lying at the base of the tentacles, over the brain. In addition there are very numerous smaller spots on the margin. These do not extend completely round the body, but only about halfway along the margin on either side. They form anteriorly two or three irregular rows.

Genital Organs.—The ovaries are dorsal. The most striking peculiarity of this species is found in connection with the hinder ends of the vasa deferentia just before they enter the vesicula seminalis. They are provided in that neighbourhood with very thick muscular walls, which are quite as thick as the walls of the vesicula seminalis itself. The prostate is divided into a number of parallel chambers, its walls are formed of muscle-fibres which have a very definite "lattice-work" appearance.

In one specimen the penis was completely everted. The vagina opens into the same wide shallow depression as that into which the antrum masculinum passes.

This species may be defined as a *Stylochus* with an incomplete series of marginal eye-spots, with the ovaries occupying a dorsal position, and with the genital apertures closely approximated. The prostate is divided into a number of parallel chambers, and the lower ends of the vasa deferentia are highly muscular.

Stylochocestus, n. gen.

Body elongated, with neither marginal nor tentacle eye-spots. Buccal aperture sub-central.

Prostate gland large, provided with a short duct which joins the vesicular duct at the base of the penis. Vagina without accessory vesicle.

Stylochocestus gracilis, n. sp.—Plate, fig. 7.

Several specimens (Gardiner).

Measurements.—Length, about 14 millims.; breadth, about 3 millims. Male aperture 4·5 millims. from hinder end of body; female aperture 0·5 millim. behind male. Buccal opening sub-median.

I have no information as to the *coloration* of this species during life.

The *eye-spots* are arranged in two parallel rows over the brain.

Body-wall.—The epidermis of the dorsal surface contains rather large rhabdites, and in places also pseudorhabdites equal in length to the rhabdites, but much broader and rather irregular in outline. These are both absent from the ventral surface, except towards the margin of the body, whilst the ventral epithelium is flatter.

The basement membrane is thin, but stains deeply. The muscles lying immediately below it on the dorsal side are first a longitudinal layer, then a double diagonal layer, and lastly a circular layer. On the ventral side this is again succeeded by an inner longitudinal layer.

The *gut branches* do not anastomose.

Genital Apparatus.—The testes, which are very numerous and of large size, lie between the gut branches at almost the same level as the ovaries, being only a trifle more ventral in position.

Terminal Ducts (see Plate, fig. 7).

Male.—The two vasa deferentia (*v.d.*) enter the anterior end of a small vesicula seminalis (*v.s.*) which lies close against the dorsal body-wall. It is lined with a ciliated epithelium, outside which is a narrow layer of circular muscle fibres; it tapers at its posterior distal end into a duct (*d.e.*) without muscular walls, but with rather a wide lumen which runs to the penis (*pe.*). At the base of the penis it joins another duct which runs a short course directly from the penis to the prostate gland (*pr.*), an elongate oval body of about twice the size of the vesicula seminalis, lined with a well-developed secretory tissue enclosed in a layer of circular muscle fibres. The prostate duct is very short. The antrum masculinum (*a.m.*) is of moderate size, and in one of the specimens from which I prepared sections it is full of the secretion from the prostate.

Female Ducts.—The vagina (*va.*) runs upwards from the female aperture, then close to the dorsal body-wall it turns forward for a short distance and ends receiving the two uteri. The shell-glands (*sh.gl.*) lie about the first part of its course.

Thalamoplana, n. gen.

Closely allied to *Discocelis.* Male and female apertures separated. Antrum masculinum very large; its walls carry muscular projections, at the free ends of which lie the prostatic glands. The penis is of large size, truncate, and also carries prostatic glands at its end. In other respects the genus is similar to *Discocelis.*

Thalamoplana herdmani, n. sp.—Plate, figs. 2–5 and 8.

Two specimens were found in the lagoon at Galle.

Measurements.—Length, about 25 millims.; breadth, 17·5 millims. Buccal opening, 12 millims. from anterior end; male opening, 2 millims. behind buccal; female opening, close behind, but quite distinct from male.

Coloration.—Dorsal surface white with brown mottling. Along the mid-dorsal line is a brown frond-like pattern consisting of a median stripe bearing lateral lobes or segments in pairs, which are irregular in shape and size, but, roughly speaking, smaller and larger pairs alternate. The ventral surface is white.

Eye-spots.—These are arranged much as in *Discocelis tigrina* (see fig. 3 on Plate). On either side of the brain is a small elongate cluster of spots; these clusters diverge from each other posteriorly. Between them lie several diffusely scattered spots over the brain. Marginal eyes are also present on the anterior margin.

Body-wall.—The epidermis consists of columnar ciliated cells which are of considerably greater length on the ventral side of the body than on the dorsal. There are no rhabdites, but the cells appear to contain secretions of the nature of pseudorhabdites. The basement membrane is very thick, especially on the dorsal side; on the other hand, the muscles of the body-wall are but feebly developed.

The *pharynx* is large and much folded. The *gut-branches* are numerous; there is no anastomosis.

Genital Apparatus.—Reference to the Plate, fig. 8, will render the account given below more readily intelligible.

Terminal Male Organs.—The two wide vasa deferentia (*v.d.*) unite to enter a median duct running to the penis. The proximal end of this duct is slightly swollen and has rather thick muscular walls; this part may be regarded as a vesicula seminalis (*v.s.*). Beyond it the duct (*d.e.*, ductus ejaculatorius) runs into the penis (*p.*), a large fleshy organ which projects backwards and downwards into the spacious antrum masculinum (*a.m.*). At its free end the penis is studded with a ring of curious large glands evidently of a prostatic character (*pr.gl.*), which lie around the rather wide opening of the lumen of the penis. These glands appear to be precisely similar in character to those found in *Discocelis tigrina.* As in that species, other glands of the same character are found on the walls of the antrum, but in the present instance they lie at the free ends of certain curious muscular prominences which project from the walls of the antrum. They are distributed as follows:—In front of the penis there is a crescentic muscular ridge which carries a number (about 15) of these glands. In the diagram it is shown in section at *m.pr.'*, the glands are marked *pr. gl.*, and they project at their distal ends to some extent from the surface of the ridge.

Behind the penis there lies on either side of the middle line a pair of prominences shaped rather like the penis, but folded in towards each other. Like the penis, they each carry glands, 3 or 4 apiece at their free ends. They are indicated on the diagram at $m.pr.^2$ (see too, Plate, fig. 4). The floor of the antrum is formed of a very thin fold of the integument, which extends backward as far as the level of the paired prominences spoken of above. The antrum is lined throughout with a thin layer of flattened epithelium which bears very short cilia.

The glands have a length of about 0·1 millim. They are pear-shaped, their narrower end is directed outwards and ends in a conical point which passes through the epithelium lining the antral walls (Plate, fig. 5, *a.gl.*). The gland is in every case filled with a fine darkly staining network, in the interstices of which in some of the glands lies a quantity of finely granular secretion. The nuclei lie about the walls of the gland, none occur in the reticulum. The walls are without muscle fibres.

Female Terminal Ducts.—These bear a very strong resemblance to those of *Discocelis tigrina.* The female aperture opens into the terminal part of the vagina (*va.*), which is at first rather wide and runs in a dorsal direction. It then turns backwards, its lumen narrows, and its muscular walls become thicker. After receiving the common opening of the uteri (*ut.*) it is prolonged back for some distance. This hinder part may be termed the accessory part of the vagina (*acc.* in diagram). It is wider than that part immediately in front of the uterine opening, its walls are thinner, and the lining epithelium is flattened and non-ciliated, whilst in the anterior part the lining epithelium is columnar or square and appears to be ciliated. At its hinder end the accessory part of the vagina opens into the accessory vesicle (*acc.ves.*) which has no muscular walls; its lining epithelium consists of large square secretory cells, and in its lumen lies a lump of secreted substance.

The shell glands are very large, they pass their secretion into the anterior part of the vagina (*sh.gl.*). A very curious feature is the presence of a considerable fold of the body-wall (*pl.*) on either side of the female aperture. This is easily visible in the whole specimen when examined with a simple lens, and in conjunction with the still more prominent external male organs serve to distinguish this species at a glance from any other with which I am acquainted. The position of the ovaries is dorsal.

This is certainly the most interesting species in the collection. It is the type of a genus which may be regarded as a specialized form of *Discocelis* which has retained a single primitive feature which the latter has lost, namely, the widely separated genital apertures.

The feature most worthy of remark is the development of muscular projections of the walls of the antrum to carry the prostatic glands, which are sessile in *Discocelis*. They are of importance, since they suggest a probable explanation of the manner in which the curious intromittent prostate organ of the Diposthiidæ may have arisen, and because they further give an indication of the manner in which a re-duplication of the penial organs may have come about. In fact, if the genus *Discocelis* were not known, one would be almost tempted to suppose that *Thalamoplana* was derived from an ancestral form possessed of a large number of penes, which are here to be seen in process of reduction.

The three genera *Semonia*,* *Discocelis*,† and *Thalamoplana* may conveniently be grouped in a distinct sub-family of the Leptoplanidæ, characterized by the possession of marginal eye-spots, of a large blunt penis, and by the absence of an internal prostate gland. *Semonia*, like *Discocelis*, has a common genital atrium, whilst *Thalamoplana* resembles *Discocelis* in possessing external prostatic glands and a bilaterally symmetrical accessory vesicle connected with the vagina.

Leptoplana gardineri, n. sp.

One specimen, collected by Mr. GARDINER in 1899.

Colour in spirit specimen uniform yellowish-white.

Measurement.—Length, about 16 millims.; breadth, 7·5 millims. Buccal opening sub-central. Female aperture about 6 millims. from the hinder end of the body.

* VON PLEHN, 'Jen. Zeitschr. f. Naturwissenschaft,' Band XXX., pp. 157–159, Taf. XI., figs. 5, 12; Taf. XIII., fig. 3. See also LAIDLAW, 'Proc. Zool. Soc.,' 1903, p. 309.

† See especially LANG, *loc. cit.*, Taf. XIII., fig. 1.

The arrangement of the *eye-spots* is shown in fig. 6 on Plate.

This species is a true *Leptoplana* belonging to the section of the genus* in which the penis is not armed with a stylet. The prostate is chambered, with some five compartments, it is small and of considerable length.

L. gardineri is nearly related to *L. chierchiæ*, VON PLEHN, from which it is readily distinguished by the very different arrangement of the eye-spots, by the greater relative length of the prostate, and by the relatively small size of the accessory vesicle of the vagina.

Pseudoceros, sp.

One specimen, referable to this genus, from the pearl banks, Gulf of Manaar, is unfortunately not in suitable condition for accurate description. It apparently belongs to the section of the genus which is provided with only a single penis; the colour is white with a fine black margin. The total length of the specimen is about 20 millims.

Prosthiostomum singulare, n. sp.

One specimen from Ceylon (GARDINER).

Measurements.—Length, about 40 millims.; breadth, about 6 millims. Buccal opening 6 millims. from the anterior end. Male aperture 16 millims. behind buccal opening; female aperture 1·5 millims. behind male. Sucker 2 millims. behind female aperture.

The *colour* of the spirit specimen is uniform white.

The marginal *eye-spots* are relatively very small and lie in an irregular row round the front margin, extending back on either side for 3 or 4 millims. There are no "brain-eyes"; in this respect *P. singulare* differs from all other known members of the genus.

Genital Organs.—The outer chamber of the antrum masculinum is very large and is provided with thick muscular walls, in which on the dorsal side the accessory vesicles, the vesicula seminalis and part of their ducts are embedded. The accessory vesicles are relatively small and their ducts short. In other respects the sexual organs are exactly as in *P. siphunculus*.

* In my list of the species of the genus *Leptoplana* given in the 'Proc. Zool. Soc.,' 1903, pp. 307, 308, *L. nationalis*, v. PLEHN, was by mistake referred to a division of section A of the genus which included species in which the prostate gland is not chambered. It should, of course, be put in the division A (*b*) near *L. vitrea*, LANG.

EXPLANATION OF PLATE.

Fig. 1. Part of a transverse section across the body of *Woodworthia insignis*. Epidermis and gut shown quite diagrammatically. The section is in the plane AB, shown in fig. 9, and the part drawn shows the median organs and those a little to the right of the middle line.

,, 2. *Thalamoplana herdmani*, sketch of the appearance of the entire animal, showing the colour pattern. × 4 diam.

,, 3. Dorsal eye-spots of the same.

,, 4. Section across the hinder end of the antrum masculinum of the same, in the plane marked AB in fig. 8. The epidermis and body-wall muscles are shown diagrammatically. The two glands (*pr.gl.*) are secreting actively and contain a finely granular secreted substance.

,, 5. Section across three prostatic glands of the same more highly magnified. These glands are exhausted and show only the protoplasmic reticulum.

,, 6. Eye-spots of *Leptoplana gardineri*.

,, 7. Diagram of genital ducts of *Stylochocestus gracilis*, n. gen. and sp.

,, 8. Diagram of genital ducts of *Thalamoplana herdmani*, n. gen. and sp.

,, 9. Diagram of genital ducts of *Woodworthia insignis*, n. gen. and sp.

Explanation of Lettering.

a.f., antrum femininum.
a.gl., aperture of prostatic gland.
a.m., antrum masculinum.
acc.ves., accessory vesicle.
b.m., basement membrane.
c.d., common uterine duct.
c.l., circular muscle layer.
d.e., ductus ejaculatorius (vesicular duct).
d.l., diagonal muscle layer.
e.l., external longitudinal muscle layer (ventral).
ep., epidermis.
g., gut.
i.l., inner longitudinal muscle layer.
l., lobes of accessory vesicle.
m.pr., muscular projection from antrum.
n., nervous tissue.
pe., penis.
pi., pigment.
pr., prostate.
pr.gl., prostatic gland.
sh.gl., shell gland.
tr.m., dorsiventral muscles.
ut., uteri.
v.s., vesicula seminalis.
v.d., vas deferens.
va., vagina.
va[2]., accessory part of vagina.
x., dark body in the accessory vesicle surrounded by gelatinous substance.

REPORT

ON THE

ECHINODERMA

COLLECTED BY

PROFESSOR HERDMAN, AT CEYLON, IN 1902.

BY

W. A. HERDMAN, D.Sc., F.R.S., AND JANE B. HERDMAN, B.Sc. (LOND.),

WITH NOTES AND ADDITIONS

BY

F. JEFFREY BELL, M.A.,

EMERITUS PROFESSOR AND FELLOW OF KING'S COLLEGE, LONDON.

[WITH TEXT-FIGURES.]

[EDITORIAL NOTE.—The HOLOTHURIOIDEA of this collection were described in Mr. PEARSON'S Report published in PART I. (p. 181, 1903), and the CRINOIDEA are reported upon separately by Mr. CHADWICK in this Part (see p. 151, below).

The greater part of the labour in connection with the remaining groups of Echinoderma has been undertaken by my wife, who separated out most of the species and identified the Echinoidea. I should naturally have let her name stand alone in the title of the Report, but as I took some part in the work, exercised a general supervision and identified the commoner starfishes, she prefers that I should be jointly responsible.

Professor JEFFREY BELL, while on a short visit to us in September, kindly went over the greater part of the collection with me and confirmed the identifications. Most of the Ophiuroids and some of the smaller or more doubtful Echinoids and Asteroids were, at his suggestion, sent to him at the British Museum, with the result that he has contributed some additions to our list, and the interesting Notes on some forms and remarks on the more general aspects of the collection, which will be found under his own name at p. 148.—W. A. H.]

ECHINODERMA.

In the year 1882, we are told by BELL, only 4 species of Echinoderms were known from Ceylon. HAECKEL'S collection, described by WALTER, added 16 species, but most of our knowledge is due to the successive collections made for the British Museum by Dr. ONDAATJE, which enabled BELL to add about 20 species in 1882 and to raise the number to over 50 in 1887. The collection of P. and F. SARASIN, made at Trincomalee in 1884–86, yielded to DÖDERLEIN 16 species of Asteroids, 10 Ophiuroids, and 18 Echinoids. Adding these, along with 16 Holothurians (LUDWIG) and 5 Crinoids (BELL), to the forms previously known raised the total in 1888 to about 90 species. A few species have since been added by THURSTON and others.

There seem to be about 109 species of Ceylon Echinoderms in all in the present collection. Mr. PEARSON recorded 30 species of Holothurioidea, and Mr. CHADWICK gives 13 species of Crinoidea in the Report that follows this. In the present lists we have 28 species of Echinoidea, 24 species of Asteroidea, and about 14 species of Ophiuroidea. There were no forms unknown to science in the three last-named groups, but some of the species are of interest from the point of view of distribution, habitat and variation.

ECHINOIDEA.

DESMOSTICHA.

CIDARIDÆ.

Cidaris metularia (LAMK.).

Station XL., 10 miles off Galle, 34 fathoms, 2 specimens, about 1 centim. diameter; Station LV., south-west of Periya Paar, 11 to 24 fathoms, 2 specimens, 1 centim. and 1·5 centim. diameter; Station LXIII., west of Periya Paar, 36 fathoms, 1 specimen, about 1 centim. diameter.

Stephanocidaris bispinosa (LAMK.).

Pearl banks, Gulf of Manaar; 4 specimens. Also another "very young Cidaris."

Phyllacanthus baculosa (LAMK.).

Many specimens were dredged from 10 to 12 miles off Galle, at Stations XL. and XLI., depths 34 to 100 fathoms. Also further on up the west coast of Ceylon, towards Colombo, and off Kaltura and Mount Lavinia, at Station XLVI., depth 25 to 30 fathoms. Also in the Gulf of Manaar, at Station LIV., south of Adam's Bridge, 4 to 40 fathoms; at Station LV., south-west of Periya Paar, 11 to 24 fathoms; at

Station LX., outside Donnan's Paar, 20 to 30 fathoms, and from Cheval Paar, 7 fathoms. obtained by the divers. The diameters of the specimens, without the spines, ranged from 1 centim. to 4·5 centims.

Phyllacanthus imperialis (Lamk.).

One specimen from the Gulf of Manaar, at Station LVII., outside Dutch Modragam Paar, 12 to 36 fathoms; it measures about 2 inches in diameter, without the spines, and about 6 inches including them.

DIADEMATIDÆ.

Diadema saxatile (Linn.).

One small specimen was obtained at Station XL., 10 miles off Galle, depth 34 fathoms. This specimen has long spines on the upper surface, banded straw-coloured and red.

Echinothrix diadema (Linn.).

Obtained at Station XL., 10 miles off Galle, depth 34 fathoms.

ECHINOMETRIDÆ.

Stomopneustes variolaris (Lamk.).

Many specimens were found at the south-eastern corner of Welligam Bay, south end of Ceylon, in hollows in rock pools and also under the sea, in cavities and crevices of the rock. They were of a very deep purple colour when alive, but are now, both the dried and the spirit specimens, of a greenish-black colour. This species was also observed in the lagoon inside the reef at Galle.

Pseudoboletia maculata, Trosch.

One specimen, diameter about 6·5 centims., was obtained from the Cheval Paar, 7 fathoms, by native diver.

Echinostrephus molare (de Bl.).

This little species was obtained in coral blocks in the Gulf of Manaar, at Station XV., on Periya Paar, 9 fathoms, 2 specimens; at Station LXII., between Periya Paar Kerrai and Periya Paar, depth 7 fathoms to 13 fathoms, 2 specimens, 1·5 centims. and 2 centims. in diameter; and on the Jokkenpiddai Paar, obtained by native divers, many specimens, 1 centim. to 1·5 centims. in diameter.

All the specimens of this little purple Echinid were dug out of deep holes in massive blocks of dead coral; and the top-shaped or obovate form of the test, with all the long spines on the abactinal surface, seems well adapted to the burrowing habit. It was noticed on the living specimen that the shorter spines on the actinal surface around the mouth are arranged so as to show a spiral twist such as would be produced by a rotation of the animal within its burrow.

TEMNOPLEURIDÆ.

Temnopleurus toreumaticus (Leske).

A number of small Temnopleurids, which probably belong to this species, were obtained (1) south of Galle, in deep water, and (2) at Station LXIII., west of Periya Paar, 36 fathoms, 9 specimens, of 1·5 centims. to 2 centims. diameter.

Temnopleurus, sp. ?

Some small cream-coloured Temnopleurids were obtained from Station XV., on Periya Paar, 9 fathoms; 10 miles off Galle, in deep water; on the Cheval Paar (off Aripu), 7 fathoms; and at Station I., west of Negombo, 12 fathoms to 20 fathoms.

Salmacis bicolor, Agass.

This species was obtained (1) off Galle, Station XXXIX., depth 16 fathoms to 30 fathoms; (2) south-west of Periya Paar, Station LV., depth 11 fathoms to 24 fathoms; (3) at various localities on Cheval Paar and other pearl banks off Aripu, depth 6 fathoms to 7 fathoms; and (4) at Station XVIII., in Palk Bay, 7 fathoms.

The specimens range from 1 centim. to 6·5 centims in diameter.

Salmacis dussumieri, Agass.

This species was obtained (1) at Station II., north-west of Negombo, 8 fathoms, 12 specimens, from 2 centims. to 4 centims. in diameter; (2) at Station XLVIII., between East and West Cheval Paars, depth 7 fathoms, many specimens, ranging from 0·5 centim. to 2·5 centims. in diameter; (3) at Station LXIII., west of Periya Paar, 36 fathoms; and at several other places on the pearl banks.

Salmacis sulcata, Agass.

Specimens were obtained (1) at Station I., off Negombo, 12 fathoms to 20 fathoms, 3 specimens, 1·5 centims. to 2·5 centims. in diameter; (2) at Station XLVIII., on the Cheval Paar; and at other localities amongst the pearl banks off Aripu, depths 6 fathoms to 8 fathoms, many specimens, ranging from 1 centim. to 4 centims. in diameter.

TRIPLECHINIDÆ.

Toxopneustes pileolus (Lamk.).

Three specimens were dredged in the Gulf of Manaar, from Station LV., south-west of Periya Paar, 11 fathoms to 24 fathoms; on North-west Cheval Paar, 8 fathoms; and again on Cheval Paar, 7 fathoms. They range in diameter from 7·5 centims. to 10 centims.

Most of the pedicellariæ of this species are very remarkable and striking, both in size and colour, when seen alive. They show the three valves connected by a large discoid membranous extension, which is of a beautiful deep-red colour edged by a band of snowy white. In the preserved specimens the membrane is now contracted to a triangular peltate form, but the white band is still visible.

CLYPEASTRIDA.

EUCLYPEASTRIDÆ.

Fibularia australis, Desml. (?).

Many specimens, ranging from 6 millims. to 10 millims. in length, were dredged outside Dutch Modragam Paar, at Station LVII., 11 to 36 fathoms; and two specimens, 8 millims. and 12 millims. in length, were obtained in deep water outside Galle. These specimens have many more than 4 pairs of pores on the petals—generally 12 to 15 pairs are present.

ECHINANTHIDÆ.

Clypeaster humilis (Leske) = **C. rosaceus**, Linn., *fide* Lovén.

Dredged all round the coast of Ceylon, at Stations I., II., IV., IX., XI., XII., XIV., XXXVIII., XLIV., XLVI., XLVIII., XLIX., LI., LIII., LVII., LXIX. The specimens ranged from 1 centim. to 15 centims. in length.

This species seems commonest in depths of 8 to 10 fathoms on the pearl banks in the Gulf of Manaar.

Clypeaster scutiformis (Gmel.).

Two specimens, about 50 millims. and 40 millims. in length, were dredged to the west of the Periya Paar, at Station LXIII., 17 to 55 fathoms.

Two specimens, about 30 millims. long, were dredged in deep water 10 miles off Galle, at Station XL., 34 fathoms, and 6 miles west of Kaltura, depth 22 fathoms, at Station XLIII.

Echinanthus testudinarius (Gray).

At Station III., off Chilaw, 9 to 14 fathoms; at Station XLI., 12 miles south of Galle, about 100 fathoms; at Station XLIX., south of Cheval and Periya paars, about 12 fathoms.

Echinanthus, sp. ?

A young specimen which we cannot identify with certainty was dredged at Station LXVI., off Mutwal Island, 10 to 35 fathoms.

LAGANIDÆ.

Laganum depressum, Less.

Many specimens, ranging in length from 1·8 centims. to 4 centims., were dredged all round the coast of Ceylon, at Stations II., XII., XXI., XLIII., XLVI., XLVIII., LIII., LVI., and LVII.

They were particularly abundant at Back Bay, Trincomalee, in 8 to 12 fathoms.

SCUTELLIDÆ.

Echinodiscus auritus, Leske.

Dredged at many points on the west and south coasts of Ceylon, including Stations I., II., XI., XII., XIV., XXXIV., XXXVIII., XXXIX., XLIX., LI., LVI., LXII., and LXIX.

The specimens ranged from 1 centim. to 11 centims. in length.

PETALOSTICHA.

CASSIDULIDÆ.

Echinoneus cyclostomus, Leske.

One specimen, about 1·8 centims. in length, was dredged to the west of Periya Paar, at Station LXIII.; depth, 17 to 55 fathoms.

Echinolampas oviformis (Gmel.).

Dredged on the pearl banks, Gulf of Manaar, at Stations IV., XI., XLVIII., XLIX., LV., and LXIII.

The specimens ranged in diameter from 2 centims. to 10 centims.

SPATANGIDÆ.

Maretia planulata (Lamk.).

A few specimens, from 2 centims. to 3·5 centims. in length, were dredged in the Gulf of Manaar, at Station IV., opposite Karkopani, 6 to 9 fathoms; Station XLIX., south of Cheval Paar, 12 fathoms; Station LV. and LXIII., west of Periya Paar, 11 to 36 fathoms.

Maretia alta, A. Agass.

At Station XXXIII., south of Arugam Bay, east of Ceylon, 18 fathoms; off Galle; and south of Modragam.

Lovenia elongata (Gray).

Several specimens were dredged between Colombo and Palk Strait, and also off Welligam and Galle, at Stations I., IV., XI., XXXIV., XXXIX., XL., XLIII., XLVIII., XLIX., LV., and LXIII., at depths of 2 to 40 fathoms. They range in length from 2 centims. to 6 centims.

LESKIIDÆ.

Schizaster gibberulus, Agass.

One specimen (2·5 centims. in length) from Station LV., south-west of Periya Paar, 11 to 24 fathoms.

ASTEROIDEA.

ASTROPECTINIDÆ.

On the characters of the species of *Astropecten* see Professor BELL's Notes (p. 148, below).

Astropecten hemprichi, M. and T.

Stations I., IV., X., XIV., XX., XXVIII., XXXII., XXXIX., XLII., XLVII. and LIV., practically all round the island, at depths of 4 to 40 fathoms. It is especially abundant on some parts of the pearl banks.

Astropecten euryacanthus, LÜTKEN.

Station XX., Back Bay, Trincomalee, 11 to 13 fathoms.

Astropecten polyacanthus, M. and T.

Station XXVIII., Trincomalee, 7 to 14 fathoms; Station XXXVIII., off Galle, 9 to 22 fathoms; Station LX., outside Muttuvaratu Paar, 20 to 30 fathoms; Station XLIII., west of Kaltura, 22 fathoms; and Station LXIII., west of Periya Paar, 36 fathoms.

Astropecten indicus, DODERLEIN.

Off Galle. Also Station XXXIV., off Welligam, at south end of Ceylon, 7 fathoms.

Astropecten zebra, SLADEN.

Trincomalee. (See Professor BELL's Notes, p. 149, below.)

Luidia maculata, M. and T.

Abundant all round Ceylon, and especially in the shallow water of the pearl banks in the Gulf of Manaar, where we obtained specimens of all sizes from a couple of centimetres up to well over a foot across.

Luidia hardwickii (GRAY).

Pearl banks, Gulf of Manaar. Professor BELL reports that "from the same locality there is a very interesting young specimen which belongs either to some undescribed species, or is, as is quite likely, the armed young of an unarmed adult, for it is provided with spines on the surface of its rays."

PENTAGONASTERIDÆ.

Stellaster incei (GRAY).

Stations XX. and XXI., Trincomalee, many; between Colombo and Palk Strait;

off Galle, 16 to 20 fathoms; 12 miles south of Galle, 100 fathoms; Station XLIV., off Kaltura, 30 fathoms; Station LIV., south of Adam's Bridge, 4 to 40 fathoms.

Young Stellasters from Station XLIII., west of Kaltura, 22 fathoms; from Back Bay, Trincomalee, and from other localities, are in the collection.

ANTHENEIDÆ.

Anthenea sp?

In the lagoon of the reef at Galle.

Goniodiscus, sp. (?)

Professor BELL adds "? young *Goniodiscus*," from locality (?) in Gulf of Manaar.

FAMILY: PENTACEROTIDÆ.

Pentaceros lincki, DE BL.

From lagoon inside reef, Galle. Common on the pearl banks in the Gulf of Manaar, and of importance as an enemy of the pearl oyster (see figure on p. 147).

Pentaceros mammillatus (M. and T.).

West of Periya Paar; at Station LXIV., south-east of Modragam Paar, 5 fathoms.

Pentaceros nodosus (GRAY).

Station III., off Chilaw, 12 fathoms; Station XLII., off Barberyn, 40 fathoms; Station LIV., south of Adam's Bridge, 4 to 40 fathoms; Station LXIV., south-east of Modragam Paar, 5 fathoms.

Pentaceros, sp. (young).

Station XLIII., west of Kaltura, 22 fathoms.

Culcita schmideliana (RETZ.).

Station LIX., Muttuvaratu Paar, 8 fathoms; and Station LX., outside Muttuvaratu Paar, 20 to 30 fathoms.

This cushion-like starfish is almost circular in outline when alive, but shows on the oral surface a bright orange-coloured pentagon closely papillated and with the ambulacral grooves running as narrow red lines out to the angles. On the aboral surface there are short red spines on the well-marked lobed areas, while the surface between has a fine fluffy or velvet-like appearance. The larger specimen measures 19 centims. in diameter and 10 centims. in height, and is much less spiny on the aboral surface than the smaller specimen, which is about 14 centims. in diameter and 8 centims. in height. The animal when alive has a much more globular form than have preserved specimens.

ASTERINIDÆ.

Asterina cepheus (M. & T.).

Station LXVI., off Mutwal Island, 10 to 35 fathoms; off Galle, in deep water; on Navakaddu Paar, April 2nd, 1902; Station IV., off Karkopani, 6 to 9 fathoms; Station XLI., 12 miles south of Galle, 100 fathoms.

LINCKIIDÆ.

Ophidiaster cylindricus (Lamk.).

Station XXXVIII., outside Watering Point, Galle, 9 to 22 fathoms.

Ophidiaster helicostichus (Sladen).

What may be the young of this little-known species was taken south of Galle, in deep water.

Linckia multiforis (Lamk.).

Specimens (including "comet forms") were obtained from Back Bay, Trincomalee; also at Station XXIII., 6 fathoms.

Linckia lævigata (Gmel.).

On the pearl banks in the Gulf of Manaar; and at Station XIV., west of Cheval Paar, 8 fathoms.

Linckia pacifica, var. **diplax** (*teste* Sladen).

Muttuvaratu Paar, Gulf of Manaar.

Nardoa tuberculata, Gray.

From lagoon inside the reef, Galle; and at Station LX., outside Muttuvaratu Paar, 20 to 30 fathoms.

Metrodira subulata (Gray).

Station XLIII., west of Kaltura, 22 fathoms.

PTERASTERIDÆ.

Retaster cribrosus, v. Mart.

At Station XLII., between Galle and Barberyn, 40 fathoms, one specimen (see Professor Bell's Notes, below).

ECHINASTERIDÆ.

Echinaster purpureus (Gray).

Station LXIV., south-east of Modragam Paar, 5 fathoms; Station VI., Muttuvaratu Paar, 6 to 9 fathoms; Station XIV., west of Cheval Paar, 8 fathoms; and other localities on the pearl banks, Gulf of Manaar.

OPHIUROIDEA.

Pectinura gorgonia (M. and T.).

Gulf of Manaar, pearl banks; Station LXIII., west of Periya Paar, 36 fathoms; Station X., off East Cheval Paar, 6 fathoms.

Both adult and young stages were found in abundance on the pearl banks.

Pectinura intermedia, Bell.

Gulf of Manaar, pearl banks; Station I., off Negombo, 12 to 20 fathoms.

Ophiura, sp.

From the Cheval Paar. This is not *O. kinbergi*, which is known from this neighbourhood.

Amphiura, sp.

At Station LIII., 10 miles north of Cheval Paar, 9 fathoms; Station XLVII., south of Cheval Paar, 9 fathoms; also off the south-east coast of Ceylon (see Professor Bell's Notes below, p. 149).

Ophionereis, **?** sp.

Young forms from the Cheval Paar, 6 to 8 fathoms.

Ophiocnemis marmorata (Lamk.).

Trincomalee, various localities, February, 1902; Gulf of Manaar, March, 1902; Station VI., Muttuvaratu Paar, 6 to 9 fathoms; Station XVII., west of Periya Paar, 11 fathoms; Station XX., Back Bay, Trincomalee, 11 to 13 fathoms.

Ophiocoma scolopendrina, Agass.

Station LX., outside Muttuvaratu Paar, 20 to 30 fathoms.

Ophiarachna incrassata, M. and T.

Very young specimens, probably of this species, were dredged in deep water off Galle.

Ophiothrix, spp. (**? O. aspidota, O. nereidina,** and others).

Station XLVI., off Mount Lavinia, 25 to 30 fathoms; Station LXIII., west of Periya Paar, 36 fathoms; off Galle, deep water, up to 100 fathoms; Station XLV., off Pantura, 25 fathoms; on Jokkenpiddai Paar, April 3rd, 1902; on Aripu Reef, shallow water.

Three "species" from Cheval Paar, from Trincomalee, and from Gulf of Manaar (see Professor Bell's Notes below, p. 150).

Ophiomaza cacaotica, LYM.

Gulf of Manaar, pearl banks; Station XV., on Periya Paar, 9 fathoms.

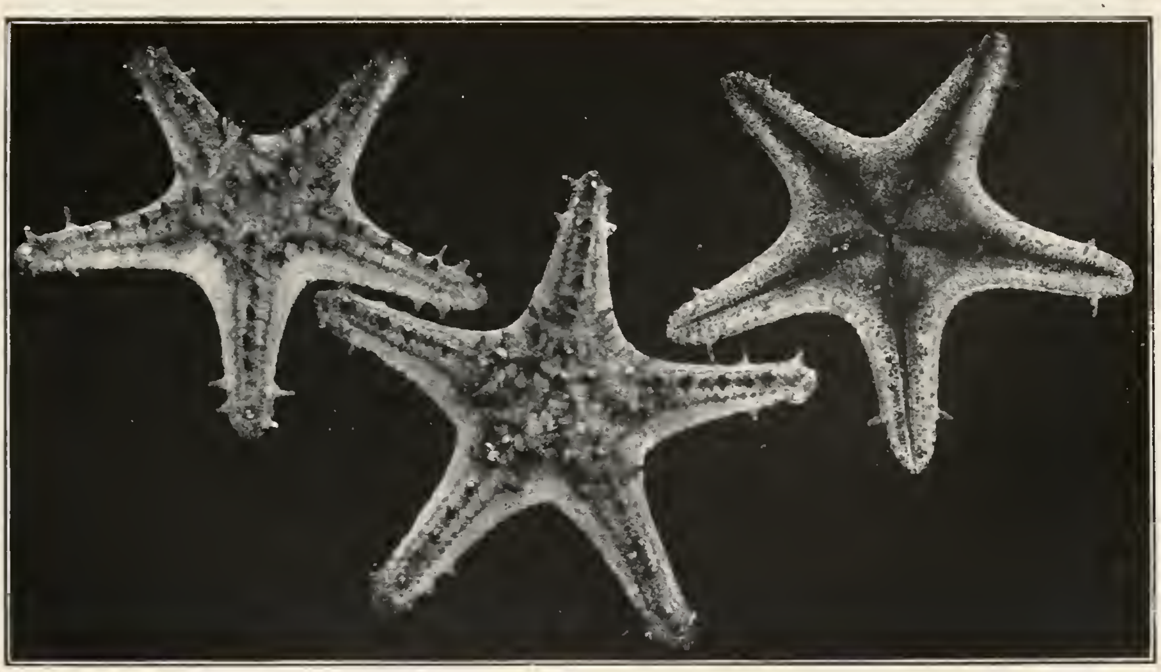
Ophiopteron elegans, LUDWIG.

Station LXIII., west of Periya Paar, 17 to 55 fathoms.

Ophiomyxa, ? sp.

Young specimens from deep water off Galle and from Trincomalee.

There are probably other species of Ophiuroids in the collection. A number of the smaller—possibly immature and in some cases imperfect—specimens remain unnamed. Professor BELL's remarks below refer to some of these.



Specimens of *Pentaceros lincki*, DE BL., from the Gulf of Manaar.

SOME NOTES ON THE ABOVE-NAMED COLLECTION OF ECHINODERMS.

BY

F. JEFFREY BELL, M.A.,

EMERITUS PROFESSOR AND FELLOW OF KING'S COLLEGE, LONDON.

I had the advantage of going through the eleutherozoic actinogonidiate Echinoderms with Professor HERDMAN himself, and he has included my determinations in the above list. The more difficult specimens I brought to London for determination in the National Collection, and on these, and on some general aspects of the subject, I take leave to say a few words.

(1.) The collection contains a large number of specimens of common Indo-Pacific Echinoderms and a goodly store of young forms; these it is most necessary to keep with their generic allies; the determination of their *species* is quite a trivial matter as compared with the importance of obtaining a rich and extensive series of stages, showing the variations due to increase in size, and also the numerous individual variations which wide-spread species of Echinoderms always exhibit.

(2.) The absence of some of the species which at present we are inclined to associate with Ceylon, such as *Asthenosoma urens*, *Fromia tumida*, *Ophiothela holdsworthi*, is to be deplored, but the general character of the collection leads us to suppose that these species are local even in Ceylon; the presence of *Ophiopteron elegans*, which Mr. STANLEY GARDINER obtained in his expedition to the Laccadives, confirms me in my view that this species is widely distributed in the tropical waters of the Indian Ocean.

(3.) On one important matter I have at last some hope that we are on the way to a solution. In 1887 the late P. M. DUNCAN* observed "One of the commonest species of the Ophiurida is a . . . . . form which is usually found without a top to the disk," but the fact, apart from the difficulty it produced as to naming the genus, did not appear to him to be of any interest.

In 1888† I somewhat pointedly drew attention to the same phenomenon, and I ventured to remark, "Naturalists who have the opportunity of observing this long-armed form in life should direct particular attention to this loss of the disk, with a view to answering such questions as to whether the loss is in any way associated with the act of reproduction, whether the disk becomes restored, and, if so, whether the restoration is effected rapidly."

* 'Journ. Linn. Soc. Zool.,' vol. XXI., p. 90.

† 'Ann. and Mag. Nat. Hist.,' p. 368.

Dr. SLUITER* has since put on record his regret that he did not become acquainted with my note, when he still had under his eyes Ophiuroids that were living in his aquaria without the dorsal covering to their disks. The phenomenon seems to be pretty common, and there are a number of interesting biological problems associated with it which should attract naturalists in tropical and subtropical seas.

After some search I lit on a long-armed Ophiuroid with the upper surface of the disk intact; it was soon easy to see that this was not the *Ophiocnida imbricata* in which Dr. SLUITER had noticed the phenomenon, and I was inclined to ascribe it to *Amphiura divaricata*, but the arms of that species, as described by LJUNGMAN, are much shorter. It appears to be a true, but unnamed, Amphiuran.

(4.) I beg once more to offer an example of the variability of Echinoderms, and to call attention to the mode of distribution of the spicules on the superomarginal plates of *Astropecten hemprichi;* the three figures here shown are taken from the three

specimens found in the bottle to which the late Mr. SLADEN affixed the name of *Astropecten zebra.* In the "Challenger" Report *A. zebra* occupies the following position in the author's "key":—

(A.) With small spinelet, on the first four or five plates.

(*a.*) With four or five spinelets. A well-developed series of pseudo-pedicellariæ . . . . *zebra.*

(*b.*) With one spine only on the first plate. No pedicellariæ . . *velitaris.*

Inspection of my photographs will show how little constant is the number of spinelets, and the uselessness of the character as an aid to specific distinction.

* 'Tijds Nederl. Dierk. Ver.,' v. (1898), p. 306.

A. zebra should, I think, be united with *A. hemprichi*.* Perhaps, also, SLADEN'S *A. notograptus* is another synonym.†

(5.) The evidence in favour of the great variability of Echinoderms is now overwhelming, and new species should only be made on the most solid grounds. The condition into which the genus *Ophiothrix* has been allowed to fall by the uncritical establishment of a multitude of species is such that I had to tell Professor HERDMAN that I could not undertake the determination of the numerous forms in his collection that appear to the cabinet naturalist to be very different, but which, if we may argue from what we know of the genus in our own seas, would be all brought up by one haul of the dredge. A critical revision of the described species of *Ophiothrix* by a naturalist of unlimited leisure would be a boon to the systematist; the uncritical addition to our list of forms "which appear to be distinct" is of no service whatever to science.

(6.) As in all carefully prepared collections, there are a number of small Ophiuroids, many more or less broken; I have referred all I can to their genus, and have sometimes made suggestions as to their species.

(7.) A small specimen of *Retaster*, from deep water off Galle, is not unlike a young example which BEDFORD has placed in the same bottle as an adult *R. cribrosus;* this species is already recorded from Ceylon. With *R. cribrosus*, BEDFORD associates *R. insignis* of SLADEN. The chorology of this species is given by its author as including "Port Jackson (*fide* BELL)." The punctuation of the sentence is faulty, but I do not delay over that, as I have to point out that I think the locality, "Port Jackson," is an error. The statement is made in a paper of mine in vol. 9 of the 'Proceedings of the Linnean Society of New South Wales,' the proofs of which were never seen by me, and which teems with misprints; *Retaster* itself is misprinted. In the British Museum there is no specimen of the species from so far south as Port Jackson, and in the report of the "Alert" collections, written while the collections of the Australian Museum were in my hands, I record specimens from Port Molle and Thursday Island (p. 134), while on p. 173 I cite the species as one limited to "inter-tropical Australia."

* I have taken the opportunity of examining the "types" of *A. velutans;* they are all immature, and are, perhaps, not members of the same species.

† Describers of young Star-fishes should have their memoirs placed in some scientific Index Expurgatorius; they take no trouble, and give much.

REPORT

ON THE

CRINOIDEA

COLLECTED BY

PROFESSOR HERDMAN, AT CEYLON, IN 1902.

BY

HERBERT C. CHADWICK,
CURATOR OF THE BIOLOGICAL STATION, PORT ERIN, ISLE OF MAN.

[WITH ONE PLATE.]

THE collection of Crinoidea obtained by Professor HERDMAN during his expedition to Ceylon, and kindly placed in my hands for examination, is a most interesting one, and makes a substantial addition to our knowledge of the Comatulid fauna of Ceylon. No less than 10 species, of which one at least appears to be new to science, are added to the list of species already known from that country, and although it is remarkable that in so large a collection no specimen of *Antedon adeonæ*, one of the first species recorded from thence, should be found, it is very satisfactory to be able to give a full description of another early, but little-known species, *A. reynaudi*.

I wish here to express my sincere thanks to Professor HERDMAN for his kindness in entrusting the collection to me, and in procuring for me copies of several important papers. For similar generous help in regard to literature I would thank also my friends Dr. W. E. HOYLE, Mr. F. W. HEADLEY, Mr. R. OKELL and Mr. C. ROEDER.

The following is a list of the stations at which Comatulidæ were obtained, arranged according to their geographical position :—

West Coast of Ceylon.

STATION I.—Five miles west and south-west of Negombo, 12 to 20 fathoms ; bottom coarse yellow sand with a few dead shells ; temperature of sea, 77·5° F.

STATION II.—From 7 to 14 miles north of Négombo, 5 miles off shore ; 8 to 9 fathoms ; bottom coarse yellow sand, shells, stones, and small coral ; temperature of sea, 77·5° F. ; specific gravity, 1·023.

STATION III.—Off Chilaw, $2\frac{1}{2}$ to 4 miles off shore; 9 to 14 fathoms; bottom coarse sand and small corals; temperature of sea, 77·75° F.; specific gravity, 1·023.

STATION XLVI.—From off Mount Lavinia northwards to off Colombo, from 7 to 12 miles off shore; depth 25 to 30 fathoms; bottom Nullipore balls (*Lithothamnion fruticulosum*), Coral fragments and some Orbitolites sand.

STATION LXVI.—From south of Donnan's Muttuvaratu Paar along the west of the northern part of Mutwal Island as far as off Mudalaikuli Paar; depth 10 to 35 fathoms; bottom Nullipore and Orbitolites sand, some red Algæ and dead Coral.

STATION LXVIII.—From off Coppeluddi southwards to Navakaddu Paar; depth 8 to $18\frac{1}{2}$ fathoms; bottom Nullipores (*Lithothamnion fruticulosum*), Coral and muddy Orbitolites sand.

STATION LXIX.—On and to the east of the north end of Chilaw Paar; depth 8 to 11 fathoms; bottom yellow quartz sand, with some Coral fragments. Yellow Algæ with Oyster spat.

Gulf of Manaar.

STATION IX.—On south-west corner of West Cheval Paar, about 12 miles from land; depth 7 fathoms; bottom fine quartz gravel, Nullipore concretions and many dead young pearl oyster shells; temperature of sea, 78° F.; specific gravity, 1·023.

STATION LIII.—Ten to 12 miles north of Cheval Paar and about 12 miles due west of Vankali (or Bangalli) Church; depth $7\frac{1}{2}$ to 9 fathoms; bottom muddy sand with some dead shells.

STATION LIV.—In northern part of Gulf of Manaar, south of Adam's Bridge; depth from 4 to 40 fathoms; bottom varied, from sand to living Coral.

STATION LVII.—Outside Dutch Moderagam Paar; $11\frac{1}{2}$ to 36 fathoms; bottom Orbitolites sand, Nullipores and dead Corals.

STATION LXIII.—To the west of Periya Paar, going south; depths 17 to 55 fathoms; bottom Orbitolites sand, some dead Coral, shells and pieces of Nullipore.

Off Trincomalee.

STATION XXIII.—Close to Swami Rock, Back Bay; depth $4\frac{1}{2}$ to 8 fathoms, mostly between 5 and 6 fathoms; bottom sand, shells, and in places stones and Corals.

STATION XXIV.—Two and a half to 3 miles north of Foul Point; depth ranging from 46 to 24 fathoms; bottom hard and rough—probably rock.

STATION XXV.—Three-quarters of a mile to 1 mile west north-west of Foul Point; depth 8 fathoms; bottom firm, Orbitolites sand and Nullipores.

South Coast of Ceylon.

STATION XXXIV.—Welligam Bay, various parts; depths 2 to 7 fathoms; bottom shell sand and a little mud; sea temperature at 7 A.M., 77·8° F., specific gravity, 1·0225.

STATION XXXIX.—From 2 miles south of Point de Galle westwards to Gallehogalle Bank; depths 16 to 30 fathoms; bottom fine sand; stones and Nullipore on the bank.

STATION XLI.—South of Galle, about 12 miles off land; depth along the 100-fathom line; bottom composed of masses of calcareous branched and ramifying Foraminiferal tubes.

List of Ceylon Comatulidæ.

The species marked with an asterisk were collected by Professor Herdman and were not previously known from Ceylon. The species new to science is indicated by a dagger. *Antedon carinata* and *A. reynaudi* are the only species in the collection previously recorded from Ceylon.

**Antedon serripinna*, Carpenter.	*Antedon palmata* (Müller).
* ,, *milberti* (Müller).	,, *reynaudi* (Müller).
,, *carinata* (Lamarck).	* ,, *anceps*, Carpenter.
,, *adeonæ* (Lamarck).	* ,, *variipinna*, Carpenter.

* ,, *bella*, Hartlaub.	* ,, *multiradiata* (Linn.).
† ,, *okelli*, n. sp.	,, *parvicirra* (Müller).

CRINOIDEA.

COMATULIDÆ.

Antedon serripinna, Carpenter.—Plate, figs. 1, 2, 2A.

The type specimen of this species described by P. H. Carpenter has only 12 marginal cirri, in which the number of joints is 18, while the specimens described by Hartlaub have 20 cirri, consisting of 20 joints. The specimens in this collection from Ceylon have 15 cirri, consisting of 17 joints, of which all from the second to the antepenultimate have a strong transverse dorsal ridge. This is near the distal end in the first few joints, but becomes median and, viewed in profile, spine-like in the later ones. The penultimate joint has a strong opposing spine (Plate, figs. 2, 2A). The arms of the Ceylon specimens are slender and serrate, and contain about 150 joints. The 2nd and 3rd syzygies are situated in the 8th and 12th brachials respectively, as in the specimens described by HARTLAUB, but in the type the 2nd syzygy is between the 11th and 15th brachials. In the specimens under notice, the succeeding syzygies occur in every 5th to 7th joint. The pinnule of the 2nd brachial (Plate, fig. 1) has 11 joints, the first 3 broad, the remaining ones cylindrical, twice as long as broad, and having 2 very minute spines projecting from their distal ends. The pinnule of the 4th brachial is stouter than, and nearly twice as long as that of the 2nd, and has 13 joints of very similar character; while that of the 6th brachial has 9 or 10 joints, and is a smaller pinnule than that of the 2nd. The pinnules of the 3rd, 5th, and 7th brachials are smaller than those of the 2nd, 4th, and 6th, but the joints are similar, as are those of the next 10 or 12 pairs, though in the latter the basal ones differ in diameter less markedly from their successors.

Localities:—Stations XXIII., XXIV., and XXV., off Trincomalee: a number of more or less mutilated specimens. Many greyish mottled ones were found upon a large colony of *Gorgonia* (*Rhipidogorgia*) *flabellum* from Station XXIII.

Antedon milberti (MÜLLER).

A small specimen of this species was obtained at Station L., and 2 full-grown ones at Station LVII. In one of the arms of one of these, unfortunately detached when found, the 5th brachial beyond the 3rd syzygy is an axillary, and there is a syzygy in each of the 3rd brachials beyond it.

Antedon carinata (LAMARCK).

One specimen of this widely distributed species was dredged at Station LIV., and several mutilated ones at Station LXVIII.

Antedon marginata, CARPENTER.

One considerably mutilated specimen of this species was dredged at Station XXXIX. It has 11 arms, and most of the 2nd pinnules agree well with those of the single specimen dredged by the "Challenger" at Station 208, off Manilla, which CARPENTER says "Terminate so abruptly that they seem to have been broken off by some accident and not completely repaired. The diameter of the joints suddenly decreases, and there are from 1 to 4 quite small joints at the end of a large and stout one which is considerably longer than wide." A small specimen from Welligam Bay (Station XXXIV.) may possibly belong to this species. The number of arms cannot be determined, but in one of the rays the outer face of the distichal axillary bears two palmars.

Antedon indica, SMITH.

One specimen of this species, with 29 arms, was dredged at Station LIV. The original visceral mass is almost completely displaced, but remains in organic continuity with a new one in an early stage of formation.

Antedon bella, Hartlaub.

Specimens of this beautiful species were dredged at Stations LIII. and LVII. One of those from the first-named station has 28 arms, and the other, now much mutilated, must have had the same number when living, palmars being present on the outer side of both distichal series in three of the rays. The specimens from Station LVII. agree with the type in possessing 20 arms. A specimen of what appears to be Hartlaub's variety *brunnea* was obtained at the last-named station.

Antedon okelli, n. sp.—Plate, figs. 3 to 5.

Centro-dorsal a moderately thick, roughly circular disk, with flat or very slightly convex dorsal surface, and bearing upon its sloping sides 20 to 25 cirri. These have 25 to 28 joints, of which the more distal ones are compressed and carinate, and the penultimate bears an opposing spine (Plate, fig. 4). First radials distinctly visible; the 2nd broad, well rounded, and forming a tubercular elevation in their median line of junction with the axillaries, which are broadly pentagonal and about $1\frac{1}{2}$ times the length of the 2nd radials (Plate, fig. 3). Two distichals and 2 palmars, the axillaries without syzygy. The palmars are borne upon the outer face of the distichal axillaries of one or both sides of the ray, generally the latter. Median tubercles formed by both distichals and palmars. The rays have slight marginal projections. Twenty-six to 30 arms, of about 120 joints, of which the first 7 or 8 are moderately thick disks. These are followed by rather more than 20 triangular joints, and these again by wedge-shaped ones, which become longer in proportion to their width as the tip of the arm is reached. Syzygies in the 3rd, 13th or 14th, 20th or 21st joints, and then every seventh or eighth joint.

Of the first pair of pinnules, that borne by the 2nd brachial on the outer side of the ray has 18 to 20 joints, of which only a few of the more distal ones are longer than wide (Plate, fig. 5). Its fellow on the 3rd brachial is smaller and more slender, and has 16 or 17 joints. The pinnule of the 4th brachial has 20 to 22, or even 24 joints. It is considerably stouter and longer than that of the 2nd, and its joints diminish in size more gradually; while that of the 5th brachial has 19 or 20 joints, but in all other respects is precisely like that of the 4th. The 3rd pair of pinnules, borne by the 6th and 7th brachials respectively, are smaller than the 1st, and have 14 to 16 joints. The basal joints of all these pinnules and of the 3 or 4 succeeding pairs are distinctly carinate, the latter especially so. The corresponding pinnules on the inner arms of the rays are a little smaller and have slightly fewer joints.

Colour in spirit—creamy white, mottled and striped with deep reddish-brown. Margins of bases of rays and long tubular anal funnel with spots of same colour (Station I.). These are described as "black and white" when living. Others ashy or purplish-grey to deep purple, almost black. In the paler specimens the skeletal joints are marked with narrow bands of deep purple, and the disk has spots of the same colour. Sacculi abundant on pinnules, less so on disk.

Disk, 1 centim., deeply incised; spread, 10 centims.

Locality:—Stations I., II., and LVII. Twenty-two specimens, of which 12 were from Station II.

This species is closely allied to *Antedon brevicuneata*, CARP., *Antedon similis*, CARP., and *Antedon regalis*, CARP. It differs, however, from each of them in having all 3 radials visible, a much smaller number of cirri, shorter arms, and carinate basal joints on the lower pinnules.

I have associated this species with the name of Mr. ROBERT OKELL, B.A., F.L.S., Hon. Secretary of the Isle of Man Sea-Fish Hatchery Committee, to whom I am indebted for much kind help with the literature of the subject.

Antedon reynaudi (MÜLLER)—Plate, figs. 6 to 12.

As this species was very briefly described by MÜLLER, and is still very imperfectly known, I have thought it useful to give the following full description of the Ceylon specimen, accompanied by the necessary figures.

Description of an Individual.—Centro-dorsal a thick disk, with convex dorsal surface, and bearing on its sloping sides, in two alternating rows, 25 cirri. Of these all but a few immature ones are rather more than 2 centims. long, and have 35 or 36 joints, all of which are slightly wider than long, the later ones being laterally compressed, and bearing, from the 14th onwards, a strong and forwardly directed spine (Plate, fig. 8).

First radials entirely concealed; the 2nd just visible beneath the bases of the cirri, and in almost complete contact laterally. Axillaries widely pentagonal, about half as long again as the 2nd radials and without syzygy. Eighteen arms of about 200 short and slightly overlapping joints (fig. 12). The 1st distichals are in almost complete contact laterally, and form a slight tubercular elevation in their median line of junction with the second. The first 8 brachials are discoid, the two 1st in almost complete contact laterally, and are succeeded by about 30 shortly triangular joints. These again are followed by discoid ones which continue to the tip of the arm.

Two of the rays have each two series of 3 distichals (fig. 7), the axillaries having a syzygy; other two have each (fig. 6) one series of 3 distichals, the axillaries having a syzygy, and one series of brachials arising directly from the radial axillary. The remaining ray has two series of 2 distichals, the axillaries having no syzygy. The position of the brachials in which syzygies occur is very irregular, as shown by their enumeration in 6 series, as follows:—

(1.)	Brachials,	3, 12, 19, 25, 33, 42, 50, 58, 66.
(2.)	,,	3, 8, 12, 18, 25, 28, 35, 42, 55, 63, 67, 73, 80.
(3.)	,,	3, 14, 23, 31, 38.
(4.)	,,	3, 14, 23, 32, 46, 55.
(5.)	,,	3, 15, 21, 28, 34.
(6.)	,,	3, 6, 29.

The distichal pinnule (fig. 9) is about 1 centim. long, flagellate, and composed of 31 joints, the first 7 broad, flattened, and carinate, the later ones gradually becoming cylindrical, longer than broad and with rounded ends. The 1st and 3rd pairs of brachial pinnules are about equal in size, those borne by the 2nd and 6th brachials (fig. 11) having about 29 joints. The 2nd pair of pinnules are the largest on the arm, that of the 4th brachial (fig. 10) being about 15 millims. long, but having 27 joints only. The basal joints of these 3 pairs of pinnules are flattened and more or less carinate. The 5th pair are the shortest, the succeeding one gradually increasing in length. Disk considerably incised and ambulacra naked. Sacculi abundant and close-set on arms and pinnules, absent on disk.

Colour in spirit—disk chocolate-brown, fading to white in the interambulacral angles; arm joints pinkish, with the articulations of the proximal fourth marked with bands of deep reddish-brown, which gradually fade into dots on the sides of the arms. Pinnules irregularly banded with brown and white.

Disk 1 centim., spread probably 22 centims.

Locality:—Station XXXIV.

It is to be regretted that strong reflexion of the arms over the dorsal surface of the disk in the only specimen obtained has made delineation of the skeleton rather difficult. The bidistichate ray is not improbably an abnormality.

Antedon anceps, Carpenter.

Two specimens of this species were dredged, one at Station XXIV., and the other at Station LVII. Both have a single distichal series and 11 arms. The colour, when living, was black.

Antedon variipinna, Carpenter.

A considerable number of specimens of this remarkable species were dredged at Station II. They have 20 to 21 fairly smooth arms, 30 to 36 cirrus joints, the later ones carinate, and the 1st radials are only visible in side view.

Actinometra notata, Carpenter.

One specimen of this species was obtained at Station LIV. Carpenter's diagnosis assigns to it 30 to 35 cirri and 31 to 50 arms, but the specimen under notice has only 20 cirri, 8 of which are quite small and immature, and 20 arms. The 1st radials are distinctly visible and almost completely united laterally. They are also connected with the centro-dorsal by five interradial projections from the latter.

Actinometra multiradiata (Linn.).

Single specimens of this species were dredged at Stations IX., XLI., LIII., and LXVI. That from the first-named station has 12 arms only. Two of the rays have each a series of 3 distichals, the axillary with a syzygy, and a syzygy in each of the 2nd brachials; but in all the arms which arise directly from the radial axillaries the 1st syzygy is in the 3rd brachial. The diameter of the 22 arms of the specimen from Station LXVI. gradually increases from the 1st to about the 20th brachial.

Actinometra parvicirra (Müller)—Plate, figs. 13, 14.

Specimens of this well-known species were dredged at Stations IX., XLI., XLVI., LIV., LVII., LXIII., and LXIX. The number of arms varies from 10 in a specimen from Station XLI. and 11 in one from Station LVII. to 48 in one from Station IX. So far as I am aware, no 10-armed specimen of this species has hitherto been discovered; and as the form and disposition of the 2nd and 3rd radials of the one under notice differ markedly from the same parts in the other specimens in the collection and from those figured in Carpenter's Report on the Comatulidæ of the "Challenger" Expedition, I have thought it worthy of illustration (fig. 13). It will be seen that the disk is covered with minute scale-like plates (fig. 14), which, I presume, are similar to those covering the disk of the specimen from Torres Straits, mentioned by Carpenter. The specimens with 44 and 48 arms respectively approach *Actinometra regalis*, Carp., in having no spines, or but feebly developed ones, on the penultimate joints of the cirri, and in the close lateral contact of the 2nd and 3rd radials and 1st distichals. Several distichal series consisting of two joints occur in most of the specimens. The colour of one of the specimens from Station LXIX. is described in Professor Herdman's diary as being, when living, "of a deep olive-brown with yellow tips to the pinnules, and having an olive-brown species of *Alphæus* striped with grey living on it." Some of those from Station XLVI. were "dark purple," others "orange coloured."

DESCRIPTION OF PLATE.

Fig. 1. Base of an arm of *Antedon serripinna*, with pinnules of 2nd, 4th, 6th, and 8th brachials. × 10.
" 2. A cirrus of *Antedon serripinna*. × 10.
" 2*a*. Portion of same, viewed from the dorsal surface. × 10.
" 3. *Antedon okelli*, n. sp. × 4.
" 4. A cirrus of *Antedon okelli*. × 8.
" 5. Base of an arm of *Antedon okelli*, with pinnules of 2nd, 4th, 6th, 8th, and 10th brachials. × 10.
" 6. A ray of *Antedon reynaudi*, with one series of distichals and an arm springing directly from the radial axillary. × 5.
" 7. A ray of *Antedon reynaudi*, with two series of distichals. × 5.
" 8. A cirrus of *Antedon reynaudi*. × 5.
" 9. Distichal pinnule of *Antedon reynaudi*. × 5.
" 10. Pinnule of 4th brachial of *Antedon reynaudi*. × 5.
" 11. Pinnule of 6th brachial of *Antedon reynaudi*. × 5.
" 12. Portion of an arm of *Antedon reynaudi*, viewed from the dorsal surface. × 4.
" 13. A 10-armed specimen of *Actinometra parvicirra*, viewed from the dorsal surface. × 8.
" 14. Disk of the same specimen, viewed from the ventral surface. × 8.

REPORT

ON THE

CUMACEA

COLLECTED BY

PROFESSOR HERDMAN, AT CEYLON, IN 1902.

BY

W. T. CALMAN, D.Sc.

[WITH PLATES I. TO V.]

THIS paper deals with the Crustacea belonging to the Order CUMACEA * collected in Ceylon by Professor W. A. HERDMAN, F.R.S., and his Assistant, Mr. HORNELL. The following ten species are described in detail, and all of these are regarded as new except one :—

1. *Eocuma taprobanica*, n. sp.
2. *Eocuma affinis*, n. sp.
3. *Eocuma sarsii* (KOSSMANN).
4. *Cyclaspis costata*, n. sp.
5. *Cyclaspis picta*, n. sp.
6. *Cyclaspis herdmani*, n. sp.
7. *Cyclaspis hornelli*, n. sp.
8. *Iphinoë macrobrachium*, n. sp.
9. *Paradiastylis brachyura*, n. sp.
10. *Nannastacus stebbingi*, n. sp.

In addition to these the collection includes the following six species which are not dealt with more fully here for the reason that they are represented by solitary or immature specimens, or that they belong to species of which more abundant material is at hand in other collections now in course of examination. The list is given in order to complete, as far as possible, the record of the Ceylon fauna as shown by the present collection :—

* Mr. STEBBING has shown (WILLEY'S 'Zool. Results,' Part V., Crustacea, p. 609) that the generic name *Cuma*, H. MILNE-EDWARDS, is preoccupied and must give way to *Bodotria*, GOODSIR, and he has proposed to change the name of the order to SYMPODA. So far as I am aware, no rule of zoological nomenclature is infringed by retaining the familiar name CUMACEA, which may still be thought not "wholly inappropriate and misleading" for an order comprising many genera with names like *Pseudocuma*, *Leptocuma*, *Eocuma* and so forth.

(1.) *Eocuma* sp.—Taken in the tow-net in Galle Bay after dark. A young and damaged specimen, apparently distinct from any of the species described below.

(2.) Bodotriidæ, n. gen. and sp.—Gulf of Manaar, near the shoal buoy, north of Karativo Island. A very young specimen belonging to an undescribed species (representing a new genus), of which a large series of specimens from the Gulf of Siam is in the collection of the Copenhagen Museum.

(3.) *Cyclaspis* sp.—From the Cheval Paar and Kondatchi Paar. Two young specimens of a species which is also represented in the Copenhagen collection from Siam.

(4.) *Cumopsis* (?) spp.—Several immature specimens from various localities on the Cheval Paar, and off Chilavaturai, in the Gulf of Manaar.

(5.) *Cumella* sp.—From the Cheval Paar and near the shoal buoy north of Karativo Island.

(6.) *Nannastacus* sp.—From the Cheval Paar, and $2\frac{3}{4}$ miles south-south-west of Chilavaturai, in the Gulf of Manaar.

The great majority of the species of Cumacea hitherto described are inhabitants of northern seas, and only a very few (some 13 out of a total of about 170 species) have been found within the tropics. It can hardly be doubted, however, that, as in the case of other groups of micro-crustacea, this preponderance of northern species is more apparent than real, and is due to the fact that collectors in tropical countries have their attention claimed by the more conspicuous elements of the fauna to the exclusion of the more minute and less obtrusive forms. No Cumacea have hitherto been recorded from any part of the Indian Ocean, although four species have been described by Paulson and by Kossmann from the Red Sea, and one of these is represented in the present collection.

The types of the species described below have been presented by Professor Herdman to the British Museum (Natural History).

Family: BODOTRIIDÆ.

Eocuma, Marcusen.

Marcusen, 'S.-B. Ges. naturf. Fr.,' Berlin, 1894, p. 170; Hilgendorf, *Tom. cit.*, p. 171; Zimmer, 'Zool. Jahrb.,' Syst. XVIII., p. 669, 1903.

Carapace sub-globular or more or less flattened dorso-ventrally, having a pair of procurved lateral cornua, behind which the lateral margin is usually sharply keeled. Four thoracic somites are free behind the carapace. First pair of legs having the basis produced distally into a pointed lobe on the upper (or inner) side of the articulation of the ischium. Second legs generally very short, composed of six segments, the ischium being suppressed. Uropods having the peduncle shorter than the rami.

The genus *Eocuma* was established by MARCUSEN in 1894 for the reception of a Japanese species, to which he gave the name *E. hilgendorfi*. The paper was published after the death of the author, with some additional notes by HILGENDORF, and was not accompanied by any figures. Recently the species has been re-described and figured by ZIMMER from two of HILGENDORF'S specimens, the actual type specimens having been lost. In the original description the chief characters given as distinctive of the genus are the flattened form of the carapace and the meeting in the middle line of the basal segments of the first pair of legs. The last-named character does not hold good, as ZIMMER has shown, for the sub-adult female, while on the other hand I find it in immature specimens of several other genera. The flattening of the carapace is much less marked in the adult male than in the female in the species described below as *E. taprobanica*, and it is clearly impossible to base the genus on this character alone. I propose therefore to modify the generic definition so as to include all those species of Bodotriidæ in which the carapace bears a pair of curved lateral horns. In this way we obtain the following assemblage of species which appears to be a natural one, the various forms agreeing also in the above-mentioned characters of the first and second legs and of the uropods :—

Eocuma hilgendorfi, MARCUSEN, 1894. Type of the genus.
E. ferox (FISCHER) = *Bodotria ferox*, FISCHER, 1872 = *Cyclaspis cornigera*, G. O. SARS, 1879 = *Cyclaspoides ferox*, BONNIER, 1896.
E. sarsii (KOSSMANN) = *Cyclaspis sarsii*, KOSSMANN, re-described below.
E. taprobanica, n. sp.
E. affinis, n. sp.

The genus *Cyclaspoides* of BONNIER ('Ann. Univ., Lyon,' 1896, "Campagne du 'Caudan,' Édriophthalmes," p. 530) is distinguished from *Cyclaspis* only by the fact that the second legs are composed of six instead of seven segments. Of the two species referred to it, *C. sarsii*, BONNIER, and *C. ferox* (FISCHER), neither is explicitly named as the type of the genus. *C. sarsii*, however, differs in so many particulars from *C. ferox* that it may conveniently be left in a different genus, for which the name *Cyclaspoides* may be retained.

The distinguishing characters of the species here referred to *Eocuma* may be summarised as follows :—

A. Lateral margins of carapace carinated.
  1. Pseudorostrum reaching forwards beyond the level of the lateral cornua. Carapace much depressed, surface smooth.
    a. Antero-lateral tooth on either side of pseudorostrum inconspicuous (♀) or absent (♂). No paired ridges on dorsal surface of carapace. *E. taprobanica.*

b. Antero-lateral teeth very prominent, reaching as far forward as pseudorostrum, from which they are separated only by a shallow concavity on each side. Dorsal surface of carapace with a longitudinal ridge on the branchial region on each side. *E. hilgendorfi.*

2. Pseudorostrum not projecting beyond tips of lateral cornua, squarely truncate. Antero-lateral teeth well defined. Carapace somewhat inflated, surface rough and uneven. *E. sarsii.*

B. Lateral margins of carapace rounded.

1. Carapace (of male) about one-fourth of total length and one-fifth longer than broad. *E. ferox.*

2. Carapace (of male) about one-third of total length, nearly twice as long as broad. *E. affinis.*

Eocuma taprobanica, n. sp.—Plate I., figs. 1 to 20; Plate II., figs. 21 to 28.

Description of *Female*, sub-adult, with developing oostegites. Total length,* 11·1 millims. (figs. 1, 2, 6):—

The carapace is about two-sevenths of the total length, very broad and flattened, with a well-marked lateral carina on each side. The greatest width is about five-sixths of the length, and is at a distance of less than one-third of the length of the carapace from the front, where are situated the incurved lateral cornua. Behind this the slightly convex sides converge towards the hind margin, where the width is about one-half of that measured across the cornua. The pseudorostrum is prominent, and the tip, as seen from above, is broadly notched. External to it on each side the antero-lateral margin forms a blunt tooth, between which and the lateral cornu the outline is again slightly convex. The dorsal surface, which is slightly arched from before backwards and more strongly so from side to side, presents a faintly marked median keel, becoming more distinct anteriorly, where there is a shallow depression on either side of the cephalic lobe. The sides of the carapace are sharply inflected at the lateral edge, so that the under surface is nearly flat. A transverse ridge runs from each of the lateral cornua to the lower or free margin of the carapace on the under side. The hinder edge, seen from the side, slopes backwards, forming an oblique angle with the lower and with the lateral margins, which meet at its lower end. The ocular lobe is slightly broader than long, and the pseudorostral plates meet in front of it for a distance equal to its width. The eye is not pigmented in the specimens examined; there are three corneal facets, large in size, but indistinctly defined. The surface of the carapace presents a faint and inconspicuous pitting which does not interrupt the minute and regularly reticulate texture of the exoskeleton.

The transverse width of the thoracic somites diminishes regularly, tapering down

* The "total length" given in each case excludes the uropods.

to the slender abdomen. The first leg-bearing somite is not distinct, though a rather faint line which marks off a narrow, diamond-shaped area from the hinder part of the carapace above may (as ZIMMER has suggested in *E. hilgendorfi*) represent its line of fusion with the carapace. The second somite also appears to be firmly united to the carapace. The third and fourth somites are reduced above to narrow transverse bars, connected with each other by wide spaces of articular membrane, so that this region of the body is very mobile and is usually strongly flexed dorsally, the dorsal portion of the third somite being quite concealed beneath the second.

The abdomen is very slender, longer by one-fifth than the cephalothoracic region. The somites, which are sub-cylindrical, with a slight median dorsal keel, diminish a little in width, so that the fifth, which is the longest, is also the narrowest, being nearly four times as long as broad. The last somite is a little depressed and broadened posteriorly. In the lateral articulations of the somites the anterior articular process of each is met by and overlaps a single process from the somite in front, instead of engaging in a notch as in most species of *Cyclaspis*.

The antennules (fig. 7) have the basal segment large and of peculiar form. Its distal half is bent at an angle to the proximal part and is flattened and triangular in form, very broad at the base, and narrowing distally to the articulation of the second segment. In the natural position of the parts this triangular portion appears to be firmly fixed in a notch in the free edge of the carapace, corresponding, no doubt, to the "antennal notch" in more normal Cumacea, but in the present case, owing to the flattening of the carapace, carried round to the under surface and quite invisible from the side or from above. The second and third segments of the antennular peduncle are slender, the third half as long again as the second. The external flagellum is about half the length of the last peduncular segment and is composed of two sub-equal segments. The internal flagellum is quite rudimentary and exceedingly minute.

The antenna (fig. 7) is a simple rounded nodule bearing two plumose setæ. No trace could be discovered of the narrow terminal segment generally present in allied genera.

The mandibles (fig. 10) are of the normal type, and carry a row of about 13 spines.

The lower lip (fig. 11) has broadly rounded lobes, clothed with fine setæ.

The maxillulæ (fig. 12) have a slender palp longer by one-half than the distance between its base and the tip of the distal lobe, and carrying two apical setæ.

The maxillæ are of normal structure.

The first maxillipeds (fig. 13) have the basis very broad and shorter than the rest of the limb. The branchial apparatus is remarkably well developed. Its posterior division (epipod) is produced forwards as a rounded lobe which reaches as far as the end of the basis. The branchial lobules are broad, lamellar, and about 22 in number. A reflexed anterior lobule could not be discovered. In the anterior division (exopod of SARS) the oval chitinous plate, which forms a valve-like lid to the respiratory aperture, is well defined.

The second maxillipeds (fig. 15) have the basis sub-equal in length to the remaining segments together. The ischium, which is not distinct in most species of *Cyclaspis*, is here well defined though small.

The third maxillipeds (figs. 16, 16A) are expanded, and are opercular in function, serving along with the basal segments of the first legs to completely cover in the other mouth parts. The basis is in the natural position of the parts partly covered by the basis of the first leg, and its distal part, which is exposed, is more strongly calcified and sharply defined from the concealed proximal part. At its distal end the segment is produced into a long and narrow curved process reaching nearly to the end of the merus. The ischium, unlike that of *Cyclaspis*, is very broad, not narrower than the succeeding segment. The three distal segments are comparatively slender.

The first legs (fig. 21) are long, extending beyond the pseudorostrum by nearly the length of the last two segments. The basis is very broad and flattened, narrowing suddenly at about its distal third and produced beyond and (in the natural position) above the articulation of the next segment into a sharply pointed process which extends beyond the distal end of the ischium. The rest of the limb is slender, and the last three segments are much elongated, the carpus and the propodus sub-equal and a little longer than the dactylus.

The second legs (fig. 17) are much shorter than the succeeding pairs and have a peculiar form. The basis is about equal to the remaining segments together. The ischium is suppressed. The merus is very short, but is produced distally on the inner side and bears a stout spine which reaches almost to the end of the limb. The next two segments are short and sub-equal, and together equal in length to the terminal segment, which bears three apical setæ and one lateral.

The fourth legs are slightly longer than either the third or the fifth (figs. 18 to 20). In each the basis bears several long setæ, and the terminal segment is very short, with a rather stout claw.

The uropods (fig. 27) are rather less than one and a-half times the length of the terminal somite. The peduncle is about two-fifths of the length of the sub-equal rami. The endopod bears a few spinules and plumose setæ on its inner edge. The outer edge of the exopod is obscurely serrate, its inner edge unarmed. The apices of both rami (fig. 27, A, B) have a rather peculiar structure. The endopod tapers down to a minute rounded knob, beyond which projects a flattened or rather winged spine consisting of a central rachis with a striated wing or web running down either side. The tip of the exopod is bifid, the two points close together, the lower having the same structure as the tip of the endopod, the upper differing in being without the knob-like process.

Adult *Male*, 9·3 millims. in length (figs. 3, 4) :—

Carapace much narrower than in the female, its greatest width about five-ninths of its length. Lateral cornua less prominent, directed forwards. Antero-lateral margins between pseudorostrum and lateral cornua simply convex with hardly an indication of the antero-lateral tooth. The lateral keel is well marked, as is also the transverse ridge running inwards from the lateral cornu on the lower surface. The median ridge is more distinct on the posterior part of the dorsal surface. The ocular lobe nearly twice as broad as long, the corneal areas much larger and more distinct than in the female. Anterior abdominal somites hardly narrower and somewhat deeper than posterior thoracic; sixth abdominal somite narrowing suddenly about the middle of its length.

Antennule (fig. 8) having three segments in the outer flagellum.

Antenna (fig. 9) of normal type, its flagellum about as long as the body. First two segments of peduncle bearing each a plumose seta.

Branchial apparatus (fig. 14) more fully developed than in the female, the laminæ much longer and 33 in number.

First leg (fig. 22) a little shorter than that of the female, the basis longer and narrower and having a group of spines on its lower surface near the inner edge.

Second leg (fig. 23) closely resembling that of female, except that the ischium is a little longer. The remaining legs (figs. 24 to 26) stouter than in the female and having more numerous and longer plumose setæ on the proximal segments.

Uropods (fig. 28) differing from those of the female in having the inner edges of the peduncle and endopod densely set with plumose setæ and in having a few setæ on the outer edge of the exopod.

Young Specimen, 4·8 millims. in length :—

The outline of the carapace (fig. 5) differs considerably from that of the adults. The lateral margins behind the cornua are nearly straight, the pseudorostral lobes are relatively much broader, the antero-lateral tooth is more prominent and more angular, and that portion of the antero-lateral margin lying between the tooth and the lateral cornu is straight instead of convex as in the female.

Localities.—Many specimens from the Gulf of Manaar, on the Cheval Paar, depth 6 to 7 fathoms; and on the Periya Paar Kerrai, depth 8 to 9 fathoms.

Eocuma affinis, n. sp.—Plate II., figs. 29 to 34.

Description of adult *Male*, 6·7 millims. in length :—

Differing from the last species in the narrower and less depressed form of the carapace, which is about three-tenths of the total length and evenly rounded at the sides without any lateral keels. Seen from above, the sides are nearly parallel, and the greatest width is little more than half of the length. The cornua are rather prominent, curved, and directed forwards. In front, the antero-lateral margin is finely serrate. On the dorsal surface a transverse depression crosses the hinder part of the cephalic lobe. The pitting of the surface of the carapace (fig. 31) is more marked than in the last species and the minute reticular texture is less distinct.

A minute granule is set in the centre of each pit, and between the pits are scattered here and there small tubercular elevations.

The first legs (fig. 32) have the basis narrower than in the last species, and the spines on its lower surface more numerous. The dactylus is only half the length of the preceding segment.

The second legs (fig. 33) have the basis very short, only one-third of the whole length of the limb. The spine on the ischium only reaches to the end ot the succeeding segment.

The uropods (fig. 34) are nearly twice as long as the terminal somite, the peduncle nearly one-third of the length of the rami. The inner edges of peduncle and endopod clothed with setæ, among which are one or two spinules. The outer and inner edges of the exopod each bear a number of setæ.

Locality.—The Cheval Paar, in the Gulf of Manaar, depth 7 fathoms. Two specimens.

Eocuma sarsii (KOSSMANN)—Plate II., figs. 35 to 38.

Cyclaspis sarsii, KOSSMANN, 'Zool. Ergeb. einer Reise in die Küstengebiete des rothen Meeres,' II., 1te Lief., III., Malacostraca (2. Theil; Anomura), pp. 88 to 90, Plate IV., fig. 3, 1880.

A single immature specimen, 4 millims. in length, probably female, which I refer to this species, has the following characters: Carapace hardly depressed, about five-sixteenths of total length, with very stout curved lateral cornua, behind which the lateral margin is marked by a low irregularly serrate ridge. The breadth across the cornua is four-fifths of the length. The cornua reach forward as far as the level of the pseudorostrum, which is broad and squarely truncate, as seen from above. External to the pseudorostrum on each side is an almost rectangular tooth, the anterior edge of which is serrate. This tooth is separated from the lateral cornu by a deep semicircular excavation. The dorsal surface is raised into a median keel anteriorly, where also there is a slight elevation on each side of the cephalic lobe. At its anterior end the median keel bifurcates on the ocular lobe to separate from each other the three not very distinct corneal areas. About the middle of the length of the carapace the median keel dies out and is replaced by a pair of longitudinal ridges some distance apart. The hinder margin of the carapace is elevated in the middle line into a rounded tubercle. The ocular lobe is nearly twice as broad as long, and there is no ocular pigment. The pseudorostral plates meet in front for a distance about equal to the length of the ocular lobe. Seen from the side, the pseudorostrum is obliquely truncated. The surface of the carapace (and, less distinctly, the rest of the exoskeleton) is covered with shallow circular pits, in the centre of each of which is a minute granule. The surface between the pits forms a raised network, which shows more or less distinctly the primary reticular texture of the exoskeleton, and is here and there raised into tubercles, giving the whole surface a rough and uneven aspect (fig. 37).

The first leg-bearing somite is not exposed. The second is much lower than the hind margin of the carapace. The remaining thoracic somites diminish gradually in width ; a pair of tubercles is present on the dorsal surface of each of the two last.

The abdomen is stout, but on account of an injury to the posterior somites the relative length of this region cannot be stated. All the somites, including the two last, have a prominent median dorsal keel. Seen from above, each of the somites is markedly constricted anteriorly, and also a little before its hinder margin. The lateral articular processes do not overlap.

The first legs are relatively short and stout, the basis not much less than half the total length of the limb.

The second legs are much shorter than the next succeeding pair. They are composed of six segments, as in the above-described species, but there is no spine developed on the merus.

The uropods (fig. 38) are short and stout, about two-thirds longer than the last somite. The peduncle is not much longer than broad, and is about two-fifths the length of the sub-equal rami. Its inner edge bears a few spinules. Both rami end in spiniform terminations marked off by indistinct suture lines, and bluntly rounded and bent outwards at the tip. A single seta accompanies the terminal spine on the exopod, which is otherwise unarmed. The endopod has a row of minute spinules on its inner edge.

Locality.—From the Cheval Paar, in the Gulf of Manaar, depth 7 fathoms.

The identity of the form here described with Kossmann's *Cyclaspis sarsii* from the Red Sea is at once suggested by its general shape, and especially by the thick clumsy form of the lateral cornua. Kossmann's figure shows the cornua as relatively smaller than in the present specimen, and the lateral margins behind them nearly straight. The paired ridges on the dorsal surface of the carapace are close together, and there are two oblique ridges on the dorsal surface of the peduncle of the uropods. It seems likely, however, that some of these differences may be due to the difference in age and in sex, Kossmann's specimen being a male, 9 millims. in length, more than twice the length of the present specimen, which is probably a young female. Kossmann's description of the sculpturing of the exoskeleton agrees exactly with that observed in this specimen.

Cyclaspis, G. O. Sars.

G. O. Sars, 'Forh. Vidensk. Selsk. Christiania,' 1864 (1865), p. 206.

The genus *Cyclaspis*, even after the removal of the species above transferred to *Eocuma*, still includes a somewhat varied assemblage of forms, and becomes increasingly difficult to define from the neighbouring genera of Bodotriidæ. Without attempting, for the present, to frame a fresh definition, it may be pointed out that the species described below, which are referred to *Cyclaspis* on the ground of general similarity in form to species already included therein, differ from them in the fact that they possess, in the adult female at least, five distinct thoracic somites behind the carapace. Since, however, the first somite is entirely hidden in most cases in the adult male as well as in immature specimens of both sexes, it seems inadvisable to make this character the ground for separating these species generically from those in which the somite in question is concealed or suppressed in both sexes at all stages of growth.

Cyclaspis costata, n. sp.—Plate III., figs. 39 to 53.

Description of adult *Female*. Total length 3·75 millims :—

Carapace about three-eighths of total length, its vertical height nearly two-thirds of its length, compressed, the dorsal surface rounded posteriorly, but keeled in its anterior half, where there is a well-marked depression on either side of the middle line. Pseudorostrum acute, prominent and slightly upturned as seen from the side. Antennal notch shallow and widely open, the antennal tooth obtuse. Ocular lobe large, sub-circular, pseudorostral plates meeting in front of it for a distance equal to its diameter. The eye pigmented and apparently well developed. The sides of the carapace, behind and below the depressions mentioned above, are beset with longitudinal ridges formed by rows of minute granules. There are about twelve such ridges on either side in the specimen figured, with fainter secondary ridges interposed between some of them. In a larger female specimen the ridges are more numerous and closer together, owing apparently to the greater prominence of the secondary ridges.

First leg-bearing somite well exposed. Second somite produced dorsally into a median crest. Fourth and fifth having the dorsal surface raised into a rounded tubercle on each side of the middle line.

Abdomen shorter than the cephalothoracic region, the somites comparatively stout, with a faintly indicated dorsal keel, and with well-developed "peg and socket" articulations laterally.

Antennules (fig. 42) very short, first segment of peduncle much enlarged and longer than the other two segments together, outer flagellum with two segments, inner flagellum very minute.

Antennæ (fig. 43) unjointed, not produced, bearing two plumose setæ.

The mouth-parts closely resemble those of *C. australis;* the mandibles bear about 13 spines. The branchial apparatus was not examined.

The third maxillipeds (fig. 44) have the basis abruptly bent at about the middle of its length, and slightly longer than the succeeding segments together. The external process of the merus is very large, extending far beyond the process of the basis. The propodus is expanded, not much narrower than the carpus, and the dactylus is almost rudimentary.

The first legs (fig. 45) are very short, just reaching to the antennal angle of the carapace when extended forwards. The basis is about equal in length to the succeeding segments together.

The second leg (fig. 47) exhibits the full number of segments; it is short and stout, and its terminal segment is armed with three spines. The third legs are longer than the second, and the fourth and fifth successively diminish in length by shortening of the basis (figs. 49 to 51). The propodus and dactylus of these limbs are rather slender.

The uropods (fig. 52) are short and stout; the peduncle is about equal to the terminal somite in length and finely serrate on its inner margin. The rami are subequal and a little shorter than the peduncle. Each is tipped by a stout spine. The exopod is otherwise unarmed except for a small spinule implanted external to the base of the large spine. The endopod has a single spine on its inner edge near the distal end.

In addition to scattered pigment spots on the carapace and free thoracic somites, there is a more or less well-marked pigmentation of the first two and the last abdominal somites.

Adult *Male*. Total length, 3·9 millims. (fig. 41) :—

The carapace is less deep than in the female, with the dorsal outline less arched. The pseudorostrum is shorter and truncated, the plates meeting for only a short distance in front of the ocular lobe. The latter is large, inflated, with large and distinct corneal lenses. On the upper part of the side of the carapace the longitudinal ridges only occupy the posterior third, stopping short at a vertical ridge in front of which the surface is irregularly granulated.

The first leg-bearing somite is exposed dorsally and the second is not distinctly crested. The posterior thoracic somites are broad and depressed, with prominent dorso-lateral corners. The abdomen is remarkably stout, a little longer than the cephalothoracic region, the anterior somites broader and deeper than long, the fifth somite narrowing suddenly about the middle of its length.

The various appendages, so far as seen without dissection, resemble closely those of the female. The basis of the first leg (fig. 46) bears on its inner edge a series of four stout spines.

The basis of the second leg (fig. 48) has its anterior edge cut into a series of fine recurved teeth not observed in the female.

The uropods (fig. 53) are shorter than in the female. The peduncle is shorter than the terminal somite and bears a series of long plumose hairs on its inner edge. The rami are broad and flattened. The endopod has a series of serrate spines on its inner edge increasing in length distally, the two distal spines close to the stout apical one and separated by a little interval from the others; the outer edge and the distal part of the inner edge are serrate. The exopod has several plumose hairs on its inner edge.

Localities.—Gulf of Manaar; several specimens from Kondatchi Paar, one specimen from Periya Paar Kerrai; depth, 8 to 9 fathoms.

This new species resembles a little in general form the *C. australis* of Sars, but differs from it and from all the species of *Cyclaspis* hitherto described not only in the longitudinally-ribbed carapace, but also in the shortness of the first legs, the short abdomen, especially of the female, and in the stoutness and armature of the uropods. In the fact that the first leg-bearing somite is distinct in the female, it agrees with the species described below, but no other species is yet known in which this somite is exposed in the male also.

Cyclaspis picta, n. sp.—Plate III., figs. 54 and 55.

Description of *Female* with rudimentary oostegites. Total length, 3 millims:—

The carapace is a little more than one-third of the total length and is somewhat compressed, the dorsal surface keeled, especially in front. Seen from the side, the dorsal edge is evenly arched, the pseudorostrum is prominent and sharply triangular, the lateral plates meeting in front of the ocular lobe for a distance equal to the transverse diameter of the latter. Antennal notch widely open, antennal tooth sharp, with a spiniform point. Ocular lobe of moderate size, acuminate anteriorly, not sharply constricted off from cephalic lobe, eye well pigmented, corneal lenses not distinct. The sides of the carapace are quite smooth, devoid of ridges or tubercles. The texture of the exoskeleton is (in this specimen) regularly reticulate, with a faintly indicated shallow pitting over the whole of the carapace.

First leg-bearing somite well exposed, but apparently firmly united to the carapace, the suture line being somewhat faintly shown.

Abdomen rather slender, nearly equal in length to the cephalothoracic region, the somites sub-cylindrical, with well-marked articular processes laterally.

First legs comparatively short, extending beyond the antennal tooth by little more than the terminal segment. Second legs with the ischium distinct.

Uropods (fig. 55) having the peduncle nearly twice as long as the last somite and more than twice as long as the rami, which are sub-equal, the endopod especially rather broad and flattened, tipped with a spine, and having two spines on its serrate inner edge. The exopod has a terminal spine and a small spinule close to it on the outer side.

Both the specimens show a peculiarly shaped pigment patch on the carapace. The last thoracic and some of the abdominal somites are also pigmented.

Locality.—Gulf of Manaar, Cheval Paar; depth, 7 fathoms; 2 specimens.

This form belongs, with the two following, to a group of species characterised by the smoothness of the carapace and including *C. longicaudata*, Sars; *C. pusilla*, Sars; *C. levis*, Thomson; and *C. argus*, Zimmer. From all of these it seems to be sufficiently distinguished by the presence of five distinct thoracic somites, by the acute pseudorostrum, and by the much longer peduncle of the uropods.

Cyclaspis herdmani, n. sp.—Plate III., figs. 56 to 59; Plate IV., figs. 60 to 66.

Description of adult *Female*. Total length, 4·4 millims. (fig. 56):—

Carapace nearly $3\frac{1}{2}$ times in total length, moderately compressed. The dorsal edge very slightly arched, keeled anteriorly where there is a shallow depression on either side, and having a more faintly marked double keel posteriorly. The junction of the median with the double keel is marked by a shallow pit. Pseudorostrum truncated, the ocular lobe reaching quite to the tip. Antennal notch narrow, antennal tooth sub-acute. Ocular lobe moderately large, not longer than broad, somewhat projecting dorsally; eye well pigmented, corneal lenses indistinctly defined. Sides of carapace smooth, with a faint pitting over the whole surface.

First leg-bearing somite well exposed in adult (in the young female, as in the male, it is wholly concealed). Second somite slightly crested dorsally.

Abdomen rather slender, a little longer than the cephalothoracic region, the somites sub-cylindrical, with well developed lateral articular processes.

Antennules (fig. 58) having the first segment of peduncle longer than the other two together, the second a little shorter than the third. External flagellum of two segments, internal flagellum not observed in the specimen dissected.

Antenna (fig. 59) produced into a narrow process defined by a distinct suture-line. Two plumose setæ on basal part.

The mouth-parts are normal.

The first legs (fig. 60) extend a little way beyond the pseudorostrum. The basis is rather narrow, and is equal in length to the remaining segments together. At its distal end, on the side which in the natural position of the limb is ventral, it is produced into a stout tooth which reaches to the end of the next segment. The merus and carpus are somewhat expanded, and the carpus, propodus, and dactylus are of equal length.

The second legs (fig. 62) have the ischium distinct, the carpus hardly more than half the length of the merus and little longer than the propodus. The dactylus is shorter than the two preceding segments together and bears three unequal spines at the tip. In the remaining legs (fig. 63) the carpus is sub-equal to the merus.

The uropods (fig. 65) are rather slender, the peduncle about $1\frac{2}{5}$ths the length of the last somite, and equal to the length of the sub-equal rami. Both rami are acutely pointed, without terminal spines, and the endopod bears a series of about six spinules on the middle third of its inner edge.

The last two or three thoracic somites are always more or less pigmented.

Adult *Male*. Total length, 4·3 millims. (fig. 57):—

The carapace resembles in shape that of the female, but is less deep. The ocular lobe is more prominent dorsally and the corneal lenses are large and conspicuous. The antennal notch is shallow and widely open. On the surface of the carapace the dorsal keels and depressions are only faintly indicated. Abdominal somites, as usual, much stouter, and the whole abdomen longer than the cephalothorax.

The first legs (fig. 61) are somewhat longer and more slender than in the female; the basal segment bears on its inner edge a group of spines, and the dactylus is a little shorter than carpus or propodus. The remaining legs do not differ conspicuously from those of the female.

The uropods (fig. 66) have the peduncle fringed on the inner edge with setæ. The exopod is a little longer than the endopod and equal to the peduncle, and has a few plumose hairs on its inner edge. The endopod has about 23 spinules on its inner edge, diminishing in length distally, and leaving the distal third of its length unarmed. Both rami are simply pointed at the tip.

Localities.—Gulf of Manaar, various parts of the Cheval Paar; depth 7 fathoms; several specimens.

This species approaches most closely to *C. levis*, Thomson, and *C. argus*, Zimmer. The latter is distinguished in the male sex by a different form of the anterior margin of the carapace, the antennal notch being widely open and shallow, by having the second leg-bearing somite produced dorsally, and by the shorter uropods, of which the peduncle is equal in length to the last somite. *C. levis* is distinguished, according to Thomson, by having a long, slender and acute process from the distal end of the basal segment of the first legs. I am inclined to suspect some error of observation in regard to this character, in which case *C. levis* would resemble very closely the form here described. The characters of the uropods, however, appear to distinguish the species, those of *C. levis* having the peduncle not longer than the last somite, and their armature being somewhat different.

Cyclaspis hornelli, n. sp.—Plate IV., figs. 67 to 71.

Closely resembling in both sexes the preceding species, but differing from it in the following characters:—The carapace is still smoother, and the dorsal keel is simple and less strongly marked. The first legs (fig. 67) are much longer, reaching far beyond the anterior end of the body; the basis is about three-fourths of the length of the remaining segments together, and the propodus is twice and the dactylus one and a half times as long as the carpus. The second legs (fig. 68) have the terminal segment longer and with more numerous spines. In the last three pairs of legs the distal segments are more elongated, the carpus of the fifth pair (fig. 70) being half as long again as the merus. The uropods (fig. 71) resemble those of *C. herdmani*, but the exopod is a little shorter than the peduncle, and bears three to five spinules about the middle of its inner margin, while at the tip are two unequal spinules and another close to them on the inner edge. The endopod is simply pointed and bears in the female six, and in the male 14 spines on its inner edge. Total length, female 5·3 millims., male 4·2 millims.

Localities.—Gulf of Manaar, Cheval Paar, depth 7 fathoms, several spp., and the Periya Paar Kerrai, depth 8 to 9 fathoms, several.

At the suggestion of Professor Herdman, I have pleasure in associating with this species the name of Mr. JAMES HORNELL, to whom, I am told, no small share of credit is due for getting together this interesting series of a group of animals neglected by most collectors.

Iphinoë macrobrachium, n. sp.—Plate IV., figs. 72 to 75.

Description of immature *Female*. Total length, 1 millim. :—

Carapace about one-fourth of the total length, its length in the middle line nearly one and a half times its height, moderately compressed, with a well marked dorsal keel. Dorsal edge slightly arched. Pseudorostrum prominent, upturned, truncated, the lateral plates meeting in front of the ocular lobe for a distance nearly equal to the breadth of the latter. Antennal notch rather deep, angular, antennal tooth acute. Ocular lobe transverse, its width more than twice its length. On the side of the carapace are two very faintly marked longitudinal ridges. The upper is continued backwards for a short distance from the pseudorostrum, the lower is just above the lower margin of the carapace. The free thoracic somites are faintly keeled dorsally.

Antennules and third maxillipeds resembling those of *Iphinoë crassipes*, HANSEN. First legs (fig. 73) very long, basis less than half the length of the remaining segments; relative proportions of the latter as in *I. crassipes*, but the propodus rather more slender. Second legs (fig. 74) resembling those of *I. crassipes*, the two distal segments indistinctly separated.

Uropods (fig. 75) with the peduncle stout and a little longer than the last somite, with five or six strong spines on its inner edge. Rami unequal, the endopod a little longer than the peduncle, its proximal segment with four or five spines on its inner edge, and nearly half as long again as the distal segment, which has three terminal spines and two or three on its inner edge. Exopod about two-thirds of the length of the endopod, unarmed except for the terminal group of six or seven spines and stout setæ.

Localities.—Gulf of Manaar, Cheval Paar, 7 fathoms, 1 specimen, and Kondatchi Paar, 4 to 5 fathoms, 1 specimen.

This species presents a close resemblance to the *Iphinoë crassipes* of HANSEN from the Gulf of Guinea. Although HANSEN'S specimen, like those here described, was immature, there appear to be sufficient grounds for regarding the species as distinct. The outline of the carapace is somewhat different, the basal segment of the first legs is much shorter, and the rami of the uropods are conspicuously unequal, while in *I. crassipes* they are nearly of the same length.

FAMILY: DIASTYLIDÆ.

Paradiastylis, n. gen.

Third maxillipeds without exopod. Third and fourth pairs of legs with no rudiments of exopods. Telson very short, the post-anal part reduced to a spiniform process tipped with two small spinules and without lateral spines.

Paradiastylis brachyura, n. sp.—Plate V., figs. 76 to 90.

Description of sub-adult *Female*. Total length 3·2 millims. :—

Carapace inflated, a little less than one-third of the total length, its breadth about three-fourths, and its depth two-thirds of its length. Pseudorostrum acute, horizontal, the lateral plates meeting in front of the ocular lobe for a distance equal to the width of the latter. The tip of the pseudorostrum is armed with a pair of divergent spines. Antennal notch shallow. Antero-lateral angle not produced, rounded, serrate. On each side of the carapace are four curved ridges running obliquely from above downwards and forwards. The most anterior and strongest of these is serrate, and the area in front of and above it is depressed on each side, leaving a median keel. The fourth or hindmost ridge on either side is much less prominent than the others. On the dorsal surface a pair of short longitudinal serrate crests, some distance apart, connect the upper ends of the first and second ridges, and form a strong tooth at the upper end of the first. The median keel bears two procurved teeth, and a pair are set side by side on the ocular lobe. On the lower part of the side of the carapace anteriorly a curved row of spines starting from the pseudorostrum runs backwards and downwards towards the lower margin, crossing the lower ends of the oblique ridges. The posterior edge of the carapace is raised to form a marginal ridge which is strongest on the dorsal side. The ocular lobe is twice as broad as long. There is no eye-pigment nor distinct corneal lenses.

The posterior angles of the last thoracic somite are not produced.

The abdomen is slender, about equal in length to the cephalothoracic region. The somites have slight serrate dorso-lateral crests. The fifth somite is not greatly elongated.

Telson (figs. 89 and 90) a little shorter than the last somite, somewhat narrowed at its base, its greatest breadth at about one-third of its length from the base, where it bears a pair of lateral tubercles, then narrowing suddenly a little before the middle of its length, the sides converging to an acute point. Viewed from the side (fig. 89), the tip is seen to project beyond the obliquely placed anal valves by about one-third of its length. A pair of very minute apical spinules are present, flanked by a pair of small setæ, with another pair of setæ a little way further down the side.

Antennules (figs. 78 and 78A) hardly reaching beyond the tip of the pseudorostrum, the proximal segment more than twice, the third segment one and a half times the length of the second. Outer flagellum shorter than the last segment of the peduncle, consisting of three segments, the terminal one very minute. Inner flagellum two-thirds the length of the outer, composed of two segments, the proximal very short.

Antennæ (fig. 80) consisting of three segments.

Mouth-parts of normal type. Mandibles with about nine spines. Lobes of lower lip with incurved tips. Palp of maxillulæ (fig. 81) not longer than the distance between its base and the tip of the distal lobe, with two apical setæ. Branchial apparatus not examined. Second maxillipeds (fig. 82) rather short, basis hardly more than one-third of the total length.

Third maxillipeds (figs. 83) without exopods. The basis is curved, much expanded distally and about equal in length to the remaining segments together. At its distal end it bears a series of very long setæ.

First legs (fig. 84) reaching beyond the tip of the pseudorostrum by about half the length of the carapace. The basis rather short, less than two-fifths the length of the remaining segments; the distal segments stout, propodus a little longer than the carpus and more than twice as long as the dactylus.

Second legs (fig. 85) about as long as the third pair, basis enlarged, ischium reduced to a narrow ring, distal segments not greatly elongated, propodus three-fourths of the length of the dactylus, which is armed with two or three apical spines and several setæ. Remaining legs (figs. 86 and 87) rather stout, successively diminishing in length, merus much longer than carpus.

Uropods (fig. 88) slender and elongate, peduncle twice as long as the sixth abdominal somite, with six spines on distal part of its inner edge, two tubercles on its lower surface and one above. Rami slightly unequal, exopod a little more than half the length of the peduncle and a little shorter than the endopod, unarmed except for a few minute setæ and for a slender apical spine equal in length to the ramus carrying it. Exopod of three segments, of which the first and longest bears two spines and each of the others one on the inner edge; distal segment ending in a slender apical spine.

No adult male is in the collection, but one or two immature male specimens, resembling the female in general form and in the sculpture of the carapace, have the antennular peduncle (fig. 79), and especially its distal segments, much enlarged, suggesting that in the adult a modification of this appendage may take place similar to that occurring in *Leptostylis;* the outer flagellum also possesses an additional segment not observed in the female. Two pairs of pleopods are present as rudiments and both are bilobed.

Locality.—Gulf of Manaar, Cheval Paar, 7 fathoms; several specimens.

The most remarkable feature of the present form, and one which distinguishes it from all *Cumacea* hitherto described, is the absence of an exopod from the third maxilliped. The facility with which this appendage becomes detached in dissection from the limb which carries it, might suggest possible error of observation on this point were it not that I have observed the same character in an undescribed species from New Zealand, closely allied to that above described. This character is so unusual that it seems advisable to recognise it by establishing a new genus for the reception of the species.

The *Leptostylis brevicaudata* described by ZIMMER ('Zool. Jahrb. Syst.,' XVIII.,

p. 685), from Japan, presents a great resemblance to this species in general form, in the shape and proportions of the telson, and in the sculpturing of the carapace. Its third maxilliped is not described, but it possesses rudimentary exopods on the third and fourth legs, a character which led to its being referred to the genus *Leptostylis*, although differing in several points from the typical members of that genus. Should it prove to be the case that *L. brevicaudata* is without an exopod on the third maxilliped, it will, I think, be necessary to include it with the present species in the genus *Paradiastylis* in spite of the difference in structure of the third and fourth legs. In the *Diastylopsis dubia* of BONNIER ('Ann. Univ. Lyon,' "Campagne du 'Caudan,'" Édriophthalmes, p. 559), the presence or absence of rudimentary exopods on these limbs seems to be a matter of individual variation, suggesting that no great importance can attach to this feature as a generic distinction within the family Diastylidæ.

FAMILY: NANNASTACIDÆ.

Nannastacus stebbingi, n. sp.—Plate V., figs. 91 to 93.

Description of adult *Male*. Total length, 1·38 millims. :—

Carapace a little over one-third of total length, rather broader than deep, dorsal surface a little depressed in middle line between the swollen branchial regions. On either side, a little way behind the eye, is a rounded knob-like prominence (present also, although less conspicuous, in *N. unguiculatus*). Pseudorostrum, seen from the side, upturned and rounded, with two faintly marked ridges parallel to its distal margin; immediately below the pseudorostrum, and above the insertion of the antennule, the concave antero-lateral margin bears a group of three curved spines, of which the upper and largest is very conspicuous. Antero-lateral angle not produced, rounded, not serrate, but with a single small spine springing from the outer surface. Seen from above, the pseudorostral plates do not meet in front of the eyes and the respiratory channel is widely open. The eyes are large, each with three prominent corneal lenses. The width of the interocular margin is about equal to the diameter of the eye.

All the free thoracic somites have sub-marginal lateral crests of laminar spines, the last three also with paired serrated crests on the dorsal surface.

Abdomen shorter than the cephalothoracic region, fifth somite not much longer than the preceding. As in *N. unguiculatus*, all the somites bear serrated lateral crests overhanging the lateral grooves, and each, except the last, has a pair of stouter dorsal crests ending behind in a strong curved tooth. On the last somite, apparently, the lateral crests alone are present running on to the dorsal surface, and the posterior border of the somite is produced into a sharp median spine.

In the last pair of legs the carpus is longer than the propodus.

Uropods (fig. 93), excluding the apical spines, longer than the last two somites;

peduncle very short, with a serrate crest on the dorsal surface; endopod about three times as long as the peduncle, serrate on the inner edge, and having an apical spine nearly two-thirds of its own length, with two short spines at its base internally; exopod nearly half as long as the endopod, apical spine one and a half times the length of the ramus.

Locality.—Gulf of Manaar, $2\frac{3}{4}$ miles south-south-west of Chilavaturai, depth 2 fathoms; 1 specimen.

This species resembles generally the male of *N. unguiculatus*, but differs in the smoother carapace, in the antero-lateral angle, not serrate, but having a single apical spine, in the group of spines below the pseudorostrum, and in the greater relative length of the exopod of the uropods. The *N. ossiani* described by Mr. STEBBING (WILLEY'S 'Zool. Results,' Part V., Crustacea, p. 612) resembles the present species in the concentric ridges of the pseudorostrum, which, however, appear to be much more strongly marked than in our specimen. It differs in the stouter abdomen, in the more pronounced dorsal depression of the carapace, in the last two thoracic somites, which have the "dorsal centre strongly raised," without the double dorsal crests, and in the absence of the group of spines below the pseudorostrum. Owing to an accident to the present specimen I am unfortunately unable to state exactly the relative proportions of the segments of the last pair of legs. As far as could be seen in the undissected specimen, however, the difference in length between the carpus and propodus was less than in *N. ossiani*. Mr. STEBBING compares his species with the female of SARS' *N. suhmii*, which he suggests may be specifically distinct from the male with which SARS has associated it. The arguments given in favour of this suggestion are not very conclusive, and in particular Mr. STEBBING'S remark that in *N. unguiculatus* "the sexual dimorphism so common in the present order is less striking than usual" does not seem at all applicable to that species. A re-examination of the type specimens of *N. suhmii* in the "Challenger" collection does not support Mr. STEBBING'S suggestion. The specimens, in consequence of the Canada balsam becoming opaque, have had to be removed from the slide on which they were mounted and are therefore more accessible for examination than formerly. I find that the male specimens almost certainly belong to two species, but that the larger and better preserved among them, which alone correspond with SARS' figure (except that the antero-lateral angle of the carapace is less narrowed and produced than is there shown), agree with the female specimen and differ from all the species of *Nannastacus* hitherto described in the extreme reduction of the exopod of the uropods. In the males this ramus, including its terminal spine, does not exceed one-fourth of the total length of the endopod.

REPORT

ON THE

PANTOPODA

COLLECTED BY

PROFESSOR HERDMAN, AT CEYLON, IN 1902.

BY

GEO. H. CARPENTER, B.Sc., M.R.I.A.,
OF THE SCIENCE AND ART MUSEUM, DUBLIN.

[WITH ONE PLATE.]

THE Pycnogons collected by Professor HERDMAN and his colleague comprise two species, both obtained in comparatively shallow water in the Gulf of Manaar and along other parts of the Ceylonese coast. One belongs to *Nymphon* and the other to *Phoxichilus*, both widely distributed genera, ranging from the Arctic Ocean to the southern seas. *Nymphon* is, however, a genus much richer in species, and shows a wider distribution than *Phoxichilus*. Both the forms seem to be referable to new species, and as numerous individuals have been collected in an excellent state of preservation, it is easy to describe and figure their distinctive characters. The *Nymphon* is abundantly distinct from any known species. *Phoxichilus*, on the other hand, is a genus whose named forms are of doubtful "specific" value. But all the more on that account is a careful study of specimens from new localities desirable as a guide to the extent and nature of variation.

I am much indebted to Professor HERDMAN for entrusting me with this interesting, if small, collection for examination and report.

FAMILY: PHOXICHILIDÆ.

Phoxichilus, LATR.

Phoxichilus mollis, n. sp.—Plate, figs. 1–7.

Length 5 millims. Body proportioned as in *P. lævis*, GRUBE,* but almost entirely unarmed, only a few minute spines on the lateral processes and on the head-segment (figs. 1, 2). Femur of each leg evenly swollen distally without angular projections, armed only with a series of minute spines along the edges and four terminal spines (figs. 1, 3). Male with 24 cement glands on each femur (figs. 3, 4, *c.g.*). False leg of male with 6th segment greatly thickened and enlarged laterally (figs. 5, 6). Propodus with 5 stout basal teeth (the 3rd the longest) and 6 small distal teeth (fig. 7).

Habitat:—Coasts of Ceylon. Two males and several females picked off experimental oyster cage hung over side of ship on the North-East Cheval Paar, 15th February, 1903. Cheval Paar, 2 males, one with eggs and one young female. Deep water off Galle; young female.

The above characters will serve to distinguish this species from any form of *Phoxichilus* hitherto described, the feeble armature of the trunk and femora being the most striking character. The armature of the tibial segments, though feebler than in the European forms, approaches the usual type of the genus, while the tarsus, propodus, and claws differ but slightly from those of other species of *Phoxichilus*. It seems, therefore, that the loss of spines begins on the trunk and extends slowly towards the extremities.

The two forms of *Phoxichilus* most nearly related to the present species are *P. meridionalis*, BÖHM,† from Singapore, and the problematical *P. inermis*, HESSE.‡ The former of these, however, has very prominent spines on the femur, and seems to approach *P. lævis* rather closely, while the latter is said to be 10 millims. long, with almost entirely unarmed legs and a 3-segmented abdomen (the last statement needs confirmation).

I have elsewhere§ drawn attention to the slight comparative characters by which the various described forms of *Phoxichilus* are distinguished from one another, and I think it likely that when specimens of this genus have been obtained from many other parts of the world, it will be impossible to maintain "specific" distinctions. Already we have a series beginning with the well-armed *P. spinosus*, MONT., passing through *P. lævis*, GRUBE, *P. vulgaris*, DOHRN, *P. meridionalis*, BÖHM, to *P. mollis* and *P. inermis*, HESSE, in which the spiny armature has become, to a great extent, lost. And it is of special interest in this connection to note that in one of the Ceylon

* 'Abhandl. d. Schles. Gesellsch. f. vaterl. Cultur,' 1869–72, p. 124–126, Taf. 1, fig. 1.

† 'Monatsber. d. Königl. Akad. Wissensch. Berlin,' 1879, p. 189–191, Plate 2, fig. 4.

‡ 'Ann. Sci. Nat.' (Zool.), (5), vii., 1867, pp. 199–201.

§ 'Sci. Proc. R. Dublin Soc.,' vol. viii., 1893, pp. 200–202.

males of *P. mollis*, the femur both in its form and armature (fig. 3A) shows some approach to what we find in the European species of *Phoxichilus*. The young individuals, too, are markedly spinose as compared with the adults.

The colour of these Ceylon specimens is a pale yellowish-green, the food-canal showing through the semi-transparent body in bluish-green streaks. The male carries the eggs in a large flat cake-like mass of somewhat irregular form (fig. 3).

Family: NYMPHONIDÆ.

Nymphon, Fabr.

Nymphon longicaudatum, n. sp.—Plate, figs. 8–14.

Length, 6 millims. to 8 millims. Head segment nearly as long as the three thoracic segments taken together, neck slender and elongate. Proboscis swollen centrally and constricted behind mouth (fig. 8). Eye eminence with low conical apex (fig. 9). Chelifori elongate; scape nearly as long as proboscis; hand rather longer than scape, with slender, tapering, evenly curved fingers (figs. 8, 10). Palp half as long as body; relative length of its segments as 2 : 8 : 9 : 10 : 6. False leg as long as body; relative length of its segments as 2 : 4 : 4 : 20 : 24 : 10 : 6 : 4 : 4 : 3; denticulate spines with a short sharp basal point, and six to eight sinuous serrations on each side (figs. 11, 12, 13). Legs slender and elongate, spines present only at the tip of the second tibial segment; propodus four times as long as tarsus; principal claw slender, slightly longer than tarsus; auxiliary claws four-fifths as long as principal claw (fig. 14). Abdomen very elongate, slender and club-shaped (fig. 8); as long as the first two thoracic segments together. Colour of body and legs yellow, with a variable amount of dark pigment which is specially well developed along two lateral longitudinal lines on the thoracic segments.

Habitat:—Gulf of Manaar, coral reefs and pearl banks, February and March, 1902. South of Manaar Island (Station LIV., 8 to 9 fathoms), March 8th, 1902. West of Periya Paar (Station LXI., 12 fathoms), March 12th, 1902.

This *Nymphon* is markedly distinguished from any species of the genus known to me by the elongate abdomen, the proportion of the tarsus to the propodus, and the distinct linear pattern on the trunk segments due to the dark pigment. The almost complete absence of spines on the body and legs—which are clothed only with a few scattered, minute hairs—is another striking character.

As usual in this genus, there is no marked difference between the sexes. In the female the proboscis and neck are relatively shorter than in the male.

It is of interest to note that both these species are remarkably poor in spiny or hairy armature or clothing as compared with other members of their genera. Possibly those naturalists who have had the good fortune to observe the animals amid their natural surroundings may be able to suggest some explanation of this modification.

REPORT

ON THE

CEPHALOPODA

COLLECTED BY

PROFESSOR HERDMAN, AT CEYLON, IN 1902.

BY

WILLIAM E. HOYLE, M.A., D.Sc.,
DIRECTOR OF THE MANCHESTER MUSEUM.

[WITH THREE PLATES.]

THE collection of CEPHALOPODA, though small, contains several forms of interest. The greatest novelty is a small Octopus, with branched processes scattered over the body, which I have named *Polypus arborescens.* In the integument of these processes are certain peculiar organs, which I have described as well as the state of preservation of the specimens would allow.

A very striking peculiarity of the collection is the preponderance of Octopods; the Decapods are represented only by very few forms, and there is an entire absence of any of the usual pelagic types, owing, no doubt, to the collection having been made for the most part in shallow water on a continental shore.

The number of small Octopods is very large; judging from it these little creatures must swarm on the reefs in those regions. Though very interesting, these immature forms are very baffling and in some respects unsatisfactory as material for a report. In the first place, it is impossible to name them. Their distinctive marks admit of their being grouped pretty readily into sets which presumably correspond to species, but to which of the numerous named adult forms they belong it is quite impossible to say. So far as I am aware, no one has yet studied or described the changes which take place in an Octopus from the time of its emergence from the egg till it attains maturity, and as we are ignorant of this in the commonest forms, it is hopeless to expect the information in the case of the rarer exotic species. I have, therefore, contented myself with describing the more conspicuous varieties of these young Octopods, but without affixing any specific names.

The information given by these young specimens is, however, satisfactory, inasmuch as it shows that even at so early a period different forms can be separated from each other by characters as definite as those which are used in the discrimination of the adult species, not that this is saying much in the case of Octopods, for we are still very much in the dark as to the best specific characters and the range of variation in this bewildering genus.

List of Stations

at which Cephalopoda were obtained, with the species collected at each. The numbers in square brackets correspond to my register of specimens examined :—

STATION I.—First haul of trawl, 31.1.02; 5 miles west and south-west of Negombo; 12 to 20 fathoms; bottom coarse yellow sand with a few dead shells; temperature of sea, 77·5° F.

Sepia rouxi [246].

STATIONS II. and III.—West Ceylon, 1.2.02; various localities between Negombo and Chilaw; 4 to 5 miles off land; depth 8 to 14 fathoms.

Polypus arborescens, n. sp.	[213–215].	*Polypus* J	[205, 206].
,, C	[203, 204].	,, *macropus* (?)	[230].
,, E	[202].	,, *granulatus*, juv.	[195].
,, G	[208].		

STATION LVI.—Half-a-mile east of Dutch Modragam, 2nd haul, 10.3.02; depth 8 to 9 fathoms; bottom coarse quartz sand, with red weed.

Polypus aculeatus	[200].	*Polypus* B	[244].

STATION L. or LI.—Pearl banks, Cheval Paar, 4.3.02; depth 7 to 8 fathoms; bottom sand and dead shells.

Polypus C [196].

STATION LXV.—South end of Cheval Paar.

Polypus herdmani, n. sp.	[231].	*Polypus granulatus*	[211].

STATION XVI.—On Periya Paar; depth 9 fathoms; bottom varied, sand to Nullipores and Coral.

Polypus arborescens, n. sp.	[217].	*Polypus herdmani*, n. sp.	[216].

STATIONS IX. to XIV., XLVIII. and XLIX.—Pearl banks, Gulf of Manaar, Cheval district.

Polypus herdmani, n. sp.	[224–226, 228, 229].	*Polypus macropus*, juv. (?)	[275].
,, *arborescens*, n. sp.	[212, 239–243].	,, A	[233–237, 636 (?)].
,, *aculeatus*	[218–221, 266, 276, 630–632].	,, B (?)	[635].
,, ,, (?)	[197].	,, C	[247–261, 633].
,, *granulatus*	[222, 223, 238].	,, D	[227, 267, 638].
,, *boscii*	[271].	,, G	[194].
,, ,, var. *pallida*	[272, 274].	,, H	[209, 210].
		Inioteuthis maculosa	[198].
		Euprymna morsei	[245].
		Sepia singalensis	[270].

STATION XVIII.—Palk Bay, 14.3.02; south-east of Catchetivo Island; 7 fathoms.

Polypus C [199]. | *Polypus granulatus* [268, 269].

STATION XIX.—Palk Bay; depth $4\frac{1}{2}$ to 8 fathoms; bottom, sand and shells to mud; sea temperature, 7 A.M., 82·8° F.; 5 P.M., 84° F.

Polypus herdmani, n. sp. [201].

STATION XXIII.—Trincomalee, close to Swami Rock, Back Bay; depth $4\frac{1}{2}$ to 8 fathoms; bottom sand, shells, and in places stones and Corals.

Polypus F [207].

STATION XXXIX.—Galle, trawled; from 2 miles south of Point de Galle westwards to Gallehogalle Bank: depth 16 to 30 fathoms; bottom fine sand; stones and Nullipore on the bank.

Sepiadarium kochi [232]. | *Sepia singalensis*, juv. [262–265].

Galle, captured by Professor HERDMAN in the lagoon.

Polypus herdmani, n. sp. [277].

CEPHALOPODA.

SUB-ORDER: OCTOPODA

FAMILY: POLYPODIDÆ.

Polypus herdmani, n. sp.—Plate I.

The Body is comparatively small, purse-shaped, considerably wider behind than at the margin of the mantle; there is no groove on the ventral surface. The mantle opening is very wide, extending more than half-way round the body, and ending a short distance below and behind the eyes. The siphon is comparatively short, extending rather less than half-way to the umbrella margin.

The Head is comparatively small, and the eyes but slightly prominent.

The Arms are long and stout, on an average nearly four times as long as the body. The umbrella is moderately developed; it is narrowest between the two dorsal arms, somewhat broader between the two ventral, and between the lateral arms about equal to the length of the body. The suckers are of moderate size and closely packed; the first four are in a single series, the remainder in two series.

The Surface is wrinkled by folds, probably due to contraction in spirit. It bears a large number of prominent warts or tubercles; on the back, these are for the most part elongated antero-posteriorly, and the skin around them is thrown up into a series of radiating folds; four of these are arranged at the corners of a rhombus with its long axis in the median line, a little distance behind the eyes, and about a dozen others are distributed more or less irregularly on the posterior part of the back. There are also a number of these elongated warts on the proximal portion of the dorsal and dorso-lateral arms. There are two or three very minute warts above and behind the eye.

The Colour is a dull brownish-grey, paler below. At the base of the ventro-lateral arm, about one-third of the distance between the eye and the edge of the umbrella, is a large eye-like spot, about 13 millims. in diameter, consisting of a pale centre surrounded by a broad dark ring; this in its turn is surrounded by a narrow pale ring, again succeeded by a narrow dark one.

Dimensions of Specimen No. 277.

		Millims.
Length, total		550
End of body to eye		95
Breadth of body		58
,, head		47

,, second arm	,, 356,	,, 316
,, third arm	,, 330,	,, 330
,, fourth arm	,, 356,	,, 285

Localities:—Galle, caught by Professor Herdman in the lagoon. One specimen, female [277].

Station XIX., Palk Bay. One specimen, sex (?) [201].

Station XVI., north of Periya Paar. One specimen, female [216].

Pearl banks, Gulf of Manaar. Five specimens [224, male; 225, 226, female; 228, 229, arms mutilated, sex uncertain].

Station LXV., south end of Cheval Paar. One specimen, sex (?) [231].

The species seems to me sufficiently characterised by the presence of the peculiar ocellar spot near the base of the ventro-lateral arm, which is presented with more than usual constancy in all the specimens of the series recorded above. A few minor modifications which occur in the different individuals may be recorded as a means of indicating the amount of variation in the species.

In specimen 201, measuring 10 millims. from the hinder end of the body to the eye, the skin is comparatively smooth, three of the four warts forming the lozenge on the back can be made out; there are a few small warts around the eye, especially on the left side, and the bases of the dorsal arms are granular. In the left ocellus the pale ring is elevated above the general surface, and the pale spot in the centre also forms a raised papilla.

Specimen 216, measuring 10 millims. from the end of the body to the eye, is very firm and shrivelled, and appears at some time to have been allowed to dry up. The four warts on the back are very distinct, and some of the ridge-like warts on the bases of the arms are also visible.

Specimen 224, measuring 10 millims. from the end of the body to the eye, is somewhat more developed than Nos. 225 and 226 found with it. The ocellar spot on the left side is very distinct, but in the centre is a minute black point instead of a pale patch. The four warts, arranged at the angles of a lozenge, are present, as well as some on the bases of the arms. There is also a wart above and behind each eye.

Polypus arborescens, n. sp.—Plate II., figs. 8, 9 and 12, and Plate III.

The Body is rounded, oblong, usually ending in an acuminate point behind; the mantle opening is narrow, extending only about one-third the distance towards the eye from the siphon, which is short and truncated, and reaches only one-third from the mantle opening towards the margin of the umbrella.

The Head is about as wide as the body, and the eyes are only slightly prominent.

The Arms are on an average about twice as long as the body, measured from the posterior end to the eye; those of the fourth pair are the largest, the first the shortest. The umbrella extends up them rather more than one-third their length. The suckers present no unusual characters, the first four are in a single row, both in a specimen with the arms strongly bent outwards and one in which they are nearly parallel. The hectocotylus is of the form usual in the genus, with a very small tip.

The Surface presents a number of branched papillæ, which constitute the most characteristic peculiarity of the species and suggested its specific name. One of these, larger than the others, occupies the acuminate posterior extremity of the body above alluded to; there are one or two over each eye, about a dozen on the back, a few on the ventral surface, and in most cases one or two on the outer aspect of each arm.

They vary somewhat both in size and arrangement. An account of their minute structure will be found below.

The Colour is a dull grey with irregular, oval ring-like markings on the dorsal surface and the bases of the arms.

Localities :—Station II. or III., west of Ceylon. Three specimens [213–215].

Cheval Pearl Banks, Gulf of Manaar. Six specimens [212, 239–243].

Station XVI., on Periya Paar ; depth 9 fathoms. One specimen [217].

I am not acquainted with any other species at all resembling this one in its surface decoration.

The fact of the proximal suckers being in a single row, not only in arms which are bent outwards, but also in those which are straight, is of some interest. The arrangement of these suckers has often been made use of as a specific character, but has always appeared to me to be of very doubtful validity, because there is no doubt that in many instances it varies with the curvature of the arm. The present instance suggests that it may have more value than I have hitherto supposed.

Structure of the Branched Papillae.

The Papillæ vary a good deal in dimensions. An average one (Plate II., fig. 8) would be 0·75 millim. high by 0·4 millim. in diameter, whilst a large one (Plate II., fig. 9) would attain 1·65 millims. in height by 0·6 millim. in diameter. Each consists of a stem and branches, both of which are plentifully bestrewn with chromatophores. Between the larger papillæ are small ones of various degrees of complexity ; some are simple, some bifurcated, some with three or more branches. Papillæ of the smaller kinds are found on the bases of the arms.

The Stem is conical in form, arising gradually from a broad base. In the smaller papillæ (Plate II., fig. 8) the stem remains unbranched to the apex and there gives rise to branches, from two or three to about half a dozen in number. In the larger (Plate II., fig. 9) the branches are given off at intervals from near the base. Sometimes the apex is seen to persist independently of the branches; in other instances there is no definite apex, but the stem divides into a tuft of branches at the top. The apex sometimes presents a yellowish appearance as though a yellow internal mass were shining through the integument.

The Branches are almost cylindrical, tapering only very slightly towards the tips, which are bluntly rounded off. Their diameter varies from 0·03 millim. at the tip to 0·15 millim. at their junction with the stem, and their length from 0·8 millim. to 0·25 millim. In most cases they are simple, but in a few instances they bifurcate (Plate II., fig. 8), and still more rarely trifurcate (Plate II., fig. 9).

When a series of sections is examined, it is found that in those taken near the base, just above the muscles of the body wall, there is in the centre a mass of tissue (Plate III., fig. 1, *cm.*) from 0·21 millim. to 0·24 millim. in diameter. It stains but faintly and presents the appearance of a number of delicate fibrils twisting about in all directions and leaving spaces in which nuclei are situated, though no definite cell boundaries can be distinguished (fig. 4, *c.m.*). The nuclei measure about 0·0058 millim. in diameter, and nucleoli can be seen in them. This central mass rises as a rounded lump to a height of about 0·18 millim.

The greater part of the centre of the stem is made up of a peculiar radially arranged supporting tissue, which stains very deeply with hæmatoxylin. In sections near the base of the papilla this tissue appears as a ring around the central mass and consists of very thin radiating fibres (Plate III., figs. 1 to 4, *r.*), which are collected together in masses forming little trabeculæ, which arise from the surface of the central mass and pass outwards, slightly diverging from each other and leaving clear spaces between them. The rounded spaces at the outer ends of the trabeculæ are occupied by bundles of fibres, which run parallel with the axis of the stem: transverse sections of these bundles are seen in fig. 4, *b.* The trabeculæ stain a deep purple with hæmatoxylin, and thus are in marked contrast with the central mass. They present a number of ovoid nuclei intercalated here and there among the fibres. Above the central mass this axial structure occupies the centre of the stem (compare figs. 1 and 2), and rises up to a height of about 0·7 millim., when it gradually merges into the other tissues of the stem. This axial supporting tissue is produced into the branches, but here it has the appearance of irregular transverse septa (fig. 6, *r.*) with spaces between. The septa are not separate, but continuous with the adjacent ones on either side, owing to their curved form and to connecting pieces passing from one to another. Towards the tip of the branches this tissue becomes less abundant and merges into the surrounding connective-tissue. In the stem this axial tissue is seen to be supplied with blood vessels (fig. 4, *bl.*), but I have not succeeded in detecting any nerves in it.

Around this central column is a layer of connective-tissue (figs. 1 to 3, *c.*) varying from 0·05 millim. to 0·02 millim. in thickness. This is of a loose open nature, with delicate fibrils and numerous large lacunæ; small ovate or spheroidal nuclei are scattered in it here and there. This layer extends into the branches, in the larger of which it is about 0·03 millim. in thickness (fig. 5, *c.*), and gradually disappears towards the tips. Within this connective-tissue layer are the chromatophores and another granular element to be described below.

The chromatophores (*ch.*) are situated in the outer layers of this connective-tissue, either immediately below the epithelium or not very far removed from it. They have the form of little sacs, on an average about 0·035 millim. in diameter. Very often there is a vacant space immediately below the chromatophores (figs. 4 and 13, *l.*). Where the section passes tangentially through the wall of a chromatophore the pigment is seen to be composed of minute granules (fig. 12, *ch.*).

In the connective-tissue layer are also seen here and there masses of substance staining of a paler and more reddish colour than the other tissues and of homogeneous granular nature (figs. 5, 7, *g.*). This substance is highly refringent and, as above mentioned, stains a pale reddish colour with hæmatoxylin and pale yellow with picronigrosin. I thought at first that it might perhaps be muscular, but on further examination it appeared to consist of rounded masses not fibrils, and at present its nature and function seem to be quite uncertain. It does not appear in the basal portion of the papilla, but commences about halfway up the stem, and is most abundant in its distal portions and in the stouter branches, where it sometimes occupies quite a large proportion of the transverse section (fig. 5, *g.*), and I think it is the cause of the yellowish appearance of the apex mentioned above. It extends in gradually decreasing amount along the branches, but ceases some distance from the tips (figs. 7 and 8). Towards the tips of the branches the various component tissues gradually disappear, leaving only the connective-tissue and epithelium (fig. 8).

The epithelium covering the papillæ (figs. 1 to 9, *ep.*) consists of a single layer of cells, and is about 0·02 millim. in thickness. The cells are of rounded quadrangular outline and have large spheroidal nuclei.

In relation with the epithelium are certain peculiar spherules (Plate III., figs. 9 to 13), the nature of which seems to me very problematical. There are between 15 and 20 of these arranged in a ring around the stem of the papilla quite close to its base. They are irregularly placed, sometimes in a single row, sometimes in two, and they vary in diameter from 0·034 millim. to 0·05 millim. Very few of them come to the surface, and I was unable to find any trace of them by surface examination. I am inclined to think that the different appearances presented by these bodies indicate developmental stages, and I will therefore first describe what seems to be the most complete form.

The central part of the organ consists of a cylindrical plug (figs. 9 to 13, *p.*), the outer end of which is almost on a level with the surface of the epithelium, the other extremity penetrating somewhat below it. The outer end is slightly convex, the inner appears to merge gradually into the tissue beneath. In transverse sections the plug is oval, the diameters being 0·03 millim. and 0·025 millim.; the length of the plug cannot be measured exactly, owing to its fusion with the other tissues at the lower end, but it may be taken at about 0·035 millim. The composition of this plug is faintly granular and almost homogeneous; it shows traces of breaking up here and there into fragments by transverse lines, but this is probably an effect of shrinkage. Below the plug and sometimes apparently rising up around it is a mass of tissue of a flattened spheroidal shape (*m.*). The plug fits into a depression in the outer surface of it, and its lateral expansions support the superficial epithelium. In the only longitudinal section I have of one of these structures (fig. 10) the diameter of this lower portion is 0·065 millim., and its depth below the epithelium 0·021 millim. approximately. In this longitudinal section it appears granular and faintly stained like that of the plug, but there is a distinct tendency for the granules to be arranged in layers (figs. 10, 11, *m.*). In sections at right angles to this the structural arrangement is concentric with the plug. Definite layers cannot be made out, but portions of greater and less density alternate with each other (figs. 12, 13, *m.*). In some instances I was able to make out a nucleus either in the plug itself or in the subjacent granular tissue. This spheroidal mass has no definite boundary, but gradually passes over into the connective-tissue lying beneath the epithelium.

The epithelium covering the surface of the papilla undergoes a modification in the neighbourhood of these organs. For a little distance around, the cells become columnar instead of cubical, and their nuclei long and attenuated instead of spheroidal (compare figs. 11 and 13). It seems probable that this is due to a compression caused by the plug pushing its way to the surface from beneath. The cells closely surrounding the plug are even more flattened, so as to form an envelope round the sides of the plug, and often to extend inwards a little way below the general lower surface of the epithelium (fig. 9), so that a section parallel with the surface shows them as a ring surrounding the plug, and in their turn encircled by the granular mass (fig. 12, *ep.*).

The upper surface of the plug shows a dense deeply stained boundary, outside which is sometimes a thicker more faintly stained layer (fig. 10), and from this arises a bunch of radiating fibres (figs. 10, 11, *f.*). These are extremely thin, straight, and many of them have slight swellings at the end. They are about 0·06 millim. in length, and their diameter too small to be measured by any appliances at my disposal; it is certainly less than 0·0015 millim. Generally they appear quite discrete, but in one section there seemed to be a delicate transparent substance connecting their tips, and spreading out beyond their extremities into a sort of thin cloud. I did not observe this in any other sections and conclude that it is in some way due to artificial causes.

It is only some half-dozen of these organs which present the appearance just described, that is to say, which come up to the surface and give off a tuft of fibrils. The remainder are completely covered by the epithelium, and hence I conclude they are similar bodies in course of development, which have not yet reached the surface.

The nature of these bodies seems to me very obscure; the different possibilities are as follows:—In the first place they may be parasitic; the radiating tuft of fibrils with thickened ends suggests an Acinetan, but against this are to be set the following considerations: these bodies appear to originate from within and not from without, there is no definite boundary between them and the surrounding connective-tissue, and their granular substance does not resemble the cell contents of the Protozoa.

Assuming that they belong to the Cephalopod, there seem to be difficulties in the way of referring them to any recognised type. The possibility of their being either glandular or phosphorescent seems to be excluded by the tuft of radiating fibrils, whilst against a sensory function must be urged the fusion of their lower portion with the surrounding tissues and the fact that no nerves have yet been traced to them. On the whole, this last view would seem to present less difficulty than the others, and it may, therefore, be adopted as a working hypothesis. Dr. ASHWORTH has called my attention to their similarity to the lateral organs of Annelids, described by EISIG ('87) and himself (:01).

With respect to the function of the papilla as a whole, the most plausible explanation appeared to me that they are protective. In the spirit specimens they are not altogether unlike the tentacle-bearing heads of polyps, such as *Hydractinia*, and I thought they might furnish the Octopus with a disguise to assist it in concealing itself. Professor HERDMAN, however, tells me that this theory does not agree with his observations on the living animal, which he kept for some time in a small tank. Under these conditions "the papillæ do not look at all like polyps; they are contractile and are kept frequently moving—uncoiling to a considerable length and then curling up again suddenly."

Polypus aculeatus (D'ORBIGNY); GOODRICH ('96)—Plate II., figs. 10 and 13.

Localities:—Pearl Banks, Gulf of Manaar, Cheval district. Ten specimens [197, male (?); 218–221, female; 266, male; 276, female; 630–632, sex (?)].

Station LVI., half-a-mile east of Dutch Modragam. One specimen, sex (?) [200].

. The coloration of these young specimens so closely resembles that of D'ORBIGNY'S species (*Octopus aculeatus*) that I feel but little hesitation in referring them to it. This identification is confirmed in most instances by the presence of small tubercles arising from the centre of the pale circular patches on the upper surface. The general appearance of these examples is shown in Plate II., fig. 13.

Specimen 197 was very small, only 5 millims. in length from the end of the mantle to the eye; the patches were indistinct and no tubercles were visible, so that the determination is less certain than in the other cases.

Specimen 266 was the largest, and measured 15 millims. from the hinder end of the body to the eye. The hectocotylised arm (Plate II., fig. 10) had apparently been mutilated and subsequently repaired. It is normal up to within 2 centims. of the extremity; there it becomes swollen up (*a*) and the suckers suddenly cease; the groove on the ventral aspect (*b*) runs out on the surface where the suckers should be and stops abruptly, about 5 millims. beyond the gap in the series of suckers. From this point there grows out a new tip, quite normal in appearance and about 10 millims. long (*c*). A new groove (*d*) has been formed, starting from a point a little beyond the place where the original groove ceases and quite disconnected from it, and the usual spud-shaped extremity has been formed at the apex of the arm (*e*). This reproduction is of special interest by reason of its rarity. STEENSTRUP ('56, p. 107, footnote) was of opinion that the hectocotylised arm was never replaced, and that consequently the animals exercised special care in order to prevent injury to it. The examination of this specimen further raises the interesting question: If the function of the groove be to transmit the spermatophores, could this action be carried out in the event of the groove being interrupted?

Specimen 276, measuring 9 millims. from the hinder end to the eye, has many characters in common with the others above mentioned, but the colouring is much darker; the papillæ in the centres of the rounded areas are black instead of pale, and there are also black papillæ on the outer aspect of the proximal half of the arms. At present it seems to me most likely a melanic example of *Polypus aculeatus*, but it may perhaps be the young of some undescribed species.

Polypus boscii (Lesueur).

Localities :—Pearl banks, Gulf of Manaar, Cheval district. Three small specimens [271, male; 272, female; 274, male].

This species has hitherto only been recorded from the Australian region. Specimens 272 and 274 are characteristic examples of the var. *pallida*, first obtained by H.M.S. 'Challenger' (Hoyle, '86, p. 81, plate I.).

Polypus macropus (Risso) (?); Goodrich ('96).

Localities :— Station II. or III., West Ceylon. One young specimen [230, female].

Pearl banks, Gulf of Manaar, Cheval district. One specimen [275, male].

Two small specimens, 11 millims. and 8 millims. in length from the end of the body to the eye respectively, may be the young of this widely-distributed species.

Polypus granulatus (Lamarck); Hoyle ('86); Goodrich ('96).

Localities :—Station II. or III., West Ceylon. One young specimen, sex (?) [195].

Station LXV., south end of Cheval Paar. One specimen, sex (?) [211].

Pearl banks, Gulf of Manaar, Cheval district. Three specimens [222, 223, 238].

Station XVIII., Palk Bay, south-east of Catchetivo Island, 7 fathoms. Two specimens [268, 269].

Specimen 195, measuring 8 millims. from the end of the body to the eye, is paler in colour than usual and has a double row of small chromatophores along the outer surface of each arm.

Specimen 211, measuring 12 millims. from the end of the body to the eye, I thought at first must be a male, in which the hectocotylisation was just beginning; it has a slight ridge along the ventral aspect of the third right arm, but no modified tip is to be seen. I have, however, since seen similar ridges on several different arms.

Polypus, juv., A—Plate II., fig. 1.

A number of small Octopods, averaging 5 millims. in length from the hinder end of the mantle to the eye, agree in having a smooth body, long slender arms, connected by a very delicate umbrella extending 4 millims. to 6 millims. from the base, a double row of small dark chromatophores on the outer surface of each arm, and a conspicuous patch of them on the under surface of the mantle.

Locality :—Pearl banks, Cheval neighbourhood, Gulf of Manaar. Five specimens [233–237].

Polypus, juv., B—Plate II., fig. 4.

A smooth form, with very prominent eyes and a few scattered granules on the upper surface.

Locality :—Station LVI. (?), half-a-mile east of Dutch Modragam, second haul. One specimen, sex (?) [244].

Polypus, juv., C—Plate II., figs. 2 and 5.

The specimens enumerated below all appear to me to be the young of one and the same species, which it is just possible may be *P. granulatus* (Plate II., fig. 2). Their most conspicuous characters are a plump, rounded body, short arms, with a rudimentary umbrella between them, a slight but distinct granulation on the back and between the eyes; there is a single row of rather large pale chromatophores on the outer surface of the arms, and one or more bands of them run along the under surface of the mantle parallel with the opening (fig. 5).

Localities :—Station L. (?), pearl banks, Cheval Paar, 4.3.02. One specimen [196].

Station XVIII., Palk Bay, S.E. of Catchetivo Island, 7 fathoms. One specimen [199].

Station II. or III., West Ceylon Two specimens [203, 204].

Pearl banks, Cheval neighbourhood, Gulf of Mánaar. Fifteen specimens [247–261].

Polypus, juv., D—Plate II., fig. 11.

A young form, 10 millims. in length from the hinder end of the mantle to the eye, with a short, rounded body, prominent eyes, with a small wart over each, long slender arms (25 millims. to 30 millims. in length), united by a broad umbrella (10 millims. in breadth, except between the dorsal arms, where it is much less), two irregular rows of small chromatophores along the outer surface of each arm, and a conspicuous patch of chromatophores on the ventral surface. There are two or three moderate-sized warts on the back and a number of small ones on the broad portion of the upper arms. The measurements are taken from specimen 227.

Locality :—Pearl banks, Cheval neighbourhood, Gulf of Mánaar. Two specimens [227, female ; 267, male].

This form agrees with that which I have marked A in the conspicuous patch of chromatophores on the ventral surface and the rather wide, delicate umbrella, but it differs in the presence of well-marked warts over the eyes, and in the chromatophores on the arms being much less delicate and regular. I think they are the young of distinct species.

Polypus, juv., E.

This specimen, 6 millims. in length from the hinder extremity to the eye, has a roughish surface, small warts over the eyes, and two rows of chromatophores widely separated along the outer surface of the arms, which are of moderate length (10 millims. to 12 millims.).

Locality :—Station II., off Chilaw, west of Ceylon. One specimen, sex (?) [202].

This form differs from the one marked A in being more granular, in having small but distinct warts over the eye, and in the arms being comparatively shorter and with a much smaller web.

Polypus, juv., F—Plate II., fig. 6.

This young specimen, 7·5 millims. from the hinder end to the eyes, has the upper surface slightly granular, more markedly so between the eyes, and to some extent on the upper and outer surface of the umbrella and between the dorsal arms. There are two small indistinct warts above each eye; the colour is a dull purplish-grey, paler below. There are two rather irregular rows of chromatophores along each arm and a few large ones scattered on the under surface. The arms are subequal and about 15 millims. in length. This species differs from the last-named in the granular surface of the upper part of the head and body, and in the fact that the chromatophores are absent on the hinder extremity and much smaller and less abundant on the inferior surface of the mantle.

Locality :—Station XXIII., off Trincomalee. One specimen, sex (?) [207].

Polypus, juv., G—Plate II., fig. 3.

Two young examples, 6·5 millims. and 7·5 millims. in length from the hinder end to the eyes, agree in a general resemblance to those marked C, but the chromatophores on the arms are in two rows, with a very narrow line between them (fig. 3), and on the under surface they are evenly distributed instead of being collected in a band along the opening of the mantle. The arms are short, 10 millims. to 12 millims. in length, measured from the eye.

Localities :—Cheval Paar. One specimen, sex (?) [194].

Station II., off Chilaw, west of Ceylon. One specimen, sex (?) [208].

Polypus, juv., H.

These two specimens, like those just mentioned, closely resemble the series marked C; they have a single row of chromatophores on the outer aspect of each arm, but the arms are much longer in proportion, measuring 10 millims. to 12 millims. in comparison with a body length of 5 millims. There is a minute wart over each eye.

Locality :—Gulf of Manaar. Two specimens [209, 210].

Polypus, juv., J—Plate II., fig. 7.

Two specimens, 5 millims. and 6·5 millims. in length of body respectively, agree in having a curious mottled and variegated surface. The smaller is decidedly darker than the larger. Here and there on the body are rough irregular warts, and it is just possible that they might be the young of *Polypus arborescens.* I do not think this is so, as I should have expected the branched warts to be more developed in a specimen of the size of No. 206.

Locality :—Station II., off Chilaw, west of Ceylon. Two specimens, sex (?) [205, 206].

SUB-ORDER: DECAPODA.

FAMILY: SEPIOLIDÆ.

Inioteuthis maculosa, GOODRICH ('96).

Locality:—Pearl Banks, Cheval neighbourhood, Gulf of Manaar. One specimen, female [198].

Euprymna morsei (VERRILL).

Locality:—Pearl Banks, Cheval neighbourhood, Gulf of Manaar. One specimen, female [245].

The *Inioteuthis morsei* of VERRILL ('81, p. 417); see HOYLE ('86, :04); STEENSTRUP ('87); GOODRICH ('96).

Sepiadarium kochi, STEENSTRUP.

Locality:—Station XXXIX. (?), two miles south of Point de Galle. One specimen, male [232].

The researches of APPELLÖF ('98) on this species and allied forms seem to me to justify his action in classifying it with *Sepiola* and *Rossia* rather than with *Sepia* and *Loligo*, as maintained by STEENSTRUP.

FAMILY: SEPIIDÆ.

Sepia rouxi, FÉRUSSAC and D'ORBIGNY ('35).

Locality:—Station I., off Negombo, first haul of trawl, 31.1.02. One specimen, female [246].

Sepia singalensis, GOODRICH.

Localities:—Pearl Banks, Gulf of Manaar. One specimen, female [270]. Station XXXIX., two miles south of Point de Galle. Four specimens, female [262–265].

Specimens 262–265 are, I think, the young of the same species, but I was not able to make out with certainty the suckers on the buccal membrane.

BIBLIOGRAPHY.

REPORT

ON THE

MARINE FISHES

COLLECTED BY

PROFESSOR HERDMAN, AT CEYLON, IN 1902.

BY

JAS. JOHNSTONE, B.Sc.,
ZOOLOGICAL DEPARTMENT, UNIVERSITY OF LIVERPOOL.

[WITH TWO PLATES AND TWO FIGURES IN THE TEXT.]

THE collection of fishes made by Professor HERDMAN in the Gulf of Manaar and elsewhere around Ceylon contains 117 species belonging to 73 genera. One species, *Salarias furcatus*, is now described for the first time. Several other specimens obtained are also of much interest. A series of stages, including the adult female, of ALCOCK'S *Psettylis ocellata* were obtained, and, since the original description of this species was based on immature specimens, I have been enabled to revise both generic and specific diagnoses. *Solea oculus*, ALCOCK, of which only two specimens have hitherto been obtained, has also been taken by Professor HERDMAN. An undescribed immature form, belonging apparently to the genus *Scatophagus*, which has previously been found off the coast of Patani, in the Malay Peninsula, was also collected.

DAY (**5**), in his revision of Indian Fishes, records about 1010 marine fishes from Indian seas, and ALCOCK (**4**) subsequently gave an additional list of 202 species, mostly deep-sea forms, which were not recorded by DAY. The present collection, therefore, contains about one-tenth of the species known to inhabit the Indian area. The Gulf of Manaar, however, has a more abundant piscine fauna than the present list represents. E. THURSTON (**10**), in a survey of the pearl banks in this area, collected 107 fishes and, owing apparently to the different method of collection adopted, only 16 species are common to the two lists. The total number of fishes obtained from the Gulf of Manaar is therefore 202.

Twelve species in the present collection are now recorded from Indian shores for the first time. These are:—

Monacanthus tomentosus (L.).—Gulf of Manaar.
Hippocampus villosus, GÜNTHER.—At Station LIV., south of Adam's Bridge.
Solenostoma paradoxum, PALL.—Gulf of Manaar.
Opichthys timorensis, GÜNTHER.—At Station LIV., south of Adam's Bridge.
Platycephalus asper, CUV. and VAL.—At Station XX., Trincomalee.
Arnoglossus spilurus, GÜNTHER.—Common.
Pseudochcilinus hexatænia, BLEEKER.—South of Galle.
Pegasus volans, LINN.—At Aripu Reef.
Aploactis aspersa, TEMM. and SCHLEG.—South of Adam's Bridge.
Erythrichthys leucogrammicus (BLEEKER).—Cheval Paar.
Apogon encastigma, RÜPPELL.—At Aripu Reef.
Apogon septemstriatus, GÜNTHER.—At Station XLIV., south-west of Ceylon.

The classification and nomenclature used by DAY have been adhered to for the most part in the following list, with such changes as have been necessitated by the works of GÜNTHER and ALCOCK.

PISCES.

ELASMOBRANCHII.

CARCHARIIDÆ.

Carcharias, sp.

A fœtus, about 14 inches long, which was taken from an unidentified shark, about 5 feet in length, caught in the Gulf of Manaar.

TORPEDINIDÆ.

Narcine timlei (BL. SCHN.)

Two specimens, largest about 6 inches long. Palk Straits.

TRYGONIDÆ.

Pteroplatea micrura (BL. SCHN.).

A small specimen, about 13 inches across the disc. Pearl banks off Aripu.

MYLIOBATIDÆ.

Dicerobatis eregoodoo, RUSSELL.

A large female was taken at the south end of the Periya Paar; the disc was 38 inches long and the tail about 13 inches. A fœtus was taken from this fish which is about 12½ inches across the disc; the disc is about 8 inches and the tail about 14½ inches long.

TELEOSTEI.

SCLERODERMI.

Monacanthus choirocephalus (Bleeker).

Two specimens from pearl banks off Aripu.

Monacanthus setifer, Bennett.

One specimen from the Aripu pearl banks. The skin is velvety and the "pile" is markedly higher on the body between the second dorsal and anal fin than elsewhere. The dorsal spine has 4 very prominent barbs on either postero-lateral margin, and each of these barbs bears a fleshy tentacle which is leaf-like and serrated on both edges. There are somewhat similar tentacles on the body.

Monacanthus tomentosus (Linn.).—Plate I., fig. 2.

Height of body (including ventral spine, but not including dorsal spine) $\frac{1}{2}$ of the total length; dorsal spine about $4\frac{1}{2}$ in the total length; diameter of eye about $\frac{1}{2}$ the length of the dorsal spine. Eyes above and in front of the gill slits.

Radial formula: D. 27; A. 27; P. 12; C. 12.

Dorsal spine with 4 rows of barbs directed downwards. The 2 anterior rows are closer together than the posterior ones, about 5 barbs in each row. A number of smaller barbs irregularly arranged at the base of the spine. Ventral spine very rough with numerous spinules, 6 of which are larger than the rest and are arranged round the base of the spine. A thick membrane joins the spine to the ventral body wall.

Lateral line with two obtuse angles.

The ground colour (in spirit) is light brown, with dark longitudinal, but rather irregular bars.

Skin velvety to the touch, covered with minute spines.

One immature specimen, 1·4 inches long, was found in the Gulf of Manaar.

Triacanthus brevirostris, Temm. and Schleg.

One specimen from pearl banks off Aripu.

Ostracion turritus, Forsk.

One specimen from Aripu.

Ostracion punctatus, Bl. Schn.

One specimen from Trincomalee.

Ostracion nasus, Bloch.

A number of immature specimens ($\frac{1}{2}$ inch and less in length) were taken at Galle. Station XX.

Balistes stellatus, Lacépède.

Skin of specimen about 17 inches long. Galle.

GYMNODONTES.

Tetrodon margaritatus, Rüppell.

One specimen, about $2\frac{1}{2}$ inches long, from Aripu.

Tetrodon lunaris, Bl. Schn.

Numerous immature specimens from Aripu, also one specimen, 6 inches long, which was taken on a line in the Gulf of Manaar.

SYNGNATHIDÆ.

Syngnathus longirostris (Kaup).

Two specimens about $7\frac{1}{2}$ inches long.

Ichthyocampus carce, Ham. Buch.

One immature specimen from south of Galle.

Gastrotokeus biaculeatus (Bloch).

One specimen, 6 inches long, from Gult of Manaar.

Hippocampus villosus, Günther.

Two specimens were obtained which I refer to this species. They differ slightly from Günther's description: the groups of filaments on the tubercles are more dendritic than is represented in his figure. There are about 45 body rings present; the dorsal fin has 16 rays; the length of the snout, which was equal to the distance between the lens of the eye and the gill opening in Günther's specimen, is less in the Ceylon ones, so that the snout appears somewhat shorter. The species, however, are most probably the same.

Two specimens, 1·9 inches long, at Station LIV. (south of Adam's Bridge).

Hippocampus guttulatus, Cuvier.

Two specimens from Station LIV. (south of Adam's Bridge).

SOLENOSTOMIDÆ.

Solenostoma paradoxum, Pall.

One specimen, about $3\frac{3}{4}$ inches in extreme length, from the Gulf of Manaar. The colours, in alcohol, are light orange on the body and crimson on the tips of the fins and on the eyes. The specimen is a female, and has a brood pouch containing both eggs and newly hatched larvæ. Mr. Hornell has since found a specimen covered with arborescent filaments (and with radial formula:—D. 5, 19; A. 21; P. 25; V. 7; C. 16; and two elongated black marks on front dorsal fin) which may be a distinct species.

MURÆNIDÆ.

Muræna picta, Günther.

One specimen from Galle Lagoon.

Opichthys timorensis, Günther.

Two eels, about $9\frac{1}{4}$ inches long, were obtained on Station LXV. (west of Cheval Paar), which appear to belong to this species. The dorsal and anal fins are very low, almost absent ; the former begins immediately above the gill slits, the latter a little distance behind the anus. The tail is a little longer than the body ; the head is contained 7 times in the distance between the snout and the anus ; the body is lumbriciform. The teeth are small and pointed ; there are 2 rows on the vomer and a single row in the upper and lower jaws. The coloration is almost uniform (in spirit), yellowish, with brown granular dots on the back.

CHIROCENTRIDÆ.

Chirocentrus dorab (Forsk.).

One specimen, about $12\frac{1}{2}$ inches long, from Palk Strait.

CLUPEIDÆ.

Engraulis commersonianus (Lacépède).

A number of specimens, about 3 inches long, from pearl banks off Aripu.

Clupea fimbriata (Cuv. and Val.).

From pearl banks off Aripu.

Pellona indica, Swainson.

From pearl banks off Aripu.

SCOMBRESOCIDÆ.

Belone, sp.

A young fish, about $\frac{9}{10}$ inch long, found in the Gulf of Manaar, is referred to this genus. The characters of the young differ so much from those of the adults, that it is hardly possible to determine the genus with accuracy. The jaws are not prolonged, and the caudal is truncated. The dorsal fin has 23 rays and the anal 22.

SCOPELIDÆ.

Saurus indicus, Day.

Galle ; very numerous ; also Palk Bay.

Saurus myops (Forsk.).

Galle ; very numerous.

Saurida tumbil (BLOCH).

Galle and Aripu; very numerous.

Saurida nebulosa (SOLANDER).

One specimen was dredged $\frac{3}{4}$ mile north-north-west of Foul Point, Trincomalee, Station XXIV.

SILURIDÆ.

Freshwater fishes were not collected, so that this family is only slightly represented.

Arius venosus, CUV. and VAL.

Three specimens, the largest of which is about 12 inches long, were obtained at Station XVII., on the pearl banks off Aripu.

PLEURONECTIDÆ.

Flat fishes are, as might be expected, very well represented in this collection. Eight genera and 16 species altogether were collected.

Psettodes erumei (BL. SCHN.).

Numerous specimens up to 14 inches long were obtained from the pearl banks off Aripu. This species appears to be indifferently sinistral and dextral. The single specimen examined was sinistral.

Pseudorhombus arsius, BLEEKER.

Numerous specimens, varying in length from 12 inches downwards, were collected from Station II., near Negombo, and from the pearl banks off Aripu.

Solea oculus, ALCOCK.

The only specimen belonging to this genus was obtained in Palk Bay, Station XIX. It agrees in every particular with the beautiful species obtained by ALCOCK (3) in Bengal Bay, 32 miles south-west of Puri. It is $3\frac{1}{10}$ inches in extreme length. The depth of water it was obtained from is curiously enough exactly that (7 fathoms) recorded by ALCOCK.

Synaptura cornuta, CUV.

One specimen, about 5 inches in extreme length, was obtained in deep water (25 to 30 fathoms) off Galle, Station XLVI. There are 14 dark bands on the ocular side which are perfectly parallel and transverse to the long axis; each is darker at its margins. The anterior thickened first ray of the dorsal fin is markedly on the blind side. The pectoral fins are short and thickened; their bases are covered with small scales, and they are continuous with the upper margin of the opercular fold. The scales are peculiar; the projecting margins are thickly covered with skin, and on the head, on the blind side of the body, these integumentary margins become thicker and might be regarded as short tentacles. The scales are continued on both sides of the body for a short distance into the gill cavities.

Psettyllis pellucida, ALCOCK.

Palk Bay, 3 specimens, 1·3 inches to 1·6 inches.

Psettyllis ocellata, ALCOCK.

Palk Bay, 7 specimens, 1·6 inches to 2·2 inches, and a mature female, 4·7 inches long—the latter is figured (Plate I., fig. 3) as only an immature stage was known.

Note on the genus **Psettyllis**.—Plate I., fig 3, and Plate II.

Psettyllis was created by ALCOCK (1) in 1890 for the reception of a number of Pleuronectids allied to *Rhomboidichthys* which he obtained off the Ganjam and Vizagapatam coasts in 7 to 13 fathoms of water. ALCOCK entertained the possibility that these forms might be "larval or stunted" flat-fish; but in the relative proportions of the body, the completed symmetry, the unilateral restriction of the pigment, the perfect ossification of the skeleton, the slight unilateral atrophy of the paired fins, and the character of the vertical fins, he saw indications of development which warranted generic and specific discrimination. Many of these characters are not, however, absolutely diagnostic of completed development; the ossification of the skeleton, for instance, is already almost perfect in very small plaice, and some pigmentation of the blind side would appear to be quite a normal feature in some tropical species of Pleuronectidæ, in some species of *Arnoglossus* for instance. Study of the specimens of *Psettyllis* obtained by Professor HERDMAN in Palk Bay affords conclusive proof that the forms described by ALCOCK as *P. ocellata* are certainly, and that those described as *P. pellucida* are probably, immature.

The 8 specimens of *P. ocellata* (Plate II., figs. 3 to 8) form a natural series and have the following characters in common:—(1) The pigmentation, in so far as the form and distribution of the ocelli are concerned: there is a most characteristic ocellus behind the lateral line elevation and a number of differently shaped ocelli on the body and vertical fins; (2) the lateral line: there is a peculiar elevation above the pectoral fin on the ocular side, which presents two almost right angles; and (3) the scales: the surface of the body is covered with small cycloid scales, but close to the bases of the dorsal and anal fins on the ocular side there are one or more rows of ctenoid scales.

Two of these specimens belong to the stage figured and described by ALCOCK. The general surface of the body is colourless; the eyes are separated by an inter-orbital space equal to 1·7 times the major diameter of the eye; the scales are very small and are apparent only on a microscopical examination of the skin; the ctenoid scales along the fin margins are just indicated; and the ratio of the height of the body to the length (exclusive in both cases of the fins) is 0·73 : 1.

Five specimens differ slightly from the above. The general surface of the body is pigmented (brownish in spirit); the interorbital space is nearly equal to the major diameter of the eye; the ctenoid scales along the fin margins are very evident; and the ratio of the height to the length of the body in the largest is 0·69 : 1.

The single large specimen (Plate II., fig. 3) is 4·7 inches in total length. It is a female with ripe ovaries. The interorbital space is nearly equal to the major diameter of the eye. The ratio of the height of the body to the length is 0·65 : 1. The length of the head is contained $4\frac{2}{3}$ times in the total length, the tail $5\frac{1}{2}$ times; the length of the maxilla is contained $3\frac{1}{2}$ times in the length of the head. The upper ray of the pectoral fin on the ocular side is elongated and is nearly $\frac{1}{3}$ of the total length. The scales are cycloid, except for several rows along the fin margins on the ocular side, which are strongly ctenoid. They are very small, and there are about 80 in the lateral line. The jaws are slightly, and the teeth markedly, asymmetrical. The cleft of the mouth is twisted dorsally on the blind side and on that side the teeth are strongly developed, there being several rows in both jaws. On the ocular side there are also several rows of less strongly developed teeth. Teeth are absent on the vomer and palatines.

The radial formula is: D. 96; A. 69; P. 8; V. 6; C. 17.

The dorsal fin begins on the snout on the blind side. The positions of the ventral fins are markedly asymmetrical.

The anus is situated on the blind side and the urinary opening on the ocular, in both cases some little distance from the ventral margin of the body.

ALCOCK's definition of the genus must then be amended. The body is sub-circular (in the young); jaws and dentition asymmetrical; length of maxilla more than $\frac{1}{4}$ of the length of the head; eyes on the left side separated by a broad concave space; dorsal fin commencing on the snout; its rays and those of the anal simple; scales small, those on the general body surface cycloid, but along the bases of the dorsal and anal fin strongly ctenoid; lateral line with an angular elevation above the pectoral fin; the latter with its upper ray (sometimes) elongated.

The genus is closely allied to *Rhomboidichthys*, and *Psettyllis ocellata* to *Rhomboidichthys ocellatus*, AGASSIZ. Some species of *Rhomboidichthys, i.e.*, *R. podas* and *R. mancus*, possess spinous scales along the fin margins, and in many others the pectoral fin may be elongate. *Psettylis*, however, seems to differ in the following characters: (1) cycloid scales on the general surface of the body and (2) the asymmetrical jaws and dentition.

It is not improbable that *Psettyllis pellucida* may be the young of some form belonging to another genus; at any rate, the characters given by ALCOCK are probably not those of the adult.

Cynoglossus arel (Bl. Schn.).

Two specimens of this fish were obtained, the longest of which is about 15 inches in extreme length. Day's figure of this species is very unsatisfactory and shows too many scales in the longitudinal diameter. Palk Bay, Station XVIII., soft mud, 7 to 8 fathoms.

Cynoglossus brachyrhynchus (Bleeker).

Pearl banks off Aripu.

Cynoglossus hamiltoni (Günther).

Pearl banks off Aripu.

Cynoglossus brevirostris, Day.

Pearl banks off Aripu.

Cynoglossus oligolepis (Bleeker).

Cynoglossus bengalensis (Bleeker).

One specimen from Palk Bay, Station XVIII. Also from Station IV., off Chilaw, about 4 inches in extreme length.

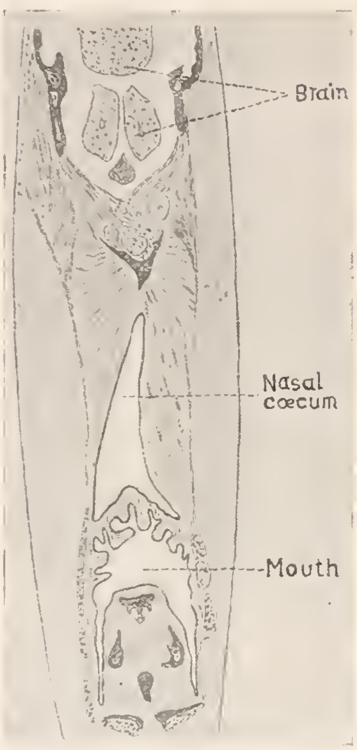
Cynoglossus, sp.

A single specimen was obtained which is unfortunately in a bad state of preservation, most of the scales on both sides being rubbed off. The extreme length is $1\frac{1}{3}$ inches, but the specimen is a mature female, the ovaries being largely distended on both sides. The colour is reddish-violet towards the margins of the body. The scales on both sides are coarsely ctenoid. The small size at sexual maturity is extraordinary, but we know little of the rate of growth of tropical Pleuronectids. Station XXV., off Foul Point, Trincomalee, 8 fathoms.

Note on "Naso-pharyngeal" Communications in *Cynoglossus*.

Kyle, in 1900 (9), gave a description of a communication between the nose and mouth in a species of *Cynoglossus*—*C. semilævis,* Günther. This was found in one specimen out of five examined and is considered by the author to be a structural detail of considerable morphological importance. A number of specimens of *Cynoglossus* were found in working over the present collection, and another from the Patani coast, several were dissected and serial sections were made of others. The following species were examined in this way: *C. arel, C. bengalensis, C. macrolepidotus, C. brachyrhynchus,* and *C. brevirostris.* In none of these specimens were any traces of a naso-pharyngeal communication to be found.

A nasal cæcum was found in every fish examined. This structure answers to the description given by Kyle; text-fig. 1, which is part of a transverse section through the head of a young specimen of *C. bengalensis*, shows the relations of the nasal cœcum to the mouth. It is a large thin-walled sac, triangular in transverse section, lying dorsally to the mouth and only separated from the latter by the buccal epithelium and its own wall. It extends backwards for a considerable distance. Anteriorly it is formed, as Kyle's figures show, by the union of two lateral, relatively narrow canals, one proceeding from each olfactory sac. These pass downwards and fuse together over the roof of the mouth.



Text-fig. 1. Transverse section through head of *Cynoglossus bengalensis*. × about 12 diameters.

The perforation joining the cavity of this sac with that of the mouth lay apparently in Kyle's specimen about the middle of the length of the cœcum.

The occurrence of this opening in only one specimen of a number examined suggests that it is quite abnormal, and most probably the result of an accident. In one specimen, *C. brevirostris*, which was cut into serial sections, a Copepod parasite possessing convoluted egg sacs was found in the cœcum. Several other larger specimens were then dissected, and in one of these (*C. brachyrhynchus*) a single Copepod parasite was found, which is described in Part I. of this Report (p. 294) as *Chondracanthus cynoglottidis*, Thompson and Scott. The anchor hooks of this Copepod were embedded in the muscles outside the dorsal wall of the cœcum, and its body lay on the thin ventral wall, so that it was immediately apparent on opening the buccal cavity sufficiently to show the roof of the mouth.

The occurrence of this Copepod in such a situation suggests what is doubtless the real explanation of the naso-pharyngeal communication—that is, that the perforation was an injury due to this or a similar parasite. Either the body and egg sacs resting on the thin ventral wall of the cœcum had produced the rupture of the latter, or the anchor hooks had themselves become embedded in this part of the wall and, as the parasite increased in size, broke through it. With such an origin the perforation would have no morphological significance whatever; and the speculations of its discoverer on the origin of the internal nares of vertebrata, which are based on its occurrence, are therefore without real value.

Rhomboidichthys azureus, Alcock.

Two specimens answer to the description of this species, except that the number of scales on the lateral line is 58 to 60 instead of about 55, the number counted by Alcock.

Galle, Station XXXIX., 16 to 30 fathoms, on a bottom of fine sand. The area from which this fish was obtained had a very rich fish fauna; about 1350 specimens were trawled belonging to the following species:—*Rhomboidichthys azureus*, *Arnoglossus spilurus* (very abundant), *A. macrolophus*, *Callionymus longicaudatus*, and *C. sagitta*.

Arnoglossus spilurus, Günther.

A large number of specimens of a species of *Arnoglossus* were collected, the characters of which correspond almost entirely with those of the above species, which was first found by the "Challenger" in the Arafura Sea.

The dorsal fin has about 86 rays, and the anal 63 to 68.

There are 48 scales in the lateral line. The upper ray of the pectoral fin is greatly enlarged in the males (in some cases, however, the sex is difficult to determine on account of the immaturity of the specimens). In most cases the extreme length of this elongated ray is two-thirds of the height of the body. There is a pointed knob on the anterior part of the maxilla on the ocular side. The blind side of the body is of a uniform smoky-grey colour (in spirit).

Size, $1\frac{1}{3}$ inches to $3\frac{1}{2}$ inches in extreme length. From the pearl banks off Aripu; Galle; south of Cheval Paar; and south of Adam's Bridge. Common.

Arnoglossus macrolophus, Alcock.

A mature female, about $2\frac{3}{4}$ inches in total length, is apparently this species. The first few rays of the dorsal fin are more elongate than the others. The radial formula is D. 85; A. 65; L.L. 55. Off Galle, Station XXXIX.

OPHIDIIDÆ.

Fierasfer homei, Richardson.

Two specimens, 4 inches and $4\frac{1}{2}$ inches long, were obtained south of Adam's Bridge, Station LIV. I refer them to *Fierasfer homei*, though they differ in a few respects from the descriptions of that species. The head is contained $6\frac{1}{2}$ times in the total length and its breadth is one-half of its length. The greatest depth of the body is $10\frac{1}{2}$ in the total length.

There are several rows of teeth in the upper jaw, the external of which are the strongest; several teeth on either side of the symphysis are larger than the rest. On the vomer there are three large teeth forming a median ridge.

The colour (in spirit) is yellowish, with a row of stellate markings above and below the lateral line on each side.

Alcock (**2**, p. 44), observed cases of commensalism between *F homei* and *Stichopus* in the seas of the Laccadive and Andaman Islands.

LABRIDÆ.

Platyglossus hyrtlii (BLEEKER).

Several specimens, about 4 inches long, from pearl banks off Aripu.

Pseudocheilinus hexatænia, BLEEKER.

One specimen, about $1\frac{3}{4}$ inches long, was obtained from south of Galle, Station XLI.

GLYPHIDODONTIDÆ.

Amphiprion sebæ, BLEEKER.

Two specimens, the largest of which was about $3\frac{1}{2}$ inches long, were taken off Aripu.

Pomacentrus jerdoni, DAY.

Numerous specimens, about 2 inches to $2\frac{1}{2}$ inches long, were obtained off Aripu.

Pomacentrus cyanopsilus, BLEEKER.

Two specimens, about 2 inches in total length, were collected. The colours in spirit are: dorsal, anal, and pelvic fins dark brown, a dark brown spot at the superior margin of the base of the pectoral.

There are light blue spots on the scales on the head and cheeks, above the pelvic and anal fins, and underneath the dorsal. The scales on the rest of the body have each a blue vertical line.

D. 12/13, A. 2/13; height of body $2\frac{1}{8}$ in total length.

Pomacentrus bankanensis, BLEEKER.

One specimen from the Pearl Bank, Station VI., uniform blackish-brown in spirit, with the exception of the caudal, which is yellow. There is a dark spot on the operculum near the origin of the lateral line.

CENTRISCIDÆ.

Amphisile scutata (LINN.).

Very numerous off Aripu; 2 inches to $5\frac{1}{4}$ inches long.

The number of fin-rays in the dorsal and caudal fins appears to be very constant; the number in the anal varies from 12 to 14, and in the pectoral from 9 to 11.

BLENNIIDÆ.

Petroscirtes breviceps (CUV. and VAL.).

Three specimens from south of Adam's Bridge, Station LIV., and also from Cheval Paar.

Petroscirtes lienardi, DAY.

One specimen from south of Adam's Bridge. It has no tentacles on the cheeks, but there are two unfringed ones on the lower jaw.

Petroscirtes cyprinoides (Cuv. and Val.).

Three specimens from off Mutwal Island.

Salarias alboguttatus, Day.

Three specimens of this Blenny were taken off Muttuvaratu Paar. The largest is nearly 2 inches long. They appear to belong to the above species, but differ in some respects. The radial formula is: D. XII. 17; A. 19; V. 2; P. 11; and the dorsal fin is deeply notched.

There are 8 or 9 broad dark bands (in spirit) with narrow interspaces descending from near the dorsal fin to the lateral line. The ground colour is light yellow. There is a short tentacle over the anterior part of the orbit.

Salarias furcatus, n. sp.—Plate I., fig. 4.

The head is contained $5\frac{1}{3}$, the height of the body $6\frac{3}{4}$, and the extreme length of the caudal 4 times in the total length.

Radial formula: D. XI., 17; A. 18; P. 13; V. 2; C. 24.

The dorsal fin is very faintly notched, but the membrane between the last spine and the first ray is wider than elsewhere in the fin; two portions are about the same height; the soft dorsal does not extend on to the caudal. The caudal is deeply forked, two of the outer rays being prolonged. The arrangement of the rays is: 1–6, **7**, 8–15, **16**, 17–24, beginning with the extreme dorsal ray; the rays outside the prolonged rays are very small.

The head is without a crest; there are two simple tentacles, one long and the other short, on each side of the head in front of the orbit.

The teeth in both jaws are movable and comb-like. Canines are absent.

The colour (in spirit) is nearly uniform blackish-brown; there is a black blotch on the dorsal fin between the first and third spines.

One specimen, 2·4 inches long, from Chilaw Paar, Station LXIX., on a bottom of sand and coral.

The diagnostic feature of the species is the deeply concave caudal fin.

CALLIONYMIDÆ.

Callionymus longicaudatus, Temm. and Schleg.

From Galle.

Callionymus sagitta, Pall.

From Galle.

A fish egg obtained in one of the tow-nettings had all the characters of the eggs of the British Callionymi. Its diameter was, unfortunately, not measured, but the reticulations on the shell are well shown in Mr. Hornell's drawing.

GOBIIDÆ.

Gobius griseus, Day.

From Palk Bay, Station XIX.

Gobius viridipunctatus, Cuv. and Val.

Two specimens, about $\frac{1}{2}$ inch in length, were taken. These have numerous rows of wart-like protuberances, not only on the cheeks, opercula, and head, but also on the pelvic fins, the rays of the latter being covered by them. Galle reef.

Gobius masoni, Day.

South of Cheval Paar, Gulf of Manaar.

Gobius melanosticta, Day.

One specimen, about 2 inches long, from Gulf of Manaar.

Gobius acutipinnis, Cuv. and Val.

South of Adam's Bridge, Station LIV.

Gobius biocellatus, Cuv. and Val.

South of Cheval Paar, Station XLVII.

Gobiodon citrinus, Rüppell.

Several specimens, the largest of which is about $1\frac{3}{4}$ inches long, from Aripu reef.

Periophthalmus kœlreuteri (Pall.).

A number of specimens, about 5 inches long and less, were taken in the mangrove swamps at Trincomalee.

Trypauchen vagina (Bl. Schn.).

A single specimen, about $5\frac{3}{4}$ inches long, was obtained in Palk Strait.

CATAPHRACTI.

Pegasus draconis, Linn.

A number of specimens, about $2\frac{1}{2}$ inches long, were obtained from Aripu reef, south of Cheval Paar, and south of Adam's Bridge.

Pegasus natans, Linn.

One specimen was collected on Aripu reef. This species has apparently been previously recorded only from Chinese and Australian seas.

Pegasus volans, Linn.

One specimen, about 2·1 inches long, was obtained from Aripu reef. The fifth rays of the pectoral fins are greatly thickened. The tail is rather over one-half of the total body length; the head is contained thrice in the body length; the rostrum is short, about one-sixth of the length of the head.

This species has not been obtained previously from Indian waters.

TRICHONOTIDÆ.

Trichonotus setigerus, Bl. Schn.—Plate I., fig. 7.

Several specimens of this species were obtained from south of Adam's Bridge, Station LIV., north of Cheval Paar Station LII., and outside Periya Paar, Station XVII. The largest is 3·8 inches long, its radial formula is D. 50; A. 40. There are 58 scales in a longitudinal, and $\frac{5}{6}$ in a transverse series. These are almost exactly the numbers given by Alcock (2) for *Tæniolabrus cyclograptus*, and they approximate very closely to the corresponding numbers for *T. setigerus*. The elongated first dorsal rays said to be present in the species are absent in the specimens from Ceylon. They may, however, be broken off, as the fins are in other respects somewhat injured.

Several specimens collected are referred to *T. setigerus* (see Plate I., fig. 7), but differ in possessing fewer rays in the dorsal and anal fins and in the larger size of the scales. They may eventually prove to be a new species.

Radial formula: D. 43; A. 35; P. 13; V.I. 5; C. 13.

Scales: L.l. 51; L.tr. $\frac{4}{4}$.

Length of the head nearly 5, height of the body 14, in total length. Lower jaw protruding, and a knob at the mandibular symphysis. Mouth very wide. Eyes close together.

Colours (in spirit), one specimen reddish-brown (ground colour), the rest colourless; a row of ocelli on the back on each side of the dorsal fin; a black blotch on the commencement of the latter.

Four specimens, $2\frac{1}{2}$ inches to $1\frac{1}{3}$ inches in total length, from Aripu reef, south of Cheval Paar, Station LXII. (on pearl banks), and in Palk Bay.

COTTIDÆ.

Platycephalus tuberculatus, Cuv. and Val.

A number of specimens were taken on Cheval Paar.

Platycephalus insidiator, Forsk.

A single immature specimen from south of Adam's Bridge.

Platycephalus serratus, Cuv. and Val.

One specimen from Station XX., Back Bay, Trincomalee.

Platycephalus punctatus, Cuv. and Val.

Several specimens, 6 inches long and less, from Cheval Paar, Station X.

Platycephalus asper, Cuv. and Val.

A large number of specimens were obtained off Galle. There are 5 preopercular spines present. The upper is the largest, and the next three become successively smaller. The lowest is large and is directed forward.

PEDICULATI.

Antennarius mummifer (Cuv.).

From pearl banks off Aripu. One specimen.

Antennarius marmoratus (Less.).

A single specimen, about 1 inch long, obtained from Galle Lagoon, is most probably a variety of this species. The colour (in spirit) is uniform blackish, with the exception of the tips of the caudal, anal, pectoral, and pelvic fins, which are white. The skin is rough, being covered with minute granules. The first dorsal spine is nearly as long as the second, and has an oval lobe or flap at the free end. D. 3/12; A. 7; P. 9.

Halieuta stellata (Wahl.).

A single specimen, about 1 inch long, from Galle.

TRACHINIDÆ.

Percis punctata, Cuv. and Val.

One specimen from off Mutwal Island.

Percis pulchella, Temm. and Schleg.

Several specimens, about $1\frac{1}{2}$ inches long, from south of Cheval Paar, Station XLVII.

STROMATEIDÆ.

Stromateus sinensis, Euphrasin.

From Palk Strait.

CARANGIDÆ.

Caranx hippos (Linn.).

One specimen, about 8 inches long, from Palk Strait.

Caranx leptolepis, Cuv. and Val.

A number of specimens, about 5 inches long, from the pearl banks off Aripu.

Seriola nigrofasciata (Rüppell).

A single specimen, $1\frac{1}{4}$ inches long.

Equula splendens, Cuv.

Numerous in Palk Bay, Stations XVIII. and XIX.

Gazza equulæformis, Rüppell.

A single specimen, about 6 inches long, from Palk Bay, Station XVIII. The other species of fishes taken at Station XVIII. in Palk Bay were *Gazza equulæformis*, *Equula splendens*, *Psettodes erumei*, *Trichonotus setigerus*, *Sciæna maculata*, *Cynoglossus arel*, *C. bengalensis*, *Pseudorhombus arsius* and *Caranx hippos*.

TRICHIURIDÆ.

Trichiurus savala, Cuv. and Val.

One specimen, 23 inches long, from Palk Strait.

The first pair of teeth in the upper jaw are very large curved fangs, which are received into depressions in the lower jaw, the remaining teeth in both jaws are much smaller and are flattened from side to side, so as to form pointed, cutting instruments.

SCIÆNIDÆ.

Sciæna diacanthus (Lacépède).

One specimen, about 12 inches long, from Palk Strait.

Sciæna maculata (Bl. Schn.).

One specimen, about 7 inches long, from Palk Bay.

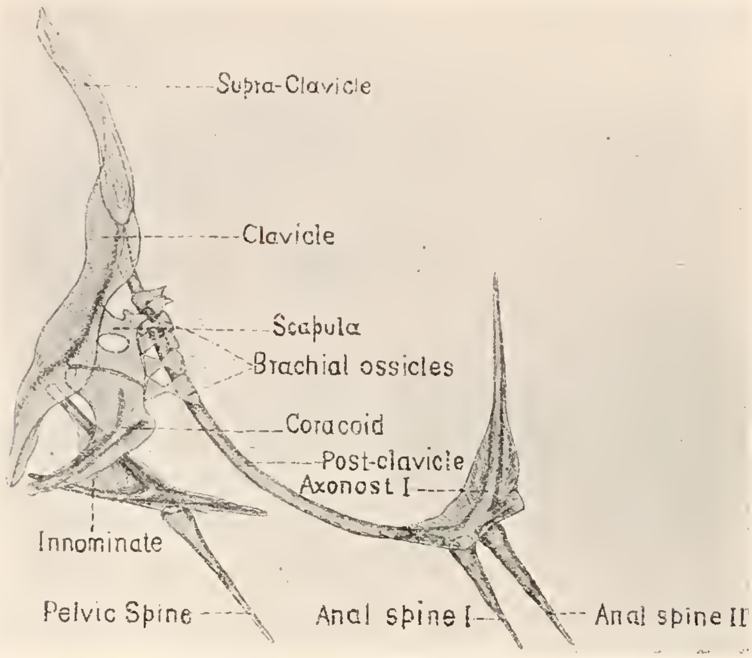
TEUTHIDIDÆ.

Teuthis oramin, Günther.

A number of specimens from south of Cheval Paar, at Station XLVII.

Note on the Limb Girdles of *Teuthis oramin*.

The limb girdles in the genus *Teuthis* present several interesting peculiarities which have not, so far as I am aware, been figured. Text-figure 2 shows the natural relations of these structures in a specimen about 2 inches long. A faint line is visible in the skin of the fish, extending from above the base of the pectoral fin to the root of the anal. On dissection this is seen to be produced by a curved bony bar, which is obviously the post-clavicle. Its upper extremity articulates with the clavicle near the upper end of the latter. Its lower extremity is connected to the anterior end of the 1st axonost by a strong fibrous bundle. The latter bone is very stout, is strengthened by anterior and posterior ridges, and is grooved on its ventral surface for the reception of the first two anal spines. Scapula and coracoid are quite distinct, but are closely connected; the former has a large fenestra; there are four brachial ossicles, three of which articulate with the scapula and one partly with this bone and partly with the coracoid. The two upper rays of the pectoral fin articulate



Text-fig. 2. Limb girdles of *Teuthis oramin.* × 4 diameters.

directly with the scapula; the coracoid is a thin bone with an external strengthening ridge.

The two innominates are very closely bound together and lie nearly in the middle line of the body. Each consists of a triradiate bony mass and the two anterior spurs are connected together by a thin bony lamella.

The post-clavicles thus form two subsidiary arches supporting the side walls of the abdominal cavity.

SCORPÆNIDÆ.

Scorpæna haplodactylus, Bleeker.

One specimen, about 3 inches long, and several much smaller ones, were obtained from south of Adam's Bridge.

Scorpænopsis guamensis (Quoy and Gaim.).

Two specimens, about $1\frac{1}{4}$ inches long.

Scorpænopsis cirrhosa (Thunb.).

One specimen, 3 inches long, from Gulf of Manaar.

Scorpænopsis oxycephala (Bleeker).

Numerous, south of Adam's Bridge; Galle; south of Cheval Paar. 2 inches or less in length.

Aploactis aspersa, Temm. and Schleg.—Plate I., fig. 5.

Length of head $3\frac{1}{2}$ inches; height of body $3\frac{1}{2}$ times in the total length. Cleft of the mouth directed obliquely upwards; length $\frac{1}{4}$ that of head. Eyes very small, diameter about $\frac{1}{7}$ of the length of the head. Nostrils, especially the anterior ones, tubular. General shape of head monstrous; prominent preorbital processes; cheeks and opercula with blunt spines and ridges.

Radial formula: D. 4, 19; A. 10; P. 13; V. 4; C. 14.

The first 4 spines of the dorsal fin are separated from the rest; there are about 10 spines following this portion, but it is difficult to determine the exact number; ventrals reduced; caudal rounded.

Skin everywhere covered with blunt, soft tubercles; these are present on all the fins and are especially large and rough on the first portion of the dorsal; 11 large tubercles on the lateral line of one side and 13 on the other.

One specimen, 2·1 inches long, from south of Adam's Bridge.

Pterois zebra, Cuv. and Val.

Pointed nasal tentacles are present. The orbital tentacles are flat and fringed on their posterior margins.

There is a flat tentacle on the premaxilla, near the angle of the mouth, and 3 short ones on the preoperculum.

Two specimens, the largest about 3 inches long, Gulf of Manaar.

Gymnapistus niger (Cuv. and Val.).

One specimen, about 2 inches long, from Periya Paar.

Gymnapistus dracæna (Cuv. and Val.).

A single specimen, about $2\frac{1}{4}$ inches long, from south of Adam's Bridge.

Minous monodactylus (Bl. Schn.).

Two specimens, about $2\frac{1}{2}$ inches long, from south of Adam's Bridge.

Choridactylus multibarbis, Richardson.

A single specimen, $1\frac{3}{4}$ inches long, from south of Adam's Bridge.

CIRRHITIDÆ.

Cirrhitichthys aureus (Temm. and Schleg.).

The free pectoral rays reach to just beyond the anal spines. The 1st dorsal ray is not prolonged. The colour is uniformly red-brown in spirit.

One specimen, about 2 inches long, Gulf of Manaar.

MULLIDÆ.

Upenoides tragula (RICHARDSON).

Several specimens, about 3 inches long, from Aripu and south of Cheval Paar.

SQUAMIPINNES.

Ephippus orbis (BLOCH).

One specimen from pearl banks off Aripu.

Scatophagus argus (GMEL.).—Plate I., fig. 1.

A single specimen of an apparently immature fish (Plate I., fig. 1) which probably belongs to this species was obtained by Professor HERDMAN, but the locality cannot, unfortunately, be traced. It is identical with a Tholichthys-like form which I have described from Patani Bay, Malay Peninsula (8), and which has been identified by Mr. G. A. BOULENGER as *Scatophagus argus*. The head is armed heavily with bony plates; the opercular pieces are very massive and carry two strong spines; the radial formula is: D. XI., 18; A. IV., 16; Pect. 16; Pelv. I., 5; C. 26. The skin is covered with minute spines. The number of spines in the dorsal fin was slightly variable in the specimens collected by Messrs. ANNANDALE and ROBINSON. Mr. ROBINSON informs me that they were "not uncommon in the Jambu estuary, generally swimming near the surface in companies of three or four."

PERCIDÆ.

This family is very sparingly represented in the present collection.

Apogon ellioti, DAY.

Several specimens from Galle, the largest of which is about $2\frac{3}{4}$ inches long.

Apogon eneastigma, RÜPPELL.

RÜPPELL obtained this species from Massana, in the Red Sea. The specimens obtained in Ceylon agree closely with his description. D. $7/\frac{1}{9}$; A. 2/8; L. l. 27.

There is a prominent dark, white edged ocellus (in spirit) behind the operculum.

Three specimens from Aripu reef, the largest of which is $2\frac{1}{3}$ inches long.

Apogon septemstriatus, GÜNTHER.

This species has been previously taken only by the "Challenger" in the Arafura Sea. The Ceylon specimens agree closely with GÜNTHER's description and figure.

The 1st dorsal spine is very small and is absent in some specimens.

A number of specimens, $1\frac{1}{4}$ inches to $2\frac{1}{4}$ inches long, from Galle and south of Adam's Bridge, Station LIV.

Therapon puta, CUV. and VAL.

Several specimens from the pearl banks off Aripu. The average length is about 5 inches.

Scolopsis phæops (BENNETT).

A single specimen, $1\frac{3}{4}$ inches long, from Aripu reef.

PRISTIPOMATIDÆ.

Erythrichthys leucogrammicus (BLEEKER)—Plate I., fig. 6.

The genus *Erythrichthys* is comparatively rare, and has not hitherto been recorded from the coasts of India. It has been found in Cuba, Molucca, and Sunda seas, Australia, New Zealand, Japan, and Sea of Valparaiso. It appears usually to inhabit open water or rather deep seas.

Height of body almost 6, length of head $4\frac{1}{2}$ in total length; body fusiform; vertical fins terminating some distance from the caudal fin; spines and rays of vertical fins very weak; caudal fin deeply forked; abdomen rounded.

Radial formula: D. IX, V, I, 10; A. III, 10; P. 19; V. I, 5; C. 17.

The first dorsal and anal spines very short; 5 free spines in the dorsal; operculum completely covered with scales; a flat, pointed spine immediately above the origin of the pectoral; inferior angle rounded. Lateral line nearly straight and with 79 scales in a longitudinal row. L.tr. $\frac{9}{19}$.

Teeth completely absent; mouth very protractile.

Colours in spirit, silvery below the lateral line; brownish above, but with a faint crimson band directly above the lateral line.

A single specimen, $3\frac{6}{10}$ inches long, from Cheval Paar in 7 fathoms.

Synagris bleekeri, DAY.

Several specimens, $2\frac{3}{4}$ inches long, from off Galle.

NOTE.—Several species of fishes, in addition to those recorded in the above list, were also observed, and have been identified from the sketches made by Professor HERDMAN and Mr. HORNELL. Several species of *Balistes* are of particular interest, since they form the intermediate host for the *Tetrarhynchus*, which is the parasite concerned in pearl-formation. *Balistes undulatus*, MUNGO PARK, and *B. mitis*, BENNETT, occur, and a third form observed may possibly be *B. erythrodon*, GÜNTHER. A large Trygon-ray, in which an adult *Tetrarhynchus* occurred, was sketched by Mr. HORNELL, and has been identified by Mr. BOULENGER as *Tæniura melanospilos*, BLEEKER; also the cockle-eating ray *Ætobatis narinari*, MARCGR. Finally, a species of *Echineis* was caught, which appears to be *E. albescens*, TEMM. and SCHLEG.

I am greatly indebted to Mr. G. A. BOULENGER, F.R.S., for much kind assistance in the identification of several doubtful species.

REPORT

ON THE

CAPRELLIDÆ

COLLECTED BY

PROFESSOR HERDMAN, AT CEYLON, IN 1902.

BY

DR. P. MAYER,
OF THE NAPLES ZOOLOGICAL STATION.

[WITH NINE TEXT-FIGURES.]

THE collection of Caprellids from Ceylon, kindly entrusted to me by Professor HERDMAN, contains nothing of unusual interest. The genera *Metaprotella*, *Monoliropus*, *Paracaprella*, and *Paradeutella* are represented. Of these *Metaprotella* and *Paradeutella* have already been reported from this region,* and exactly the same species have now been found again, viz., *M. excentrica*, *M. problematica*, and *P. bidentata*. *Paracaprella* is represented in the collection by a single female, concerning the specific identity of which I am uncertain. On the other hand, there is no doubt that the species of *Monoliropus* in this collection is new. The genus itself was known before from East Indian waters, but not from Ceylon.

I will first give a list of the species arranged according to the localities at which they were collected, and will then make such remarks as seem necessary on the specimens, and describe the single new species.

LIST OF CEYLON CAPRELLIDÆ FAUNISTICALLY ARRANGED.

Gulf of Manaar, Station LVIII., 10 to 20 fathoms: *Monoliropus falcimanus*, n. sp.
Cheval Paar, shoal buoy, 4 fathoms: *Monoliropus falcimanus*, n. sp.
Pearl Banks, off Aripu, 7 to 8 fathoms: *Monoliropus falcimanus*, n. sp. (?).

* P. MAYER, 'Die Caprellidæ der Siboga-Expedition,' 1903, p. 145.

Gulf of Manaar, Station V., Chilaw Paar, 10 fathoms: *Metaprotella excentrica*, Mayer; *Monoliropus falcimanus*, n. sp.

East of shoal buoy, Pearl Banks, 6 fathoms: *Metaprotella excentrica*, Mayer; *Monoliropus falcimanus*, n. sp.

Kondatchi Paar, 5 fathoms: *Monoliropus falcimanus*, n. sp.

Periya Paar Kerrai, 9 fathoms: *Metaprotella excentrica*, Mayer; *Monoliropus falcimanus*, n. sp.

Muttuvaratu pearl oyster washings, 8 fathoms: *Metaprotella problematica*, Mayer (?); *Monoliropus*, sp. (?).

East Cheval Paar, 6 fathoms: *Metaprotella excentrica*, Mayer; *Monoliropus*, sp. (?).

Cheval Paar, 7 fathoms: *Metaprotella excentrica*, Mayer; *Monoliropus falcimanus*, n. sp.

From pearl oyster washings, East Cheval Paar, 6 fathoms: *Metaprotella excentrica*, Mayer; *Metaprotella problematica*, Mayer; *Paradeutella bidentata*, Mayer; *Monoliropus falcimanus*, n. sp.

Cheval Paar, 8 fathoms: *Paracaprella*, sp. (?)

Notes on the Species.

Metaprotella excentrica, Mayer.

This species, already reported from the East Indies, is represented by specimens from various localities.

A.—From Station V., north end of Chilaw Paar, 10 fathoms. The heads, antennæ, and backs of the larger examples are covered with small mussels. The largest male is over 13 millims. long, and the flagellum of the first antenna has 14 joints; the tubercle at the base of the antenna is very variable. The old males do not possess the pair of spines on the back of segment 3; a younger male, however, possesses it, besides an unpaired spine on the back of segment 2. The only female (with 13 joints in the flagellum) has the same spines as this male, but the pair of spines on segment 2 is very conspicuous; ventro-laterally on the end of segment 4 is an obtuse ridge. The spine at the base of the second antenna in the female is small, and it is entirely wanting in the young males. For the rest, the examples agree well with my former description ('Nachtrag zur Monographie,' 1890, p. 25).

B.—From the East Cheval Paar oyster washings there are some good sized males, one female with eggs in the brood-pouch, and numerous young ones. The large males are provided also on segment 3 with a pair of spines of quite variable length.

C.—From East Cheval Paar, 6 fathoms, the examples all have their hind extremities missing. Of the four females, two carry eggs in the brood-pouch; the pair of spines on segment 3 is not always present.

D.—Periya Paar Kerrai affords only a young female; Cheval Paar, 7 fathoms, only a young male and a young female.

I do not feel quite sure whether the four specimens from East of shoal buoy, 6 fathoms (all of them without the hind legs), also belong to *M. excentrica*, since they seem to be rather clumsier, and their gills rather rounder, than usual. The largest male has 12 joints in the flagellum, and a pair of spines both on the head and segment 2; another male has the same also on segment 3. But evidently they do not belong to any other known species of *Metaprotella*.

Metaprotella problematica, Mayer.

The washings from East Cheval Paar oysters furnish a good many examples of this species which I described in 1890 ('Nachtrag zur Monographie,' p. 26). The largest male is 7 millims. long and has 16 joints in the flagellum of the first antenna; a female, 5·5 millims. long, has a 15-jointed flagellum, and is accordingly older than that which I had formerly described. The palmar edge of the hind legs is not particularly concave; nevertheless it is much more concave than that of *Metaprotella excentrica*, as I correctly supposed.

Very probably the two badly preserved young males from the Muttuvaratu pearl oyster washings belong to *M. problematica*.

Paradeutella bidentata, Mayer.

There are 10 examples from the East Cheval Paar oyster washings. The largest male is not quite 5 millims. long and has 12 joints on the flagellum of the first antenna. One female has on its head a Foraminifer of rather gigantic dimensions relatively to its host.

Paracaprella, sp. ?

The locality "Cheval Paar, 8 fathoms," affords a female 4·5 millims. long, and without hind legs, which belongs to the genus *Paracaprella*. The animal is quite smooth. Flagellum of the first antenna 9-jointed. The mandibular palp is represented by only one bristle. The hand of the second leg (= second gnathopod of author's) has no poison-tooth. To which species this female belongs I would not venture to determine.

Monoliropus falcimanus, n. sp.—(Text-figures, p. 226.)

The genus *Monoliropus*, which I founded only a short time ago ('Siboga-Exped.,' 1903, p 53), on examples of the species *M. agilis* from Siam, now is enriched by a second species. Of this new species a good deal of material is furnished from the following localities:—Station LVIII. (5 specimens); Shoal buoy, 4 fathoms (3 specimens); Station V. (4 male specimens); East of shoal buoy, 6 fathoms (14 specimens); Kondatchi Paar (3 quite small specimens); Periya Paar Kerrai (2 female specimens); Cheval Paar, 7 fathoms (30 specimens); and East Cheval Paar oyster washings (12 specimens).

Unfortunately, in most of the specimens the hind legs are lost.

This new species is distinguished from *Monoliropus agilis*, first, by the fact that the locking spine ("Einschlagdorn") on foot 6 and 7 is not notched terminally as in *Proto ventricosa*, but is simply obliquely truncated. Further, the hand of the second

Fig. 1. *Monoliropus falcimanus*, n. sp. Lateral view of nearly adult male; of the hind legs only the last one is represented. × 19.
,, 2. ,, ,, ,, Second leg of adult male. × 19.
,, 3. ,, ,, ,, ,, ,, young male. × 45.
,, 4. ,, ,, ,, ,, ,, adult female. × 45.
,, 5. ,, ,, ,, Mandibular palp } of male represented in fig. 1. × 165.
,, 6. ,, ,, ,, Maxilliped } of male represented in fig. 1. × 165.
,, 7. ,, ,, ,, Gill and corresponding leg of young male represented in fig. 3. × 78.
,, 8. ,, ,, ,, Gill and corresponding leg of adult female represented in fig. 4. × 78.
,, 9. ,, ,, ,, Lateral view of abdomen of male represented in fig. 1. × 78.

leg of the old male (fig. 2) is sickle-shaped,* while in the oldest-known male of *M. agilis* it is shaped as in the young males and in the females of the new species.

* The *specific* name is based on this character.

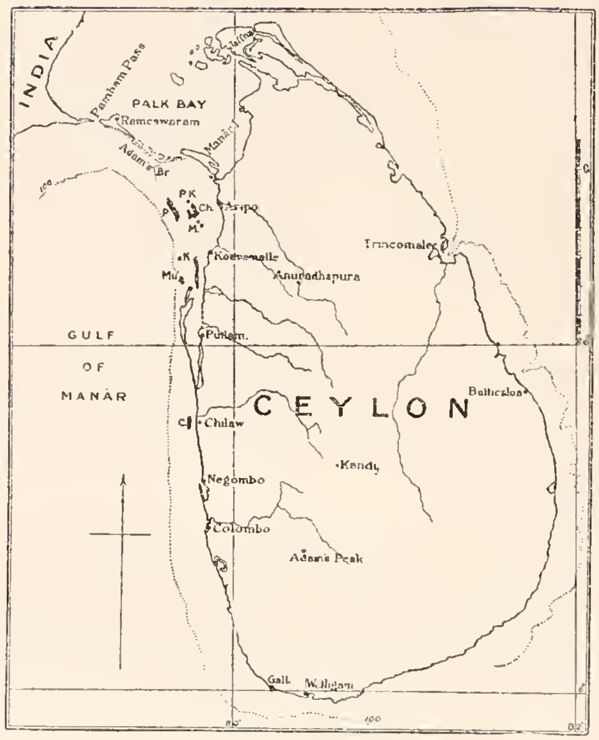
Finally, the penultimate joint of the palp of the maxilliped (fig. 6) is produced into a pointed process, which appears to be occasionally absent, and, at any rate, affords no easily distinguishable characteristic.

The length of the male is about 8·5 millims., that of the female not quite 4 millims. Dorsal surface of body smooth, save that the second segment in the male may bear a pair of very small tubercles anteriorly (fig. 1). Laterally, on segments 2 to 4, short ridges are present anteriorly, which in the female project less strongly, just as in *M. agilis*. First antenna short; flagellum in the male with 9, in the female with 8 joints. Second leg short; arm thin, joints 2 and 3 with a short lateral ridge, which in the old male (fig. 2) is relatively small; joint 4 round. The hand of the male is long, slender and sickle-shaped, its palmar edge covered with long bristles; in females and young males (figs. 4 and 3) it is relatively broader and not sickle-shaped; the locking spine is proximal, the poison-tooth distal, the claw is long. Gills long and slender; the corresponding legs very small in the old males, in the females and young males (figs. 8 and 7) relatively larger and less pointed. Leg 5, in place of the locking spine, has one or two somewhat strong hairs; legs 6 and 7 have one (exceptionally, in old males, two, one after the other) locking spine which is obliquely truncated.

The mandibular palp in the old males has at the end of the third joint a palette and 1 long, 3 small, and 2 middle-sized hairs (studied *in situ*). I give a figure of that of a not quite adult male (fig. 5) and also of the maxilliped (fig. 6). The first maxilla bears on its outer plate 7 hairs.

A profile-view of the abdomen of the male is given in fig. 9.

I am not quite certain whether to this species belong some small and badly preserved specimens from the following localities:—Pearl banks off Aripu (1 female); Muttuvaratu pearl oyster washings (1 female with two large eggs in the brood-pouch); and East Cheval Paar, 6 fathoms (1 young female).



Sketch-map of the Ceylon coast, showing the principal pearl-banks in the Gulf of Manaar, from which most of the specimens were collected. C., Chilaw Paar; Ch., Cheval Paar; K., Karativo Paar; M., Modragam Paars; Mu., Muttuvaratu Paar; P., Periya Paar; P.K., Periya Paar Kerrai.

REPORT

ON THE

AMPHIPODA

COLLECTED BY

PROFESSOR HERDMAN, AT CEYLON, IN 1902.

BY

ALFRED O. WALKER, F.L.S., F.Z.S.

[WITH EIGHT PLATES.]

THE collection of AMPHIPODA made by Professor HERDMAN and Mr. HORNELL on the coasts of Ceylon is undoubtedly the most important that has ever been brought from a tropical sea. It consists of 80 species, of which 36 are new to science. Six new genera have been found necessary for the reception of some of the species. Several interesting forms have been found among them. The new genus *Vijaya* is characterized by a curious difference in the structure of the upper antennæ in the males and females, as is also the case with the remarkable genus *Platyischnopus*, STEBBING, the male of which is now first described. *Gallea tecticauda*, n. gen. and sp., seems to be an abundant form of peculiar structure, being a link between the Amphilochidæ and Leucothoidæ, though I have thought it desirable to place it in the former family. *Cheralia aviculæ*, again, I have found difficult to place—its affinities are with the Photidæ on the one hand, and the Corophiidæ on the other. So far it has only been found in pearl oyster washings, and as it is probably, from the structure of the last 3 pairs of peræopods, tubicolous, it is possible that it may be confined to these shells.

Two of the species taken, *Hyperia galba* and *Leucothoë spinicarpa*, appear to be cosmopolitan, and as the first is commonly found in Medusæ and the second in Tunicates, it is interesting to note that, possibly from this cause, they show a remarkable power of accommodating themselves to great changes of temperature.

The size of the Ceylon specimens is generally small, even as compared with Amphipoda from our own coasts, while they are pigmies alongside of those from the Arctic and Antarctic seas. The largest measured is 10 millims. long; our own *Amathilla homari* is 25 millims. and some of the Arctic and Antarctic species are still larger.

Two species of different families, viz., *Melita anisochir* and *Cheiriphotis megacheles*, deserve notice from the great size of the "hands" of the 2nd pair of feet (gnathopods) in the males and their resemblance to a broken bit of shell. One would suppose their use to be protective, as they are large enough to cover the animal when half buried in sand, but it is difficult to see why the males only should be so protected; in both instances the females have quite small hands.

The list of areas from which species have been previously recorded is only to be regarded as an indication of distribution and does not pretend to be complete, nor is that of much importance, as the Amphipoda have been so little collected in most seas. Roughly speaking, it may be said that of the Gammaridea 19 species have been recorded from the Northern Hemisphere, 8 from the Southern, and 7 may be considered Equatorial, but it must be remembered that the number of collectors is far greater in the North. The greatest number of individuals taken in this collection belong to the Southern genus *Platophium*.

The Caprellidæ are treated separately, by Dr. PAUL MAYER, in the Report that precedes this in the present volume.

The following Amphipoda were taken by Professor HERDMAN while tow-netting in the Indian Ocean to the south of Sokotra and eastwards towards Ceylon from January 15 to January 18, 1902:—

Vibilia viatrix, BOVALLIUS, 2 specimens;
Paraphronima gracilis, CLAUS, 2 specimens;
Hyperia bengalensis (GILES), several specimens;
Phrosina semilunata, RISSO, 1 young male, length 2 millims.;
Anchylomera blossevillei, M. EDW., a considerable number of specimens;
Sympronoë parva, CLAUS, 1 male specimen.

CLASSIFIED LIST OF SPECIES IN THE COLLECTION.

The capital letters affixed to the names of the species in the list below indicate parts of the coast of Ceylon, as follows:—

(A), south of Karativo to Colombo (Stations I. to V. and LXVI. to LXIX.).
(B), north of Karativo to Kodramallai Point (Stations VI. to VIII. and LVI. to LX.).
(C), north of Kodramallai to Bengalli (Stations IX. to XVII., XLVII. to LII., LV., and LXI. to LXV.).

(D), north of Bengalli (Stations LIII. and LIV.).
(E), south of Colombo (Stations XLII. to XLVI.).
(F), in or near Galle Harbour (Stations XXXV. to XLI.).
(G), in or near Trincomalee Harbour (Stations XX. to XXXI.).
(H), general coast of Ceylon, under 100 fathoms, exact locality not recorded.

The localities and other details of the stations referred to in Roman numerals will be found in the "Narrative," at p. 17, in Part I. of this series of Reports.

Tribe: HYPERIIDEA.

Family: HYPERIIDÆ.

Hyperia galba (Mont.)—(F). Probably cosmopolitan.
H. crucipes, Bovallius—(B). Tropical Atlantic; off Barbadoes (Bov.).
H. bengalensis. Giles—(B). Bay of Bengal.
Hyperoche cryptodactylus, Stebbing—(F). Near Cape of Good Hope.

Family: PHROSINIDÆ (Stebbing, 1888).

Phrosina sp.

Family: SCELIDÆ (Claus, 1879).

Parascelus parvus, Claus—(C). Atlantic Ocean.

Family: LYCÆIDÆ (Claus, 1879).

Elsia indica, Giles—(B) (D). Bay of Bengal.

Tribe: GAMMARIDEA.

Family: ORCHESTIIDÆ.

Hyale nilssoni (Rathke)—(B). Atlantic and Mediterranean; Azores; Sokotra.

Family: LYSIANASSIDÆ.

Ichnopus taurus, Costa—(F). Mediterranean.
Socarnes schmardæ (Heller)—(B). Mediterranean.
Socarnella bonnieri, n. gen. and sp.—(F).
Lysianax cinghalensis, Steb.—(B) (C). Ceylon.
L. calochir, n. sp.—(B) (D).
Orchomenella nana (Kröyer)—(C). Norwegian, British and French coasts.
Tryphosa cucullata, n. sp.—(B).
Vijaya tenuipes, n. gen. and sp.—(H).

Family: PONTOPOREIIDÆ.

Urothoë spinidigitus, n. sp.—(C).

Family: ARGISSIDÆ, nov.

Argissa hamatipes (Norman)—(B). Greenland (Hansen); Norway; Britain.
Platyischnopus herdmani, n. sp.—(C).

Family: PHOXOCEPHALIDÆ.

Leptophoxus uncirostratus (Giles)—(G). Bay of Bengal.

Family: AMPELISCIDÆ.

Ampelisca tridens, n. sp.—(B) (C) (D) (F).
A. scabripes, n. sp.—(A) (C) (H).
A. brachyceras, n. sp.—(B) (C).
A. brevicornis, Costa—(B) (F). Atlantic; Mediterranean.
A. cyclops, n. sp—(B) (F).
A. chevreuxi, n. sp.—(B) (C).

Family: AMPHILOCHIDÆ.

Amphilochus neapolitanus, Della Valle—(B). Mediterranean; Britain.
Gallea tecticauda, n. gen. and sp.—(B) (C) (D) (F).

Family: LEUCOTHOIDÆ.

Leucothoë spinicarpa (Abild.)—(A) (B) (C) (F) (H). Probably cosmopolitan; from Greenland to the Azores and perhaps Australia.
L. hornelli, n. sp.—(A) (D) (G).
L. stegoceras, n. sp.—Singapore.

Family: ANAMIXIDÆ (Stebbing, 1898*).

Anamixis stebbingi, n. sp.—(B).

Family: STENOTHOIDÆ.†

Stenothoë marina (Sp. Bate)—(C). Norway; Britain; France; Mediterranean.
S. monoculoides (Mont.)—(C) (F). do. do. do. do.
S. gallensis, n. sp.—(B) (C) (F) (H).

Family: ŒDICERIDÆ.

Perioculodes serra, n. sp.—(B) (C).
Synchelidium brevicarpum (Sp. Bate)—(C). Britain; Norway.

* 'Ann. and Mag. Nat. Hist.' (7), vol. IV., 1898, p. 210.

† Owing to the connexion between Amphilochidæ and Leucothoidæ shown by *Gallea*, I have placed the latter family before instead of after Stenothoidæ.

Family: SYRRHOIDÆ.

Tiron thompsoni, n. sp.—(B).

Family: CALLIOPIIDÆ.

Eusiroides cæsaris, Steb.—(B) (C) (F). Australia.
E. orchomenipes, n. sp. (?)—(C).

Family: ATYLIDÆ.

Paratylus granulosus, n. sp.—(C).

Family: DEXAMINIDÆ (Stebbing, Ann. and Mag., *loc. cit.*).

Dexamine serraticrus, n. sp.—(A).
Tritata antarctica, Stebbing—(A) (C) (H). Australia.
Guernea lævis, Chevreux—(B) (C). France.

Family: GAMMARIDÆ.

Hornellia incerta, n. gen. and sp.—(B) (C).
Melita obtusata (Mont.)—(A) (C) (D) (E) (G). Norway; Britain; France; Mediterranean.
M. anisochir (Kröyer)—(A) (B) (C) (G) (H). Rio Janeiro.
Mæra othonides, n. sp.—(A) (C) (D) (F) (H).
M. scissimana, Costa—(B) (F) (H). Mediterranean.
M. rubromaculata (Stimpson)—(B) (C) (E) (F). Pacific; Australia; Cape Agulhas.
M. tenella (Dana)—(C). Fiji Islands.
M. tenuicornis (Dana)—(C). New Zealand.
Elasmopus subcarinatus (Haswell)—(A) (B) (C) (D) (F) (G). Australasia.
E. spinimanus, n. sp.—(F).
E. serrula, n. sp.—(C) (F).
E. dubius, n. sp.—(C).
Parelasmopus suluensis (Dana)—(C). North Australia; Sulu Sea.
Cheirocratus sp.—(C).
Megaluropus agilis, Norman—(B) (C). Britain; Holland; Mediterranean.

Family: LILLJEBORGIDÆ (Stebbing, *loc. cit.*).

Lilljeborgia pallida, Sp. Bate—(B) (D) (H). Norway; Britain; France.

Family: AORIDÆ (Steb., *loc. cit.*).

Lembos podoceroides, n. sp.—(B) (C) (D) (G) (H).
L. chelatus, n. sp.—(A).

FAMILY: PHOTIDÆ.

Gammaropsis zeylanicus, n. sp.—(A) (B) (C) (D) (F) (G).

Cheiriphotis (n. gen.) *megacheles* (GILES)—(A) (B) (C) (D). Bay of Bengal.

Photis longicaudata (SP. BATE)—(B) (C) (F). Norway; Britain; France; Mediterranean.

P. longimanus, n. sp.—(C).

P. nana, n. sp.—(B).

Chevalia aviculæ, n. gen. and sp.—(B) (C).

FAMILY: AMPHITHOIDÆ (STEB., *loc. cit.*)

Amphithoë intermedia, n. sp.—(A) (B) (C) (Station XXXIV.).

A. vaillanti, LUCAS—(B). Mediterranean.

FAMILY: ISCHYROCERIDÆ (STEB., *loc. cit.*).

Ischyrocerus anguipes, KR.—(H). Arctic Seas; Norway.

Jassa, sp.—(B).

Erichthonius abditus (TEMPLETON)—(A) (B) (C) (F). European coasts; Azores.

E. macrodactylus (DANA)—(D). Sulu Sea.

FAMILY: COROPHIIDÆ.

Cerapus calamicola (GILES)—(C) (D) (H). Bay of Bengal; Australia; Sokotra.

Siphonœcetes orientalis, n. sp.—(A) (B) (D).

Corophium crassicorne, BRUZELIUS—(C). Jan Mayen; Norway; Britain; France.

FAMILY: DULICHIDÆ.

Platophium læve (HASWELL)—(A) (B) (C). Australia.

P. synaptochir, n. sp.—(B) (C) (F).

P. zeylanicum, n. sp.—(C).

FAMILY: COLOMASTIGIDÆ (STEB., *loc. cit.*).

Colomastix pusilla, GRUBE—(B). Britain; France; Mediterranean.

DESCRIPTION OF THE SPECIES.

The following terms are used in the description :—

"Pleon" = Metasome, G. O. SARS; the first 3 abdominal segments.

"Urus" = Urosome, G. O. S.; the last 3 abdominal segments.

"Ocular lobe" = Lateral angle of the head.

"Appendage" = Secondary or accessory appendage of the upper antennæ.

In the peduncle of the antennæ the "first joint" is the ante-penultimate; in the limbs it is the basipodite, the propodos, or hand, thus being the 5th joint.

The measurements are from the tip of the uropods to the base of the antennæ when the Amphipod is laid straight.

When a joint is said to be as long as two or more it means as long as those joints united.

In the following classification the system used by Professor G. O. SARS in his 'Amphipoda of Norway' has been followed, except as to the position of the genus *Leucothoë*.

TRIBE: HYPERIIDEA.

FAMILY: HYPERIIDÆ.

Hyperia, LATREILLE, 1825.

Hyperia galba (MONT.).

Two from the Reef, Galle, the largest 7·5 millims.

The serration of the hind margin of the 1st gnathopod is simple, as figured by BOVALLIUS for *H. gaudichaudi*, M. EDW. (Hyperidea, Plate X., fig. 20). If *H. latreillei*, M. EDW., is to be united to *H. galba*, as proposed by SARS ('Amph. of Norway,' p. 7), there seems to be no reason why *H. gaudichaudi*, which BOVALLIUS (*loc. cit.*, p. 176) considers "a link between" these 2 species, should not also be included. The shape of the gnathopods in the present specimens is nearer to *H. galba* than to *H. gaudichaudi* as figured by BOVALLIUS.

Hyperia bengalensis (GILES).

Lestrigonus bengalensis, GILES, 'Journ. of Asiatic Soc. of Bengal,' 1887, p. 224.

Hyperia dysschistus, STEBBING, '"Chall." Amph.,' p. 1388, Plate 167, 1888.

There can be little doubt of the identity of the above; STEBBING, with his usual acuteness, observed the similarity, but was misled partly by the distance between the two stations (*H. dysschistus* was taken off Cape Howe, Australia) and partly by errors in GILES' description of the telson and uropods. As suggested by BOVALLIUS (*loc. cit.*, p. 200), GILES has mistaken the projecting hind margin of the urosome for the telson, which is unusually diaphanous and easily overlooked; while he has mistaken the 1st uropods for the 2nd owing to the former crossing the latter, as is common in a mounted specimen. As a matter of fact, the uropods are quite normal. The line of demarcation between the 2nd and 3rd urosome segments is also very difficult to see; it is correctly shown by STEBBING (*loc. cit.*, Plate 167) at the base of what was believed by GILES to be the telson. The posterior angle of the 3rd pleon segment is a sharp right angle as in *H. dysschistus*, and not rounded as drawn by GILES.

There is no doubt that our specimens are *H. dysschistus*, STEB., and, considering the localities and the deceptive nature of the characters in which Dr. GILES has erred, that they are also *H. bengalensis* (GILES).

The gnathopods agree well with the figures of *H. dysschistus* in BOVALLIUS (*loc. cit.*, Plate XI., figs. 1, 2).

This species presents a curious case of male dimorphism. The lower antennæ of the *smallest* males (2·25 millims.) have the very long and slender flagella generally considered characteristic of sexual maturity, while other males, with the antennæ imperfectly developed, measure 3·25 millims. Perhaps, as in the case of *Bathyporeia pilosa*, LIND., mentioned by BONNIER (' Travail du Lab. de Zoologie de Wimereux'), the males become sexually mature before they are full grown, and lose their nuptial appendages after copulation.

Several specimens from various localities at Ceylon.

Hyperia crucipes, BOVALLIUS.

In addition to the distinctive characters given by BOVALLIUS may be mentioned the great relative width of the 4th and the ciliate margin of the 5th joint in the 1st and 2nd peræopods.

Two, young, Station LXVI. Length 2·5 millims.

Hyperoche, BOVALLIUS, 1887.

Hyperoche cryptodactylus, STEBBING, ' "Chall." Amph.,' p. 1399, Plate 170.

One male, length 4 millims., Galle harbour.

The "Challenger" specimen was taken near the Cape of Good Hope.

Phrosina, RISSO, 1822.

Phrosina sp.

One, young—no locality. Length 2·5 millims.

Too young for identification.

Parascelus, CLAUS, 1879.

Parascelus parvus, CLAUS—Plate I., fig. 1.

One, male, length 3·5 millims.

The first (upper) antennæ have the 1st joint of the flagellum very wide and as long as the next two (fig. 1. ant.[1]).

The second antennæ have the last 3 joints subequal.

The gnathopods agree with STEBBING'S description ('"Chall." Amph.,' p. 1501); I could see no trace of the teeth shown on the carpus in CLAUS' figure ('Platysceliden,' p. 47, Plate VII., fig. 15); this is probably, from his description, exaggerated in the drawing.

Elsia, GILES, 1888.*

Elsia indica, GILES—Plate I., figs. 2.

Five or six male, female, and young. Length of male 5 millims., female with ova rather less.

Description of male (now found for the first time):—The head is produced and tumid in front, the eyes occupying the posterior half; it is fully as long as the first 4 segments.

Mesosome rather longer than pleon; the first 2 segments together as long as the 3rd, the 5th and 6th longest. The 1st segment of the pleon is longest, the 3rd shortest, the hinder angle of the latter is bluntly rectangular.

Upper antennæ attached to the extreme edge of the lower part of the front of the head, inflated, with the upper surface depressed and the lower convex. Flagellum minute, apparently 2-jointed (fig. 2. ant.[1]).

Lower antennæ of the usual form in males of this family, the 1st joint widened distally; the 3rd longer than the 4th and 5th, the latter very short.

No mouth organs or maxillipeds were found.

Gnathopods alike, small; 1st joint narrow, margin straight and parallel, longer than the remaining 5 joints; 2nd and 3rd subequal; hind margin of wrist extending nearly to the end of that of the hand, like a pair of shears with smooth inner margins; hand much shorter and narrower than the wrist, tapering slightly to the dactylus, which is very small (fig. 2. gn.[1]).

First and 2nd peræopods very slender, 1st joint as long as and scarcely wider than the 3rd and 4th; margins straight, parallel; 4th and 5th subequal; dactylus minute.

Third peræopods very powerful; 1st joint ovate, about as long as and but little wider than the 4th, narrowing distally; front margin obsoletely serrate; 3rd about two-thirds of the 4th, both widening distally; 4th and 5th subequal in length and width, the 4th rather wider at its distal end, both obsoletely serrate on both margins; dactylus very minute (fig. 2. pp.[3]).

Fourth peræopods like the third, but rather smaller.

Fifth peræopods small; 1st joint oval, widest near the base, and scarcely as long as the remaining joints; 3rd about twice as long as 4th; 5th as long as 3rd and 4th, narrowing distally; dactylus minute (fig. 2. pp.[5]).

* 'Journ. Asiat. Soc. of Bengal,' 1888, p. 250, Plate VI.

Uropods shortening progressively in extent, so that the 1st project the furthest; the inner ramus of the 1st is about half as large as the outer; the rami of the 2nd and 3rd pairs are subequal in length and breadth, and are all ciliate on the inner margins.

The telson is semi-oval, covering two-thirds of the rami of the 3rd uropods.

The only known species of the genus, and easily recognizable by the powerful 3rd and 4th peræopods.

Hyale, RATHKE, 1837.

Hyale nilssoni (RATHKE), var.

Station XLVII., 1 male; Station LVIII., 9 specimens.

This is the same form as that taken by Dr. H. O. FORBES on shore on the island of Abd-el-Kuri ('Nat. Hist. of Sokotra and Abd-el-Kuri,' 1903, p. 219). As there stated, it differs from the type in the length of antennæ (in the specimen from Station XLVII. not even in that); in the more rounded lobe of the wrist in the 1st gnathopod of the male and the 1st and 2nd gnathopods of the female; and in the 1st joints of the last 3 pairs of peræopods, which are serrate instead of smooth. I do not consider these differences sufficient to constitute a new species, but, if anyone wishes to do so, I suggest the name "*kuriensis*." They seem to me, however, quite as important as those that characterize some other species, such as *H. stebbingi*, CHEVREUX, and *H. grimaldii*, CHEV. ('Résult. des Camp. Sci. de "l'Hirondelle,"' pp. 8–10), but the genus appears to have been rather overworked.

Ichnopus, A. COSTA, 1853.

Ichnopus taurus, COSTA.—Plate I., fig. 3.

One male, Station XLI., about 100 fathoms.

The only point in which this species seems to differ from DELLA VALLE's description, &c. ('Gamm. d. Golfo di Napoli,' p. 802, Plate 27), is in the comparative squareness of the 1st joint and the greater width of the 3rd and 4th joints of the 3rd peræopods in our specimen (fig. 3, pp.[3]). I agree with DELLA VALLE that *I. spinicornis*, BOECK, and *I. affinis*, HELLER, can hardly be considered distinct species.

Socarnes, BOECK, 1870.

Socarnes schmardæ (HELLER).

> **Anonyx schmardæ**, HELLER, 'Amph. des Adriatischen Meeres.'
> **Ichnopus schmardæ**, HELLER, DELLA VALLE, *loc. cit.*

One male, Station VI.

Lateral angle of the head moderately produced, acute. Eyes occupying almost the whole head. Posterior margin of the 3rd pleon segment slightly convex, lower margin straight, angle rounded. The 1st urus segment is dorsally depressed.

The wrist of the 1st gnathopods is considerably wider at the distal end than the base of the hand; the latter has 2 or 3 spines on the posterior margin just beyond the widest part.

Socarnella, n. gen.

Upper antennæ with the 2nd and 3rd joints well developed, and the 1st joint of the flagellum like the succeeding joints.

Mandibles as in *Amaryllis*.

First maxillæ with a palp.

First gnathopod not subchelate.

Second gnathopod with hand long and widening distally.

Outer ramus of 3rd uropods without a terminal joint.

Telson small, emarginate at the tip.

Socarnella bonnieri,* n. sp.—Plate I., figs. 4.

One female; length 5 millims. Reef, Galle, with compound Ascidians (February 16, 1902). Head with the ocular lobe produced; convex on the upper side. Eyes large, oval, dark, with large crystalline facets.

Third segment of pleon with the hind margin convex, the lower margin straight, posterior angle rounded (fig. 4. pl.[3]); the 2nd segment has the posterior angle acute.

First 4 side plates rather deeper than the segments.

First segment of urus even.

Upper antennæ: 1st joint twice as long as wide, and as long as the 2 succeeding; 2nd rather longer than 3rd, which is subequal to the 1st joint of the flagellum. Flagellum setose, 9-jointed; the 1st joint like the succeeding, but twice as long as the 2nd. Appendage strong, 5-jointed, reaching to the 4th joint of the flagellum. The 1st and 2nd joints of the peduncle are acutely produced below, the 2nd more than the 1st (fig. 4. ant.[1]).

Lower antennæ: 2nd joint widening distally, rather longer than the 3rd, the two together about as long as the 7-jointed flagellum.

Mandible much as in *Amaryllis*, the palp placed near the proximal end, the 3rd joint about one-third of the 2nd, bent at a right angle (fig. 4. m.).

First maxillæ with a strong 2-jointed palp; outer plate with about 7 dentate spines; inner plate half as high as the outer, pointed, with 2 or 3 unequal setæ at the tip (fig. 4. mx.[1]).

Maxillipeds: inner plates reaching beyond the 1st joint of the palp, dentate at the ends, setose on the inner margin; outer plates broad, reaching the middle of the 3rd joint, margins smooth. Dactylus distinctly unguiform, acute (fig. 4. mxp.).

* I have much pleasure in dedicating this species to Mons. JULES BONNIER, who has contributed so much to a better knowledge of the Amphipoda.

First gnathopods: 1st joint with almost parallel margins, as long as the next 4; 2nd as wide, about one-fourth as long as the 1st and longer than 3rd or 4th; the 3rd overlapping the 4th, cordate, the point distal, hind margin very convex; wrist rather shorter than the hand, widening distally; base of the hand as wide as the wrist, narrowing to the dactylus; the latter short, curved, with a secondary tooth near the point. All the joints, except the 1st and 6th, have long setæ on the hind margin. Side plates subrectangular with rounded angles, wider than the next two (fig. 4. gn.[1]).

Second gnathopods: 1st joint about as long as the next 3, curved and widening distally; 2nd almost as long as the 4th, with 2 or 3 long stiff setæ in a depression on the hind margin near the distal end; 3rd very convex, with a group of erect setæ on the hind margin. Length of wrist to hand as 5 : 3, the former narrow, hind margin slightly concave, with short setæ and scanty fur at the distal end: the hand widens gradually to the end, furred on the hind margin, with short setæ on the front and a tuft of long setæ at the base of the dactylus; this is strong and overlaps the hind margin (fig. 4. gn.[2]).

First and 2nd peræopods slender, with few setæ and no spines.

Third peræopods: side plates wider than deep, lobes equal, larger than the 1st joint, which is suborbicular, flattened behind, margins smooth, a few setæ on the lower part of the front.

Fourth peræopods: the 1st joint flattened behind, the lower part of the front margin spinous; the upper part of the hind margin faintly serrate.

Fifth peræopods: the 1st joint rounded and more distinctly serrate behind, spinous on the lower part of the front margin.

First uropods spinous, the rather slender peduncle considerably longer than the subequal rami.

Second uropods: peduncle wide at the base, narrowing distally and about as long as the outer ramus, which is rather longer than the inner and spinous; the inner has one spine near the end (fig. 4. up.[2]).

Third uropods: peduncle longer than the rami, with 2 or 3 spines and a distal tooth on the outer margin; outer ramus rather the longer, *without a terminal joint*, with 2 spines dividing it into 3 equal parts (fig. 4. up.[3]).

Telson about half the length of the peduncle of the 3rd uropods, oval, deeply emarginate at the end, with a short spine on each of the lobes (fig. 4. ur.).

This genus differs from *Amaryllis* in the presence of a palp to the 1st maxillæ and in the smaller side plates of the first 4 segments. From *Socarnes* it differs in the mandibles, maxillipeds, 2nd gnathopods, telson, and 3rd uropods. It may be considered as connecting these two genera. The excavated point of the telson separates it from *Lysianax*, though DELLA VALLE (*loc. cit.*, p. 789, plate 25) has described a species under the name of *L. punctatus* with a similar telson. From this the present species differs in the antennæ, 1st maxillæ, &c.

Vijaya,* n. gen.

Upper antennæ in the male with the 1st joint of the flagellum much longer than any of the succeeding joints and very setose.

Mandibular palp set on in the middle of the trunk.

The remaining characters and the female antennæ as in *Amaryllis*, STEBBING, '"Chall." Rep.,' p. 699.

The curious difference in the male and female antennæ makes a new genus necessary.

Vijaya tenuipes, n. sp.—Plate I., figs. 5.

Coast of Ceylon, shallow water, 2 specimens, length 4 millims.

Head very deep, rostrum small, bent downwards; ocular lobe obtuse-angled. Eyes very large, long-oval.

Third pleon segment with the hind margin slightly convex, lower almost straight; the posterior angle acute, upturned, with a sinus above it, as in the other species of this genus (fig. 5. pl.[3]).

Antennæ in female subequal, reaching the hind margin of the 4th side-plates, which are very large.

Upper antennæ (female): 1st joint about twice as long and wide as the 2nd, produced below in a distal tooth; the 2nd the same proportion to the third; flagellum considerably longer than the peduncle, *the 1st joint resembling and rather shorter than the 2nd, quite naked;* appendage barely reaching the end of the 1st joint of the flagellum; 2-jointed, the 1st twice as long and wide as the 2nd (figs. 5. ant.[1]).

The upper antennæ in the male have the 1st joint of the flagellum as long as the next three and densely setose on the inner side, both flagella are broken, one at the 12th joint; the appendage is 3-jointed, the 1st joint twice as long as the 2nd, which is about in the same proportion to the 3rd: this is extremely narrow and reaches the end of the 2nd joint of the flagellum (fig. 5. ant.[1]).

Lower antennæ: the 1st joint very short, the 2nd half as long again as the 3rd (figs. 5. ant.[2]).

Maxillipeds: inner plates reaching beyond the middle of the palp, the ends cut into 3 teeth, sides setose; outer plates transparent, broad, reaching the end of the 3rd joint, dentate on the distal half, the indentations deeper towards the end. Second joint of the palp rather longer than the 1st or 3rd, which are subequal. Dactylus slender, with the inner margin finely denticulate and 2 or 3 setæ on the point.

First gnathopods: 1st joint as long as the remaining joints, about 5 times as long as wide; margins subparallel, 2nd longer than 3rd, which is irregularly triangular; wrist about two-thirds as long as the hand, with 3 fascicles of setæ on the hind

* VIJÁYA, an ancient king in Ceylon. See this Report, Part I., 'Introduction,' p. 1.

margin. The hand tapers gradually to the base of the dactylus without a palm, the hind margin finely pectinate with 4 spines and as many pairs of unequal setæ. Dactylus about one-fifth the length of the hand, curved. Side-plates small, oval below (fig. 5. gn.[1]).

Second gnathopods long and slender, the joints of almost uniform width throughout; the 1st slightly curved, about 6 times as long as wide; the 2nd twice as long as the 3rd; the wrist about equal to the two last named, margins straight, the hind margin setose; hand about two-thirds as long as the wrist, margins parallel, the hind margin with long setæ directed forwards. Side-plates nearly as long as the 1st joint, about twice as deep as wide, oval below (fig. 5. gn.[2]).

First and 2nd peræopods: 1st joint about as long as the next three: 2nd very short, 3rd, 4th, and 5th subequal; dactylus strong, about half as long as the preceding joint. Side-plate of the 2nd about as wide as one-fourth of the length of the whole body; hind margin excavated above and rounded below; *front margin with the lower angle produced and acute* (fig. 5. pp.[2]).

The remaining peræopods have the 1st joints expanded and serrate behind, the lower margins in the 3rd and 4th rounded, in the 5th almost straight; front margins spinous; 3rd joints spinous before and behind.

The uropods are damaged; the 1st pair extends the furthest, then the 2nd, which have the peculiar character shown by STEBBING in his figure of *A. macrophthalmus* ('"Chall." Rep.,' Plate 29). The rami of the 3rd pair are straight and lanceolate.

The telson reaches to about one-third of the length of the peduncle of the 3rd uropods, and is cleft for about one-third of its length, the cleft dehiscent.

This species may be distinguished by the acute anterior angle of the 4th side-plate, and by the straightness of the wrist and hand of the 2nd gnathopods. It may be identical with *Glycerina affinis*, CHILTON ('Trans. N.Z. Institute,' vol. xxiv., p. 2, Plate XLVII.), but the description of that species is not sufficient to determine the point.

Lysianax, STEBBING, 1888.

Lysianax cinghalensis, STEBBING.*—Plate I., fig. 6.

L. urodus, A. O. WALKER, 'Nat. Hist. of Sokotra,' &c., 1903, p. 220, Plate XIV., fig. 4.

Various localities round the coast of Ceylon.

This appears to be a variable species. Most of the specimens examined have a 4-jointed appendage to the upper antennæ, and, while in one male the 1st gnathopod resembles that of Mr. STEBBING's specimen, in another the hand is conical, with a straight dactylus continuous with the hand. The 1st joint of the 5th peræopods also varies, having the lower margin truncate in some and rounded in other specimens.

* 'Trans. Linn. Soc.,' Ser. 2, vol. 7, p. 28; Plate VII., A, 1896.

The apex of the telson is sometimes truncate. The small setiferous notch in the front margin of the side-plate of the 1st gnathopod, figured by STEBBING, is a constant character; it occurs also in *L. urodus*, which I consider identical with this species.

The mandibular palp has 1 or 2 spines in the middle of the concave side of the 3rd joint, which is rather more than half as long as the 2nd (fig. 6. mp.).

Length of male, 6 millims.; of female, 10 millims.

Lysianax cœlochir,* n. sp.—Plate I., figs. 7.

Stations LIII., LVIII.—about 16 specimens, males and females.

Head rather longer than the 1st segment; ocular lobe produced, subacute.

Epistome prominent.

Hind margin of the 3rd pleon segment rounded.

Anterior angle of 1st pleon segment rounded, posterior acute.

Upper antennæ subequal to the lower; 1st joint more than half as wide as long and rather longer than the next two. First joint of the 8-jointed flagellum subequal to and like the 2nd, shorter than the 3rd; appendage 4-jointed, the 2nd and 3rd the longest (fig. 7. ant.[1])

Mandibles normal, the 2nd joint of the palp nearly 3 times as long as the 3rd, which has no spine on the concave margin. Remaining mouth organs normal.

First gnathopods strong, the hand and dactylus in the same line; side plates large, much widened below with a small notch in the anterior margin near the lower angle, as in *L. cinghalensis* (fig. 7. gn.[1]).

Second gnathopods: 1st joint almost as long as the next 3; 2nd joint subequal to the 4th; 3rd much shorter and almost as wide as the wrist, which has the hind margin very convex and squamous, the front margin straight, with divergent setæ. The hand is about two-thirds the length of the wrist, the front margin rather convex and truncate at the end; the distal portion of the hind margin hollowed out, the whole very setose. Dactylus much curved, the base at the angle formed by the truncate end and the posterior sinus (fig. 7, gn.[2]).

Peræopods as in *L. cinghalensis.*

The 2nd uropods have spines on both the subequal rami and extend beyond the 3rd (fig. 7. ur.).

The 3rd uropods have the peduncles produced to a tooth at the outer angle and considerably longer than the rami, of which the outer is slightly the longer; the whole limb without spines (fig. 7. ur.).

Telson oval, barely reaching half the length of the 3rd uropods, not truncate.

Length 7·5 millims.

This species can hardly be distinguished from *L. cinghalensis*, except by the characteristic and peculiar hand of the 2nd gnathopods.

* From κοῖλος, hollow, χεὶρ, hand referring to the excavated palm of the 2nd gnathopods.

Orchomenella, Sars, 1894.

Orchomenella nana (Kröyer) = **O. ciliata**, Sars, 'Amph. of Norway.'

Cheval Paar; February, 1902; 30–40 specimens.

Length of male, 5·5 millims.

Tryphosa, Boeck, 1870.

Tryphosa cucullata,* n. sp.—Plate IV., fig. 8.

Kondatchi Paar; 17th November, 1902; one male. Length 5·5 millims.

Body compressed; first 4 side-plates twice as deep as the segments, the 4th deeply excavated behind; the 5th deeper than wide. The 3rd pleon segment has the hind and lower margins straight, the posterior angle bluntly rectangular; the upper margin produced in a subacute tooth behind. The 1st urus segment has a deep dorsal depression with a subangular carina behind it.

Head nearly as long as the 1st segment, produced in front; ocular lobe acute, produced to the 2nd joint of the upper antennæ. Eyes large, oval, red.

Upper antennæ: 1st joint tumid, projecting over the 2nd, which again completely overhangs and conceals the 3rd. First joint of the flagellum fully as long as the remaining 5, with about 10 rows of setules and a dense brush of long setæ. Appendage 5-jointed, not reaching the end of the 1st joint of the flagellum, the joints subequal (fig. 8).

Lower antennæ of the usual character of the males of this family, the flagellum reaching the urus.

Mouth organs and maxillipeds not examined.

First gnathopods as in *T. angulata*, G. O. Sars, the palm very oblique.

Second gnathopods: wrist much expanded below, without furring or setæ; lower margin of the hand produced; dactylus small.

The last 3 pair of peræopods are subequal and have the 1st joints wide, smooth, and rounded behind, spinous in front; the 3rd joints are much expanded behind, more so than in any of the species of *Tryphosa* figured by Sars.

The 3rd uropods have the rami widely lanceolate, rather longer than the peduncle, and spinous on their inner margins; they extend rather beyond the 2nd and as far as the 1st pair.

Telson convex on the upper side, long, reaching to the middle of the 3rd uropods, divided nearly to the base, with 2 or 3 submarginal spines and a larger apical spine on each division.

The single specimen was not dissected, but it is distinguished by the peculiar hooded character of the peduncular joints of the upper antennæ, in which respect it resembles the genus *Ambasia*, from which, however, it differs in the form of the 1st gnathopod.

* From the hood-like character of the first 2 joints of the upper antennæ.

Urothoë, Dana, 1852.

Urothoë spinidigitus,* n. sp.—Plate I., figs. 9.

Cheval Paar; November, 1902. One male, length 4 millims.

Body rounded, as deep as wide. Pleon segments all rounded behind.

Eyes very large, contiguous above, round, with large facets, red (fig. 9. c.).

Upper antennæ: 1st joint about three-fourths as long and twice as wide as the 2nd.

Lower antennæ: 1st joint very short, 2nd considerably longer than the 3rd; widening distally, setose on the upper and outer margins, and with an irregular row of spines (longer and sharper at the distal end) on the lower outer margin; 3rd joint swollen in the middle, with calceoli on the upper margin, and 7 or 8 long and weak setæ below. Flagellum very long and slender (fig. 9. c.).

Mandibles normal; the last joint of the palp with 6 setæ on the distal half and one or two very long setæ at the tip.

Maxillipeds: inner plates reaching half way up the outer, narrowed distally and crowned with 2 strong spine-teeth and one or two intermediate setules. Outer plates with curved spines and intermediate setæ; they barely reach the end of the 2nd joint of the palp, which is very broad.

First and 2nd gnathopods: side-plates very small, the 1st acutely angled in front, the 2nd rectangular, both without setæ. The limbs are similar in form and armature, the 2nd pair being rather the larger; the 1st joint is pyriform, as long as the hand and wrist; the 2 next short, with very long setæ on the hind margin of the 2nd, as also on the distal portion of the 1st. The wrist is rather longer than the hand in the 1st pair and subequal to it in the second—this joint and the hand are of the usual form, the hand being widest in the middle; the palm of the hand is defined by a peculiar rod-like spine, the end obliquely truncate with a setule at the tip; that of the 1st pair is half as long as the 2nd. The wrist is clothed with long setæ on the projecting portion, and the hand just below the palmar spine on the hind margin. Dactylus slender, with a setule on outer margin near the point (fig. 9. gn.[1]).

Side-plates of the 1st peræopods small, irregularly oblong; 1st joint rather longer than 3rd and 4th, the 3rd longer than the 4th, which has 4 blunt spines on the hind margin; 5th joint shorter and much narrower than the 4th, dilated and rounded at the end, where there are 4 spines of unequal length on the hind margin and 2 very short ones at the base of the dactylus. The dactylus is straight and slender, with 5 denticles on the inner side, the one nearest the point being the largest (fig. 9. pp.[1]).

Third peræopods: the 1st joint has the upper part projecting behind with 7 or 8 marginal setæ; front margin almost straight; 2nd joint very short; 3rd twice as long as 2nd, with a row of blunt spines just above the lower margin and 4 or 5 plumose setæ on the hind margin; 4th greatly expanded, with 2 parallel transverse ridges bordered with strong blunt spines and very long plumose setæ; 5th longer

* From the peculiar character of the dactylus of the 3rd peræopods.

and narrower than the 4th, with 3 irregular rows of similar, but more unequal, spines and setæ. Dactylus wide, with 4 long and 4 short spines in 2 parallel longitudinal rows on the front side (fig. 9. pp.[3]).

Fourth peræopods: 1st joint oblong, widening distally, and almost as long as the 3rd and 4th; a submarginal row of plumose setæ near the hind margin, which ends in a blunt right angle, and a few spines and simple setæ on the front margin; 2nd joint about half as long as the 3rd, which is about three-fourths of the 4th, and has 7 long plumose setæ on the hind margin; the 4th is nearly twice as long as the 5th, very spinous on the front and with simple setæ on the hind margin; 5th spinous in front and at the end; dactylus almost straight, slender, minutely and irregularly tuberculated with a denticle near the points (fig. 9. pp.[4]).

Fifth peræopods like the 4th, except the 1st joint, which is more than twice as long as wide, narrowing distally and rounded behind, without setæ or spines on either margin; the 3rd joint has no setæ on the hind margin except a distal tuft (fig. 9. pp.[5]).

First and 2nd uropods: peduncles with a distal spine at the outer and a seta at the inner angle; rami straight and subequal.

Third uropods as in *U. norwegica*, BOECK, as figured by G. O. SARS ('Amph. of Norway,' Plate 47), except that there are fewer spines on the outer margin of the outer ramus. Telson also as in *U. norwegica*.

A small male and female from the same tube, with well-developed lower antennæ, but only 2·5 millims. long, might, from observation of external characters only, be *U. elegans*, SP. BATE. I have long believed that differences of age would account for some of the species that have been established, and for which I would refer to Mr. STEBBING's valuable paper on the genus ('Trans. Zool. Soc. of London,' vol. 13, Part 1, 1891). The species described above may be distinguished by the curious spiny dactylus of the 3rd peræopods (Plate I., fig. 9. pp.[3]).

FAMILY: ARGISSIDÆ, nov.

First or upper antennæ in the males with the flagellum longer and more slender than in the females.

Gnathopods subequal and similar.

Last one or two pairs of peræopods much more powerful than the rest of the limbs.

Argissa, BOECK, 1870.

Argissa hamatipes (NORMAN).

Argissa hamatipes, NORMAN, 'Ann. and Mag. Nat. Hist.,' 7, vol. 10, p. 480, 1902.

Kondatchi Paar; 17th November, 1902; one female with ova.

Length 2·5 millims.

Platyischnopus, Stebbing, 1888.

Platyischnopus herdmani, *n. sp.*—Plate II., figs. 10.

Periya Paar Kerrai and E. Cheval Paar, November, 1902.

About 21 specimens. Colour in spirit, light brown.

Body compressed. Head nearly as long as the first 4 segments, produced to a point which is wrinkled or puckered, as in *P. mirabilis*, Stebbing, and surrounded with short spines (fig. 10. c. ♂). No eyes discernible.

The first 3 segments are subequal and shorter than the other mesosome segments, which increase in length successively.

The 3rd pleon segment has 2 dorsal and 1 or 2 dorso-lateral teeth just below the dorsal on each side on the hind margin, the posterior angle upturned, acute; the lower margin convex (fig. 10. pl.^{3}).

Upper antennæ placed considerably in front of the lower: in the female they are short, the 3rd joint of the flagellum reaching the end of the head; two joints only of the peduncle are visible, the 1st shorter than the 2nd; the flagellum 6-jointed; appendage barely reaching the end of the 2nd joint of the flagellum, 2-jointed, the 1st longer than the 2nd; the whole antenna without spines or setæ, except single ones at the ends of joints (fig. 10. ant.^{1} ♀).

In the male the upper antennæ are entirely different: the 1st joint of the peduncle is swollen and hemispherical, the 2nd twice as long as the 3rd, which has a dense fringe round the distal end: the flagellum is longer than the whole animal and very slender, the 1st joint as long as the next 3; appendage 2-jointed, about one-fourth the length of the 1st joint of the flagellum, which is more than twice as long as the 2nd (fig. 10. c. ♂).

Lower antennæ (female): the 2nd joint four times as long as, and but little narrower than the 1st, and one-third longer than the 3rd, with 4 nearly equi-distant spines on the front margin and 2 setæ at the end of the hind; otherwise the whole antennæ is naked; the flagellum is 9-jointed, as long as the last 2 joints of the peduncle (fig. 10. ant.^{2} ♀).

Mandibles as in *P. mirabilis* (fig. 10. m.).

Maxillipeds with the inner plate very small, and tapering, with a short spine and strong plumose setæ on the top; inner edge almost smooth. Palp with the 3rd joint shorter than the 2nd, widening distally.

First gnathopods: side-plates small and narrowly oval; 1st joint as long as the next two, much distended distally; wrist almost as long as the 1st joint, narrow; hand about half as long as the wrist, sub-triangular, the hind margin produced to form a chela as in *P. mirabilis* (fig. 10. gn.^{1}).

Second gnathopods like the first, but the wrist nearly twice as long (fig. 10. gn.^{2}).

First peræopods: side-plates rhomboidal, widening below. First joint as long as the next 3; the 3rd longer than the 5th, which is longer and narrower than the 4th; the 4th has a long and a short spine, and the 5th a group of strong spines on the postero-distal margin. Dactylus slender, slightly curved.

Second peræopods with the side-plates much produced behind, otherwise like the 1st (fig. 10. pp.^{2}).

Third peræopods: 1st joint narrow-oblong, widening distally, about as long and wide as the 4th, naked except a long spine on the produced end of the front margin, the remaining joints spinous, the 5th about half as wide as the 4th. Dactylus slender, straight (fig. 10. pp.^{3}).

Fourth and 5th peræopods: 1st joints broadly oval, with two teeth on the lower part of the hind margin; 2nd very small; 3rd much expanded behind, almost as wide as the 1st and considerably wider than the 4th; remaining joints as in the 3rd peræopods. The three last pairs of peræopods increase in length successively, the last two pairs being much the strongest, the 3rd hardly reaching below the 1st joints of the 5th (fig. 10. pp.^{5}).

The 1st and 2nd uropods are slender, the peduncles shorter than the equal rami, all spinous; the 1st are much longer than the 2nd. Third uropods: peduncle strong, cylindrical, with 2 or 3 teeth on the distal margin; outer ramus lamellar, spear-shaped; inner apparently wanting in all the specimens (fig. 10. up.^{3}).

Telson convex above, broad, cleft less than half its length; a tooth on the outer side, 2 upright spines near the middle and a group by the tooth of each division (fig. 10. t.).

This curious genus was first described by STEBBING in the '"Challenger" Report,' from two imperfect specimens of which only one, a female, had a head, so that he was not aware of the remarkable development of the *upper* antennæ in the male. He therefore placed the genus provisionally in the Pontoporeiidæ. I have thought it advisable to form a new family for it and the genus *Argissa*, which also has been placed by SARS, with hesitation, in the same family and, like *Platyischnopus*, is characterised by a similar development of the last peræopods and of the upper antennæ of the male. The present species has much the same general appearance as *P. mirabilis*, STEB., but differs in the sculpture of the last pleon segment, the absence of eyes, the proportions and armature of the antennæ, form of telson, &c. Subsequently ('Ann. and Mag. Nat. Hist.,' Ser. 6, vol. xix., 1897, p. 1, plate v.) Dr. C. CHILTON described another species (*P. neozelanicus*) from Otago, also from an imperfect female specimen, which differs in the gnathopods, and many other points from the other two species. It is to be hoped that specimens of the present species will be taken with perfect 3rd uropods; from the appearance of the peduncle I should expect the inner ramus to be long and easily detached as in the case of some of the Gammaridæ.

Leptophoxus, G. O. SARS, 1895.

Leptophoxus uncirostratus (GILES).

Phoxus uncirostratus, GILES, 'J. Asiat. Soc. Bengal,' vol. 59, Pt. II., 1890, p. 65, pl. ii., fig. 2.

Station XXXVII., one old female; length, 10 millims. Station LVIII., one young female.

Ampelisca, KRÖYER, 1842.

It will be useful to give here a synopsis of the following species of the genus:—

Upper antennæ extending beyond the peduncle of the lower by *more* than 3 joints of the flagellum.—*A. tridens*, n. sp.

Upper antennæ extending beyond the peduncle of the lower by *less* than 3 joints of the flagellum.

Lower antennæ reaching beyond the pleon.—*A. scabripes*, n. sp.

,, ,, not reaching beyond the pleon.—*A. brachyceras*, n. sp.

Upper antennæ not reaching the end of the peduncle of the lower.

Third uropods ovate; inner margin of outer ramus distinctly serrate.

Posterior angle of 3rd pleon segment acute, much produced, and upturned; head angular below.—*A. brevicornis*, COSTA.

Posterior angle of 3rd pleon segment scarcely produced or upturned; head rounded, narrow; one large red eye on each side of the head.—*A. cyclops*, n. sp.

Third uropods lanceolate, outer ramus not serrate.—*A. chevreuxi*, n. sp.

Ampelisca tridens,* n. sp.—Plate II., figs. 11, and Plate IV., figs. 11.

Generally distributed round the coast of Ceylon.

Head rather longer than the first 2 segments, not much produced, with a distinct but rounded lateral angle, just below which the lower and larger eye is placed; the other is close to the base of the upper antennæ (Plate II., fig. 11. c.).

Third pleon segment with the hind margin slightly convex; the posterior angle acute, scarcely upturned; the 2nd pleon segment has the hind margin more convex and the angle less produced.

First urosome segment with a deep dorsal depression, on which are 3 carinæ, each ending in a knob-like prominence. The 2nd segment is also dorsally depressed, with the sides elevated distally, forming a rounded prominence on each side of the base of the telson. The 3rd segment is hidden by the 2nd (Plate IV., fig. 11. ur.).

Upper antennæ reaching to about half the length of the flagellum of the lower, the peduncle to a little beyond the middle of the 2nd joint of its peduncle.

* From the three prominences on the 1st urosome segment.

Lower antennæ about as long as the body.

First and 2nd gnathopods normal; hind margins very setose. Side-plates wider below, with a strong curved tooth at the posterior angle.

First and 2nd peræopods: dactylus nearly twice as long as the 2 preceding joints. Side-plates of the 2nd with the upper posterior angle hollowed, leaving an acute angle below (fig. 11. $pp.^2$).

Third peræopods: 1st joint convex in front, with a rounded expansion behind; a submarginal row of 5 short spines on the 4th joint; 5th joint widening distally, with 3 short submarginal spines on the proximal half.

Fourth peræopods: 1st joint subquadrate.

Fifth peræopods: lower margin of the 1st joint slightly concave, reaching to the end of the 2nd joint, with many long setæ; 2nd joint subquadrate; 3rd joint shorter than 4th, front angle produced with 2 or 3 spines, hind angle slightly produced; 4th joint rather shorter than 2nd, front angle much produced, hind angle not at all; 5th joint oval, widest near the base, about one-fourth longer than the 2nd, a few short spines at the distal end. Dactylus as long as the 5th joint, tapering gradually to a long crooked point (fig. 11. $pp.^5$).

First uropods reaching the end of the peduncle of the 2nd; rami slender, curved, unarmed, about as long as the peduncle. Second reaching beyond the end of the peduncle of the 3rd, rami wider than those of the 1st pair, straight, subequal; a few short spines on their inner margins, the outer with a long serrate spine near the end of the inner margin.

Third uropods: the peduncle narrowed abruptly in the middle, where there is a curved spine and a setule; outer ramus narrower and a little shorter than the inner, with a long simple spine near the tip and a few plumose setæ on the distal half of the inner margin; inner ramus with the end slightly curved outwards, 3 slender spines near the end of the inner margin and 2 unequal setæ on the rounded point; both rami are widest at about one-fourth their length from the peduncle (fig. 11. ur.).

Telson divided to the base, without spines; a few setules on a median fold of each division; this is sometimes notched at the end with a setule in the notch (fig. 11. t.).

Length, 10 millims.

Distinguishable by the prominences on the urosome segments.

Ampelisca scabripes,* n. sp.—Plate II., figs. 12.

Areas (A), (C), (H): apparently not abundant.

Head as long as the first 2 segments, rounded below the upper antennæ. Eyes distant, with a crimson spot behind each, and a smaller one behind the uppermost (fig. 12. c.).

Hind margin of the 3rd pleon segment convex, the angle upturned but rounded (fig. 12. $pl.^3$).

* From the scabrous 4th joint of the 3rd and 4th peræopods.

First urosome segment with a dorsal depression, not carinate.

Upper antennæ reaching a little beyond the peduncle of the lower; the latter longer than the body.

First gnathopods strong; side-plates rounded before, straight behind. First joint widening distally; wrist and hand subequal, about twice as long as wide, setose.

Second gnathopods: 1st joint twice as wide at the distal end as any of the remaining joints; wrist half as long again as the hand.

First and 2nd peræopods: dactylus hardly as long as the two preceding joints (fig. 12. pp.[1]).

Third and 4th peræopods very short and much alike, except that the upper margin of the membranous posterior lobe of the 1st joint originates from the top of the hind margin in the 3rd, and from lower down in the 4th pair. The 4th joint is broad and produced behind in a truncate lobe, which is scabrous with minute spines, and terminates in a group of unequal spines, of which the longest reaches the end of the 5th joint and is denticulate (fig. 12. pp.[4]).

Fifth peræopods: hind margin of the 1st joint extending downwards to the end of the 2nd, a few short setæ on the lower part of the posterior curve and a long plumose one on the upward recurvature; 2nd joint the longest and the 3rd the shortest of the remaining joints, neither produced at the angles; 4th and 5th subequal in length and width, the latter ovate; last joint ovate, with a minute point and setule at the end (fig. 12. pp.[5]).

First uropods reaching the end of the 2nd pair; rami curved, rather shorter than the peduncle.

Second uropods with straight rami considerably shorter than the peduncle, inner ramus finely serrate on the outer, outer ramus on the inner margin.

Third uropods: rami* nearly twice as long as the peduncle, lanceolate, the inner the wider dentate along the distal half of its inner margin, the teeth increasing in size distally, and 3 or 4 setæ near the end of the outer; outer ramus minutely spinous near the end of the outer margin, with 3 or 4 fine submarginal and a pair of terminal setæ (fig. 12. ur.).

Telson divided to the base and covering a fourth of the length of the rami of the 3rd uropods; a notch and spine at the end of each division, a marginal spine just behind the end, and a seta behind the spine.

Characterized by the spinous 4th joints of the 3rd and 4th peræopods, the form and proportions of the joints of the 5th and the serrate and dentate 3rd uropods.

Length, 6 millims.

A. brachyceras,† n. sp.—Plate II., figs. 13.

Kondatchi Paar, 1; Cheval Paar, 1; both November, 1902.

* In the specimen figured the rami are double—probably the result of an imperfect moult.

† In allusion to the shortness of the antennæ.

Head of an unusual form in this genus, the lower antennæ originating immediately below the upper with a well-defined but rounded lateral angle. Eyes scarcely discernible (fig. 13. c.).

Third pleon segment with the hind margin slightly convex, the lower margin straight till turned up to meet the slightly produced angle (fig. 13. pl.[3]).

First segment of the urus with a small carina.

Antennæ short, the lower rather the longer, reaching the end of the 2nd mesosome segment. First joint of the upper about twice as long and as thick again as the 2nd; 3rd not distinguishable from the flagellum, which is 5-jointed without the above doubtful joint, with a long terminal seta. The lower have the first 2 joints subequal, the 3rd the longest, with 5 spines on the lower margin.

Gnathopods normal.

First and 2nd peræopods of the usual form, the dactylus about as long as the 2 preceding joints.

Third and 4th peræopods: 1st joint fully as wide as long; 4th joint has the posterior longitudinal half produced downwards for two-thirds of the length of the 5th joint, terminating in 2 long, unequal serrate spines. In the 4th pair the dactylus is rudimentary (fig. 13. pp.[4]).

Fifth peræopods: 1st joint with the front margin longer than the remaining joints; it is concave on the upper and convex on the lower part; the hind margin evenly convex, reaching downwards to the 5th joint; about 9 simple unequal setæ and 4 or 5 setules on the lower part; 2nd joint longer than any of the succeeding, 4th, 5th, and 6th subequal, the last lanceolate, acute. None of the joints have their angles materially produced (fig. 13. pp.[5]).

First uropods: peduncles almost twice as long as the subequal rami; 2 spinous and finely pectinate ridges on their upper sides; rami curved, unarmed, except a spine near the base of the inner.

Second uropods: peduncles rather longer than the subequal rami, sparsely spinous; rami straight, 5 spines on the inner margin of the inner (fig. 13. ur.).

Third uropods: rami rather longer than the peduncles, the outer having the outer margin very convex, the distal half beautifully ornamented with a double row of minute spines; the inner margins straight with a few long setæ; inner rami concealed by the outer—apparently as long and wide as these—with long and dense setæ at the tips (fig. 13. ur.).

Telson divided about three-fourths of its length, with long upright setæ along the margins of the cleft.

Length 4·5 millims.

Easily recognisable by the short antennæ, the peculiar structure of the 4th joints of the 3rd and 4th and the 1st joint of the 5th peræopods, and the curiously formed and ornamented 3rd uropods.

Ampelisca brevicornis (Costa, 1853).

A. lævigata, Lilljeborg, 1855.

For the synonomy of this species, see Norman in 'Ann. and Mag. Nat. Hist.,' Ser. 7, vol. V. (1900). p. 342.

Stations XXXIV., XXXV., and pearl oyster washings, Muttuvaratu Paar.

Length 5 7 millims.

Ampelisca cyclops,* n. sp. Plate II., figs. 14.

Galle, 14th February, 1902; Kondatchi Paar, 17th November, 1902.

Head as long as the first 3 segments, produced to the end of the 1st joint of the upper antennæ, where it is almost cylindrical. At the extreme end are 2 large confluent crimson spots in which are placed 1 or 2 (I could only see one, apparently between the 2 red spots) crystalline lens (fig. 14. c.).

The 2nd and 3rd segments of the pleon have a low dorsal carina, and the 1st urus segment a higher one, ending abruptly. The hind margin of the 3rd pleon segment is convex and hollowed out just above the acute posterior angle.

The upper antennæ are placed much in front of the lower and reach nearly to the end of the peduncle of these; the 1st joint twice as thick and more than half as long as the 2nd; the 3rd rather shorter than the 1st joint of the flagellum, which is 5-jointed and scarcely as long as the peduncle; this, in the adult, has 9 or 10 long plumose setæ on the lower side.

The lower antennæ reach to the pleon; the 1st joint does not reach the end of the 1st joint of the upper, though nearly twice as long; the 2nd joint is nearly twice as long as the 1st, the 3rd a little shorter than the 2nd.

Palp of the mandibles long and slender, the 1st joint about half as long as the 3rd, the two together about equal to the 2nd. *This is not dilated, the 3 joints being subequal in width* (fig. 14. m.).

Maxillæ normal, a single setule near the top of the inner lobe of the 1st.

Maxillipeds with the outer plate reaching the top of the 3rd joint of the palp and furnished with 6 disproportionately large oval spine-teeth.

First and 2nd gnathopods normal; the side-plates widened below and fringed with plumose setæ.

First and 2nd peræopods: 5th joint 3 times as long as the 4th, dactylus longer than the two united; side-plates of the 2nd with the upper posterior angle cut away and slightly hollowed; front and hind margin parallel.

Third peræopods: 1st joint wide, posterior lobe rather small, projecting; a long spine on the distal end of the front margin of the 4th joint.

Fourth peræopods: 1st joint subquadrate, 4th and 5th joints very spinous on the front margin. Dactylus like a bird's head (fig. 14. pp.[4]).

* From the apparently single eye.

Fifth peræopods: posterior lobe of the 1st joint reaching to the end of the 2nd, the anterior half of the lower margin fringed with long plumose setæ; 2nd and 3rd joints short, their angles hardly produced; anterior angle of the 4th joint produced one-third of the length of the 5th, spinous on the truncate end; 5th joint wide oval, truncate at the end; 6th as long as the 5th, tapering gradually to a long curved, very sharp point (fig. 14. pp.^{5}).

First uropods reaching to the middle of the rami of the 2nd; rami smooth, curved, subequal, considerably longer than the peduncle; 2nd pair longer than the 1st, peduncle longer than rami, which are subequal, straight and spinous, the spines slender and, at the distal end of both, very long (fig. 14. up.^{2}).

Third uropods: peduncle shorter than the rami in the proportion of 3 : 5, unarmed except 3 slender spines on the inner side; outer ramus a little longer than the inner, outer margin, with 4 small spines and plumose setæ, prolonged to a point beyond the inner, which is furnished with long plumose marginal setæ on the distal half; this ramus is narrow near the base and widest near the middle; the inner ramus is widest about one-third of the distance from its base and is naked except 2 or 3 slender spines near the rounded point and 3 slender spines and 2 plumose setæ on the tip (up.^{3}).

The telson is convex on the upper side, cleft rather more than half its length, the sides of the cleft contiguous almost the whole length; margins of the divisions parallel, the ends rounded with a terminal notch and 2 slender spines (fig. 14. t.).

The peculiar shape of the head and appearance of the eye distinguishes this species at once. In the form of the mandibular palp it differs from G. O. SARS' definition, but as one or two of Mr. STEBBING'S "Challenger" species differ in the same way, it would seem advisable to disregard that part of the definition.

Ampelisca chevreuxi,* n. sp.—Plate III., figs. 15.

Station LIII. One specimen. Length, 7 millims.

Head narrow and rounded in front, longer than the first 2 segments. Eyes large and prominent, one at the extreme end of the head, the other below the base of the upper antennæ.

Third pleon segment: the hind and lower margins rather convex, the posterior angle a little produced, obtuse (fig. 15. pl.^{3}).

Urus with a shallow carina on the 1st segment.

Upper antennæ reaching to about one-third of the last joint of the peduncle of the lower; 1st joint more than half as long as 2nd, 3rd shorter than the 1st joint of the flagellum, which is about 8-jointed.

Lower antennæ scarcely half the length of the body, the 3rd joint rather longer than the 2nd.

Gnathopods and 1st and 2nd peræopods of the usual form; dactylus of the latter rather longer than the 2 preceding joints.

* Named after that distinguished Amphipodist, Monsieur E. CHEVREUX.

Third peræopods: 1st joint wide, as long as the next 3, the posterior lobe projecting one-third of the length of the hind margin below the top of it; front margin with plumose setæ on the upper part and irregular spines on the lower; 4th joint considerably longer than the 5th, the hind margin produced in a spinous lobe (fig. 15. pp.[3]).

Fourth peræopods: 1st joint as wide as long, the front margin subangular, the part below the angle irregularly spinous; posterior lobe large, the margin evenly rounded and smooth; 2nd joint short, with an angular prominence behind and 2 or 3 short spines in front; 3rd joint longer than the 2nd, with 3 spines on the front margin; 4th joint twice as long as the 3rd, unevenly spinous on the front margin, which ends with 1 long and 2 short spines; the hind margin is naked, but ends in a cluster of unequal spines (one very long) on a truncate lobe; the 5th joint has 12 spines, increasing in length distally and a long terminal one on the front margin, and 3 short ciliate spines on the hind (fig. 15. pp.[4]).

Fifth peræopods: 1st joint produced behind to the end of the 2nd joint, with long plumose setæ on the lower margin; 2nd joint as long as the 2 next and much wider at the top than any of the succeeding joints—*the distal third of the front margin cut away;* 3rd joint about half as long as the 4th, somewhat produced in front; 4th as wide and more than half as long as the 5th, the front angle rounded off and spinous, hind angle slightly produced and spinous; 5th joint oval; 6th narrowed rather suddenly to a long crooked point (fig. 15. pp.[5]).

First uropods: rami curved, subequal, rather longer than the peduncle, inner margins of peduncle and inner ramus spinous.

Second uropods: rami straight, shorter than the peduncle, and spinous on their inner margins, the peduncle stout, with a strong spine at the end of the inner margin.

Third uropods: rami narrow, lanceolate, longer than the peduncle, subequal; the outer the narrower, with a few very small spines on the outer and plumose setæ on the inner margin: the inner has a few setæ on the outer margin near the end (fig. 15. ur.).

Telson divided almost to the base, the divisions pointed, with 3 spines before the point on the outer margin (fig. 15. ur.).

This species may be known by the form of the 2nd joint of the 5th peræopods, &c.

Amphilochus, Sp. Bate, 1862.

Amphilochus neapolitanus (?), Della Valle.

Muttuvaratu pearl oyster washings; 19th November, 1902.

One young and imperfect specimen, length 1·5 millims.

For the synonomy of this species see 'Jour. Linn. Soc.,' vol. 28 (Zool.), p. 300.

Gallea,* n. gen.

Body tumid, integuments strong; 3rd and 4th side-plates very large. Head with a deflexed rostrum. Antennæ subequal; the upper without an appendage and having the 2nd joint produced in a hood-like process over the 3rd. Mandibles with the molar tubercle obsolete; the palp long and slender, the 3 joints subequal.

Gnathopods stout, dissimilar, the 1st pair complexly subchelate as in *Leucothoë;* the 2nd pair rather less powerful, subchelate, as in *Amphilochoides.* Peræopods slender.

Second pair of uropods longer than the 3rd.

A carina runs along each side of the pleon and urus, uniting to form a pointed roof-like projection above the telson. Telson entire.

This is an aberrant genus resembling *Leucothoë* in its first and *Amphilochoides* in its second gnathopods. The length of the 2nd uropods is also unusual in this family, in which they are generally shorter than the 3rd; and the absence of a molar tubercle in the mandibles is inconsistent with G. O. Sars' definition of the family. It is a link between Amphilochidæ and Leucothoidæ.

Gallea tecticauda,† n. sp.—Plate III., figs. 16, and Plate VIII., fig. 16.

An abundant species in several localities round Ceylon.

Head with a small pointed and deflexed rostrum; no ocular lobe. Eye large, round, red, with many facets.

First and 2nd side-plates very small and hidden by the very large 3rd plate, which, with the still larger 4th plate, forms a complete cuirass (Plate VIII., fig. 16).

The 4th and 5th segments are subequal, and each of them as long as the 6th and 7th together; the latter have their lower part produced behind in an acute point; the 2nd pleon segment has the hind angle acute, and the 3rd is considerably produced behind, the convex hind and lower margins together forming a semi-oval.

Urus as long as the last 2 pleon segments, not counting the hood-like process; the 1st segment dorsally depressed, the 2nd produced in a roof-like process convex above and extending over half the telson (Plate III., fig. 16. ur.).

Upper antennæ: 1st joint shorter and wider than the 2nd, its upper and lower margins produced distally: 2nd with an elevated ridge produced above the short 3rd joint for half its length; flagellum 8 or 9-jointed, with 1 or 2 jointed (?) setæ at the end of each joint.

Lower antennæ: 1st joint contracted beyond the middle, the lower margin produced in a short tooth, about two-thirds the length of the 2nd; 3rd rather longer than the 2nd; flagellum 3-jointed, about as long as the 1st joint.

* From the port of Galle.

† From the roof-like projection over the telson.

Mandibles much hollowed below with a roughened portion, which probably represents the molar tubercle and spine row, in the concave part near the cutting edge; this is double in one mandible (in which the spine row also is more conspicuous), is expanded, and has 9 strong teeth (fig. 16. m.).

The palp is as long as the mandible, slender and tapering from the base to a point with a single seta, the joints subequal, the 2nd rather the longest.

First maxillæ: palp 2-jointed, the 2nd the longer; the outer plate is rather wide and crowned with simple spine-teeth; inner plate small, quadrate, with rounded corners and a few fine setules on the top (fig. 16. mx.[1]).

Second maxillæ normal.

Maxillipeds: inner plate hardly reaching beyond the base of the 1st joint of the palp, with 2 spine teeth a little below the upper margin; outer plate reaching half-way up the 1st joint, with a strong in-curved spine at the outer angle. First and 3rd joints of the palp subequal and longer than the 2nd; dactylus rather long and slender (fig. 16. mxp.).

First gnathopods: 1st joint about as long as the 4th and 5th; 2nd produced behind in a setose spur about half as long as the hind margin of the 3rd; the 3rd longer than the 2nd, produced at both angles; wrist with the hinder part produced in a pointed spur to the end of the hand as in *Leucothoë*, with a few stiff setæ on the inner margin. Hand oblong, with the palm at right angles to the hind margin, the angle rounded; hind margin finely serrate on the distal half, with an intra-marginal row of equidistant spinules; dactylus rather longer than the palm (fig. 16. gn.[1]).

Second gnathopods less powerful than the 1st; the 1st joint rather longer than the hand with a carina on the distal half of the front margin; wrist rather less than half as long as the hand, the hind margin prolonged in a setose spur along the hand for about one-third of its hind margin, and ending in a cluster of long spines; front margin of the hand straight, hind margin evenly curved, without a definite palm, the edge very minutely pectinate and with an intra-marginal row of spinules. Dactylus curved and slender, not reaching the end of the carpal spur, finely pectinate on the inner margin of the proximal half (fig. 16. gn.[2]).

First and 2nd peræopods: side-plates rounded below and obtusely angulated above, the 2nd larger than the 1st; limbs slender and naked, except a few spinules on the front margin of the 5th joint; 1st joint narrow (fig. 16. pp.[1 & 2]).

The remaining peræopods are like the first 2 pairs, but the side-plates are small and much wider than deep, those of the last pair produced behind to an acute angle.

First uropods: peduncle nearly twice as long as the smooth, styliform, equal rami.

Second uropods: peduncle longer than the rami, which are rather unequal, minutely pectinate, and spinulose on the inner margins.

Third uropods: peduncle shorter than the inner and about as long as the outer ramus; rami styliform, the margins minutely pectinate.

The 1st uropods extend beyond the 2nd, and these beyond the 3rd.

2 L

Telson entire, oblong-oval, concave above, reaching to the end of the peduncle of the 3rd uropods (fig. 16. ur.).

Length 4 millims.

Leucothoë, Leach, 1813.

Leucothoë spinicarpa (Abildgaard).

Generally distributed.

I can find no differences in the specimens examined to justify referring them to any later species. In a male, 7 millims. long, from Cheval Paar the distal half of the palm of the second gnathopod was more deeply toothed than in Sars' figure, while in smaller specimens from the same tube it agreed. The hind angle of the 3rd pleon segment varies from a blunt right angle to an acute angle in different specimens.

Leucothoë hornelli,* n. sp.—Plate III., figs. 17.

Various localities: in the branchial sacs of Tunicates, &c.

Head as long as the 1st body segment; ocular lobe square, with the upper and lower angles rounded.

Eyes large, dark, pyriform, with the small end lowest.

Segments of the mesosome subequal; first 4 side-plates scarcely deeper than the segments.

First and 3rd pleon segments respectively longer than the 2nd; posterior angle of the 2nd acute; the 3rd has the hind margin of the epimere at first straight, then abruptly incurved, forming a sinus above the acute and slightly upturned angle (fig. 17. pl.^{3}).

Antennæ, mouth organs, maxillipeds, and 1st gnathopods as in *L. spinicarpa*.

Second gnathopods: hand more than twice as long as wide; front margin almost straight or very slightly convex; hind margin with a deep sinus about one-third of its length from the base of the dactylus, followed by 2 smaller sinus, the 3rd being close to the base of the dactylus. In other respects the limb resembles *L. spinicarpa* (fig. 17. gn.^{2}). Peræopods as in *L. spinicarpa*.

Third uropods with the inner ramus almost as long as the peduncle, outer about one-fourth shorter (fig. 17. up.^{3}).

Telson reaching beyond the end of the peduncle of the 3rd uropods, tapering gradually to a very diaphanous blunt point, with 2 small spines on it (fig. 17. up.^{3}).

Length, 5 millims. to 6 millims.

This species resembles *L. spinicarpa* very closely, except in the sculpture of the hand of the 2nd gnathopods and the posterior angle of the 3rd pleon segment, which is nearer *L. lilljeborgii*, Boeck. In young specimens, 2 millims. long, "from *Rhabdocynthia*, Station XIX.," the characteristic indentation of the 2nd gnathopod is plainly

* Named after Mr. Jas. Hornell, F.L.S., now Marine Biologist to the Ceylon Government, by whom, when assisting Professor Herdman, many of the species of Amphipoda described in this work were taken.

to be seen. From *L. furina*, Savigny, it differs in the convex front margin of the hand of the 2nd gnathopod; in the 3rd uropods reaching beyond the 1st and 2nd; and in the quite different shape of the telson.

Leucothoë stegoceras,* n. sp.—Plate III., figs. 17A.

Three specimens from the branchial sac of an Ascidian (*Polycarpa*) from Singapore, sent by Dr. Hanitsch to Professor Herdman in 1898.

Head a little longer than the first segment, *produced in front to a hood-like projection over the base of the upper antennæ.* Ocular lobe rounded. Eyes round, colourless in spirit, probably red (fig. 17A, c.).

First 5 segments of the mesosome subequal, the remaining 2 longer.

Posterior angle of the 3rd pleon segment subrectangular.

Upper antennæ a little longer than the lower; the proximal third part of the 1st joint overlapped by the hood of the head; flagellum a little longer than the 2nd joint, 8–9-jointed.

Lower antennæ: flagellum about half as long as the 3rd joint, 6-jointed.

First gnathopods: side-plates securiform, the angles rounded. The rest of the limb as in *L. spinicarpa*, except the 1st joint, which is stronger.

Second gnathopods: side-plates subquadrate, angles rounded. First joint strong, two-thirds of the length of the hand. Carpal process about one-third of the hind margin of the hand, setose. Hand widest opposite the end of the carpal process, where the palm is obscurely defined by a small obtuse tooth; this is succeeded distally by a slightly concave space; then 2 deep sinus and a smaller one followed by a nodular tubercle near the base of the dactylus: this does not quite reach the palmar tooth (fig. 17A. gn.[2]).

The rest of the animal resembles *L. spinicarpa* so closely that further description is unnecessary. Length, 6 millims.

Easily distinguished by the form of the head.

Anamixis, Stebbing, 1896.†

Anamixis stebbingi, n. sp.—Plate III., figs. 18.

Muttuvaratu pearl oyster washings, 19th November, 1902. One imperfect specimen. Head produced in the middle. Ocular lobe rather deep, the lower angle produced and upturned. Eye round, colourless in spirit.

First body segment apparently coalesced with the head. Posterior angle of the 3rd pleon segment a rounded right angle.

First side-plates rudimentary and concealed by the 2nd, which are much deeper than the segments, pyriform, widest below the middle with a small tooth on each

* Στεγος = roof; κερας = horn; from the roof-like projection over the base of the antennæ.

† 'Trans. Linn. Soc.,' vol. 7, p. 35, Plate 11.

margin; 3rd similar in form, but narrower and without the teeth; 4th rather smaller, with a shallow emargination on the lower margin; remaining side-plates comparatively small.

Upper antennæ rising from the point of the hood-like projection of the head, the peduncle reaching to the end of the 2nd joint of the lower antennæ; the 1st joint much wider and rather longer than the 2nd, which is subequal to, but thicker than, the 3rd. Flagellum 6-jointed, about as long as the last 2 joints of the peduncle.

Lower antennæ apparently originating behind the articulation of the 2nd gnathopods to their side-plates; the 3 peduncular joints subequal. Flagellum 3-jointed, half as long as the last joint of the peduncle.

Mouth organs obsolete, except a pair of minute processes called by STEBBING "oral laminæ" in the form of 2 small plates below the head, which are probably rudimentary mandibles.

Maxillipeds: no inner or outer plates; palp apparently 5-jointed, including the dactylus, the joints subequal, but the 3rd rather the shortest and widest with a long spine on an angular projection on the inner margin; the 4th rather the longest and narrowest; the dactylus is slender, curved, and as long as the 4th joint.

First gnathopods very small and perfectly chelate; the 1st joint as long as all the rest, narrow at the top and widening suddenly a little below the middle; 2nd joint rather shorter than the 3rd; this takes the place of the wrist, which is obsolete, and supports the hand; this has the hinder part produced in an immovable finger as long as the rest of the hand, the end curved upwards and rounded at the point. The dactylus is a little shorter than the immovable finger and curved downwards, the ends of the fingers crossing; to complete the resemblance to the chelipede of a crab, the inner margin is furnished with blunt teeth. The entire limb extended is slightly longer than the hand of the 2nd gnathopods (fig. 18. gn.^{1}).

Second gnathopods: the 1st joint conspicuously articulated to the middle of the side-plate, as long as the hand, curved and widening distally; 2nd joint with a wide groove to receive the base of the wrist; 3rd joint oval, pointed, and articulating with the wrist at about one-fourth of its length from the base; wrist produced in a curved and pointed process almost as long as the hind margin of the hand, denticulate on the inner margin near the base. Hand widest near the base, front margin convex, hind rather concave beyond the middle. Dactylus about two-thirds of the length of the hand and meeting the end of the carpal spur, convex and denticulate on the proximal half (fig. 18. gn.^{2}).

First and 2nd peræopods: side-plates wide and irregularly angulated below; 1st joints reaching below the side-plates, widening distally.

Third and 4th peræopods: 1st joint expanded and rounded behind.

Fifth peræopods: 1st joint expanded behind with the margin subangular above and divided by a series of short transverse ridges into 10 or 11 irregularly angulated spaces (fig. 18. pp.^{5}).

Uropods: the 1st and 2nd have the inner ramus about twice as long as the outer, both styliform; the 3rd are wanting.

Telson entire, concave above, spoon-shaped.

Length 2 millims.

This curious genus was described by Mr. STEBBING from 2 specimens in the Copenhagen Museum, taken by Dr. H. J. HANSEN in the West Indies, and named *A. hanseni.* Mr. A. SCOTT, A.L.S., who was kind enough to dissect, mount, and draw the gnathopods of the very small specimen, informs me that there were 2 oral laminæ, Mr. STEBBING having only observed one. In their general appearance the two species resemble each other, but differ considerably in the structure of the 1st and 2nd gnathopods. I have taken the liberty of naming the present species after the distinguished naturalist, to whom all Amphipodists owe a deep debt of gratitude for the invaluable "Challenger" volumes.

Stenothoë, DANA, 1852.

Stenothoë marina (SP. BATE), var. **sinhalensis.**

Cheval Paar, 1st March, 1902. One female with young. Length 4 millims.

Differs from the type in its larger eye, in having the penultimate joint of the upper antennæ produced in an infero-distal tooth; the flagellum of the lower antennæ longer than the peduncle; and the absence of spines on the telson.

Stenothoë monoculoides (MONT.).

Tow-nets, Galle, 7th July, 1902, 3 specimens; Cheval Paar, February, 1903, 5 specimens. Length 2·5 millims.

The upper antennæ are about one-fourth longer than the lower; the 3rd joint of the latter is not longer than the 2nd; and the telson has 2 pairs of submarginal spines, but in other respects it agrees with G. O. SARS' description.

Stenothoë gallensis, n. sp.—Plate III., figs. 19.

An abundant species on the Ceylon coast.

Head scarcely produced in a rostrum. Ocular lobe truncate. Eyes round, rather large.

Segments of the mesosome increasing in length successively. Posterior angle of the 3rd pleon segment acute.

Upper antennæ a trifle longer than the lower; 1st and 2nd joints subequal in length, 3rd rather longer than the 1st joint of the flagellum, which has 22 joints in the female.

Lower antennæ: 2nd and 3rd joints subequal; flagellum longer than the peduncle, 18-jointed.

Mouth organs and maxillipeds as in *Stenothoë marina.*

First gnathopods: side-plates small, rounded below; wrist barely half as long as the hand, otherwise as in *S. marina* (fig. 19. gn.[1]).

Second gnathopods (male): very like *S. marina*, but the 3rd joint has the hind margin crenate, with a setule in each notch. Hind margin of the hand straight and densely hirsute; near the base of the dactylus a double-pointed tooth, the proximal point the highest, the irregular distal one with 6 intra-marginal setules. Dactylus as in *S. marina* (fig. 19. gn.² ♂). In the female the posterior margin of the hand is convex, even, with the palm quite undefined, but 4 nearly equidistant spines and some setæ near the middle (fig. 19. gn.² ♀).

First and 2nd peræopods as in *S. marina*.

Third peræopods: side-plate small, produced and rounded behind; 1st joint oval, about half as wide as long, longer than the next 2; 3rd joint but little produced behind; 5th joint nearly as long as the 2 preceding; dactylus strong (fig. 19. pp.³).

Fourth and 5th peræopods as in *S. marina*, hind margin of the 1st joint obscurely crenate.

First uropods reaching to the end of the 3rd; peduncle longer than the rami; rami subequal, a spine in the middle of the inner and 2 or 3 spines in the middle of the outer (fig. 19. ur. ♂).

Second uropods shorter than the 1st and 3rd.

Third uropods: the peduncle longer than the 2 remaining joints, with 5 or 6 spines on the upper margin; the last joint bent upwards in the middle and finely denticulate on the upper margin (fig. 19. ur.).

Telson concave above, oblong, with 4 spines increasing in size distally on the proximal half of each side (fig. 19. ur.).

Length of adult male, 6 millims.; female, with ova, 5 millims.

This species is undoubtedly very near *S. valida*, DANA, 1852, but the dentition of the hind margin of the hand in the male is somewhat different in that species as figured, and the same part in the female is described and figured as having "the palm nearly straight and armed with a stout tooth towards the apex." From *S. marina* it may be distinguished by the relatively short wrist of the 1st gnathopods and the different dentition of the 2nd; the wider 1st joint of the 3rd peræopods; the peculiar structure of the last joint of the 3rd uropods, and the oblong truncate form and armature of the telson.

Perioculodes, G. O. SARS, 1894.

Perioculodes serra,* n. sp.—Plate IV., fig. 20.

Kondatchi Paar and Cheval Paar, November, 1902.

Head as long as the first 3 segments. Rostrum deflexed to the level of the rounded ocular lobe and reaching the end of the 1st joint of the upper antennæ.

First segment of the mesosome twice as long as the 2nd, which is the shortest.

Pleon segments obscurely carinate.

* From the saw-like character of the 1st uropods.

First uropods not reaching the end of the 2nd, outer rami half as long as the inner, *the upper margins of the rami in adults strongly serrate;* 2nd and 3rd uropods subequal in extent, denticulate on the inner and spinous on the outer margins (fig. 20. up.[1]).

Length of adult male, 5 millims.

This species much resembles *P. longimanus* (Sp. Bate), the details above indicating the principal points of difference. As is usual with its congener on sandy coasts in the British Seas and Mediterranean, it is found associated with a *Synchelidium.*

Synchelidium, G. O. Sars, 1894.

Synchelidium brevicarpum (Sp. Bate).

Kroyera brevicarpa, Bate and Westwood, 'Brit. Sess. Crust.,' App., p. 508.

Cheval Paar, November, 1902, 1 specimen. Length 3 millims.

Agrees with British examples even to the dark brown blotches on the 5th and 6th segments of the mesosome.

Tiron, Lilljeborg, 1865.

T. thompsoni,* n. sp.—Plate IV., figs. 21.

Kondatchi Paar, 17th November, 1902, 1 specimen; Station LXVI.; 1 female with ova.

Head rounded above, almost as long as the first 3 segments; the front deflexed; ocular lobe rounded; eyes obliterated.

First mesosome segment almost as long as the next 2 and subequal to the 4th. Segments of the pleon and first 2 of the urus slightly carinate, the carinæ produced to teeth which are very conspicuous on the urus, as in *Tiron acanthurus,* Lillje.

Upper antennæ reaching the end of the peduncle of the lower; 1st joint twice as wide and long as the 2nd, with a long distal spine; 3rd much narrower and almost as long as the 1st; flagellum 6-jointed; appendage reaching the end of the 2nd joint of the flagellum, 3-jointed, the first 2 subequal, the last minute (fig. 21. ant.[1]).

Lower antennæ: 1st joint thick, about half as long as the 2nd, which is subequal to the 3rd; flagellum 6-jointed, shorter than the 2 last joints of the peduncle (fig. 21. ant.[2]).

Maxillipeds: inner plate reaching a little beyond the end of the 1st joints of the palp, the top rounded with plumose submarginal setæ; outer plate membranous, the surface concave, margins irregular and setose; 1st joint of the palp shorter than the 2nd, which is swollen and about as long as the 3rd; dactylus slightly curved, acute (fig. 21. mxp.).

First gnathopods: side-plates widened below, rounded in front, with about 6 submarginal setæ on the lower margin; 1st joint shorter than the next 3, widening distally; wrist rather longer and considerably wider than the hand to which it

* Named after my late friend and fellow-worker, Mr. Isaac C. Thompson, F.L.S.

tapers, 4 pectinate spines and a few long setæ on the hind margin. Hand slightly tapering, with 5 or 6 pectinate spines on the hind margin. Dactylus continuous with the hand and about one-fourth as long, contracting to a curved point beyond the middle (fig. 21. gn.[1]).

Second gnathopods are rather longer than the 1st; the wrist has 4 pectinate spines on the distal half, of which the 2nd and 3rd are longer than the others and have a shorter spine at the base.

First and 2nd peræopods are much shorter than the gnathopods, the 1st joint as long as all the rest; 3rd, 4th, and 5th subequal. Dactylus small and curved, with a seta in the middle of the front margin; a curious strong curved spine rises from the distal end of the anterior margin of the 5th joint and appears to duplicate the dactylus (fig. 21. pp.[1]).

Remaining peræopods are alike; the 1st joint oval; the 3rd much longer and wider than the subequal 4th and 5th, which have the anterior margin spinous and minutely pectinate. Dactylus with a supplementary point.

First uropods extending beyond the 2nd, rami shorter than the peduncle, subequal

Second uropods extending a little beyond the end of the peduncle of the 3rd, outer ramus the shorter.

Third uropods: rami narrow, lanceolate, considerably longer than the peduncle, subequal in extent; the outer spinous on the distal half of the outer margin and with a central row of spines; the inner with the tip truncate and emarginate, with a spine at each angle (fig. 21. up.[3]).

Telson not quite reaching the end of the 3rd uropods, cleft almost to the base, the divisions pointed, tips spinous, a submarginal spine near the distal end of the inner margins (fig. 21. up.[3]).

Superficially very like *T. acanthurus*, LILLJE., but differs in the single dorsal tooth instead of the serrate hind margin of the pleon segments, and in the structure of the maxillipeds, gnathopods, antennular appendage, 3rd uropods, &c.

Eusiroides, STEBBING, 1888.

Eusiroides cæsaris, STEB. var.—Plate IV., fig. 22.

Various localities round Ceylon.

Agrees with the type except as regards the pleon segments, which are not dorsally produced, and the 3rd has the hind margin only slightly convex, with but 3 teeth on the lower third part; the posterior angle is a rounded right angle (fig. 22. pl.[3]). The telson is divided more than half its length.

Length of female with ova 8 millims.

Eusiroides orchomenipes, n. sp.—Plate IV., figs. 23.

In a tube marked "Cheval Paar, February, 1902," with 2 large normal specimens of the last form, was an ovigerous female 5 millims. long. This has the entire hind epimeral margin of the 3rd pleon segment faintly crenate (fig. 23. pl.³), a dorsal carina on the 1st urus segment; the 3rd joint of the last 3 pairs of peræopods about as wide as long and very convex behind; the rami of the 3rd uropods unequal, the outer being much the longer and *with a terminal joint* (fig. 23. ur.). In spite of these very considerable differences, I am disposed to think that sexual maturity has here preceded that of the integument and limbs, which probably require another moult or two to bring them to the fully adult form. I believe this to be a not uncommon condition in the Amphipoda, and one that accounts for a good many so-called species. At the same time it must be admitted that the changes required to make this form identical with *E. cæsaris* are great, and it would almost seem as if it were passing through a Lysianassid form; the 3rd peræopods with their bi-lobed side-plates larger than the wide 1st joint (fig. 23. pp.³); their shortness compared to the next 2 pairs, and the structure of the 3rd uropods reminding one of *Orchomene*. On the other hand, the fore part, including head and mouth organs, is distinctly *Eusiroides*. On the whole, I have thought it advisable to record this as a new species, which I would call *E. orchomenipes*.

Paratylus, G. O. Sars, 1894.

Paratylus granulosus, n. sp.

Cheval Paar, 8 specimens.

Body moderately compressed, *the whole integument granulose*. Second pleon segment with a shallow carina slightly produced behind; 3rd segment with a deeper carina produced in an acute tooth.

First segment of the urus as in *P. vedlomensis* (Sp. Bate), *i.e.*, with a small setiferous tooth, a deep depression, and a large arched and pointed hood-like process. Second segment elevated behind. Third peræopods with the 1st joint considerably wider than in *P. vedlomensis*.

Length of male, 4 millims.; female, with ova, rather smaller.

In other respects the animal closely resembles *P. vedlomensis*.

Dexamine, Leach, 1814.

Dexamine serraticrus, n. sp.—Plate IV., figs. 24.

Cheval Paar, 1; Talaivillu Paar, 1. Length 3 millims.

Head as long as the first 3 segments, with a distinct rostrum. Eyes very large, roundish oval, dark; ocular lobe rounded.

Mesosome segments increasing in length successively. Pleon segments carinate, the carinæ produced behind as in *D. spinosa* (Mont.). Hind margin of the 3rd segment concave, the angle produced and upturned. First segment of urus with a prominent carina.

Antennæ subequal, not half as long as the body, like *D. spinosa*.

First and 2nd gnathopods almost alike, the wrist as long as the hand, which is subtriangular, the palm almost rectangularly transverse (fig. 24. gn.[1]).

Peræopods as in *D. spinosa*, *except the last pair, which have the 1st joint expanded behind and coarsely and irregularly toothed or serrate* (fig. 24. pp.[5]).

Telson divided nearly to the base; the divisions truncate at the tips, the outer margin acutely produced, then a spine and 4 minute spinules (fig. 24. t.).

Very near *D. spinosa*, from which it differs in the more transverse palms of the gnathopods, the coarsely serrate and expanded 1st joint of the last peræopods, and the armature of the telson.

Tritæta, Boeck, 1876 (= **Polycheria**, Haswell, 1880).

Tritæta antarctica, Stebbing*—Plate IV., fig. 25.

> **Polycheria tenuipes**, Haswell, 'Proc. Linn. Soc. N.S. Wales,' vol. 4. (For further remarks on the synonomy of this species, see "Challenger Report," pp. 451, 512, 945.)

Station XLIX., 7 specimens. Talaivillu Paar, 1. Length of ovigerous female, 3·5 millims.

I have no doubt that these specimens are identical with Mr. Stebbing's species. It is a question, however, whether, owing to the different structure of the terminal joints in the peræopods, this can properly be included in the genus *Tritæta*. In the type, *T. gibbosa* (Bate), the clasping by these limbs is effected by the point of the dactylus meeting the prominent hind margin of the *carpal* joint, and G. O. Sars, in his definition of the genus, says that "the 2 outer joints are modified for grasping," so that unless one may consider the dactylus as one of the 2 joints (in which case the definition is insufficient as regards the type), it does not apply to *T. antarctica*, in which the short dactylus and the somewhat expanded and transverse palm of the propodos form the grasping part (fig. 25. pp.[1]). Haswell's genus *Polycheria* might be revived if thought desirable.

This species exactly resembles *T. gibbosa* in two respects: its extreme dirtiness and its habit of carrying the antennæ flexed at a right angle from the 2nd joint of the peduncle.

Guernea, Chevreux, 1887† (= **Helleria**, Norman, 1868‡).

In his definition of the genus *Helleria*, Canon Norman writes: "Superior antennæ . . . with secondary appendage"; but his figure of the head and antennæ does not show one.§ Chevreux also, in his definition of *Guernea*, writes: "*Antennæ*

* 'Ann. and Mag. Nat. Hist.,' Ser. 4, 1875, vol. 15, p. 184, Plate XVA.

† 'Bull. de la Soc. Zool. de France,' vol. 12, 1887.

‡ 'Ann. and Mag. Nat. Hist.,' December, 1868, p. 418, Plate XXII., XXIII.

§ Canon Norman informs me that the words "with secondary appendage" are an accidental error, Monsieur Chevreux no doubt took his description from Norman's. See also Stebbing, 'Ann. and Mag. Nat. Hist.,' Ser. 6, vol. 5 (1890), p. 192.

superiores flagello appendiculari instructæ": but neither does he show any appendage in his figure (which in my copy is accidentally misplaced and numbered as fig. 1, p. 5). I have not been able to find one either in the species to be described or in British specimens of *G. coalita* (NORMAN). DELLA VALLE ('Gam. d. Golfo di Napoli,' p. 570, Plates 31 and 58) neither figures nor mentions one.

Guernea lævis, CHEVREUX.*—Plate IV., figs. 26.

Station LXVI., Cheval Paar, February; Shoal Buoy, Karativo, February.

Description of female :—

Body tumid. Head longer than the first 2 segments, which are much shorter than the rest, the 5th and 6th being the longest; first 4 side-plates as deep as the segments. Pleon not much longer than the 3 last segments of the mesosome. Urus rather shorter than the last 2 segments of the pleon, the segments coalesced and carinate, *the edge of the carina not denticulate.*

Ocular lobe rather deep, flattened in front, rounded below. Eye large, round; colour red.

Upper antennæ rather longer than the head; 1st joint twice as long as and much wider than the 2nd; 3rd about half as long and thick as the 2nd. Flagellum 4-jointed.

Lower antennæ about as long as the head; 1st joint very short, 2nd longer than the 1st and 3rd united; flagellum very small, about half as long as the 3rd joint. (In the male the 2nd joint is convex below, setose above; the flagellum long and slender, reaching the pleon.)

Mandibles without palps; these organs were not clearly distinguished owing to their small size, but they appear to be of a more complex structure than is shown by DELLA VALLE in *G. coalita.* The remaining mouth organs and maxillipeds seem to agree with DELLA VALLE's figures.

First gnathopods: side-plates oblong, rounded below: the 1st joint much swollen distally, as long as the 3rd, 4th, and 5th together; 2nd and 3rd subequal; wrist as long and almost as wide as the hand, with 4 spines on the hind margin; hand with subparallel margins, a few fine setæ on the hind margin, palm obliquely truncate, defined by 3 long spines, the margin straight, spinous and setose. Dactylus scarcely as long as the palm, with a secondary tooth; a tuft of long setæ at the base (fig. 26. gn.^{1}).

Second gnathopods very like the 1st, but rather longer and more slender in all the parts; the 1st joint with 3 long setæ on the hind and about 6 short setules on the front margin.

First and 2nd peræopods: side-plates oblong, rounded below; 1st joint with subparallel margins, about as long as the next 3; 4th joint with 4 spines on the hind margin, increasing in length distally.

* 'Crust. Amph. de S. O. Bretagne,' p. 41 (separate copy), Note.

Third peræopods: side-plates broad; 1st joint expanded before and behind, as wide as the side-plate, the front margin setose; 3rd joint longer and twice as wide as the 4th; 5th about as long as the 3rd (fig. 26. pp.[3]).

Fourth peræopods like the 3rd.

Fifth peræopods: side-plates much smaller than the 1st joint, which is much expanded behind, straight in front; 3rd joint widening somewhat distally and produced at the posterior angle; 4th shorter and narrower than the 3rd, oblong, narrowing distally; both these joints densely setose and spinous on the front and sparsely on the hind margin; 5th joint as long as the 4th, very slender, naked. Dactylus small, in a straight line with the 5th joint. The setæ on the 3rd and 4th joints are simple, *i.e.*, not plumose (fig. 26. pp.[5]).

First uropods extending beyond the 2nd and these beyond the 3rd: rami of the 1st hardly as long as the peduncle; inner ramus of the 2nd shorter than the outer; rami of the 3rd pair wider than the others, about twice as long as the peduncle, without setæ or spines.

Telson divided almost to the base with a setule at the tip of each division.

Length of female with ova 2 millims.

The most conspicuous difference between this species and *G. coalita* is the smoothness of the dorsal surface of the urus, but there are also differences in the form and armature of the limbs. Both NORMAN and DELLA VALLE have described male specimens; besides the shorter lower antennæ and absence of plumose setæ on the 3rd uropods, there is a curious difference in the relative proportions of the mesosome segments in the 2 sexes of both species.

Hornellia,* n. gen.

Body rather tumid. Segments of pleon and urus with postero-dorsal teeth.

Head not rostrate or vaulted in front. Eyes distinct, not coalescent.

Upper antennæ with an appendage; flagellum slender, much longer than the peduncle.

Mandibles with well-developed molar tubercle, spine-row, and toothed cutting edges; palp long, 3-jointed, 2nd and 3rd joints subequal (fig. 27. m.).

First maxillæ with the 2nd joint of the palp widened towards the obliquely truncate end, which is crowned with spine-teeth and setæ alternately (fig. 27. mx.[1]).

Maxillipeds well developed in all parts; 4th joint of palp dactyliform (fig. 27. mxp.).

Gnathopods subequal and similar, like those in *Halimedon*.

Third uropods of moderate length, with subequal rami.

Telson long and deeply cleft.

This genus will probably find a place in the as yet undefined family Melphidippidæ, STEBBING.

* See footnote, p. 258.

Hornellia incerta, n. sp.—Plate IV., figs. 27.

Station LIII., 4 or 5 : off Chilavaturai. 4 ; Cheval Paar.

Description of female with ova.

Head as long as the first 2 segments, which, as well as the head, are shorter in the male. Eyes large, wide-oval, red.

Second and 3rd pleon and 1st and 2nd urus segments postero-dorsally dentate, the teeth subequal. Hind margin of the epimere of the 3rd pleon segment rather concave, the angle produced and acute.

First segment of the urus dorsally depressed, twice as long as the 2nd or 3rd.

(In the male the teeth on the hind margins of the segments and the dorsal depression are more conspicuous than in the female.)

Upper antennæ more than half as long as the body, the peduncle scarcely half the length of the flagellum ; the 1st joint considerably wider and longer than the 2nd, which is more than twice as long as the 3rd ; flagellum slender, 14-jointed ; appendage 2-jointed, the 1st the longer.

Lower antennæ imperfect in all the specimens. In the male the 2nd joint is as wide as the 1st of the upper antennæ, and reaches to the 3rd joint of the upper flagellum ; it is densely setose above.

Mandibular palp projecting beyond the end of the 1st joint of the upper antennæ.

First gnathopods : side-plates oblong, deeper than wide, expanding below with marginal setules and intramarginal setæ. Wrist as long and wide as the hand, being much widened behind : hand oval, widest near the base ; palm scarcely defined by 2 sets of spines ; the 3rd, 4th, and 5th joints are furnished with many long spines, of which many are pectinate ; dactylus slender, about two-thirds the length of the hind margin of the hand (fig. 27. gn.[1]).

Second gnathopods nearly resembling the 1st, but rather larger ; the spines fewer and simple. The coxopodite is remarkably large and distinct in both the gnathopods.

First and 2nd peræopods : side-plates of the 1st as in the gnathopods ; of the 2nd much wider below and sloped away behind ; 1st joint rather longer than the 2 next, narrow, slightly curved ; 3rd joint somewhat dilated behind, subequal to the 5th, the 3rd shorter. Dactylus strong, slightly curved. A few slender spines on all the joints.

Remaining peræopods imperfect : the 1st joint about twice as long as wide, sub-ovate : the 3rd joint about as long as the 1st.

First uropods long, slender, and spinous ; rami and peduncle all subequal.

Second uropods : outer ramus as long as the peduncle, the inner about one-fourth longer : both spinous.

Third uropods : narrow, lanceolate ; the inner ramus rather longer than the outer and twice as long as the peduncle.

Telson cleft almost to the base, each division notched at the tip, the outer angle of the notch longer and wider than the inner (fig. 27. t.).

Length of female with ova. 3 millims.

Melita, Leach, 1813.

Melita obtusata (Montagu).

Stations V., XVII., XXIII., XLIII., LIII., LXIV.

Females only.

Melita anisochir (Kröyer).—Plate IV., figs. 28.

Gammarus anisochir, Kröyer, 1845.

Melita cotesi, Giles, 'Journ. Asiatic Soc., Bengal,' 1890, vol. 59, p. 64, Pl. ii., fig. 1.

It is probable that the following species ought also to be referred to *M. anisochir*, viz., *M. valida* (Dana), *M. setipes* (Dana), and *M. australis*, Haswell. According to Della Valle all these should be referred to *Gammarus fresnelii*, Audouin and Savigny, 1825.

This is an abundant species all round Ceylon.

Description of female :—

Head longer than the first 2 segments of the mesosome, which increase in length progressively. Eyes large, round, red.

Pleon segments with dorsal teeth on the hind margin, the teeth increasing in size posteriorly ; the 1st has 4 subequal teeth, the 2nd and 3rd 6 unequal ; the epimeral hind margin of the last is concave, with marginal setules, the posterior angle produced and acute (fig. 28. pl. & ur.).

The 1st urus segment has a small central tooth, with a large and a small one below it ; there is a dorsal indentation on the anterior part ; the 2nd segment, which is the shortest of the three, has a small central tooth, with a long spine and 2 minute subdorsal teeth on each side ; the 3rd segment has a conical tooth just above the base of the telson. The number and proportions of the teeth, especially in the pleon segments, vary considerably (fig. 28. pl. & ur.).

Upper antennæ nearly as long as the body, the 1st joint twice as wide and two-thirds as long as the 2nd, lower margin convex, with 2 or 3 subcentral and a distal spine ; 2nd joint 4 times as long as the 3rd. 1st joint of the flagellum as long as the next 2. Appendage varying in the number of joints, generally 3 subequal, with a minute terminal, reaching beyond the end of the 3rd joint of the flagellum.

Lower antennæ about two-thirds of the length of the upper and stouter than these, except the 1st joint.

Mouth organs normal ; the 3rd joint of the mandibular palp is rather longer than the 2nd.

First gnathopods : side-plates oblong, with rounded angles, wider below, with marginal setules ; 1st joint widening distally, as long as the next 3 ; wrist longer than and fully as wide as the hand, with many short and a few long setæ on the hind margin ; hand widely oval, palm undefined, hind margin very convex and setose like the wrist. Dactylus about half as long as the hand (fig. 28. gn.¹).

Second gnathopods larger than the 1st ; side-plates oblong, not wider below ;

1st joint subequal in length and width to the hand, which is rather longer than the wrist, front and hind margins subparallel, slightly convex; palm oblique, well defined, uneven and setose (fig. 28. gn.[2] ♀).

First and 2nd peræopods: 1st joint widening abruptly. Dactylus strong, with a secondary tooth on the outside and a short spine on the inside (fig. 28. pp.[1]).

Third peræopods: 1st joint oblong and subequal in length to the 5th.

Fourth and 5th peræopods much more powerful than the 3rd, and reaching backwards much beyond the ends of the uropods; the joints spinous. All the peræopods have the secondary tooth on the dactylus.

First uropods extending a little beyond the 2nd, slender; peduncles and rami subequal, spinous; 2nd pair resembling the 1st.

Third uropods with the outer ramus about twice as long as the peduncle, with 3 "whorls" of spines between the base and the extremity; inner ramus quite rudimentary.

Telson not unlike that of *M. palmata* (Mont.), but the divisions are sharply pointed without terminal spines, but with a long upright one at the angle on the inner side, and a horizontal one between it and the point.

Length 5 millims.

The male has been described and figured by Dr. Giles (*loc. cit.*). It is remarkable for the large size and peculiar form and colouring of one of the 2nd gnathopods. I think there can be little doubt, from its resemblance to a bit of broken shell, that its use is protective, the animal covering itself with it as it lies partly buried in the sand. Dr. Herdman informs me that he has seen them in this position.

Mæra, Leach, 1813.

Mæra othonides, n. sp.—Plate V., figs. 29.

Stations V., LIII., LXIV., Cheval Paar.

Very near *M. othonis* (M. Edwards), from which it differs as follows:—

The ocular lobe is *rounded*.

The 3rd pleon segment has *no teeth on its lower* and from 1 to 3 teeth on the hind margin (fig. 29. pl.[3]).

The appendage of the upper antennæ is 3-*jointed*.

The palp of the mandibles has the 3rd joint *considerably shorter than the 2nd*.

The side-plates of the gnathopods are *not serrated* below; there is a single tooth at the posterior angle of the 1st pair. In the hand of the 2nd pair in the female the palm is concave.

The 3rd uropods have their ends *truncate* with a group of spines (fig. 29. up.[3]).

The telson has a *second notch* above the terminal one on the inside of each division (fig. 29. t.).

Length 8 millims.

Of the above characters the least valuable is that of the 3rd pleon segment, as the number and position of the teeth vary considerably.

Mæra rubro-maculata (STIMPSON).—Plate V., fig. 30.

Gammarus rubro-maculatus, STIMPSON, 'Proc. Acad. Nat. Sci.,' Philadelphia, 1855.

M. rubro-maculata (STIMPSON), '"Challenger" Amphipoda,' p. 1008, Plates XCV., XCVI.

Ceradocus rubro-maculatus (STIMPSON), DELLA VALLE, 'Gamm. d. Golfo di Napoli,' p. 720.

From Kodramallai Point southward to Galle.

Length of adult male 10 millims.

In the specimen dissected, the mandibular palp was set far back, the 1st joint produced forward in a sharp point; the 2nd widened abruptly near the base, then narrowing gradually (fig. 30. m.).

Mæra tenella (DANA).—Plate V., figs. 31.

Gammarus tenellus, DANA, 'U.S. Explor. Expn.,' p. 952, Plate 65, fig. 7.

Mæra tenella, SP. BATE, 'Cat. Amph. Crust. Brit. Mus.,' p. 193, Plate XXXV., p. 3.

Cheval Paar, 10th November, 1902. One male, length 6 millims.

Head about as long as the first 2 segments. Eye nearly round, rather small.

Mesosome and pleon without dorsal teeth; epimere of the 3rd pleon segment with 6 or 7 unequal teeth on the hind margin, the posterior angle acute and somewhat upturned (fig. 31. $pl.^3$). First segment of the urus with 3 small postero-dorsal teeth and a dorsal depression; 2nd segment with 1 tooth.

Upper antennæ reaching to the end of the pleon; 1st joint twice as thick and nearly as long as the 2nd; 3rd very short; flagellum rather shorter than the first 2 joints of the peduncle, 13-jointed; appendage 8-jointed, two-thirds of the length of the flagellum.

Lower antennæ scarcely reaching beyond the end of the peduncle of the upper; the flagellum about as long as the 3rd joint.

Both upper and lower antennæ are sparsely setose, except the flagellum of the lower, which is more hairy.

First gnathopods: side-plates small, produced in front to an acute angle; wrist longer than the hand, the hind margin densely setose; hand with the palm ill-defined, and transverse rows of setæ on the hind margin (fig. 31. $gn.^1$).

Second gnathopods: side-plates small, quadrate, with rounded angles; 1st joint stout, two-thirds of the length of the hand and nearly twice as long as the next 3 joints together; wrist transverse; hand large, widening distally; hind margin as long as the front, straight, with a few setæ, and ending in a strong curved tooth which defines the palm; this is transverse, convex, uneven, and spinulose (fig. 31. $gn.^2$).

First and 2nd peræopods slender, slightly longer than the 1st gnathopods; 1st joint narrow, subequal to the next 2; 5th longer than 4th and not so long as 3rd; 2 distal spines on the hind margin of the 4th and a row of 4 on that of the 5th joint. Dactylus with a strong tooth behind the point (fig. 31. pp.[2]), giving it the appearance of being bifid (fig. 3K, SP. BATE, *loc. cit.*).

The rest of the peræopods are altogether wanting.

The 1st and 2nd uropods are subequal in extent, not quite reaching the middle of the outer ramus of the 3rd pair; the rami are subequal; in the 1st they are rather shorter and in the 2nd rather longer than the peduncles; all spinous on both margins, with groups of terminal spines.

Third uropods: peduncle little more than half as long as the outer ramus, which is but little longer than the inner and has 4 deep notches with fascicles of long spines on the outer margin; both are truncate, with groups of long spines at the ends (fig. 31. up.[3]).

Telson small, cleft to the base, and widely dehiscent, each division ending in a double point with 2 long and 2 or 3 short spines (fig. 31. t.).

DANA's specimen was from the Fiji Islands. This species has a strong general resemblance to the next, from which, however, it differs in the toothed epimeres of the 3rd pleon segment; the relatively longer and more equal 3rd uropods; the different form of the dactyli of the 1st and 2nd peræopods, &c. It is unfortunate that the specimen had lost the last 3 pairs of peræopods, as these have a very distinctive character in *M. scissimana*.

Mæra scissimana (COSTA)—Plate V., fig. 32. pp.[1].

Gammarus scissimanus, A. COSTA, 1853.

Mæra truncatipes (WHITE), DELLA VALLE, *loc. cit.*, p. 725, Plate 22.

West Coast of Ceylon.

Length 5 millims.

This species forms a connecting link between the genera *Mæra* and *Elasmopus*. The fore part, including the 3rd peræopods, is typical *Mæra*, while the massive and very spinous 4th and 5th peræopods (a character that is much more marked in Ceylon than in Mediterranean specimens), and the comparatively short rami of the 3rd uropods, resemble *Elasmopus*. Another peculiarity of the species is that the size and shape of the hand of the 2nd gnathopods is much the same in males and females.

Mæra tenuicornis (DANA)—Plate V., figs. 33.

Melita tenuicornis, DANA, *loc. cit.*, p. 963, Plate 66, fig. 5.

Mæra tenuicornis, SP. BATE, 'Cat. Amph. Crust. Brit. Mus.,' p. 195, Plate XXXV., fig. 6.

Tow-net off Marichchikadi, 1st February, 1903. One male, and one young.

Segments of the mesosome and pleon without carinæ or dorsal teeth. Hind margin of the 3rd pleon epimere concave, smooth; lower margin rather convex, obscurely toothed; posterior angle acute (fig. 33. pl.[3]). First segment of urus with a double carina produced backwards in 2 points; 2nd segment with a small tooth and a long upright spine (fig. 33. ur.).

Upper antennæ: 1st joint stout, two-thirds as long as the 2nd and about twice as long as the 3rd. Flagellum long and slender, broken at the 18th joint. Appendage small, with 2 subequal joints and a minute terminal one, barely reaching the end of the 1st joint of the flagellum.

Lower antennæ: peduncle reaching a little beyond that of the upper; 1st joint short, 2nd and 3rd subequal in length, but the 2nd much the wider; flagellum shorter than the last 2 joints of the peduncle.

Mandibles as in *Elasmopus subcarinatus* (*vide* '"Challenger" Amph.,' Plate 98, *E. persetosus*), but the 2nd joint of the palp is subequal to and rather wider than the 3rd; very few setæ (fig. 33. m.).

First maxillæ: the inner plate oblong, with 7 plumose terminal setæ (fig. 33. mx.[1]).

Maxillipeds as in *E. persetosus*, but the outer plate reaching the end of the 2nd joint of the palp.

First gnathopods: side-plates subtriangular, with rounded angles; 1st joint stout, margins parallel, as long as the 3rd and 4th united; 2nd and 3rd subequal. Wrist nearly twice as long and about as wide as the hand. Hand widening distally, the hind margin straight, the front convex and bent at the distal end at a right angle round the base of the dactylus in a tooth-like process reaching beyond the middle of the dactylus, and having the appearance of a 2nd dactylus; the hind margin ends in a densely spinous lobe. The dactylus is very small, crooked, and deeply sunk in the hand. The whole limb is setose and recalls the 2nd gnathopod of a *Lysianax* (fig. 33. gn.[1]).

Second gnathopods: side-plates deeper than wide, oblong, rounded and a little wider below, about as long as the 1st joint; this is rather longer than the next 3 joints, but shorter than the hand; 2nd and 3rd joints subequal. Wrist triangular, about as wide as long; the hind margin with about 8 setiferous ridges. Hand long-oval, widest about one-third of its length from the base; palm undefined, the hind margin densely clothed on the distal half with incurved plumose setæ. Dactylus fully half as long as the hind margin (fig. 33. gn.[2]).

First and 2nd peræopods: side-plates fully as deep as the segments, rounded below; hind margin of the 2nd pair concave. The entire limb is as long as the last 2 pairs of peræopods, in which respect they differ from DANA's description and figure; 1st joint as long as the 3rd and 4th united; 3rd longer than 4th; 4th and 5th subequal, a few small spines on their hind margins; the rest of the limb has only a few scattered setæ (fig. 33. pp.[2]).

Remaining peræopods of similar form, the 3rd rather the shortest; 1st joint wide-oval, the width more than half the length, the hind margin smooth, front margin with small spines; 2nd joint short; 3rd joint very wide, 3 times as wide as the 4th, with long spines on setæ, before and behind; 5th joint three-quarters of the length of the 3rd and 4th together. Dactylus rather small, curved at the point (fig. 33. pp.[1]). In the 3rd pair the hind margin of the 1st joint is straight, in the 4th and 5th convex.

First uropods: rami subequal, shorter than the peduncle; all spinous.

Second uropods like the 1st, but the rami rather longer than the peduncle.

Third uropods wanting.

Telson cleft almost to the base, the divisions pointed with an angle on the inside.

Length 5 millims.

There are certain discrepancies between our specimens and DANA's description and figures of the New Zealand form, as given by SP. BATE. I attach no importance to the omission of the antennular appendage, as this is small and not easy to see. But if we are to take the proportions of the first 2 and last 3 pairs of peræopods shown in the figure as even approximately correct, they are quite different from ours. On the other hand, the 1st gnathopods are so peculiar and the description and figures of both pairs agree so well, that I feel justified in considering them identical. The species requires a new genus, but the absence of the 3rd uropods makes a satisfactory definition impossible.

Elasmopus, COSTA, 1856.

The mandibular palp in this genus is of two distinct forms; the one (A) with the 3rd joint slender, its hind margin straight, and its front margin rather sparsely setose or naked, approaching the same appendage in *Mæra*, *e.g.*, *M. obtusata* (MONT.); the other (B) as in *E. rapax*, COSTA, with the 3rd joint strong, the hind margin convex and the front margin pectinate.

To (A) belong, of the species under consideration,

E. subcarinatus (HASWELL) = *E. persetosus*, STEBBING.

To (B) belong the new species *E. serrula*, *E. spinimanus*, and *E. dubius*.

(A) **Elasmopus subcarinatus** (HASWELL)—Plate V., figs. 34.

Megamæra subcarinata, HASWELL, 'Proc. Linn. Soc. N.S.W.,' vol. 4, p. 335, Plate XXI.

E. subcarinata (HASWELL) (**E. persetosus**, STEBBING), '"Chall." Amph.,' p. 1019, Plate XCVIII.

Abundant and occurs all round Ceylon.

Length of adult male 7·5 millims.

The antennular appendage is 2-jointed instead of 6, otherwise it agrees with the "Challenger" description, except in the sculpture of the hand of the 2nd gnathopods of the male, which varies considerably. In the smaller specimens there is generally a single flat-topped lobe near the base of the dactylus; in the larger this is divided in two by a sinus. In the largest of all there is hardly a trace of a lobe or tooth on any part of the hind margin, which is densely setose in all (figs. 34. gn.[2] ♂ and ♀). None are quite like the "Challenger" drawing. The 3rd joint of the mandibular palp is distinctly longer than the 2nd.

(B) **Elasmopus dubius**, n. sp.—Plate V., figs. 35.

One male from pearl oysters, East Cheval Paar, 8th November, 1902.

Body smooth, without dorsal teeth.

Head: ocular lobe rounded, with an acute, re-entering angle and a narrow rounded lobe below, as in *E. rapax*. Eyes large, wide-oval, dark.

First 4 side-plates about as deep as the segments.

Upper antennæ of moderate length; the 1st joint as long and twice as thick as the 2nd and about one-third longer than the 3rd. Flagellum 16-jointed, a little shorter than the peduncle. Appendage 2-jointed, the 2nd rather the longer, a little longer than the 1st joint of the flagellum.

Lower antennæ reaching the end of the peduncle of the upper, 2nd and 3rd joints subequal; flagellum 8-jointed, rather longer than the last joint of the peduncle.

Mouth organs as in *E. rapax*.

Maxillipeds as in *E. rapax*.

First gnathopods: side-plates irregularly rhomboidal, the anterior angle rounded, with a few setæ on the lower margin. First joint about as long as the next 3; wrist rather shorter than the hand, the hind margin densely setose; hand with the palm rounded off into the hind margin, but defined by a spine (fig. 35. gn.[1]).

Second gnathopods: side-plates rounded below, not reaching half-way down the 1st joint; this is longer than the next 3; 3rd joint produced behind in a narrow lobe with 5 or 6 setæ; wrist very short and wide, hind margin with a dense tuft of setæ. Hand nearly twice as long as the 1st joint, margins subparallel and subequal, the front slightly the longer and smooth, except 2 or 3 setules; the hind margin has 9 or 10 fascicles of setæ and ends in a strong tooth which defines the palm; this is transverse, not oblique, narrow, with a central tubercle; the hinge of the dactylus is as wide as the palm. *Dactylus peculiar, bulbous at the base and very strong, with a curved blunt point which meets the defining tooth of the hind margin* (fig. 35. gn.[2]).

First and 2nd peræopods almost as long as the 4th and 5th; 1st joint narrow, as long as the 3rd and 4th together; 4th and 5th spinous on the hind margin.

Third peræopods wanting.

Fourth and 5th peræopods subequal and similar, stout; 1st joint five-sixths as wide as long, hind margin serrate, front spinous; 3rd joint produced downwards *in front;* otherwise subequal to 4th and shorter than 5th; all the joints spinous. Dactyli strong (fig. 35. pp.[5]).

First uropods: rami subequal, shorter than the peduncle; all spinous.

Second uropods short and stout; outer ramus shorter than the inner and subequal to the peduncle; all spinous.

Third uropods wanting.

Telson reaching beyond the middle of the 2nd uropods, divided nearly to the base, the divisions notched at the tip with a long and a short spine in each notch.

Length 5 millims.

This species is certainly very near *Mæra festiva*, CHILTON, 'Proc. Linn. Soc., N.S.W.,' vol. 9, Part 4, p. 3, Plate XLVI., fig. 2. As, however, Professor CHILTON has only described the antennæ and gnathopods, and as both of these differ somewhat from the specimen described above (considering also the distance between Sydney and Ceylon), it seems better to consider them as distinct. It is unfortunate that, in both cases, the 3rd uropods, so important in this family, should be wanting.

Elasmopus spinimanus, n. sp.—Plate V., figs. 36.

Reef, Galle, Station XXXVIII.

Very near *E. rapax*, from which it differs in the following points :—

The hind margin of the epimere of the 3rd pleon segment is slightly concave, the lower margin convex with submarginal spines, the posterior angle upturned, acute (fig. 36. pl.^{3}).

The 1st gnathopods have the hand longer than the wrist, the palm very oblique and only defined by a spine. The anterior angle of the side-plates is rounded.

The hand of the 2nd gnathopods in the male has no tubercle, except near the base of the dactylus; *this is flat-topped and crowned with 7 or 8 spines; below this is a row of 6 spines on the distal third of the hind margin*, with rather scanty fascicles of setæ below this. The side-plates are rounded below (fig. 36. gn.^{2}. ♂). In the female the limb nearly resembles that of *E. rapax*, female.

The last 3 pairs of peræopods are more slender than in *E. rapax*; the 1st joint with the hind margin obscurely serrate, and in the 3rd pair concave.

The 3rd uropods have the rami subequal in length and breadth, and considerably longer (as 5 : 3) than the peduncle, the outer with 4 fascicles of spines on the outer margin (fig. 36. up.^{3}).

The divisions of the telson are narrower at the end and more deeply notched.

Length 5 millims.

From *E. affinis*, DELLA VALLE, it differs in the absence of the median tubercle and the presence of the 6 spines on the hind margin of the hand of the 2nd gnathopods.

Elasmopus serrula, n. sp.—Plate VIII., figs. 37.

Galle; basket hung to buoy, 9th May, 1902, 1 male; from pearl oyster washings, Cheval Paar, several.

This species resembles *E. rapax* in the form and character of the body, the head, antennæ, mouth organs, peræopods (so far as relates to their proportions), and uropods.

The 3rd pleon segment has the hind margin almost straight, the lower convex and the posterior angle a little produced and upturned.

The side-plates of the first gnathopods have the front margin concave and the angle rounded; the limb as in *E. rapax*.

The 2nd gnathopods in the male have the hand of similar form to *E. rapax*, but *the hind margin is without spines or dentiform projections, except the large flat-topped one* (as in the last species) *at the base of the dactylus;* it is densely clothed with long setæ rising from numerous transverse ridges (fig. 37. gn.[2]). In the female the hand resembles *E. rapax.*

The 3rd peræopods are very short and stout, the hind margin of the front joint almost straight, narrowing distally, and obscurely toothed.

The 4th and 5th peræopods are subequal; the 1st joint, which is rather wider and more convex in the 5th, *has the greater part of the hind margin elegantly cut into flat-topped teeth* of a peculiar form (fig. 37. pp.[4]).

The telson has the end of the divisions rather deeply notched, with the angles equally produced; 2 unequal spines and 2 spinules in each notch (fig. 37. t.).

Parelasmopus, STEBBING, 1888.

Parelasmopus suluensis (DANA).—Plate VI., figs. 38.

> **Gammarus suluensis**, DANA, 'U.S. Exploring Expedition,' 1852.
> **Megamæra suluensis**, SP. BATE, 'Cat. Amph. Crust. Brit. Mus.,' 1862.

Cheval Paar, Gulf of Manaar.

The palm of the 2nd gnathopod in the male is much less oblique than in the "Challenger" figure.* In the female this limb resembles the 1st gnathopods, except in being rather longer and more slender. The hand is considerably longer and narrower than the wrist, with 5 fascicles of setæ on each margin; palm very oblique (fig. 38. gn.[2]).

The 3rd uropods (wanting in the "Challenger" specimen) have the rami half as long again as the peduncle, subequal in length and width, the outer slightly the longer, with 4 spiniferous notches on the outer edge; the inner has 4 pairs of submarginal spines on the inner side (fig. 38. up.[3]).

The telson reaches to the end of the peduncle of the 3rd uropods.

The length of a female (tube 94) is 13 millims.

Cheirocratus, NORMAN, 1865.

A single female with ova from Periya Paar Kerrai, November, 1902; length 4 millims. There was only one postero-dorsal tooth on the urus and that on the 1st segment. A description without the male would be useless.

Megaluropus, NORMAN,† 1889.

Megaluropus agilis, NORMAN.

> **Cheirocratus drechselii**, MEINERT, 'Crust. Malacostr. Daniæ,' 1890.
> **Megaluropus agilis**, NORMAN, DELLA VALLE, *loc. cit.*, p. 695, plates 3 and 34.

Kondatchi and Cheval Paars, November, 1902. About 30 specimens.

Notwithstanding the following differences between the Ceylon and English speci-

* In this respect our specimens resemble *P. setiger*, CHEVREUX ('Mém. de la Société Zool. de France,' t. xiv., p. 412, fig. 32, 1901), as also in some other small details.

† 'Ann. and Mag. Nat. Hist.,' Ser. 6, vol. 3 (1889), p. 446, Plate XVIII., and vol. 4, p. 123.

mens, I consider them to be substantially identical. In the former the denticulation of the hind margin of the 3rd pleon segment is finer; the flagellum of the upper antennæ is 9-jointed and considerably *longer* than the peduncle in the female; the last 3 pairs of peræopods have the 1st joint narrower, the hind margin concave, obscurely serrate, and produced downwards.

Length barely 4 millims.

To illustrate the difficulties one has to contend with in determining species from specimens sent from abroad in spirit, I may mention that of the 30 odd specimens only one had the lower antennæ, and perhaps 5 or 6 the broad 3rd uropods. It would be far better if specimens, when picked out, were sent home in *pure* glycerine.

Lilljeborgia, Sp. Bate, 1862.

Nicippe pallida (Bate), Della Valle, *loc. cit.*, p. 658, plate 19.

Stations XIX., LI. Length 4·5 millims.

Lembos,* Sp. Bate, 1857 (= **Autonoë**, Bruzelius, 1859, in part).

Lembos podoceroides, n. sp.—Plate VI., figs. 39.

Coast of Ceylon, under 100 fathoms, generally distributed.

Head as long as the first 2 segments; ocular lobe as in *L.* (*Autonoë*) *websteri*, Bate. Eye round-oval, dark.

Third segment of the pleon, with the hind and lower margins of the epimere convex, the posterior angle subacute and produced; a diagonal line running forward and upward from it (fig. 39. pl.[3]).

First segment of the urus almost as long as the remainder, including the telson.

Upper antennæ reaching to the pleon, peduncle reaching about the middle of the last joint of that of the lower; 1st joint about 3 times as wide and three-fourths as long as the 2nd, and 3 times as the 3rd. Flagellum about 22-jointed in the male, the joints lengthening distally. Appendage 7-jointed, the last minute, reaching the 7th joint of the flagellum.

Lower antennæ reaching to the middle of the flagellum of the upper; 2nd and 3rd joints subequal; flagellum in female 5-jointed, shorter than the last joint of the peduncle. Both pair of antennæ very sparsely setose.

Mandibular palp large and projecting, the 3rd joint as long as the 1st and 2nd united; the 2nd expanded distally (fig. 39. m.).

First gnathopods in the female (fig. 39. gn.[1] ♀):—

Side-plates rhomboidal, shorter than the 1st joint, the anterior angle blunt; 1st joint stout, rather longer than the next 3; wrist about half the length of the

* For the reasons for re-instating this genus see Stebbing, 'Ann. and Mag. Nat. Hist.,' Ser. 6, vol. xvi., 1895, p. 206.

hand, hind margin convex and setose. Hand wider than the wrist and widening distally, the palm about half as long as the hind margin, oblique, with a shallow sinus above the palmar angle, below which is a strong spine; the hind margin, palm, and sides of the hand and wrist are furnished with fascicles of setæ. The dactylus has the inner margin serrate and reaches below the strong spine mentioned above.

In young male: side-plates with the anterior angle acute; the first 4 joints very stout, the 1st about half as long as the hand and longer than the next 3; wrist about one-fourth of the length of the hand; the front margin of this is convex and naked; the hind margin has near the base a strong, somewhat everted tooth, above which is an angular sinus; above this is a flat-topped projection, with a rough edge and submarginal setæ, and a small sinus near the base of the dactylus: this has a central projection on the inner side which corresponds with the flat-topped one; the point reaches slightly beyond the basal tooth; the outer margin is rough with minute granules, as also is the lower margin of the basal tooth (fig. 39. gn.[1] ♂ jr.).

In adult male: the first 4 joints as in the young male, except the 1st joint, which is wider, being half as wide as long. The hand has the base produced backwards in a long pointed spur, above which the hind margin is straight, with a small semicircular sinus near the hinge of the dactylus; the latter is relatively much longer than in the young male, evenly curved like a sabre, without the central projection, and with a row of 7 or 8 setules along the inner margin (fig. 39. gn.[1] ♂ adult).

The 2nd gnathopods are as usual in this family small and alike in both sexes, except that in the female the wrist is rather shorter and in the males subequal to or slightly longer than the hand; of this the margins are subparallel, the palm obliquely transverse. This limb and the rest of the animal so closely resemble *L.* (*Autonoë*) *websteri*, SP. BATE, that I refer my readers to Professor G. O. SARS' excellent description and figures ('Amph. of Norway,' p. 547, plate 194).

Length 8 millims.

The resemblance between the *first* gnathopods of the young and old males of this species and the *second* gnathopods of the same in *Jassa* (*Podocerus*) *falcata* (MONT.) is very striking (*conf.* SARS, *loc. cit.*, plate 212, p^2 ♂–p^2 ♂′).

Lembos chelatus, n. sp.—Plate VI., figs. 40.

One specimen from north end of Chilaw Paar, 2nd February, 1902.

Head longer than the first 2 segments. Ocular lobe prominent, angular. Eye roundish, large, dark.

Third pleon segment rounded behind.

Upper antennæ: peduncle shorter than that of the lower; 1st joint twice as thick and more than half as long as the 2nd; the 3rd rather shorter than the 2nd; 1st joint of the flagellum almost as long as the last of the peduncle; appendage very small, 2-jointed, about one-third of the 1st joint of the flagellum. The flagellum was broken at the 2nd joint.

Lower antennæ reaching the 4th body segment; the 2nd joint rather shorter than the 3rd; flagellum subequal to these united.

Mandibular palp with the 3rd joint shorter and wider than the 2nd, sub-oval, widest near the distal end, which is truncate; 1st joint very short (fig. 40. mp.).

First maxillæ: inner plate minute, with a single setule near the rounded top.

Palps of the maxillipeds more slender than in *L. websteri*, the outer plates reaching about the middle of the 2nd joint, armed with spine-teeth which increase in length distally.

First gnathopods: side-plates fully as deep as the segments, wider below, the angles rounded; 1st joint about twice as long as the next 3, rather shorter than the hand; 3rd joint rounded behind; wrist small, triangular, almost coalescent with the base of the hand; this has the front and hind margins subparallel and sparsely setose; the latter produced in a strong tooth beyond the base of the dactylus to the point of which it is opposed, forming a chela; a smaller tooth between this and the base of the dactylus; this has a prominent rounded tooth on the inner margin (fig. 40. gn.[1]).

Second gnathopods: side-plates irregularly rhomboidal, with rounded angles; 1st joints stronger than in the 1st pair, wider than any of the other joints, and about as long as the hand; this is a little longer than, and subequal in width to, the wrist, margins parallel, setose; palm small, oblique. Dactylus reaching much beyond the palm (fig. 40. gn.[2]).

First and 2nd peræopods: side-plates rounded below, deeper than the segments; 1st joint relatively wide, 3rd nearly twice as long as the 4th, and wider at the distal end; the whole very sparsely setose (fig. 40. pp.[1]).

Third peræopods but little longer than the 2nd; 1st joint widely oval and about as long as the next 3; 3rd longer than 4th, the two together rather longer than the 5th, which is slender, and has 2 or 3 spines on the front margin.

Fourth and 5th peræopods are subequal, the latter shorter than is usual in this genus, only reaching the 2nd urus segment; they are but little longer than the 3rd pair, which they resemble, except the 1st joint, which is relatively shorter and narrower (fig. 40. pp.[5]); the 3 pairs are almost entirely without setæ.

The 3rd uropods extend a little beyond the 2nd, and these beyond the 1st; the outer ramus of the 3 pairs is shorter than the inner; in the 3rd the inner ramus is as long as the peduncle, with a spine near the middle and 3 unequal terminal spines; the outer has 2 or 3 short and 2 or 3 long terminal spines (fig. 40. up.[3]).

Telson rounded at the end, with a spine and a seta at each side.

Length 2·5 millims.

The characteristic features of this species are the angular ocular lobes, resembling *Gammaropsis*, the chelate hand of the 1st gnathopods, and the comparative shortness of the last peræopods. It is, however, very possible that the specimen was immature.

Another species of *Lembos* from Cheval Paar has the 1st gnathopods very like

L. websteri. Another from East Cheval Paar appears to be a *Lemboides*, STEBBING, 'Ann. and Mag. Nat. Hist.,' Ser. 6, vol. 16 (1895), p. 209, plates ix. and x., but both are too imperfect for description.

Aora, KRÖYER, 1844.

Aora gracilis (?), SP. BATE.

Pearl oyster washings, Gulf of Manaar.

A very small (2 millims.) and imperfect male from Muttuvaratu had the characteristic gnathopods of this species, and a female, with ova, length 2·5 millims., from East Cheval Paar may possibly belong to it.

Gammaropsis, LILLJEBORG, 1854.

Gammaropsis zeylanicus, n. sp.—Plate VI., figs. 41.

Generally distributed round the coast of Ceylon.

Head as long as the first 2 segments. Ocular lobe produced to more than one-third of the length of the 1st joint of the upper antennæ, subangular; the extremity generally entirely occupied by the eye, which is dark and variable in size and shape.

Hind margin of the 3rd pleon segment rounded. Urosome about as long as the last pleon segment, its 1st segment dorsally depressed.

Upper antennæ more than half as long as the body and longer than the lower, the peduncles subequal; 1st joint twice as thick and two-thirds as long as the 2nd, which is longer than the 3rd; flagellum subequal to the peduncle, with about 14 joints; appendage reaching the middle of the 5th joint of the flagellum, 5-jointed, the last joint the longest.

Lower antennæ: 2nd and 3rd joints subequal, longer than the 11–12-jointed flagellum. Both pairs of antennæ are sparsely setose.

Mouth organs and maxillipeds normal.

First gnathopods (female): side-plates rhomboidal, front not produced, angles rounded; 1st joint subequal to the next 3; wrist subequal to the hand in length and width, very setose on the side and hind margin; hand oval, palm undefined, with setiferous ridges on both margins; dactylus rather long, serrate. In the immature male from the same tube as the female (Station LVIII.) the 1st joint is stronger and has 3 strong curved pectinate setæ at the end of the hind margin; these were not seen on the female or the adult male. In this last the front margin of the side-plates is considerably produced to a rounded acute angle and the 1st joint is very stout, with scattered setæ along the hind margin (fig. 41. gn.[1] ♀).

Second gnathopods (female): side-plates as in the 1st pair, but rather wider; 1st joint strong, the margins subparallel, considerably longer than the next 3 joints; wrist triangular, about half as long as the hand; this is oval, palm only defined by a blunt spine a little beyond the middle of the hind margin, which, as well as that of the wrist, is very setose; the dactylus reaches a little beyond the spine and is not serrate (fig. 41. gn.^{2} ♀).

In the young male the side-plates are oblong, about twice as wide as deep, the angles rounded; 1st joint very stout (width to length as 3 : 5) and longer than the next 3, a number of long setæ on the outer side; wrist short and triangular; hand subovate, margins to the palmar angle subparallel; palm very oblique, uneven, defined by a small blunt tooth, and occupying nearly half of the hind margin, which is setose; the front margin is naked; the dactylus reaches to the palmar tooth and is not serrate (fig. 41. gn.^{2} ♂ jr.).

In the adult male the anterior angle of the side-plates is less rounded. The palm of the hand is deeply sculptured with a double tubercle in the middle. The dactylus has an obtuse tooth in the middle of the inner side (fig. 41. gn.^{2} ♂ adult).

First and 2nd peræopods: 1st joint rather longer than and twice as wide as the next 2; 3rd joint much longer than the 4th and rather longer than the 5th, which tapers to the base of the dactylus. The whole very sparsely setose.

Third peræopods much shorter than the 4th, the 1st joint wide-oval with smooth margins; 3rd and 4th much wider, but together scarcely longer than the 5th, on which there is a row of spines.

Fourth and 5th peræopods like the 3rd, but longer; the 3rd pair reaches the 4th joint of the 4th pair, and the 4th pair to the same joint of the 5th.

The uropods are subequal in extent, the peduncles of the 1st and 2nd subequal to the rami, with a row of spines on the outer margin; rami also spinous. The 3rd pair have the peduncle considerably longer than the rami, of which the inner is the shorter and pointed with 3 small spines on the outer margin and a terminal spine; the outer has a short spine on the upper side near the middle, with 3 or 4 short and 2 long spines on the tip (fig. 41. up.^{3}).

Telson as in *G. erythrophthalmus* (Lillje.).

Length 6 millims.

Cheiriphotis, n. gen.

Body very slender, scarcely compressed laterally; side-plates very small.

Head slightly produced in front, ocular lobes more so, angular or cuspidate.

Upper and lower antennæ subequal, the latter stronger; appendage well developed.

Mandibles with the palp long, 2nd and 3rd joints subequal, the whole as in *Gammaropsis*.

Second gnathopods of moderate size in the female, but immensely developed and peculiarly formed in the male; urus small; the 3rd uropods with the outer ramus very short, without a terminal joint, and the inner rudimentary.

This genus is nearly allied to *Microprotopus*, from which it differs chiefly in the smallness of the side-plates.

Cheiriphotis megacheles (Giles).—Plate VI., figs. 42.

Melita megacheles, Giles (male), 'Journ. Asiatic Soc. Bengal,' 1885, vol. liv., p. 70, pl. iii.

Eurystheus hirsutus, Giles (female), 'Journ. Asiatic Soc. Bengal,' 1887, vol. lv., p. 227, pl. viii.

Rather abundant along the West Coast from Colombo northwards.

Third pleon segment rounded behind; lower margin straight, hind margin convex.

Head not quite as long as the first 2 segments, of which the 1st is the shorter; ocular lobe moderately produced, angular, the angle obtuse and apiculate (fig. 42. o.l.).

Upper antennæ: peduncle subequal to that of the lower; 1st joint shorter and wider than the 2nd, longer than the 3rd; flagellum rather variable in length, generally subequal to the last 2 joints of the peduncle, about 13-jointed. Appendage (in female) reaching the end of the 4th joint of the flagellum, 4-jointed, the first 2 joints together subequal to the 4th. In the males the appendage is 3-jointed, the 1st joint shorter than the 2nd, the 2nd and 3rd subequal; the whole reaching to the end of the 2nd joint of the flagellum; the appendage has, in addition, a minute terminal joint in both sexes.

Lower antennæ rather stronger than the upper, the 1st joint about one-third of the 2nd; 2nd, 3rd, and flagellum subequal, the last 9-jointed. Both pairs of antennæ are rather thinly clothed on the under side with long setæ.

Mouth organs as in *Gammaropsis*, except the inner plate of the 1st maxillæ, which is round-oval, with 4 setules on one side.

Maxillipeds as in *Gammaropsis*.

First gnathopods: side-plates acutely produced in front and fringed round the blunt point and below with long setæ, especially in the female. The 1st joint is as long as the wrist, which is longer than the hand and has the hind margin rather flattened and very setose; the hind margin of the hand is evenly convex, with no definite palm, and is setose on the middle part. Dactylus about half as long as the hind margin, with a row of setules on the inner margin (fig. 42. gn.[1]).

Second gnathopods (female): Side-plates small subquadrate, angles rounded, lower margin fringed with long setæ. First joint very strong, subequal to the hand, with long setæ on the front margin; wrist half as long as the hand, triangular, produced and setose behind; hand subovate, palm oblique, uneven, defined by a strong tooth just below the point of the dactylus (fig. 42. gn.[2] ♀).

The young male has the hand much wider than the female, though less so than the adult male; the palm is somewhat obliquely transverse, defined by a strong pointed tooth; near the middle is a double pointed tooth and a single one near the base of the dactylus; the latter is wider in the middle than in the adults. The wrist is produced towards the *front* margin of the hand and cannot be seen behind (fig. 42. gn.[2] ♂ jr.).

In the adult male the 1st joint is shorter, the width being three-fourths of the length, which is subequal to the next 2 joints. The wrist has disappeared or can only be seen in a reduced form through the wall of the 3rd joint. The hand is subquadrate, as long and wide as the first 3 segments united; the proximal part of the front margin is very convex and fringed with long plumose setæ; the palm is rectangularly transverse, defined by a sharp tooth with 5 equidistant, irregular teeth between it and the hinge of the dactylus. The hind margin is almost straight and about two-thirds as long as the front, with a few setæ below the palmar angle. Dactylus slightly curved, narrow, with subparallel margins, the point meeting that of the defining tooth (fig. 42. gn.^{2} ♂). Dr. GILES' specimen had only 3 teeth on the palm, but this is a feature that doubtless varies with age.

First peræopods rather longer than the first 3 joints of the 2nd gnathopods in the male, and as long as the whole limb in the female; 1st joint curved in the male, straight in the female, rather stout; 3rd and 5th subequal in length, the 3rd widened distally with a group of long stiff setæ at the anterior angle. Dactylus rather slender and recurved (fig. 42. pp.^{1}). In the female this limb is much more setose than in the male.

Second peræopods in the female like the 1st pair; in the male smaller and with the 1st joint straight.

Third peræopods about as long as the 2nd pair in the male: 1st joint much expanded behind and fringed on both margins; next 3 joints subequal in length and width; 5th longer and narrower, with 5 or 6 spines on the hind margin. All the joints have long plumose setæ on the front margin and the 3rd and 4th joints have a group at the posterior angle as long as the next joint. Dactylus rather short, recurved, and reversed as in *Photis* (fig. 42. pp.^{3} ♂).

The remaining peræopods increase in length successively, the last pair extending beyond the uropods and having the 1st joint broader than the 4th pair. Both pairs are densely hirsute.

The first uropods extend a little beyond the 2nd, and these beyond the 3rd; in the 1st and 2nd the rami are subequal and shorter than the peduncles, all the parts being spinous.

The 3rd uropods have the outer ramus shorter than the peduncle, without a terminal joint, but with 3 short spines and some stiff setæ at the tip; inner ramus a spiniferous tubercle (fig. 42. up.^{3}).

Telson as in *Microprotopus*, squarely truncate when seen from above mounted, with 3 or 4 setæ in each angle; it does not quite reach the end of the peduncle of the 3rd uropods.

Length of male, 4 millims.

Incubatory lamellæ elongate-triangular, the apex below.

The great size and resemblance in shape and colour to a broken piece of shell in the hands of the 2nd gnathopods of the male suggest, as in *Melita anisochir*, KR., a protective purpose. It is, however, not easy to see why, in both species, the males only should be protected. There can, I think, be little doubt that *Eurystheus hirsutus*, GILES (*loc. cit.*), is the female of this species.

Photis, Kröyer, 1842.

Photis longicaudata (Sp. Bate).—Plate VI., figs. 43.

West Coast of Ceylon, from Galle northwards; generally abundant.

Length of female with ova, 3·5 millims.

I have referred the specimens examined to the above species chiefly on account of the prominence of the ocular lobe (fig. 43. c.). In other respects it is equally near the other two species described by G. O. Sars, the limbs in some specimens being as robust and hairy as in *P. reinhardi*, Kr., while the hand of the 2nd gnathopods resembles that of *P. tenuicornis* (fig. 43. gn.^{2}). It is a question whether these 3 species and *P. pollex*, A. O. Walker, ought not to be merged in the oldest recorded form, *P. reinhardi*. The Ceylon specimens are remarkably variable. The colour in spirit is dark yellowish-green spotted with black or brown.

One of the forms has the hind margin of the outer ramus of the last 2 pairs of pleopods expanded near the base and furnished with peculiar longitudinally-striated, tapering plumose setæ radiating symmetrically from the curved margin (fig. 43. plp.). In this form the side-plates and gnathopods are setose.

Photis longimanus, n. sp.—Plate VII., figs. 44.

From pearl oysters, East Cheval Paar, 8th November, 1902; 5 specimens.

Male.—Head about as long as the first two segments.

Ocular lobe reaching almost to the end of the 1st joint of the lower antennæ. Eye large, occupying almost the whole lobe, dark.

Hind angle of the 3rd pleon segment rounded.

Upper and lower antennæ subequal, scarcely reaching to the pleon, sparsely setose; 1st joint of the upper twice as thick as, but shorter than, the 2nd, and subequal to the 3rd; flagellum 6-jointed, subequal to the 2nd and 3rd joints of the peduncle together.

First joint of the lower antennæ about half as long as the second, which is subequal to the 3rd; flagellum 6-jointed, rather shorter than the last 2 joints of the peduncle.

Mouth organs and maxillipeds normal.

First gnathopods: side-plates oblong, much wider than deep, angles rounded; 1st joint as long as the 3rd and 4th and at least as wide as the hand; wrist as wide as, and considerably longer than, the hand, which is oval; the palm undefined (fig. 44. gn.^{1}).

Second gnathopods: side-plates small, rounded-oblong; the first 4 joints very short and stout. *Wrist brought round the base of the hand on the outside and produced beyond it in an oval lobe.* Hand long, narrowing distally, a strong blunt tooth near the base on the *inner* surface, the hind margin divided into 3 nearly equal concave spaces by this and 2 other teeth, the middle one being the smallest. Dactylus strong, reaching the basal tooth (fig. 44. gn.^{2} ♂).

The peræopods do not differ materially from those of *P. reinhardi*, Kr., except in being less setose; the last pair extends to the end of the 3rd uropods.

The segments of the urus decrease successively in length; the 1st has a dorsal depression.

The uropods are subequal in extent, short and stout; the outer rami in the 1st and 2nd rather shorter than the inner and about half as long as the peduncles, without terminal spines or setæ. The 3rd pair has the inner ramus almost rudimentary, the outer curved, rather longer than the peduncle, with a minute terminal joint and 1 or 2 slender spines on it. With the exception of 2 or 3 setules on the telson, the urus appears to be entirely destitute of setæ.

Telson not quite reaching the end of the peduncle, of the usual form.

Length 3 millims.

Colour in spirit yellowish, with a few dark-red blotches on the body and limbs. No female was observed. The species may be distinguished by the peculiar form of the wrist and hand of the 2nd gnathopods.

Photis nana, n. sp.—Plate VII., figs. 45.

Pearl oyster washings, Muttuvaratu, 19th Nov., 1902. Two females with ova.

Head longer than the first 2 segments. Ocular lobe distinct, but not prominent. Eye round, rather small.

Posterior angle of the 3rd pleon segment rounded.

Antennæ subequal in length and width, except the 1st joint of the upper, which is at least twice as wide as any of the other peduncular joints; both pairs are almost naked. In the upper pair the 3 joints of the peduncle are subequal in length, the 1st with a group of setæ at the distal end; the flagellum about as long as the last 2 joints of the peduncle, with 3 rather long subequal joints and a minute terminal one which, as well as the 2 preceding, has one or two strap-shaped setæ at the end. The lower antennæ have the 1st joint very short; the 2nd shorter than the 3rd; the flagellum as long as the peduncle.

First gnathopods: 1st joint curved, as long as the next 3; wrist about two-thirds as long as, but wider than, the hand, with a group of setæ on the convex hind margin. The hand narrows distally to the base of the dactylus, the distal half of the hind margin setose (fig. 45. gn.[1]).

Dactylus with a spine and 2 setules on the inner margin, which is finely pectinate.

The 2nd gnathopods resemble the 1st in size and form, but the 1st joint is less curved and the 3rd has the end of the hind margin squarely truncate (fig. 45. gn.[2]).

First and 2nd peræopods: 1st joint pyriform, longer than the next 3, the hind margin convex and setose at the distal end (fig. 45. pp.[1]).

Third peræopods as in *P. reinhardi*, but without setæ, except one at the end of the hind margin of the 4th joint and one at the base of the dactylus.

Fourth and 5th peræopods as in *P. reinhardi*, except the 1st joint, which is more oblique and the whole less setose.

The uropods are without spines or setæ, except at the ends of the joints. The 3rd pair extends slightly beyond the 2nd; the inner ramus very small, the outer almost as long as the peduncle, curved, with a minute terminal joint, no spines or setæ (fig. 45. up.[3]). Telson obtusely pointed.

Length 2 millims.

The peculiar gnathopods of this small species seem to indicate that a new genus will be required for it when the male is found.

Chevalia, n. gen.

Body laterally compressed.

Head without a rostrum.

Antennæ subequal, the upper with an appendage.

Mandibles small; palp long and slender, 3-jointed.

First and 2nd maxillæ as in *Cerapus*, but relatively smaller.

Palp of the maxillipeds with the last joint blunt.

First gnathopods slender, as in *Gammaropsis*.

Second gnathopods with large wrist and hand alike in both sexes.

The last 3 pairs of peræopods with the dactyli inverted, as in *Cerapus*.

First and 2nd uropods with dissimilar rami; 3rd with 2 well-developed rami.

Telson, as in the Photidæ.

This curious genus is intermediate between the Photidæ and the Corophiidæ. It resembles the former in the form of the body, head, antennæ, gnathopods, and telson; and the latter in the inverted peræopods and the dissimilar rami of the 1st and 2nd uropods, though in the new genus the dissimilarity is greater. Notwithstanding these points and the similarity of the 2nd gnathopods in the males and females, I have placed this form under the Photidæ as the family with which it has the greatest affinity.

Chevalia aviculæ, n. sp.—Plate VII., figs. 50, and Plate VIII., fig. 50).

Pearl oyster washings, East Cheval and Muttuvaratu paars: about 20 specimens

Body smooth, without dorsal spines or teeth; much curved; speckled with red.

Head as long as the first 2 segments; ocular lobe subangular, not very prominent.

Eyes oval—colourless in spirit.

Segments of the mesosome increasing in length successively, the 7th twice as long as the 1st.

Pleon segments with a pair of upright setæ on their postero-dorsal margins; the epimere of the 3rd rounded behind and below.

First 2 segments of the urus coalesced and subequal to the last pleon segment; 3rd segment about half as long.

Antennæ about two-thirds of the length of the body, subequal in the female; the upper rather the longer in the male; in the upper the 1st and 2nd joints are subequal, about one-third longer than the 3rd; flagellum 7-jointed; appendage 1-jointed, as long as the 1st joint of the flagellum.

Lower antennæ: 1st joint about half as long as the 2nd, which is rather longer than the 3rd; flagellum 6-jointed, subequal to the last 2 peduncular joints. Both pairs are similarly fringed below with long curved setæ.

Mandibles small, shorter than the 2nd joint of the palp; cutting edge double; molar tubercle rather large, but not prominent, palp projecting to the middle of the 2nd joint of the lower antennæ; 1st joint very small, 2nd and 3rd subequal (fig. 50. m.).

Maxillipeds: inner plate reaching the end of the 1st joint of the palp, spinous on the angle: outer narrow, reaching the middle of the 2nd joint, with slender curved spines near the top: 1st and 3rd joints of palp subequal; 2nd about twice as long; 4th rather more than half as long as the 3rd, the apex rounded and setose.

First gnathopods: side-plates small, front angle acute, with a setule on the point; 1st joint subequal to the wrist, curved; wrist subequal to the hand in length and width, the hind margin setose; hind margin of the hand convex and setose, the palm undefined. Dactylus half as long as the hind margin (fig. 50. gn.^{1}).

Second gnathopods: side-plates as in the 1st, but smaller; 1st joint stout, subequal to the next 3; wrist subequal in width to the hand, along the anterior margin of which it is carried for about one-third of its length. Hand longer than the wrist, subquadrate, the palm almost rectangular to the hind margin, convex, and defined by a strong tooth, behind which is a notch which receives the point of the dactylus (fig. 50. gn.^{2}).

First and 2nd peræopods are rather longer than the 2nd gnathopods and strongly built; the side-plates alike small and triangular, the angles rounded. The 1st joint is subequal to the next 3, about twice as wide as the 3rd joint, and widening distally; the front margin distally convex in the 1st pair and straight in the 2nd; the 3rd joint as long as the 2nd, 4th, and 5th together, and twice as wide as the last 2. Dactylus short (fig. 50. pp.^{2}).

Third peræopods hardly reaching the end of the 1st joint of the 2nd pair; 1st joint almost as wide as long, the front margin very convex; the 2nd subequal to the 4th and the 3rd to the 5th, which is the narrowest; the 3rd and 4th are obcordate. Dactylus reversed, with a secondary tooth on the outer side (fig. 50. pp.^{3}).

Fourth peræopods like the 3rd, but longer.

Fifth peræopods rather longer than the 4th; the 1st joint with the hind margin almost straight and ending in a rounded right angle; otherwise as in the preceding pairs (fig. 50. pp.^{5}).

The last 3 pairs of peræopods are feeble, the last pair hardly reaching the 3rd pleon segment, and neither as long or strong as the first 2 pairs of peræopods; they are almost devoid of spines or setæ.

First uropods: peduncle rather shorter than the upper ramus, which is styliform, curved and spinulous on the proximal half of the inner margin; the lower ramus is about one-fourth shorter than the upper, obliquely truncate at the end, where there is a crowded group of short blunt spines; the inner margin has a row of microscopic ciliæ (fig. 50. up.[1]).

Second uropods of similar structure to the 1st, but shorter in extent.

It is very difficult to determine which is the "inner" or the "outer" ramus, as, in fact, the one lies immediately above the other in these 2 pairs.

Third uropods: peduncle subequal to the inner ramus, which is rather longer than the outer; both are alike and simple, with obliquely truncate setose ends (fig. 50. up.[3]).

Telson as in *Gammaropsis*.

Length of ovigerous female 4 millims.

Probably a tubicolous species, from the structure of the last 3 pairs of legs. So far it has only been obtained from the washings of pearl oysters.

Amphithoë, Leach, 1813.

Amphithoë intermedia, n. sp.—Plate VII., figs. 46.

West Coast of Ceylon, from Colombo northwards.

Head shorter than the first 2 segments. Ocular lobe slightly produced, subangular. Eye round, red.

Third pleon segment: lower and hind margins convex, angles rounded.

Upper antennæ: 1st joint stout, almost as long as the slender 2nd; the 3rd barely one-third of the 2nd; flagellum slender, 30-jointed.

Lower antennæ: 1st joint very short, 2nd and 3rd subequal, but the 2nd the wider; *flagellum subequal to the last joint of the peduncle, 9-jointed.*

Mandibles normal, the palp scarcely as long as the mandible; 1st joint about half as long as the 2nd, which is subequal to the 3rd; this widens distally and is obliquely truncate, with 7 pectinate setæ on the truncate part and 1 below (fig. 46. m.).

First maxillæ: inner plate with 3 setæ (fig. 46. mx.[1]).

Remaining mouth organs and maxillipeds normal.

First gnathopods in the female as in *A. rubricata* (Mont.), the side-plates rather wider below, with a few setæ on the rounded posterior angle. In the male the whole limb is more robust; the hind margin of the wrist straight, crenate, setose, and ending in an acute angle; the hand scarcely as wide as the wrist, oblong; the dactylus strong and serrate (figs. 46. gn.[1] ♀ and ♂).

Second gnathopods in the female very like and but little larger than the 1st; the side-plates oblong, with setæ as in the 1st; the wrist is produced behind in a truncate lobe which is densely setose; the hand is about half as long again as the wrist, *the palm slightly convex, defined by a spine, but rounded off into the hind margin,* which is rather the longer; the whole hind margin setose. Dactylus reaching a little beyond the palmar spine, serrate (fig. 46. gn.[2] ♀).

In the male the side-plates are suborbicular, the diameter less than the length of the 1st joint, which is subequal to the next two; the front margin of the wrist is about half as long as that of the hand, and has a few unequal spines near its proximal end; the hind margin is a small, rounded, setose lobe. The hand has its anterior surface furnished with numerous setiferous ridges, the setæ very long; this part is produced in a rounded lobe beyond the base of the dactylus. The hind margin is subparallel with the front for about half its length, where it forms a strong tooth* which forms a deep V-shaped sinus with the palm. The point of the dactylus just meets that of the tooth (fig. 46. gn.[2] ♂).

The peræopods resemble those of *A. rubricata*, but are rather more slender.

The 1st and 2nd uropods have their outer rami subequal to the peduncles, the inner rather longer; all the parts are spinous.

The 3rd uropods have the inner ramus slightly longer than and subequal in width to the outer, the end rounded with a group of unequal spines at the end and 4 along the inner margin; the outer as in *A. rubricata*.

Telson as in *A. rubricata*.

Length of female with ova, 4 millims.

This species appears to connect *A. rubricata* with *A. vaillanti*, LUCAS; the female agreeing with the former, but differing from the latter in the hand of the 2nd gnathopods, while the reverse is the case in the male. The form described by DELLA VALLE as *A. rubricata* is, as pointed out by CHEVREUX ('Amphipodes des campagnes de "l'Hirondelle,"' 1885–8, p. 100,† who also gives the synonomy of that species), *A. vaillanti*.

The incubatory lamellæ of the 2nd gnathopods are narrow; the branchial pyriform broader at the lower end than in *A. rubricata*.

Amphithoë vaillanti, LUCAS.

Station LVIII., two females with ova; length 6 millims.

Ischyrocerus, KRÖYER, 1838.

Ischyrocerus anguipes, KR. (?).

Coast of Ceylon, under 100 fathoms, exact locality not known.

One male and 1 female with ova; length 2·5 millims.

I should not hesitate to refer these specimens to KRÖYER'S species were it not for the entire absence of their antennæ, their very small size (neither of these characters being, however, of much importance in this genus), and the fact that the species has not been recorded south of the Kattegat. The shape of the hand of the 2nd gnathopods in the male agrees exactly with SARS' figure of *I. anguipes*, differing in the concave hind margin from its nearest and more southern ally, *I. minutus*, LILLJEBORG. With the latter species I am well acquainted, having formerly described it under the name of *Podocerus isopus*.

* In a male from Station LVI. (tube 43) this tooth becomes a lobe.

† "Résultats des Campagnes scientifiques du Prince de Monaco," 1900.

Jassa, Leach, 1813 (= Podocerus, Auct.).

Jassa falcata (Montagu) (?).—Plate VII., fig. 47.

Muttuvaratu Paar, 19th November, 1902. One female without ova; length 4 millims.

In the absence of a male it is impossible to be sure of the species, but in its principal features this agrees with the above. The limbs and antennæ are more robust: the flagellum of the upper antenna is 6-jointed, about as long and half as wide as the last joint of the peduncle, the 1st joint as long as the next 3; appendage 1-jointed, about one-third of the 1st joint of the flagellum. The terminal joint of the palp of the maxillipeds is oblong, not pointed. The 2nd gnathopods are very robust, but of much the same form as in *J. falcata.* The 1st joint is about half as long as the hand; the separation of the 2nd and 3rd joints is not very distinct, and the wrist appears to be entirely coalesced with the hand. The dactylus is apparently encased in a sort of sheath to within a short distance of the point, the lower margin being studded with minute equidistant denticles.

Erichthonius, Milne Edwards, 1830.

Erichthonius abditus (Templeton).

Abundant from a basket hung to a buoy in Galle Harbour, 9th May, 1902; also from other localities along the coast.

Length of female with ova, 7 millims.

Erichthonius macrodactylus (Dana). -Plate VII., figs. 48.

Pyctilus macrodactylus, Dana, 'U.S. Exploring Exp.,' p. 974, plate 67.

Station LIII., north part of Gulf of Manaar; a few specimens.

Head as long as the first 2 segments, of which the 1st is very short, the remainder subequal. Ocular lobe moderately produced. Eye medium sized, dark, roundish-oval.

Upper antennæ reaching the middle of the flagellum of the lower; the 1st joint little more than half the length of the 2nd, which is rather longer than the 3rd; flagellum 13-jointed, subequal to the last 2 joints of the peduncle.

Lower antennæ: peduncle longer than that of the upper, the 2nd joint shorter than the 3rd, a red blotch upon both; flagellum rather longer than these two together.

Mouth organs normal except the palp of the mandible, which, both in this species and in *E. abditus*, differs from the European form of the latter in having the 3rd joint rather narrower than the 2nd and less expanded towards the tip (fig. 48. m.).

Maxillipeds normal.

First gnathopods as in *E. abditus.*

Second gnathopods as in *E. abditus* in the female. In the male it is very near to *E. difformis*, M. Edw., *but the thumb-like process of the wrist has the outer margin* *quite straight, while the inner is parallel to the outer for half its length, and thence tapers to a very sharp point*, with a tuft of setæ on the outer margin; the distal half of the proper hind margin of the wrist is quite straight. The hand is narrow and curved, *the margins parallel without any prominence on the inner.* Dactylus fully as long as the hand (fig. 48. gn.² ♂).

First and 2nd peræopods as in *E. abditus.*

Third peræopods: in the male the 1st joint has the hind margin produced downwards in a narrow rounded (not "acute," as described by DANA, though figured rounded) lobe reaching beyond the end of the 2nd joint; the 3rd joint is longer than the next 3, curved and expanded at the end (fig. 48. pp.³ ♂). In the female the 1st joint is without the lobe, and the 3rd joint is straight and shorter than the next two.

The 4th pair are slender and much longer than the 3rd, the 3rd and 5th joints subequal.

The 5th pair are longer than the 4th and extend considerably beyond the uropods; *the 5th joint is as long as the 3rd and 4th together.*

First uropods: peduncle considerably longer than the rami, the inner margin with 5 or 6 spines, rounded off and pectinate or finely serrate at the end; inner ramus a little shorter than the outer, both spinous and minutely pectinate.

Second uropods like the 1st, except the inner margin of the peduncle, which is not rounded or pectinate on the inner margin.

Third uropods as in *E. abditus*—two unequal spines near the middle of the outer margin and a small one near the base of the peduncle.

Telson as in *E. difformis*, with an obtuse central tooth.

Length 5 millims.

The colour of the specimens (in spirit) was lighter than in *E. abditus*, with dull red blotches and transverse bars on the body and limbs. This species may be considered as the eastern form of *E. difformis*, from which the male differs in the even hind margin of the hand, the somewhat differently formed wrist of the 2nd gnathopods, and, still more, in the peculiar construction of the 3rd peræopods. The female can only be distinguished from *E. abditus* by its greater slenderness generally, and especially by the great length of the 5th joint of the last peræopods.

Cerapus, SAY, 1817.

Cerapus calamicola (GILES).

Cyrtophium calamicola, GILES, 'Journ. Asiatic Soc. Bengal,' vol. liv., 1885, p. 54, pl. ii. ♂.

Cerapus flindersi, STEBBING, '"Chall." Amph.,' p. 1163, plate cxxv. ♀.

Cerapus flindersi, STEB., CHILTON, 'Rec. Aust. Mus.,' vol. ii., p. 1 (separate copy), pl. 1. ♂.

Station LIII., Periya Paar Kerrai, many, with tubes. East Cheval Paar.

A female from Station LIII. measured 6 millims.; those from Periya Paar Kerrai only 3 millims.

Siphonœcetes, Kröyer, 1845.

Siphonœcetes orientalis, n. sp.—Plate VII., figs. 49.

Station V., several; Station LIII., two; and Station LVIII., two specimens.

Rostrum acute deflexed, as long as the ocular lobes, which are almost rectangular, narrowing distally. Eyes small but distinct, with about 6 lenses.

First 4 side-plates acutely angled and fringed with rather long setæ.

Upper antennæ reaching beyond the middle of the 3rd joint of the peduncle of the lower, the 1st and 3rd joints equal; flagellum shorter than the peduncle, 14-jointed.

Lower antennæ almost as long as the whole body, the 1st joint about half as long as the 2nd, which is a little longer than the 3rd; flagellum about half as long as the last joint of the peduncle, 3-jointed, the 2nd one-fourth as long as the 1st, the 3rd minute. The whole of the flagellum is armed with a row of 5 or 6 strong recurved spines on each margin of the lower side. The lower side of the 2nd joint of the peduncle is sparsely, and that of the 3rd densely, clothed with long plumose setæ (fig. 49. ant.^{2}).

First gnathopods: 1st joint, hand, and wrist subequal, the hand throughout narrower than the wrist, and narrowing gradually from the base to the end with 4 spines on the hind margin; both hand and wrist setose on both margins. Dactylus with a row of spines on the inner margin, increasing in size distally (fig. 49. gn.^{1}).

Second gnathopods: much as in *S. colletti*, Boeck, but the hand narrower, the widest part near the base, from which point to the dactylus the hind margin is slightly concave, with 5 spines increasing in size distally (fig. 49. gn.^{2}). Dactylus as in the 1st gnathopods.

The rest as in *S. colletti*.

Length 5 millims.

The narrowness of the hands of the gnathopods distinguishes this species from the others, but I confess that I am inclined to agree with Della Valle (*loc. cit.*, p. 362), that the points of difference between *S. typicus*, Kröyer, the original Arctic species, *S. colletti*, Boeck, and *S. pallidus*, Sars, are not greater than can be accounted for by age, &c., so that both these species, as well as the present one, might well be united to *S. typicus*.

Corophium, Latreille, 1807.

Corophium crassicorne, Bruzelius.

Periya Paar Kerrai, 9th November, 1902. Two males, one female.

Length 2·5 millims.

The only difference observed between this and the European form was that there are 2 spines on the 3rd joint of the lower antennæ in the female instead of one.

Platophium, Dana, 1852.

Platophium læve (Haswell).—Plate VII., figs. 51.

> **Dexiocerella lævis**, Haswell, 'Proc. Linn. Soc., N.S. Wales,' vol. x., 1886, p. 111, pl. xviii.
> **Cyrtophium haswelli**, Chevreux and De Guerne, 1888.

Stations V., XLVII., LVIII., all in Gulf of Manaar.

The first 5 segments of the mesosome with a median transverse depression, the last segment and the first 2 of the pleon carinate, the carinæ not produced behind.

Head considerably longer than the 1st segment. Lower angle of the ocular lobe bluntly rectangular. Eyes wide-oval, dark in the centre.

Upper antennæ about as long as the head and first 2 segments; 2nd and 3rd joints of peduncle subequal, the flagellum the same length, 4-jointed in the females, 5-jointed in the males, the 1st joint much the longest. Appendage about one-third of the 1st joint. The whole setose below.

Lower antennæ are longer and less setose in the male than in the female, the 2nd joint considerably shorter than the 3rd and subequal to the 3-jointed flagellum.

First gnathopods: side-plates rhomboidal; 1st joint rather shorter than the next 3; hind margin of the wrist almost straight, setose. Hand subtriangular, longer than the wrist in the male, widest near the base, the palm occupying two-thirds of the hind margin and defined by a group of spines. Dactylus barely reaching the palmar spines; a row of spines on the inner margin and an obscure denticulation on the outer near the point, which has a secondary tooth, giving it a split appearance. In the female the hand is proportionately shorter than in the male, being only about as long as the wrist (figs. 51. gn.^{1}).

Second gnathopods, female (fig. 51. gn.^{2} ♀): the whole limb short and stout; the 1st joint subequal to the next 3; 3rd joint produced behind to a point tipped with a spine; wrist triangular, cup-shaped, with spines round the margin, about one-third as long as the hand; this is widely oval, the palm about 3 times as long as the rest of the hind margin, from which it is defined by a spine; about 6 spines and 4 long setæ on the palmar edge, and 4 marginal and 3 submarginal spines on the front margin; dactylus rather longer than the palm. In the male the hand is 4 times as long as the wrist, about 3 times as long as the hand in the female and proportionately narrower; the palm occupies nearly the whole of the hind margin, is defined by a small tooth, and is spinous, with a few short setæ throughout its length; there are 5 groups of spines (1 long and 2 short spines in each) along the front margin (figs. 51. gn.^{2}).

First and 2nd peræopods: the 1st joint narrow and as long as the next 2; the 3rd joint expanded distally, the front margin subangulate; 5th joint almost as long as the 3rd and 4th; all the joints spinous (fig. 51. pp.^{1}).

Third peræopods: 1st joint with a projecting lamina behind narrowing distally; 3rd and 4th joints subequal, 5th nearly twice as long; dactylus strong (fig. 51. pp.^{3}).

Fourth and 5th peræopods like the 3rd, except the 1st joint, which is wider and rounded behind.

The outer rami of the 1st and 2nd uropods are shorter than the inner and are terminated by a long spine, as also the inner ramus of the 2nd pair; the inner ramus of the 1st pair has 3 shorter and unequal spines and the inner margin finely pectinate and spinulose (fig. 51. ur.).

The 3rd uropods are uni-ramous, oval, acuminate, with a setule at the tip, about two-thirds covered by the telson (fig. 51. up.[3]).

The telson seen in profile is triangular, with 2 spines on the summit and the margin of the extended base upturned (fig. 51. t.).

Length of female with ova, 3·5 millims., but the females appear to become sexually mature very young in this genus, as much smaller females are full of ova.

In 1888, CHEVREUX and DE GUERNE referred HASWELL'S genus *Dexiocerella* to *Cyrtophium*, DANA, and as the specific name *læve* was preoccupied by *C. læve*, HELLER, they re-named HASWELL'S species *C. haswelli*. As, however, the species belongs to *Platophium*, I have reverted to HASWELL'S name, HELLER'S species having no antennular appendage.

It is possible that this species is identical with *Cyrtophium orientale*, DANA, in which, however, no antennular appendage is figured or described.

Platophium synaptochir,* n. sp.—Plate VIII., figs. 52.

Galle Harbour and Bay, very abundant. Kondatchi Paar, Periya Paar Kerrai, East Cheval Paar. All taken from May to November, 1902.

Male:—The first 4 segments of the mesosome are subequal, the 5th rather shorter, the 6th longer; the 7th the longest; all, as well as the pleon segments, have a transverse dorsal depression, and are elevated behind, but not carinate or produced behind. Urus with 3 distinct segments. Head longer than the 1st segment; ocular lobe subangular. Eye large, round, dark red.

Upper antennæ reaching to one-third of the last joint of the peduncle of the lower; the 1st joint twice as thick and more than half as long as the 2nd, which is about one-fourth longer than the 3rd. Flagellum as long as the 3rd joint, 5-jointed, the 1st joint as long as the remaining 4. Appendage 1-jointed, nearly half as long as the 1st joint of the flagellum; the whole rather sparsely clothed below with long, simple setæ.

Lower antennæ as long as the mesosome; the 1st joint less than half as long as the 2nd, which is much shorter than the 3rd. Flagellum shorter than the 2nd joint, 4-jointed, the 1st longer than the remaining 3; the whole sparsely furnished with short setæ.

* From συνάπτω, to join, and χειρ, hand, in allusion to the coalescence of the hand and wrist in the 2nd gnathopods of the male.

Palp of the 1st maxillæ with the 2nd joint not wider than the 1st and not expanding distally (fig. 52. mx.[1]).

Other mouth organs as in *P. inconspicuum*, STEB. ('Chall. Amph.,' p. 1194, pl. cxxxi.).

First gnathopods: side-plates small, produced to a blunt point with a setule. First joint short and stout, longer than the next 2; wrist shorter than the hand, but fully as wide, the front margin with curved spines, the hind margin flattened and densely setose; the hand has the hind margin concave near the base, with a straight and very setose palm; the front margin convex (fig. 52. gn.[1] ♂).

Second gnathopods of male: side-plates oblong, wider than deep, rounded in front. First joint about half as long as the hand, 3rd joint convex and setose, with the hind margin produced distally. Wrist merged in the hand, which is narrow-oval, with the hind margin slightly concave and densely setose; the palm is undefined. The front is convex, with groups of spines. Dactylus reaching rather beyond the middle of the hind margin (fig. 52. gn.[2] ♂).

The gnathopods in the female much resemble those of *P. inconspicuum*, STEB., but the wrist of the 1st pair is as wide as the hand, and the point of the dactylus is not divided as in that species. In the 2nd pair the 3rd joint is more produced behind, and the wrist, which is quite distinct, though small, is not produced at all (fig. 52. gn.[2] ♀).

First and 2nd peræopods: first joint narrow and subequal to the 4th, with long spines on the front margin: the 5th the longest, its hind margin, with 5 spines, increasing in length distally (fig. 52. pp.[1]).

Third peræopods: side-plates bilobed, the front lobe the larger. First joint with the lamina projecting beyond the proximal part of the hind margin, the distal part fringed with slender, unequal spines; 3rd joint acutely produced behind; 5th joint rather shorter than the 3rd and 4th together; the whole limb spinous (fig. 52. pp.[3]).

Fourth and 5th peræopods resembling the 3rd, except in the 1st joint, in which the posterior lamina is continuous along the hind margin (fig. 52. pp.[5]).

Uropods: the outer ramus of the 1st as long as the inner of the 2nd, the peduncles shorter than the inner rami; the whole spinous (fig. 52. ur.).

The 3rd pair small and spoon-shaped, with a setule on the inner margin, barely reaching beyond the end of the telson.

Telson as in the last species, but with 2 groups of 3 or 4 spines on each side.

Length of adult male, 6·5 millims. Female, with ova, 3·5 millims.

Platophium zeylanicum, n. sp.—Plate VIII., figs. 53.

From pearl oysters, East Cheval Paar, November, 1902; several.

Segments of mesosome and pleon dorsally depressed in the middle, not carinate or dentate. Urus with 3 segments, the division between the 2nd and 3rd somewhat indistinct. Head shorter than the first 2 segments. Ocular lobe little produced. Eyes round and prominent.

Upper antennæ: the 1st joint half as long and twice as wide as the 2nd, which is equal to the 3rd; flagellum subequal to the 3rd joint, 3–4-jointed, the 1st as long as or longer than the remainder; appendage about half as long as the 1st joint of the flagellum, 1-jointed (fig. 53. ant.[1]).

Lower antennæ: the 1st joint sub-globose, more than twice as wide as the 2nd, which is considerably shorter than the 3rd and subequal to the flagellum; this is 3–4-jointed.

First gnathopods: side-plates much produced in an acute angle, with a seta at the tip; the rest of the limb much like the last species (fig. 53. gn.[1] ♂).

Second gnathopods of female: side-plates small, subquadrate, with rounded angles. First joint rather shorter than the hand; 3rd more than twice as long as the 2nd, and produced beyond the wrist as in the last species; wrist small and triangular; hand wide-oval, both margins convex, especially the front, and setose; palm hardly defined, but a spine within the point of the dactylus, which is slender; the setæ are stiff and spine-like. Incubatory lamellæ very large, sub-oblong, the upper part spotted with red (fig. 53. gn.[2] ♀).

Second gnathopods of male: 1st joint expanded distally, longer than the next 3, with a channel in front to receive the hand; 3rd joint twice as long as the 2nd, the hind margin rectangular; the wrist very small and almost concealed by the 3rd joint; hand much longer than all the preceding joints united, oval, a strong tooth near the middle of the hind margin defining the palm, between which and the base of the dactylus are two tubercles with concave interspaces, the whole clothed with unequal plumose setæ. Dactylus barely reaching the palmar tooth, with a row of denticles on the inner margin. The sculpturing of the palm is somewhat variable (fig. 53. gn.[2] ♂).

First and 2nd peræopods: the 1st joint subequal to the 4th joint, with a laminar expansion of the front margin which is rounded and furnished with a group of stiff setæ; 3rd joint shorter than the 4th, produced and spinous in front; 5th joint almost as long as the 3rd and 4th united (fig. 53. pp.[1]).

Third peræopods: 1st joint shorter than the 4th, with a semicircular membranous expansion behind (fig. 53. pp.[3]); the rest as in the preceding pairs.

Fourth and 5th peræopods: 1st joint wider above, but otherwise like the 3rd pair: the 5th pair reaches far beyond the ends of the uropods (fig. 53. pp.[5]).

First uropods: peduncle subequal to the outer ramus, reaching beyond the telson; inner ramus about one-fourth longer and wider (fig. 53. ur.).

Second uropods shorter in extent than the 1st; peduncle reaching to the end of the telson, shorter than the outer ramus, which is one-third shorter than the inner. In both pairs the rami are spinous, the terminal spines about one-fourth of their length.

Third uropods not reaching beyond the end of the telson.

The telson has the form of a truncated cone, the apex directed backwards, with a long terminal and 2 shorter subterminal spines (fig. 53. t.).

Length of male, 4 millims.; of female, with ova, 2·5 millims.

The males of this species may be distinguished by the 2nd gnathopods; the females in the genus *Platophium* are very much alike, but in this case may be known by the triangular expansion of the 1st joint of the 1st and 2nd peræopods.

SUPPLEMENTARY REPORTS.

PREFACE.

In this Part III., I have thought it best to place proportionately more of the Supplementary Reports and less of the Pearl-oyster work than was the case in Parts I. and II., for the following reasons:—

1. The Supplementary Reports here printed were ready and it might have been unfair to the authors and unfortunate for Science if there had been avoidable delay in publication by excluding any from this Part.

2. Those sections of the Pearl-oyster work which were completed, or nearly so, are of such a nature that the results can be communicated in writing to the Authorities in Ceylon, and a delay of a few months in making them known to the public seemed comparatively unimportant.

3. It seemed advisable, for obvious reasons, to have as much of the Pearl-oyster work as possible placed together in Part IV., which will, I hope, be the final volume of the series. This plan, moreover, presents the further advantage of allowing of observations and conclusions to be drawn from the coming fishery in the spring of 1905—probably the last which will be available for the purposes of this Report.

Consequently the sections on Pearl-formation and Pearl-distribution and on the different kinds of pearls and their natural classification have been postponed, and I have inserted in this Part only (1) a discussion of the recent fishery (1904) based on a report sent to me by Mr. Hornell, (2) a statement as to the present condition and future prospects of the beds of oysters on the Banks, based on Mr. Hornell's letters and other documents, and (3) a further account of the internal Parasites of the Pearl Oyster, by Mr. Shipley and Mr. Hornell, in which several new species of Cestode, Trematode and Nematode worms are described and figured.

The Supplementary Reports now issued deal with the Sponges, the Alcyoniidæ and the other Alcyonarians, the Opisthobranchiate Mollusca and the Ostracoda.

The very considerable collection of Sponges (146 species, of which 77 were new to science) has enabled Professor Dendy to make an extensive report, which is a notable contribution to the taxonomy of the group. At least two of the Ceylon sponges are of economic importance. The sponge of commerce, found in abundance at Trincomalee, is of good form and consistence and might prove worth further cultivation; and one of Professor Dendy's new species, *Cliona margaritiferæ*, is the boring sponge which ruins the shell of the pearl oyster and occasionally causes great mortality. Other sponges from the Gulf of Manaar must probably be regarded as enemies, from the damage they do in smothering the pearl oysters they encrust and surround.

Another report of a comprehensive nature, dealing with about 77 species, is that by Professor J. ARTHUR THOMSON and Mr. W. D. HENDERSON on the Alcyonaria —with the exception of the family Alcyoniidæ, reported on by Miss E. M. PRATT. Professor THOMSON has kindly provided the beautiful coloured drawings, by Mr. G. DAVIDSON, from which his plates have been produced. But I am really much indebted to *all* the authors for the careful and excellent drawings with which they have illustrated their reports. Mr. FARRAN'S report deals with a considerable number of species of a group (the Nudibranchiata) which I had hoped to have been able to examine myself. Consequently, when collecting in the Gulf of Manaar, I made some colour notes and sketches from the living animals which Mr. FARRAN has been able to make use of in his descriptions. Mr. ANDREW SCOTT records 77 species of Ostracoda, 35 of which are new to science. To all these authors I am very much obliged for their kindness in undertaking the work and for the skill they have exercised in carrying it out.

It may be well to indicate here the Supplementary Reports that remain. They are all, I think, well advanced, and ought to be ready for publication some time in the summer:—Corals, by Mr. G. C. BOURNE; Medusæ, by Mr. E. T. BROWNE; Antipatharia, by Professor J. ARTHUR THOMSON; Polyzoa, by Miss L. R. THORNELY; Polychæta, by Dr. ARTHUR WILLEY; Schizopoda and Stomatopoda, by Mr. W. TATTERSALL; Macrura, by Mr. J. PEARSON; Brachyura, by Mr. D. LAURIE; Isopoda, by Rev. T. R. R. STEBBING; Molluscan Shells, by Mr. R. STANDEN and Mr. A. LEICESTER; Marine Insects, by Professor G. CARPENTER, and the Tunicata, by myself The remaining sections of the Pearl-oyster work, and our Summary of Results and Recommendations as to the Conservation of the Banks, should then complete the Report.

The records of observations sent to me by Mr. HORNELL during the latter part of 1904, and especially his detailed reports upon the great spring fishery and the November inspection—upon which I have based the two first articles in this volume (see p. 1 and p. 37)—show that very considerable changes have taken place in regard to the condition of the beds of oysters on the paars and the prospects of fisheries during the next few years. Under the heading "CONCLUSIONS," in the article on the "History of the Principal Pearl Banks" in the last volume (Part II., p. 36) it was stated:—"Finally, there are prospects of good fisheries both next year and in 1906 on the Modragams and several divisions of the Cheval Paar—possibly also on the Muttuvaratu and the Dutch Modragam in the latter year. The results in 1907 and the immediately succeeding years will, so far as we can now see, depend upon whether large measures of transplantation are adopted without delay." In writing of the Cheval Paar (p. 20), also, I recommended that young oysters be transplanted there from the Periya Paar "at the earliest opportunity and in sufficient quantities."

Following upon that recommendation, Mr. HORNELL was authorised by the Ceylon Government to make preparations for transplanting young oysters in quantity from the Periya Paar to the Cheval Paar in November, 1904, should it still be found necessary. This was the only wise course to take. A great part of the Cheval Paar was denuded, and there was no certainty that a fresh fall of spat would occur.

It is essential that the Inspector of the Pearl Banks should have the power, and the means, of ordering transplantation to be carried out whenever it may be required. In the present instance, however, the necessity has been obviated. In the late summer, or early autumn, an abundant deposit of spat has fallen over the greater part of the Cheval Paar, clothing the barren sandy wastes and covering the patches of old oysters and the rock alike, so that they are said to be indistinguishable to the diver. These young oysters, now about 4 months old, cover an enormous area, and must be present (judging from the samples examined) in numbers that run to thousands of millions. No doubt the vast majority of them will die off from natural causes during the next few years, but a fair proportion should remain to yield fisheries in 1908 and succeeding years. In the meantime, the barren areas of the Cheval Paar denuded by the two last fisheries are once more occupied. Transplanting is, for the moment, unnecessary, but cultching of some parts of the ground is urgently required. The position of affairs and the work necessary to improve the condition of the banks are fully discussed in the articles that follow.

The other change in conditions which has to be announced is that, of the various beds of adult oysters on the Cheval and Modragam paars, some are now dying off, or will probably do so during the coming year, while others are apparently healthy and undiminished. Under these circumstances certain beds (detailed in the article on the Present Condition of the Pearl Banks, p. 44) are clearly indicated for fishing first, and fortunately there seem to be sufficient adult oysters in sight to yield at least two and possibly three successive good fisheries. But, although the prospects are so good, it is the Biologist's duty to point out that now—when there are so many beds of oysters of different ages living together on the Banks—is especially the time when vigilance and effort must on no account be relaxed, when inspections must be frequent and complete and the scientific examination of sample oysters must be thorough, when cultching of sandy ground must be extensively undertaken, when thinning out of overcrowded beds should be carried out, and when the Inspector should be authorised to dredge up and transplant young oysters whenever it may seem desirable.

Next after the healthy development of beds of oysters comes the question of infection with the parasites necessary for pearl production. In the preface to Part II. the further work that lay before us in tracing the Fish-host upon which this infection must depend was pointed out, and Mr. HORNELL has continued to take every opportunity to get information and specimens bearing on the matter. Since the November inspection he has devoted some time to work amongst the fishermen on the shores of Dutch Bay (between Colombo and the Pearl Banks) with the view of obtaining for dissection some of the larger Elasmobranch fish caught by the natives. In this he has been very successful, and recent letters inform me (1) that he has now determined the Trygon-Rays which eat the oysters as being the "Walwadi tirikkai" of the Tamils, *Rhinoptera javanica*, and the still larger "Mundakanni tirikkai," *Rhinoptera adspersa ;* and (2) that amongst the Entozoa he obtained from the former species was a Tetrarhynchid agreeing in the armature of its proboscides with the larval *Tetrarhynchus unioniformis* from the Pearl oyster. As the result of this work with the fishermen, Mr. HORNELL has recently made a large and varied collection of parasites which will be the subject of a final report by Mr. SHIPLEY and himself in PART IV.

W. A. HERDMAN.

THE UNIVERSITY, LIVERPOOL,
January, 1905.

REPORT ON THE PEARL OYSTER FISHERIES OF THE GULF OF MANAAR.—PART III.

THE PEARL FISHERY OF 1904.

[*Based on a Manuscript Report and Letters from Mr.* JAMES HORNELL, *F.L.S., Marine Biologist and Inspector of Pearl Banks.*]

SINCE this present investigation was commenced in the spring of 1902, the Government of Ceylon, after an interval of eleven barren years, has held two most successful pearl fisheries—the last of which, that in the spring of 1904, yielded over forty-one millions of oysters, and established a record from having given receipts amounting to well over a million of rupees. This is, however, by no means the whole of the value of the fishery, since the divers carry off as their share one-third of the spoil, and the benefits conferred directly and indirectly upon thousands of attendants and traders may be said to affect the prosperity of a large district. But, dealing only with nett proceeds, these two last fisheries combined have brought in to the Government of Ceylon considerably over £100,000. The prospects for another good fishery in the spring of 1905 are now excellent, and the adult oysters at present known to us on various parts of the Cheval Paar ought, if no unforeseen calamity occurs, to yield fisheries in 1906 and 1907. If cultching of the barren parts of the Cheval Paar and transplantation of young oysters from the Periya Paar, as recommended in the earlier parts of this Report, be carried on with vigour there is every reason to believe that still other fisheries will follow. Spat may fall naturally upon suitable ground at any time, or it may be prevented from so falling, for a series of years, by natural causes beyond the control of man. It cannot be trusted to come when and where it is wanted and we must not depend upon it.* But if a continuity of profitable fisheries, or even a fairly constant succession, can be ensured by the

* Since the above was written, Mr. HORNELL'S report on the November inspection shows that a fall of spat has taken place on the Cheval Paar; but I leave my words unaltered, as I believe them to be generally applicable, and their truth is not affected by this unexpected, somewhat exceptional, but very welcome, occurrence.—W. A. H., January 2nd, 1905.

expenditure of a few thousand pounds annually in cultching the banks and transplanting the young oysters, it is evident that the proceeding will be economically a sound one.

Mr. HORNELL, since I left him on the pearl banks in April, 1902, has kept me supplied with frequent letters and occasional longer reports—constituting, in fact, a journal of his doings and a discussion of his observations. He has now furnished me with a very full report upon the record fishery of 1904, and from this, supplemented by the letters received from him during the progress of the fishery, I have drawn up the following account. This Report upon our pearl oyster investigation would, I feel, have been incomplete without some description of the conditions under which a great fishery is held and of the methods adopted, both administrative and scientific, on the occasion.

Mr. HORNELL's MS. report, though giving most valuable information, was not in a form intended for publication. It was sent to me as *material to make use of*. Parts of it, such as details of the "Racial types represented among the divers," are more or less irrelevant to our present purpose; other parts, such as discussions of the value of "Beacon marks," lists of "Casualties," and record of "Services of Staff," are of purely local interest from the administrative point of view. Consequently a good deal has been omitted and much has been re-cast. I have frequently, however, as will be seen from the quotation marks, employed Mr. HORNELL's own words. Elsewhere his account has been used as the basis of the statements, or as the text which has called forth remarks or upon which an argument has been founded. From the knowledge which I gained of the locality and of the conditions of life during my visits to the pearl banks in 1902, on the "Lady Havelock" and the "Rangasami Puravi," I find it easy to follow and to realise the changes in the oyster beds; and I have no hesitation, in the light of the fresh evidence, in pressing my former recommendations that the "paars" be cleaned, thinned and improved by dredging and cultching, and that deficiencies in spat deposit be made good on all possible occasions by the transplantation of young oysters.

THE PREPARATORY INSPECTION OF THE NORTHERN PEARL BANKS.

From the 26th January, 1904, on which date Mr. HORNELL was appointed Inspector of Pearl Banks in addition to his duties as Marine Biologist, until the 18th of the following month, his time was largely occupied with the multifarious preparations necessary before sailing for the pearl banks. Boats had to be repaired and painted, old stores overhauled and new ones procured, and at the same time a general supervision given to the fitting up of the steamer "Ready," which was to serve as an oyster-dredger. However, by February 18th, the last stores were on board, inclusive of over 6900 gallons of fresh water for the 70 men (divers, munducks, boatmen, &c.)

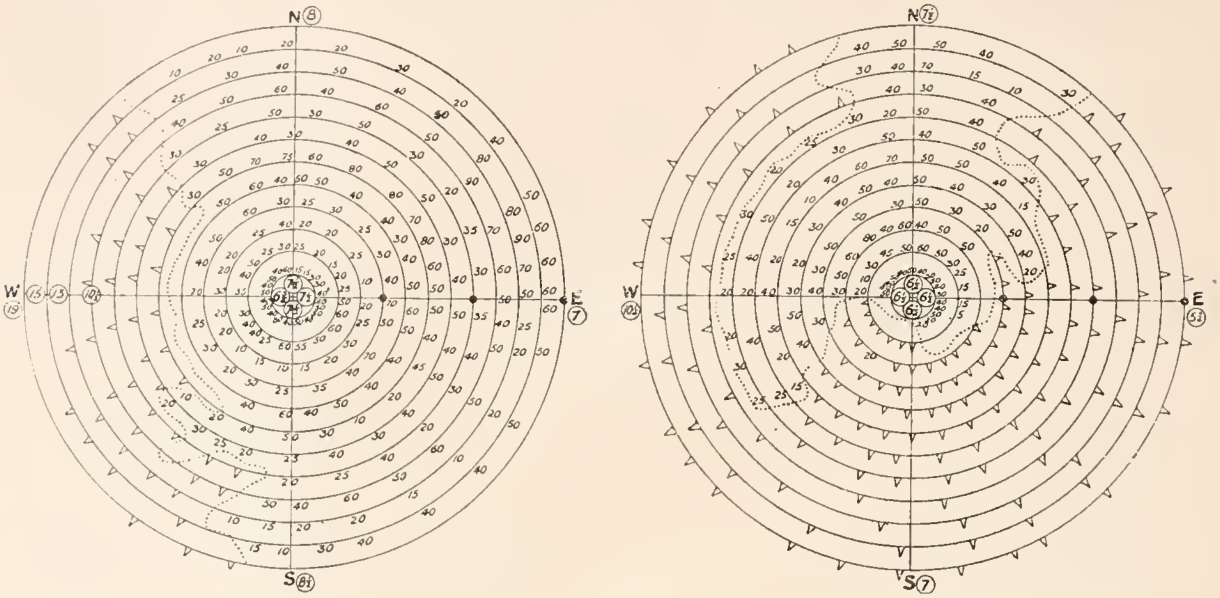
for whom provision had to be made, and the Inspector left Colombo in the native barque "Mohideen Bux" in tow of the steam dredger.

On arrival at Marichchukaddi, near the mouth of the Modragam River, the place selected as the centre of the pearl fishery and the site of the camp, on the morning of February 20th, it was found that—"no Government divers had arrived. The next day, seven Manaar men having put in an appearance, I resolved that the urgency of immediate inspection was too great to permit waiting longer for the laggards and left at 6.40 A.M. to do the best possible with these few divers—half the usual complement. The first step was to locate Captain DONNAN's sunken tanks marking the 'shoal buoy' position on the tail of Karativo shoal, and I was so fortunate as to find them within 10 minutes after anchoring on the place where I reckoned them to be according to the bearings of landmarks ashore. After laying down a large beacon buoy, as is usual at the beginning of inspections, I proceeded to take up my first inspection position at the centre of the South-west Cheval Paar."

Although the banks have been inspected on the previous November, it is always necessary to make an inspection of the beds of oysters which it is proposed to fish immediately before a fishery opens, so that the Inspector may be in a position to mark off the ground and regulate the number of boats and days allotted to particular areas. The method of inspection adopted was that introduced by Captain DONNAN (who was Inspector of the banks during our visit in 1902), modified in some details. The essential features are as follows:—Three flag-buoys are laid out by the attendant launch or tug-boat in the direction of each cardinal point of the compass, at distances apart of $\frac{1}{4}$ mile, the innost buoys taking their distance from the inspection vessel, which is anchored to serve as a pivot mark in the centre of the circular area to be inspected (see fig. 1, p. 4).

Four inspection boats (modified whaleboats), each manned by a crew of six, together with three divers and two munducks, under the charge of an experienced coxswain, take up equidistant positions between the ship and the first flag-buoy on the north radial line, and row slowly round the ship, retaining with wonderful accuracy their relative positions the while. At regular intervals the crew rest on their oars to allow the divers opportunity to make descents and bring up oysters if any are present. The result of each dive is reported to the coxswain of the boat, who records the condition of bottom and oysters upon a diagram form with which he is provided. The oysters are retained in the boat for the Inspector to examine. The four boats, having each made a complete circuit, are next ranged in line abreast in the same manner as before, between the $\frac{1}{4}$-mile and the $\frac{1}{2}$-mile flag-buoys, and each then makes a second circuit. The day's work is completed by a third and last series of circles, in this case between the buoys distant respectively $\frac{1}{2}$ mile and $\frac{3}{4}$ mile from the ship. The four boats thus make a total of twelve concentric circuits, each boat making three. The results shown upon the coxswain's diagrams—each of which has three concentric circles drawn upon it representing the three circular paths covered—

are transferred by the Inspector to a final diagram or plan furnished with twelve concentric circles. When this has been done, the distribution of old and of young oysters is graphically shown for a circular area having a diameter of $1\frac{1}{2}$ miles (fig. 1 represents two such inspection areas on the Muttuvaratu Paar in 1902).



A. B.

Fig. 1. Inspection charts of (A) northern and (B) southern parts of Muttuvaratu Paar in November, 1902. There are four concentric circles made by the divers' boats between the centre and the $\frac{1}{4}$-mile buoy, four between that and the $\frac{1}{2}$-mile buoy, and four from that to the $\frac{3}{4}$-mile. Each complete area is therefore $1\frac{1}{2}$ mile in diameter. The numbers enclosed in rings indicate depths in fathoms. The numbers on the concentric circles give the quantities of oysters brought up at a dive on that spot. The cones indicate dives on a rocky bottom with no oysters. The dotted line therefore surrounds the oyster-bearing area.

After calculating in square yards the area occupied by oysters, the approximate number of oysters thereon may be estimated by taking the average number of oysters per dive (ascertained by examining the divers' results) in conjunction with the average amount of ground which a diver is credited with being able to clear at one descent. Usually this area is considered, on normal ground, to be from $2\frac{1}{2}$ square yards to 3 square yards. By assuming the area per dive to be 3 square yards, the danger of an overestimate is avoided. Inspection estimates are usually less than the total number of oysters obtained at the ensuing fishery. "Thus, at the 1904 fishery, I estimated the number of mature oysters to be 35,000,000, whereas the number actually fished from the area in question was roughly 37,000,000 (41,000,000 minus the amount of immature oysters fished on April 2nd)."

The North and South Modragam Paars were examined on March 5th, and in addition a series of diving and dredging traverses was made further north, in the region of the Vankali Paar, in fruitless search for the oysters found there during our visit in 1902. "The absence of good landmarks in the Aripu district made the inspection of this paar difficult, and I had to rely almost entirely on biological data, such as the nature of the bottom and the fauna, for the verification of my position. Without this help I could not have arrived at any certain conclusion."

How the Valuation Sample of Pearls is Procured.—Before a fishery it is also necessary to obtain samples of the oysters to be fished in order that their pearls may be officially valued for purposes of advertising the fishery. Consequently, during intervals in the inspection, three large samples of oysters of fishable age were collected from the three western blocks of the Cheval Paar, partly by means of divers and partly by the use of dredges. The results obtained showed the sample

Fig. 2. Valuation sample of pearl oysters from the Cheval Paar, being brought on board the "Rangasami Puravi," from the inspection boats—from a photograph by Mr. Hornell.

of the South-west Cheval to be well ahead of the other two lots in the weight and the number of pearls to each 1,000 oysters; the Mid-west was extremely poor in both respects. The washing of the sample oysters and the sifting and subsequent valuation of the pearls was carried out in the usual way, the two former processes by the Government divers and munducks, the latter by three Mohammedan pearl merchants; all under the constant supervision of Mr. Hornell, assisted by Mr. V. Vraspillai, the able Adigar of Musali.

"When the samples are brought into the Government Kottu, a palisaded enclosure, the sacks of oysters are emptied into dug-out canoes or 'ballams,' and covered carefully with mats. In this state they are left under guard for a period of from

7 to 10 days. Bacterial putrefaction alone is not relied upon to get rid of the flesh, the maggots of a species of blow-fly being the agency most in evidence and most desired. Under favourable conditions, at the end of 7 to 10 days, the so-called rotting period, the fly maggots should have eaten their way through everything, and have left nothing but empty shells and pearls behind. When the oysters are rotted in sacks, the time for washing is rendered evident by the pile of brown chrysalis cases—full and empty—that litter the ground immediately around the pile of sacks as well as encrust the sacks themselves.

"The time to wash having arrived, the covers are removed from the ballam, and coolies fill it to the brim with water. As the water level rises to the edge, a mad race for the points above the flood ensues among the maggots which float up in myriads from the lower recesses. The washers range themselves in line along either side, squatting on anything convenient—a canoe outrigger, an overturned tub, empty kerosine tins, and the like. They are stripped to the loin-cloth, and are not allowed to take their hands out of the water save to drop out the empty shells. The first process is to rinse the shells thoroughly, to separate the valves, and, by rubbing the outside of one valve against that of the other, to remove any detritus in which a pearl might lodge. The men scrutinize the nacreous lining for attached or shell pearls, placing any found in a special basket. The other shells, after a final rinse, are dropped outside the ballam at the washers' feet.

"After the quantity is reduced somewhat, the floating maggots are skimmed off, lifted by hand, and some of the water is baled out through a sieve, any material that remains therein being carefully returned to the ballam lest a pearl might be contained or entangled in the dirt. More water is then added, and the process of washing the shells is continued. At last all the shells have been removed and the men are then free to stand up and stretch their cramped limbs.

"A fresh supply of water is now poured in till the ballam overflows—a rough method of elutriation. Time after time this is repeated till the bulk of the lighter filth is got rid of. Then the remainder of the water is decanted, and the heavy *débris* in which the pearls are mingled is exposed on the bottom. More water is repeatedly poured in, the detritus or 'sarraku' the while being kneaded and turned over and over again.

"When this apparently interminable cleansing process comes eventually to an end, every scrap of sarraku is removed with scrupulous care to a cotton cloth and bundled up. One ballam full of oysters will usually furnish from two to three such bundles of pearl-containing dirt. The bundles of sarraku are opened later and spread to dry in the sun, undergoing a preliminary search at the beginning, and if wished at intervals during the drying. These early searchings yield usually the largest and therefore the most conspicuous of the contained pearls.

"When dry, the material is sifted out into several grades, and each is gone over time after time by the men employed (fig. 3). The final search—after it appears that even the dust-pearls, the 'masi-tul,' have been removed—is carried on by women and children, and it is amazing to see what a large quantity of small pearls their keen eyes and fine touch enable them to obtain. After the pearls are picked out it is

Fig. 3. Government divers picking out pearls from oyster washings.—Photo. by Mr. HORNELL.

the custom to offer the apparently exhausted dirt for sale, and ready buyers can always be found."

After the valuation was completed, and the results had been telegraphed to the Colonial Secretary for the purpose of advertisement, Mr. HORNELL utilized the few remaining days, prior to the advertised opening of the fishery on the 14th March, in an examination of the Karativo and Dutch Modragam Paars.

Method of Marking out the Fishing Ground.—On the 13th March Mr. HORNELL returned to the Cheval Paar and took up a position on the south-west corner of the south-west section, and marked out the ground for fishing in the following manner:—

"As the plan adopted was a novel one, the Government Agent kindly acceded to my request to notify the method by beat of tom-tom in the divers' quarters, intimating that the boundaries of the fishing ground would be marked by buoys bearing red flags, while a series of white flag buoys would be placed wherever fishable oysters were present. The divers were instructed to cluster their boats round the various white flags.

"These oyster buoys were placed according to the distribution of oysters mapped out after the inspection, but to guard against the possibility of mistake I verified the abundance of oysters at selected spots by preliminary dives before anchoring the buoys in position. The system proved a success, as by placing but a few white flags down at a time I was able to control the movements of the fleet and ensure the bank being fished in a methodical manner. At the next fishery I propose to introduce further improvements in this flag system, among others the marking of the flags individually with distinctive numbers and signs.

" **Discovery of Brood Oysters on the Periya Paar.**—The advertised date of opening the fishery found but a handful of divers assembled at the Fishery Camp at Marichchukaddi. The commencement being in consequence postponed, I took the opportunity afforded to examine the Periya Paar, and ascertained that over an area measuring at least 5 miles in length by $1\frac{1}{2}$ miles in width the bank bore its accustomed brood of young oysters.* As oysters have but once come to maturity upon any part of this paar during the past century, and that but a small patch, I hastened to recommend to Government a wholesale transplantation to the Eastern Cheval—the area cleared of oysters during the 1903 fishery—requesting the use of the dredging steamer for the purpose. This was granted, and I inspected a likely area on the East Cheval and laid down on the selected ground a set of five mark buoys for the guidance of the Master of the 'Ready' when engaged upon the distribution of the dredged oysters. Unfortunately for these plans, the dredger, by reason of rough weather, was able to put in but $2\frac{1}{2}$ days at this work prior to April 9th, on which date I received instructions to place the 'Ready' at Mr. Dixon's disposal for the purpose of dredging mature oysters, and when, later on, the vessel again reverted to me, continuous bad weather had set in, rendering it impossible to work upon the exposed Periya Paar. As a consequence I had to cancel the cultching arrangements I had made to prepare the ground, and transplanting operations are in consequence postponed probably for at least a year.

" With regard to the future need of transplantation, I can but endorse Professor Herdman's reiterated statement that *in this lies the true salvation of the pearl banks.* This being so, if Government approves of such recommendation, it will be absolutely necessary, in order to ensure success, to give me permission to arrange for and carry out an extensive programme of transplantation and cultching and to provide me with adequate means for the purpose, that is to say, I should have a dredging steamer at my disposal from the very date of finding young oysters fit for transplanting, and this steamer should be devoted solely to this work for the whole of the fine weather available and suitable for dredging. Only by transplantation on the greatest possible scale can success be assured. We have to remember the largeness of the object in view—nothing less than the formation of a bed of oysters of sufficient extent to allow for extensive wastage, due to a dozen different causes, and after such wastage to give a fishery of mature oysters calculable in millions.

" **Necessity for Extensive Cultching.**—Our observations show that the sections of the Cheval and Modragam paars giving the finest oysters and the most valuable pearl-yield are those possessing a well-cultched sandy surface, with somewhat restricted rocky outcrops. Unfortunately such areas are comparatively limited in extent, and

* The condition of these oysters will be discussed further on.

the major part of the Cheval, the north, north-east, mid-east and part of the south-east and south-west, with all the three central sections, consists of sandy bottom inadequately supplied with material suitable to serve as foothold to oysters.

"We now have sufficient knowledge of our local conditions to see that transplantation must go hand in hand with extensive cultching if we are to obtain a full return for the labour and money expended on the former operation—indeed we may go further and say that the transplantation of young pearl oysters will be labour wasted unless adequate cultching operations be carried out concurrently. Appreciation of the vital importance of this fact caused me to apply for authority to obtain several hundred tons of broken rubble for cultching purposes as soon as transplantation was seen to be advisable last March. The proposal was at once sanctioned, and while waiting to begin transplanting I arranged, by the kindness of the Public Works Department, for the preparation of a trial shipment of 100 tons of broken calcareous sandstone from Kalpitiya. The stone was to be roughly broken to the size of the fist—about $3\frac{1}{2} \times 3\frac{1}{2} \times 2\frac{1}{2}$ inches. The full quantity had been prepared when the transplanting scheme was arrested and now lies ready for shipment whenever it be next required.

"It may be useful to add here that whenever good prices cannot be obtained for the pearl oyster shells accumulated during a fishery, the best purpose they can be put to is to relay them upon the depleted banks, where the ground is in need of cultch.

"I calculate that at the very lowest estimate 1 ton of shells will furnish as much cultch as 3 tons of Kalpitiya stone or rubble. As this quantity of the latter costs Rs. 11.25 (three tons at Rs. 3.75 per ton) I believe that it will be more economical for Government to refuse to sell the shells at any less price than Rs. 10 per ton, and to use them as cultch unless this minimum price be obtained.

"**Clean Banks Essential to Successful Cultivation.**—In this, as in the matter of cultching, we may with great advantage profit by the experience of European oyster culturists. They find it necessary to check the growth of many other organisms upon the banks, not only those that are active enemies of the oyster—star-fishes, whelks and the like—but also such animals as curtail the area which oysters may occupy or which consume food that would otherwise fall to the oyster. Seaweeds, too, are for the most part weeded out. As a consequence much can be done in cleaning 'foul' beds by means of the dredge. If the beds are in preparation to receive spat, all harmful matter is taken ashore—both direct enemies, such as star-fish, whelks, mussels, and also the various other animals that compete for food and so may be termed the indirect enemies of the oyster.

"Fortunately the Ceylon pearl banks are comparatively 'clean.' No fact struck me so forcibly when first I began to make diving descents as the paucity of injurious life on the better quality of the oyster-bearing paars. Wherever oysters were found thriving, wherever they were seen in vigorous growth and perfect health, the bank appeared to be comparatively free from deleterious matters.

"Where 'foul' areas are found, *i.e.*, where Sponges, Corals, Alcyonarians, Echinoderms and Ascidians abound, as on many parts of the Western Cheval and Muttuvaratu paars, the oysters, while numerous enough, are stunted and poor, suffering by competition with the host of creatures living upon the same diet of microscopical organisms. The only means of cleaning such a bed is to dredge it thoroughly, separating and removing the materials brought up."

On the Ceylon pearl banks the beds are too extensive to permit of dredging being undertaken with this sole object in view, but as this cleaning can and should go on concurrently with the dredging of spat for transplantation or of mature oysters for sale, we have herein an additional argument in favour of taking up dredging on a scale of considerable magnitude. We must not lose sight of the fact that dredging has a fourfold utility, namely, (*a*) in fishing oysters, (*b*) in cleaning the ground and removing enemies, (*c*) in thinning out overcrowded beds, and (*d*) in spat transplantation. Its value is not properly assessed if account be taken of the first item alone, or even of the first and the last. Every live coral removed and replaced by a fragment of clean cultch may mean the addition of three oysters at the next fishery; every star-fish destroyed probably means scores of oysters saved from destruction; every *Cliona*-riddled block of coral bleached on the shore will tend to reduce the widespread havoc this inconspicuous sponge causes amongst the oysters. The immense advantage that accrues from keeping the banks in a state of thorough cleanliness can well be appreciated by an agriculturist, who knows how his crops fall off if weeds be left unchecked, and if fungoid and insect pests be ignored.

Beacon Marks.—Sir WILLIAM TWYNAM has pointed out the need of fixed, well-defined landmarks from which bearings may be taken at all parts of the banks; and he states his belief (p. 20 of his 1902 Report) that this want of adequate landmarks resulted in the wrong bank being fished in 1836—two beds of young oysters being fished instead of the one proposed. Again he states that the fishery of 1860 on the Modragam was all but lost for the same reason—a long continued search of 3 days being necessary before the bed was re-discovered.

A notable advance was made this year by the erection of a permanent beacon on the tail of Karativo shoal, immediately to the south of the South Cheval Paar, to serve as the point of departure at the inspection of the whole Cheval area. Many years ago (1878) Captain DONNAN sank an iron tank close to this spot and subsequently (1883) he added a second. It was his custom at the beginning of each inspection to locate these tanks by bearings taken from Kudiramalai and by means of the inspection divers, and, when found, to mark the position temporarily during the inspection by a large beacon buoy—the so-called shoal buoy.

Captain DONNAN'S successor, Captain LEGGE, appreciating both the loss of time involved in the oft recurrent hunt for sunken tanks, and the danger of taking incorrect bearings when these tanks could not be located, requested sanction to have a permanent beacon erected. This was granted, but all efforts to erect it last year were rendered futile by unfavourable weather. Before leaving for inspection this year, Mr. HORNELL pressed upon the attention of Government the importance and urgency of another effort being made to place the beacon in position. Accordingly it was sent up once more under the care of Mr. LINDSAY, the general foreman of the Harbour Works Department, who, after very great difficulties due to the heavy ground swell always present on the shoal, eventually completed the erection successfully. One great safeguard has thus been created against the loss, by oversight, of oyster patches in the Cheval region, and valuable time will also be saved at inspections. "This Karativo shoal beacon consists of four iron piles driven 6 feet into the sand, braced together securely and bearing an iron telegraph pole secured by four wire stays. The apex of the pole bears two circular metal discs set vertically at right angles, the top being 43 feet 6 inches above sea-level, and therefore visible at a distance of $11\frac{1}{2}$ miles to an observer whose eye is 12 feet above sea-level. The depth of water where and when it was erected was 25 feet 6 inches at low tide. The position of the sunken tanks is latitude 8° 39′ 15″ N., longitude 79° 45′ 0″ E.; and the new beacon is distant therefrom 233 feet N., 3° W."

Mr. HORNELL states:—"My experience during the last two years, and especially during the last inspection, makes clear to me that a beacon in the Aripu district, together with an improvement by heightening of the present Kudiramalai beacon, is essential to efficient inspections. With respect to the cost of these, I would point out that whatever it might be, the amount would be as nothing compared with the loss of revenue entailed by the loss of a bank of fishable oysters through lack of proper beacon marks—a mischance which has occurred in the past probably oftener than we imagine. At a later date the scheme of land-marks might be completed and perfected by the erection of a beacon at the Doric and by the raising of Kallar Tower another 20 feet. For the present, however, urgency centres in the raising of Kudiramalai Tower and the erection of a beacon on Aripu Reef."

PARTICULARS OF THE FISHING OPERATIONS.

The news that a pearl fishery is advertised to take place in the Gulf of Manaar is conveyed throughout India and other parts of the coast of the East with amazing rapidity, and at the appointed time a heterogeneous population of from 20,000 to perhaps 40,000 natives gathers in a few days on what is usually an uninhabited desert—a bare sandy coast with jungle extending for miles inland. A temporary town, covering a site of about one square mile, and having streets (Main Street, Old and New Moor Street, Tank Street, Divers' Street, Chetty Street, Muttu Bazaar, and the like) of houses and shops, Government buildings, such as court house, prison, hospitals, markets, and offices of various kinds, is rapidly run up. 'Camp Town' is erected under the supervision of the Adigar of Musali, largely of bamboos and palm leaves (fig. 4), and is a prosperous and very busy centre of industry and trade during the few weeks of its existence. In the neighbourhood large water-tanks are constructed, some for the drinking supply, others for washing and for the divers to

Fig. 4. Beachmaster's (Muttutamby) house, tom-tom beater and other natives. Pile of cadjans (palm-leaf mats) for building in foreground.—Photo. by Mr. HORNELL.

bathe in when they return from the day's work. At the same time the fleet of some 200 fishing boats assembles on the shore (fig. 5), and a port with the necessary officials is constituted. The whole organisation is under the Government Agent of the province.

Fig. 5. Part of the pearl-divers' fleet at Marichchukaddi.—Photo. by Mr. HORNELL.

"Four distinct racial types were represented among the divers both at last year's fishery and at this—Coast Tamils, chiefly from the Madras Presidency; Moormen, or

Lubbais, drafted largely from Kilakarai and the neighbouring villages on the Madura Coast of the same Presidency; Malayalam men, from the southern portion of the Malabar Coast (Travancore principally), and lastly a compact body of some 250 so-called Arabs from Colombo and Jaffna. The first two groups comprised the bulk of the diving community (including both divers and munducks), accounting for 1989 and 3732 respectively out of a total of 7408 who attended at last year's fishery (*vide* ' Report on Fishery of 1903,' by Mr. R. W. Ievers, C.M.G.)."

Most extravagant statements are current in regard to the time a diver can remain under water. The Arabs are far ahead of all the others in endurance, their time under water being generally from 70 to 85 seconds. The Tamil and other divers have a lower average, varying from 35 to 50 seconds. The maximum for the best divers, in our experience, is not over 90 seconds. The diving goes on from daybreak (about 6 A.M.) to noon, and the divers' boats set sail for the banks soon after midnight, taking advantage of the land wind which then blows off shore, so as to be ready to start work with the light.

" On the 15th March, twelve Colombo and Jaffna boats, manned entirely with Arab divers, had taken up positions by daybreak around the barque. As is the habit of Arabs, these men fished quietly and methodically, and with great energy. By noon they were tired and satisfied with their catch, an average of 22,811 oysters per boat, and, hoisting sail, made for the camp. The next day a number of Tamil and Moorish divers appeared, and on the 5th day of the fishery the number of boats actually at work had increased to 148, while for several days in the height of the fishery just over 200 boats (202) were employed.

" The boats used by the divers at this fishery were of at least five distinct types—narrow single-masted canoes, with an outrigger, from Kilakarai on the Madura Coast; larger 3-masted canoes, from the Tanjore Coast; large ' Dhoneys,' from Jaffna and the north of Ceylon; large sailing lighters, from Tuticorin; and ' luggers,' with square sterns, from Paumban. Some of the large boats accommodated as many as 30 divers, and with the ' munducks ' (the men who attend to the divers' ropes) and crew must have had about 65 men on board.

" Fishing on the South-west Cheval went on methodically and in a perfectly satisfactory manner for 17 days, by which time the bank proper was practically cleared of oysters. On the 18th day of the fishery the fleet, instead of settling down to glean over the fished ground, flocked to a patch of mixed oysters on the north-east corner of the south-west section, and as a heavy swell was rolling in from the south-west I did not judge it advisable to attempt to move them away. This day's catch of oysters proved phenomenal, totalling close upon 4,000,000 (3,919,712), of which the Government share, 2,609,445, sold for Rs. 39,058.79, being at an average rate of nearly Rs. 15 per 1,000. The oysters on this patch lay extremely thickly strewn in bunches upon a sandy bottom ; I had not included them in my estimate of the south-west bed, considering it preferable to leave them for next year's fishery. However, the thinning out which this day's fishing entailed will have excellent results and conduce to more rapid growth during the intervening 12 months.

"Judging it time to abandon the south-west region, I moved the ship to the bed upon the North-west Cheval on the 3rd April, laying out a series of red flag buoys along the boundary and white flag buoys as fishing centres, as upon the South-west, and accordingly the fleet began work there upon the following day. A break in the hitherto excellent fishing weather unfortunately coincided, and from the 5th April more or less unfavourable weather prevailed steadily and practically without intermission, rendering fishing increasingly difficult. As a consequence the north-west bed was not exploited in the thorough manner characteristic of the fishery on the south-west section, and whereas 26,000,000 5-year-old oysters were taken from the latter bed as against an estimate of 19,500,000, upon the north only 4,500,000 were fished as against the estimate of 9,000,000. This less satisfactory result was, however, not due entirely to rough weather; many large patches were so thinly furnished with oysters that 5, 7, and 10 oysters per dive were the best possible—a condition of matters ill-suiting men who had been accustomed for over a fortnight to averages of 25 and 35 per dive.

"It became expedient therefore to open the last section—the mid-west—to fishing on April 12th, and on that date the boats lifted 1,244,070 oysters from this bed. From this date the wind increased greatly in force and, being accompanied by a heavier swell, it became impossible to set definite limits to the ground to be fished upon. The number of the boats at work began to diminish rapidly, and by April 16th the fishery terminated, so far as the fleet as a whole was concerned.

"From the 16th to the 18th April the weather was too boisterous to permit of any fishing. On the latter date, some of the Arab divers being willing, it was arranged that they should be sent out aboard the steamers 'Ready' and 'Serendib' to carry on diving from these vessels. In all 44 responded to this emergency call, and I superintended their work on April 19th, beginning fishing at 10.10 A.M. and ceasing at 3 P.M. During the whole time the weather conditions were the worst possible, a heavy sea running, accompanied by a chill, cutting wind. The men worked most pluckily and with the utmost good humour. The majority did not touch food all the time they were aboard, from 5.30 A.M. to nigh on 6 P.M. This day's work by these 44 Arabs stirred up emulation in the breasts of their co-religionists, the Kilakarai Moormen, and enabled the fishery to be carried on in spite of the boisterous character of the weather for 4 days longer and with a gain to Government of Rs. 15,580.

"By this time the great majority of the divers' boats had left Marichchukaddi, and on the 23rd April it was seen to be impossible to attempt to further prolong the fishery, which thus expired, after a nominal length of 33 fishing days; on 7 days, however less than 200,000 oysters fell to Government share, owing to the unfavourable nature of the weather on these days; so under these circumstances the grand total of just over 41,000,000 oysters was an extremely satisfactory result. Last year's fishery produced an almost identical number, 41,169,637, spread over 38 fishing days of continuously fine weather. Had similarly favourable conditions prevailed this year the divers would certainly have fished another 8,000,000 oysters, and would probably have raised the grand total to 50,000,000."

It is said that even the large amount of pearls obtained from these oysters is not the total number fished up, as during the 3 or 4 hours' sail home from the banks opportunity is given to the divers and their boats' crews to abstract some of the finest from an occasional gaping shell. These illicit pearls, concealed it may be in the eyes, or in the cavities of the nose, are often discovered by the official searchers before the men leave the Government kottus. So there is some ground for supposing that the divers really carry off a good deal more than the one-third of a fishery to which they are entitled. The kottus where the oysters are received from the boats and separated into piles are large enclosures close to the beach, surrounded by high fences of wattling (fig. 6) and having sheds thatched with palm leaves. Here the

Fig. 6. Government divers and munducks picking out pearls in the kottu.—Photo. by Mr. HORNELL.

Government officials and clerks assign a separate compartment to each boat's crew as it arrives with a load of oysters. The first proceeding is for the divers to divide their oysters into three heaps, one of which is destined to be their own, and there can be no doubt that they make these piles as nearly equal as they possibly can, since they have no means of knowing which one the official will presently point out as their share. The divers now carry off their own oysters and emerge from the kottu on the landward side after running the gauntlet of the searchers. They are at once surrounded by a crowd of natives anxious to buy oysters in small quantities, by the dozen or even singly. The diver usually disposes of his whole stock in this way in a very short time, and then spends the remaining hours of the day in bathing and resting.

Inside the kottu the clerks are now counting the millions of oysters left as the Government's share; and about sunset the Government Agent puts them up for sale by auction at the Court House. The prices bid are per thousand, and may vary from 20 to 80 rupees, and the buyer can take one or more thousands at the price he bids. The kottu with its valuable contents is closed and guarded during the night, and in the morning the buyers remove the oysters to their own enclosures, and then the lengthy and unpleasant process of washing the rotting oysters begins. Some of our figures (fig. 3 and fig. 6) show the examination of the "sarraku" or residue for pearls, while fig. 7 shows Tamils, outside the kottu, searching for attached or blister

Fig. 7. Tamils searching the washed shells.—From a photograph by Mr. Hornell.

pearls amongst the piles of shells thrown out after washing. Fig. 8 shows two pearl merchants, who sit all day ready to buy or sell, weighing, discussing and playing with their gems. They have basket-like sieves for grading the pearls, and curious little scales with scarlet seeds for certain weights. These capitalists (many of them Moormen and Bombay merchants) are an important section of the population of "Camp Town." There are also the pearl-cutters and "fakers," who carry on their business in the street at little three-legged wooden work-tables and with simple bow-drills, by means of which they pierce the pearls for stringing. All these workers who have some definite connection with the fishery or the pearl require others to

Fig. 8. Pearl merchants.—From a photograph by Mr. HORNELL.

supply them with the necessaries and the luxuries of life, and so is brought together the large heterogeneous population. But as soon as the fishery closes the whole town appears to dissolve in a day, the people separate in all directions as rapidly as they gathered, and Marichchukaddi is again a solitary sandy waste.

THE OYSTER DREDGING EXPERIMENT.

At the 1904 fishery, amongst other new departures, some of which have already been noted, oyster dredging from a steamer was tried for the first time with a view to supplement the work of native divers.

The experiment was, however, carried on with imperfect apparatus and under difficulties which will certainly disappear as further experience is gained. The steamer "Ready," engaged for this work during the greater part of the fishery, was found to be unsuitable in several particulars, and Mr. HORNELL has made a number of recommendations in regard to the deck fittings and gear, which will lead to greater efficiency and economy of time by working a larger number of dredges simultaneously.

Mr. HORNELL has kept an exact record of the dredging results day by day, which, however, considering the imperfect nature of the experiment on this first occasion, need not be published. After a discussion of the results he concludes as follows:—"At 70,000 to 80,000 oysters per day I should consider the steamer to be giving very satisfactory results, but I wish to emphasize the fact that the best results can be hoped for only from a few of the banks, *i.e.*, the North Modragam, certain large regions of the Cheval, and some of the smaller and less important paars. The South Modragam and the remainder of the Cheval occupy a somewhat doubtful position, and further working experiments are necessary before we can pronounce a definite verdict regarding the prospects of commercial success in fishing by means of the dredge. I believe, however, the advantages of dredging to be greatest in regard to spat transplantation—as has been explained elsewhere in this Report. Dredging is also of great assistance in the preliminary or prospecting inspections—when it is necessary to ascertain the presence or the absence of oyster patches on grounds too extensive for detailed examination by means of divers."

Details of the Oysters Found.

The oysters found during the recent inspection were of two distinct generations, the older being from $4\frac{1}{4}$ to $4\frac{3}{4}$ years old, the younger from $2\frac{1}{4}$ to $2\frac{1}{2}$ years. The former were of the same brood as those fished on the Eastern Cheval in 1903, and were therefore of a very satisfactory age for fishing this year (1904). Those of the younger brood will hereafter be termed "immature," not in the sense of sexual immaturity, but in regard to pearl-yield.

The fishable oysters lay as a discontinuous north and south band along the seaward or western side of the Western Cheval. Save for a scattered remnant left over from last year's fishery (1903) on the Eastern Cheval, and for occasional individuals forming the nuclei of bunches of younger oysters on the parts covered by the immature generation, no other oysters of fishable age were found. Those present last year on the Periya Paar Kerrai and Vankali Paar were gone, and the huge bed upon the Muttuvaratu Paar, estimated by Captain Donnan, in 1902, at a total of 277,000,000 oysters, and which would have been fishable this year, had also disappeared, being partially replaced by a later brood of $2\frac{1}{2}$-year-olds. On the Karativo Paar, also, none of the 25,000,000 oysters, $1\frac{1}{2}$ to 2 years old, found there in April, 1902, remained, the bank being bare save for a few handfuls of 2-year-olds. A small bed of this fresh generation of oysters was also discovered on the Dutch Modragam Paar.

The details respecting the number and distribution of the oysters present may be summarized thus:—

Number, Distribution, and Sizes of the Fishable Oysters.

The beds of $2\frac{1}{2}$- to 3-year-old oysters on the Western Cheval (comprising the south-west, mid-west, and the north-west sections), which we saw for the first time during our visit to the banks in February, 1902, were found to have the same general disposition, but to have largely decreased in area and to be represented by several detached patches thickly covered with $4\frac{1}{2}$- to 5-year-olds on the South-west Cheval, by a large area of more thinly spread oysters of the same age on the north-west section, and by a third of rather smaller extent on the mid-west, the southern end of the last named joining the north-west patch on the south-west section.

"The south-west patches covered in the aggregate an area of 2,754,021 square yards, with an average of 22 oysters per dive on 1,778,676 square yards and of 21 on the remainder. As each dive is estimated to account for an area of 3 square yards, I estimated the total number of oysters on this section to be 19,500,000, sufficient to give daily loads of 10,000 oysters per boat to a fishing fleet numbering 100 boats for a period of $19\frac{1}{2}$ days, each boat being presumed to have a complement of 10 divers.

"The oysters on the north-west section amounted to 9,000,000, covering an area of 1,685,460 square yards, a number based upon an average of 20 oysters per dive on 716,100 square yards and 13 per dive on 969,360 square yards. Although apparently sufficient to give fishing for 100 boats for 9 days at an average load per boat of 10,000 oysters, the result of the fishery showed that the number of oysters per dive on certain portions of this bed was too low to give profitable results, with the consequence that the fleet had to be moved off after only five days' fishing and the removal of a little over 4,000,000 oysters—rather less than half of those present.

"The bed on the mid-west had an area of 992,250 square yards, whereon I estimated there were 6,500,000 oysters, being at the rate of 20 per dive. These oysters were smaller for their age than those of the south-west and most of those on the north-west sections.

"The total number of fishable oysters on the three sections of the Western Cheval I estimated at 35,000,000, equal to 35 days' fishing for 100 boats. By far the most important of the beds found in respect of numbers as well as condition were the patches on the south-west section, for here not only were the oysters splendidly grown for their age, but they were absolutely free from mixture with young. Everywhere else there was more or less admixture of young of 2 to $2\frac{1}{2}$ years of age, especially upon the eastern margin of the ground where they adjoined the beds of the immature generation.

"Over those parts of the South, South-east, and South-central Cheval, and North Modragam occupied by oysters, the older oysters, while nearly universally present, were in a very small minority, averaging not more than 1 to 6 of those $2\frac{1}{2}$ or 2 years old. Here and there on the northern edge of the South-east Cheval were small patches of little mixed $4\frac{1}{4}$- to $4\frac{3}{4}$-year-old oysters, the remnants of the bed fished last year.

"As was to be expected, the Periya Paar Kerrai, ravaged by ray-fish (Trygonidæ) in March, 1903, gave no results, and but a few oysters of no fishery value were found on the Kondatchi Paar, ground that is utterly bad for oyster growth under present circumstances (*infra*).

"The sizes of average samples from the three sections of the West Cheval are as follows :—

Name of Bank.	Height of oyster.	Length.	Breadth.
	millims.	millims.	millims.
South-west Cheval . . .	76·20	69·20	32·32
Mid-west ,, . . .	72·30	65·25	31·70
North-west ,, . . .	72·87	66·50	31·57

"Some exceptionally fine oysters from a patch at the extreme south end of the Mid-west, a patch lying upon sandy bottom, rose to the high average dimensions of 76·56 millims. by 69·16 millims. by 34·44 millims. If we exclude the last-mentioned oysters as being exceptional, we get as the general average of the $4\frac{1}{4}$ to $4\frac{3}{4}$-year-old oysters fished this year 73·79 millims. by 66·98 millims. by 31·86 millims.

"During the course of last year's fishery (1903) I found the average size characteristic of oysters on the Eastern Cheval to be 75·51 millims. by 69·18 millims. by 31·18 millims. Both lots originated from the same brood, and it is significant that, although this year's oysters are a full year older, their size, except in respect of breadth, is decidedly inferior to the average of those fished last year from the Eastern Cheval. This marked character, due to stunted growth, has long been associated with oysters from this particular region, and has frequently been referred to by Sir WILLIAM TWYNAM and by Captain DONNAN. Occasionally this stunted growth has been so extreme that the divers and merchants have referred to such oysters as being of the 'Kottapakku' variety, a form which is undoubtedly correlated with overcrowding on extensive stretches of rocky bottom."

Number, Distribution, and Sizes of the Immature Oysters.

"Immense quantities of immature oysters varying from $2\frac{1}{4}$ to $2\frac{1}{2}$ years old covered practically the whole space on the eastern half of the Mid and North-west sections, extending eastwards into the North-central, Central, and South-central areas. The South and the South-east Cheval also bear very large quantities, as do also the North and South Modragams.

"A fair-sized bed, plentifully covered with oysters, is at present on the Dutch Modragam Paar, but they are too young to fish for at least a year, as the age of the majority varies from 2 to $2\frac{1}{2}$ years. These oysters represent the young spat which was noted as abundant in November, 1902 ; their growth has been at the expense of the older oysters that were present that year, and which have been killed off by the more vigorous and numerous young.

"The size of those on the North and South Modragam paars and those on the South, South-east, and South-central Cheval, is greater than that of those upon the remaining sections, including also the Dutch Modragam, indicating more vigorous growth and a better food supply. Indeed, many of the oysters have a superficial appearance of being from 3 to $3\frac{1}{2}$ years old. The general superiority of these oysters is well brought out in the following tabulation of the average size of representative oysters from each of the localities named:—

Locality.	Height of oyster.	Length.	Breadth.
	millims.	millims.	millims.
South-central Cheval	$67\frac{3}{25}$	$61\frac{4}{25}$	$27\frac{6}{25}$
North-west ,,	56	$51\frac{4}{5}$	$23\frac{13}{15}$
North-west ,, (another part)	$61\frac{1}{3}$	$57\frac{1}{2}$	$23\frac{3}{4}$
Mid-west ,,	$56\frac{3}{5}$	$52\frac{3}{5}$	$24\frac{3}{5}$
South Modragam	$68\frac{17}{25}$	$64\frac{4}{25}$	$27\frac{7}{25}$
Dutch ,,	$58\frac{19}{25}$	$53\frac{18}{25}$	$25\frac{11}{25}$
Karativo Paar	$58\frac{19}{25}$	$55\frac{8}{25}$	$24\frac{4}{5}$

"There are few oysters of an age less than 2 years mixed with these—an important favourable factor, as the fall of abundant spat upon a bed of oysters approaching maturity is one of the most serious dangers that beset the fruition of an oyster bed, and one that is most difficult to combat."

Summary of the Past History of the Oysters Found.

The oysters fished this year were first seen in March, 1900, by Captain Donnan, who reported that over the whole of the Western Cheval, an area nearly $5\frac{1}{2}$ miles long by 1000 to 4000 yards wide, young oysters 3 to 9 months old were thickly spread. The area actually covered was estimated at 5800 acres. During the 12 months following a great decrease took place in the number of oysters present and in the acreage covered, the Inspector reporting that the solid phalanx of 1900 had been broken up into three detached beds totalling only some 1685 acres bearing 80,000,000 of oysters.

A year later (February and March, 1902), during our visit to the banks in the "Lady Havelock" and with Captain Donnan in the "Rangasami Puravi," we saw these oysters and noted the marked inferiority of their size to that of oysters of similar age upon the Eastern Cheval. Captain Donnan's estimate of their numbers was 123,357,000 oysters, spread over an area of 2170 acres. At the same time it was noticed as a disquieting feature that the fresh fall of spat so generally distributed over the banks had invaded the Western Cheval—a large proportion of the older generation bearing each several young attached to the valves. These young oysters, upon which we now rely for the next immediate fisheries, appeared when first seen (February, 1902) to be from 2 to 6 months old. Besides having invaded the Western Cheval, immense quantities were found on the South and North-central, South and South-east Cheval regions, and also upon the two Modragams, as well as upon many of the southern banks extending from Negombo to Karativo.

In November, 1902, the numbers on the Western Cheval bank were given by Captain LEGGE as 57,605,000, occupying 936 acres, but, owing to bad weather, the whole of the bank was not surveyed. No other numerical estimate was made till Mr. HORNELL'S inspection of this year, when a very careful estimate placed the number remaining at 35,000,000 upon 1122 acres. Tabulation of the above facts shows this history clearly.*

Date.	Number estimated.	Age in years.	Acreage.	Number per dive.
March, 1900	Too great for calculation	$\frac{1}{4}$ to $\frac{3}{4}$	5800	—
„ 1901	80,000,000 (?)	$1\frac{1}{4}$ „ $1\frac{3}{4}$	1685	21 to 30
„ 1902	123,357,000	$2\frac{1}{4}$ „ $2\frac{3}{4}$	2170	27 „ 40
November, 1902 (inspection incomplete)	Over 57,605,000	3 „ $3\frac{1}{2}$	Over 936	—
February, 1904.	35,000,000	$4\frac{1}{4}$ „ $4\frac{3}{4}$	1122	13 to 22

The discrepancy between the estimates for 1901 and March, 1902, appears largely explicable by the estimate of oysters per dive having been either too low for the former year or too high for the latter, estimates being liable to variation with every condition that affects a diver's powers of working. Divers have been known to bring up from one particular spot only 10 oysters per dive when the weather conditions were unfavourable, and yet the following day, the sea being calm and warm, the same men would report double the number. To arrive at accurate estimates, the weather conditions, if adverse, should be allowed for, and the total number increased accordingly.

In November, 1902, the encroachment of the younger generation had markedly increased, and with the growth of the smaller ones many portions of the Western Cheval bank—the parts where they were most abundant—had to be transferred from the category of regions bearing maturing oysters to those monopolised by the younger generation.

"In February, 1903, no regular inspection was made of these latter regions, but by means of numerous descents in a diving dress I was able to obtain a fair knowledge of the distribution of the younger oysters. On the Cheval and the North and South

* See also Part II. of this Report (1904), p. 15, and figs. 9 to 14.

Modragam the young already noted were found well grown and flourishing, and, while their actual age was only $1\frac{1}{4}$ to $1\frac{1}{2}$ years, many, especially upon the Modragams and South Cheval, had the appearance of being 2 years old. On the Muttuvaratu and Dutch Modragam the older oysters had made no increase in size, and were in an unhealthy and miserable condition. Mixed with them were considerable numbers of a younger generation, apparently over 1 year old. This year, as already stated, the older generation proved to have died off upon the Karativo, while the younger generation found last year had made fair progress and appeared moderately healthy. Similar conditions, I believe, characterise the Muttuvaratu this year, judging from the rather meagre data at my command."

Rate of Increase in Size.—So little is known with exactitude concerning the rate of growth of oysters, that the following tabulation by Mr. HORNELL of the observed increase in size of these younger oysters has considerable value.

TABLE showing Rate of Growth of Oysters aged $2\frac{1}{4}$ to $2\frac{1}{2}$ Years, March, 1904.

Date.	Age in years.	Size in millimetres.
I. SOUTH-EAST AND SOUTH-CENTRAL CHEVAL :—		
March, 1902	$\frac{3}{12}$ to $\frac{6}{12}$	35·00 × 32·00 × —
November, 1902	$\frac{11}{12}$ „ $1\frac{2}{12}$	50·57 × 47·52 × —
March, 1903	$1\frac{1}{4}$ „ $1\frac{1}{2}$	54·41 × 49·75 × 20·38
„ 1904	$2\frac{1}{4}$ „ $2\frac{1}{2}$	67·12 × 61·16 × 27·24
II. MODRAGAM PAARS :—		
March, 1902	$\frac{3}{12}$ „ $\frac{6}{12}$	37·15 × 33·20 × —
„ 1903 (North) . . .	$1\frac{1}{4}$ „ $1\frac{1}{2}$	61·17 × 54·50 × 24·28
„ 1904 (South) . . .	$2\frac{1}{4}$ „ $2\frac{1}{2}$	68·68 × 64·16 × 27·28
III. NORTH-WEST CHEVAL :—		
March, 1902	$\frac{3}{12}$ „ $\frac{6}{12}$	33·50 × 30·75 × —
November, 1902	$\frac{11}{12}$ „ $1\frac{2}{12}$	47·64 × 44·36 × —
March, 1904	$2\frac{1}{4}$ „ $2\frac{1}{2}$	56·60 × 52·60 × 24·56
„ 1904 (another locality)	$2\frac{1}{4}$ „ $2\frac{1}{2}$	61·33 × 57·40 × 23·70

When these records are extended over the remaining life-period of these oysters we shall have, for the first time, reliable data as to the relative rate of growth from year to year upon three of the most important of our oyster banks.

The respective increases during the first two annual intervals are as follows :—

	South-east and South Cheval.	North-west Cheval.	Modragams.
	millims.	millims.	millims.
12 months from age 3 to 6 months.	19·41 × 17·75 × —	—	24·02 × 21·30 × —
12 months from age $1\frac{1}{4}$ to $1\frac{1}{2}$ years	12·71 × 11·41 × 6·86	—	7·51 × 9·66 × 3·00
Total for two years .	32·12 × 29·16	25·46 × 24·25 (average)	31·53 × 30·96

It will be noted that while the growth of the Modragam and of the South-east and South Cheval oysters has been greater and more rapid than that of those upon the Western Cheval, the Modragam oysters, growing more quickly than those of the South-east and South Cheval up to the age of $1\frac{1}{4}$ to $1\frac{1}{2}$ years, and thereby attaining larger size, suffered retardation in the rate of increase thereafter, making but 7·51 millims. × 9·66 millims. × 3·00 millims. increase, whereas the South-east and South Cheval oysters made 12·71 millims. × 11·41 millims. × 6·86 millims. in the same period, and so reduced the disparity in size caused by the more rapid growth of the Modragam individuals at the earlier age—so much so that the difference between them at the age of $2\frac{1}{4}$ to $2\frac{1}{2}$ years is but 1·56 millims. × 3·00 millims. × 0·04 millim.

This lends support to our previous statement (this Report, Part I., 1903, p. 136) that shell growth is most vigorous during the first two years of life, or, as we may now put it, up to the size of about 60 millims. × 54 millims. × 24 millims., and that thereafter it slackens to a very slow rate, actually coming to a stand, or even retrograding as regards height and length in the case of the stunted oysters of the Muttuvaratu and the Mid-west Cheval.

As examples of this slowness of growth in older oysters we may take those fished this year from the South-west Cheval. These were the most vigorous and freely grown as regards the general average, and yet the increase made from November, 1902, to March, 1904, was but 5·31 millims. in depth by 3·77 millims. in length, *i.e.*, between the ages of say $3\frac{1}{2}$ to $3\frac{3}{4}$ and $4\frac{1}{2}$ to $4\frac{3}{4}$ years (size in November, 1902, was 71·25 millims. × 65·39 millims.). Contrast with this the increase *within the same period* (16 months) when the oyster is younger, say between the ages of $\frac{11}{12}$ to $1\frac{2}{12}$ and $2\frac{1}{4}$ to $2\frac{1}{2}$ years. In the case of oysters of this age from the South Cheval, the increase has been, as shown above, as much as 16·55 millims. × 13·64 millims., and in the case of the North-west Cheval 13·69 millims. × 13·04 millims.—a remarkable difference indeed.

Again we see that the disparity of growth is most marked during early life—up to the age of 2 years—so that oysters situated in exceptionally favourable conditions attain such dimensions that they are liable to be credited with greater age than knowledge of their origin will warrant. This circumstance may account for some of the differences of opinion as to the ages of young oysters in the past (see, for example, the oysters attached to the Karativo buoy in 1866, described by Mr. HOLDSWORTH and discussed by Sir W. C. TWYNAM—Report, &c., Colombo, 1900).

CAUSES OF DECREASE AMONG THE FISHABLE OYSTERS SINCE MARCH, 1902.

The factors which tend to reduce the number of oysters, both old and young, have been treated of at some length in former parts of this Report, and it is only necessary here to discuss the causes which have led to great decrease since 1902 in the old oysters that were fished this year on the Western Cheval and the disappearance of the same generation from the Muttuvaratu, the Dutch Modragam and the Karativo paars. The decrease appears to have arisen from two chief causes, overcrowding and sand disturbance, the ill-effects of which have been intensified by several other influences of subsidiary importance. The former affected the beds in the North-west and Mid-west of the Cheval sections, with the Muttuvaratu and Karativo paars; the latter those of the South-west Cheval.

Sand Disturbance did the greatest harm upon the South-west Cheval, as this area has but few stretches of exposed rock surface, while "cultch" is not sufficiently abundant. When first seen by Captain DONNAN in 1900, the whole area was thickly spread with oysters on the sand as well as on the rock and on the cultch-strewn areas. With every recurrent period of stormy weather since that time these oysters have suffered thinning by encroachment and overwash of sand, till eventually they were cleared from off the sandy uncultched areas and only those were left that lay on rocky ground and on sufficiently cultch-covered bottom.

A subsidiary cause of destruction was the ravages of the boring sponge, *Cliona margaritiferæ*, which appeared specially active on this section, riddling the valves and apparently sapping the vitality of the oyster by the drain it caused upon nacre-secretion. Out of 400 individuals examined 310 were affected by *Cliona*—less than 23 per cent. were free from the infection.

Apart from this the oysters of the South-west Cheval were the healthiest, the bodies being plump and well developed, whereas a considerable proportion of those from the Mid-west and North-west sections were thin and of poor appearance.

The Effects of Overcrowding.—Sand disturbance produced comparatively little numerical reduction upon the North-west and Mid-west sections, these regions possessing more extensive stretches of rocky bottom than any others in this neighbourhood. The reduction here was due primarily to the effects of overcrowding, not, perhaps, so much because of their own numbers, great as these were originally, but rather because of deposits of spat which fell in July and December of 1901 upon the older oysters along the eastern part of these sections. For the first year the effects were little marked, but as the myriads of new-comers flourished and increased in size the well-being of the older generation was affected, a result that showed itself first by arrest of the growth of the shell and then, later, by starvation, lowered powers of vitality and reproduction, and wide-spread mortality.

Regarding the arrest of growth, we noted that the older oysters on the Mid-west Cheval measured 69·42 millims. × 64·54 millims. in March, 1902, when they were $2\frac{1}{2}$ to $2\frac{3}{4}$ years old, while survivors on less thickly populated parts of the bank were only 72·30 millims. × 65·25 millims. in March, 1904, an increase in size of but 2·88 millims. in height by 0·71 millim. in length in 2 years, a growth so slight as to justify the conclusion that oysters from the Western Cheval practically attain their maximum height and length upon reaching the age of 3 years, increasing thereafter in no appreciable extent save in thickness, which is due to deposits of nacre upon the inner surface of the valves.

In the case of the Muttuvaratu, the Karativo and the Dutch Modragam paars, the disappearance of the oysters has been total, caused not so much by the competition introduced by the presence of myriads of vigorous young—though this also existed and no doubt had some effect—as by the overcrowding and diseased condition set up by the immense number of adults. This has had such baneful effect that when Mr. Hornell saw them in March of last year they showed marked deterioration upon their condition 4 months previously, while their average size showed actually a decrease in height and length (58·84 millims. × 54·32 millims. in November, 1902, as against 57·54 millims. × 54·00 millims, in March, 1903). These oysters are in a shrunken, poorly nourished condition, and out of 227 examined, 25, or over 11 per cent., were affected with the "yellow" disease—a malady marking the imminence of wide-spread mortality, and characterised by the invasion of most of the tissues by immense numbers of leucocytes crowded with yellow granules.

That the Muttuvaratu oysters should have been entirely cleared away, while a relatively large number of the same generation is left upon the Western Cheval, is undoubtedly due to the overcrowding having been less acute and less wide-spread in the latter case.

Subsidiary Causes.—The general enemies of the pearl oyster were present as usual, such as star-fish, boring molluscs and the smaller oyster-eating fishes (*Balistes*, &c.). The two former, the star-fishes especially, do much harm, and their reduction in number is one of the benefits to be derived from dredging on a large scale. The smaller oyster-eating fishes have not been excessively numerous upon the Cheval and are not at present a destructive agency, seeing that the oysters are now too large and too strong to be crushed by the small jaws of these fishes. Their ravages are only to be feared when a bank is covered with spat; then these fishes gather from all quarters and, if the deposit is limited and the nature of the bottom sufficiently smooth, the attack may involve partial or even entire annihilation of the bed. The boring-annelid, *Polydora* sp., was markedly abundant on the South-west Cheval, but comparatively few bad cases could be traced to its tunnelling. Far otherwise was it with the inroads of the boring sponge, *Cliona margaritiferæ*, already alluded to. Hundreds of valves were examined where not only was the substance of the shell riddled by its honeycomb-like tunnels (see fig. 9), but, a more serious matter, the

Fig. 9. Pearl-oyster shell honeycombed by *Cliona margaritiferæ*, DENDY.

insertion scar of the adductor muscle was tuberculated and diseased, a condition due to the inferior powers of nacre-production of the epidermal layer in this region. "So great indeed was the nacreous tuberculation in some cases, that I have seen the natives save these shells with a view to cutting the tubercles off to use in the manufacture of native pearl jewellery." Whenever the inroads of *Cliona* were extensive, the sub-epidermal tissue in particular, and the other tissues in general, were thin and diseased-looking. A fairly large proportion of the dead shells found during the fishery on the South-west Cheval was badly affected; *Cliona* must undoubtedly be included among the more destructive agencies with which we have to contend.

"There was no evidence of any depredations on the part of Ray fishes this year, like the destruction of the Periya Paar Kerrai oysters last year. Rays were, however, several times seen; on the 27th February a large shoal, heading south, passed the ship at anchor on the North-west Cheval. The sight was a remarkable one, the sea for over 20 yards square being one patchwork of yellow disk-like bodies. Fair-sized examples of *Trygon walga* were caught from time to time. None of them furnished direct incriminating evidence, the stomachs being filled with crustacean *débris* and fragments of lamellibranch shells other than those of the pearl oyster. Like the trigger fishes, these smaller rays would appear to find the present size and strength of the oysters too great for the power of their teeth and jaws."

No sharks were seen on the fishing grounds. Mr. HORNELL says: "During all the months I have spent upon the pearl banks during the last $2\frac{1}{2}$ years, I have never had a glimpse of a shark dangerous to man. Several times the boatmen have caught 'basking-sharks'* of considerable size, but all were of a species that lives almost entirely upon small fishes and mollusca."

Condition of Spat on the Periya Paar in 1904.

"March 14th was devoted to an inspection of the Periya Paar, with the result that an immense bed of oyster spat† was there discovered. The young oysters were incredibly abundant, spread densely over an area fully 5 miles in length by from 1 mile to $1\frac{1}{2}$ miles in width. The age was under 3 months, so that they must have been spawned not earlier than December of 1903, more probably towards the end of the month. Alike on sandy and on rocky ground was this profusion seen, but on the rock the numbers were notably greater. On the sandy stretches the oysters formed bunches often of large size, the individuals attached in most cases to one another, but generally having a nuclear fragment of small cultch which most frequently was a cockle shell, a nullipore ball (*Lithothamnion*) or a small fragment of 'paar.' The spinning mussel (*Modiola barbata*), 'Suran' as it is called by the Tamil divers, was in places abundant, especially upon the sandy ground, but not sufficiently so to constitute a grave danger to the bed. This discovery of spat paralleled in extent and nature that made by Professor HERDMAN in February, 1902, when he estimated approximately the numbers of the young oysters at 100,000,000,000, and which, it will be remembered, had all disappeared when I next examined the bank in November of the same year.

"A very remarkable fact was that some of the largest of these young oysters when last seen, 3rd April, had already developed gonads filled with reproductive products fully formed and ready to be shed. The average size of these sexually mature individuals was $25\frac{1}{2}$ millims. $\times$ $26\frac{1}{2}$ millims. $\times$ 9 millims. The smallest was $24\frac{3}{4}$ millims. $\times$ 25 millims. $\times$ $8\frac{3}{4}$ millims. The extreme age of these cannot be more than $3\frac{1}{2}$ months, and we are fully warranted in considering that sexual maturity is reached by the pearl oyster soon after the age of 3 months. Previous to this record, the age of 6 months was the earliest at which reproduction had been observed."

Sexual maturity at such a small size and early age, in itself remarkable, has a practical bearing upon the replenishing of the banks from time to time—a subject to be treated of again.

Principal Spawning Seasons.—The gonads of this year's fishable oysters were nearly all in a spent condition during February and March, and this taken in conjunction with the presence of enormous multitudes of very young oysters—so young indeed that they could not have been set free earlier than the middle of the December

* The sketch of one of these which Mr. HORNELL has sent home has been identified by Mr. G. A. BOULENGER as *Stegostoma tigrinum* (GMEL.).

† The term "spat" is used in these pages in a wide sense to comprise all sizes of attached oysters under the age of 4 months.

preceding—points to December and January as being the period ot one of the maxima of reproductive activity in the pearl oyster of Ceylon.

In April the gonads began to show signs of increase, and a small quantity of spat was seen. It now seems that the two maxima do not coincide, as we at first supposed, with the intervals of fine weather and variable winds between the monsoons, *i.e.*, November in the one case, March and April in the other. This year's observations point distinctly to the chief spatting seasons having December and January, and June. July or August, as the central periods respectively—times when the monsoon winds are blowing steadily and strongly. It may be noted that a wide dispersal of the embryos can be more effectually attained during these boisterous periods of strong currents than if they were expelled during the inter-monsoon lulls, characterised by light winds and erratic surface drift.

Prospects of Future Fisheries.*

"The prospects of a large fishery, both next year and in 1906, upon the Cheval and Modragam paars are excellent; the immense quantities of young, 2 to $2\frac{1}{2}$ years old, occupying the Modragams, the South-east, South, Mid-west, North-west, and the greater part of the three central blocks of the Cheval Paar being ample for 2 years' fisheries. Those on the Modragams, and on the South, South-east, and South-central Cheval will, I hope, be fit to fish next March, being more advanced in growth than those on the Mid-west and North-west Cheval. Apart from this reason it will be advisable to fish the former at as early a date as the valuation of samples may show to be profitable, because, as many of the oysters on the beds named lie loose in bunches on a sandy bottom, they are thereby exposed to the danger of destruction by currents of exceptional force—a contingency infrequent but not unknown (*e.g.*, fishery of 1888). By March of 1905 these oysters will be about $3\frac{1}{2}$ years old, and, judging from the rapidity of their growth and their present large size, by that date they should be sufficiently matured to give a profitable fishery. They will then be practically of the same age as those of the 1903 fishery, which realised just under Rs. 30 per 1000, average price.

"If the fishery be postponed till 1906, the pearl yield would be greater, but if this were done, even supposing the oysters remained in safety till March, 1906, upon the banks, there would then be too great a quantity to fish in one year, and a portion would be left for the succeeding year, 1907. But in 1907 the remainder would be $5\frac{1}{2}$ years old, and under the conditions prevailing on the Western and Median Cheval, where these oysters are, it is most improbable that they would be still alive. A definite decision cannot be arrived at till the next valuation has been made† in November of the present year.

* I give this as Mr. Hornell's opinion in the Summer of 1904. It must be read in conjunction with the next article (p. 37) based upon the inspection of last November.

† See below, p. 43.

"The oysters at present on the Muttuvaratu and the Dutch Modragam paars should also be ready to fish in 1906, but I do not build confidently upon this; even now these oysters are extremely stunted and sickly looking, and are certain to decrease very much before they are ripe for fishing.

"Beyond 1906, or at latest 1907, there is likely to be a break in the fishery sequence, a more or less prolonged blank* whereof the duration will be to some extent dependent upon whether or not large measures of transplantation are resorted to, seeing that there has been no fall of spat upon the Cheval, Modragam, or Muttuvaratu paars within the last two years, that is to say, since June, 1902. The only other hope lies in the possibility that a younger generation may be growing up on some of the paars that have not been inspected of recent years. I therefore trust that I may be given the opportunity to make exhaustive inspections during the next 2 years. The more I learn at first hand about the banks and the more I read of the old records, the more convinced I am that limited and narrow-compassed inspections have been the cause of the loss of many valuable fisheries. To give a concrete instance of the essential need for thorough periodical examinations of the whole pearl-bank area, the following extract from Captain DONNAN's Report of the 1878 inspection furnishes significant reading:—

" 'While inspecting the Cheval I discovered oysters on a new bank, $2\frac{1}{4}$ miles to the 'westward of the Cheval, where it has generally been considered that there was 'nothing but an extensive sandy flat. I saw it recorded in the diary of inspection 'by Captain LAUGHTON, in March, 1802, that he found oysters of 4 or 5 years in 'abundance in 9 fathoms, rocky bottom, Kudiramalai bearing S.E. $\frac{1}{4}$ E.; and being 'anxious to test if rocky bottom really existed in that neighbourhood, I took all the 'inspection boats in tow of the launch out to the verge of the bank of soundings, 'and directed them to dive all the way back to the inspection vessel, so as to cross 'the position noted by Captain LAUGHTON, and they came upon rocky ground and 'oysters, where they placed a buoy. On subsequent examination this bed of oysters 'proved to be about $1\frac{1}{2}$ miles in its longest direction N.N.W. and S.S.E., and about '$\frac{3}{4}$ mile broad at its broadest part, having a depth of water over it of from $8\frac{1}{4}$ to '$9\frac{1}{4}$ fathoms, and a sandy flat of 9 fathoms between it and the Cheval. I believe it 'to be an extension of the Periya Paar in a S.E. direction. I have duly recorded 'its position in my diary. The superficial area of the bed is 3,845,935 yards, and 'the oysters on it average 22 to a dive. I estimate the total number of oysters on 'it at 3,500,000, sufficient to give 10 days' fishing for 50 boats with loads of '7000 oysters each. I found, however, 13 per cent. of dead shells, which is an 'unfavourable sign, and a large quantity of seaweed growing on the oysters. I have 'been much puzzled about the age of these oysters, as they appear to be old, although 'of small size. I believe them to be of the description known to the natives as

* The position of affairs is now altered by a great fall of spat on the Cheval Paar (see below, p. 37).

' "kottapakku," which are said to be a small class of oyster but rich in pearls. They ' resemble the oysters of the Chilaw banks, which I know to be 4 years old now, and ' therefore they ought to be fit for fishing in March next. I can find no record of ' this bed having ever been inspected since 1802, and it is a curious coincidence that ' what was then recorded of its condition might be recorded now on its most probably ' first examination since that time.' "

The oysters referred to in the above extract were fished the following year, 1879, and the question is at once suggested, "How many times between 1802 and 1878, the interval during which this paar received no attention, did oysters mature unknown upon this ground; and, further, how many other oyster-bearing patches have been left unnoticed for want of more extended inspections?"

Parasites of the Pearl Oyster.

"Entozoa were plentiful in the oysters fished this year, both nematode worms and encysted cestode larvæ being found; the former especially were more numerous than I had before seen, and many oysters contained two individuals. A solitary example of the trematode *Aspidogaster margaritiferæ* was found, located as usual in the pericardium. Cestode larvæ were particularly abundant in the oysters from the North-west Cheval, and this fact will be referred to when we come to treat of the relative pearl yield of the three sections.

"More specimens are still needed to enable us to complete our knowledge of the life-history of the pearl-inducing parasite, and till I have an opportunity to dissect a number of individuals of the large oyster-eating sting-rays, the Walwadi tirikkai of the Tamils, there can be no hope of filling up this important gap in our investigation. No opportunity offered to obtain one of these rays at the late fishery, my position 12 miles from land precluding access to the fishermen of Pukkulam and Marichchukaddi, the only possible places where I could hope to procure specimens. Several small individuals of *Trygon walga* were caught by the inspection boatmen. This species does not, however, possess teeth sufficiently powerful to destroy oysters more than a few months old and no parasites belonging to the species found in the pearl oyster were discovered when these fish were dissected. Besides pearl oysters a large number of fishes were dissected in search for the adult stage of the pearl-parasite, and a continuation of such work will form the subject of a detailed report in the future."

The Yield and Character of Pearls from Different Regions.

During the inspection of the Cheval Paar representative samples of mature oysters were collected from the South-west, Mid-west and North-west beds respectively, and from the 7th to the 9th of March Mr. Hornell was engaged superintending the washing of these samples and the valuation of the pearls picked out. The results showed that the South-west oysters were the richest in pearls, the North-west following closely, with the Mid-west unmistakably much poorer in yield.

The following table will make clear the relative returns:—

Bed.	Quantity.	Total weight of pearls.		Weight per 1000.		Valuation per 1000.	Size of oysters in millimetres.
		Kalanchu.	Manchadi.	Kalanchu.	Manchadi.	Rs. cts.	
South-west Cheval	12,000	7	13·25	—	12·76	36.01	76·20 × 69·20 × 32·34
North-west Cheval	7,200	2	17·00	—	7·91	33.75	72·67 × 66·50 × 31·50
Mid-west Cheval	6,000	2	0·88	—	6·81	20.25	72·30 × 66·50 × 31·57

"The weight of pearls per 1000 oysters was very high in the case of those from the South-west, which fact may be correlated with the size of these oysters being considerably greater than that of the other two lots. In regard to the quality of the pearls, the North-west oysters, while yielding a less weight, contained a much greater proportion of 'cyst pearls' of excellent quality than those from the South-west, which owed their greater proportionate weight of pearls to a noteworthy abundance of 'muscle pearls.'

"External characteristics give the most meagre indication of what the pearl yield may be—in regard to 'cyst pearls' the abundance, or otherwise, is connected with the factors which control the relative abundance of the pearl-inducing cestode and those which conduce to its death during encystment in suitable localities within the tissues—problems as yet obscure. The fact, however, is to be noted that dissection showed the oysters from the North-west Cheval to be more extensively infested with cestode cysts than those from the other districts, while the valuation sample showed that cyst-pearls were much more abundant in these oysters than in those from either the Mid-west or South-west Cheval sections. With regard to muscle pearls the general fact stands out, deduced from my experience of two fisheries, that the more vigorous and well grown are the oysters the more abundant are the muscle pearls."

Shell-pearls.

"At the close of the inspection, when the valuation samples of oysters had been washed, I seized the unique opportunity thus afforded to examine over 30,000 pairs of separated valves of the pearl oyster. I did this chiefly to see if any considerable proportion of shell-pearls were induced by the irritation caused by perforation of the shell by boring parasites—sponges, lamellibranch molluscs and annelids. The result negatived this idea and showed that these animals have little or no influence upon pearl production; the sponge, *Cliona margaritifera*, causes occasional roughening, or even rugged tuberculation (fig. 10), at the insertion scar of the adductor muscle, and the annelid, *Polydora*, may produce an occasional discoloured internal excrescence, usually sharp-pointed: more rarely a parasitic nematode, free or encysted, is cemented to the nacre and sealed up in a pearly sarcophagus.

Fig. 10. Inside of pearl oyster shell, showing adductor impression affected by *Cliona* borings on the outside. × ½.

" By far the larger number of shell-pearls, fully 90 per cent. of the whole number, are due to the attachment of cyst- and muscle-pearls to the nacreous lining of the shell, consequent upon fusion of the pearl-forming sac with the epidermal layer outside, and rupture of these tissues caused by the pressure of the growing pearl, thus placing the pearl in actual contact with the nacre and converting its closed pearl-secreting sac into a pouch or ampulla, the open neck directed outwards and in continuity with the general epidermal layer upon the exterior of the mantle.

" Shell-pearls originating in this manner are at first pedunculated, and at this stage may be detached readily. The peduncle tends, however, to become obliterated, and eventually the pearl may be entirely lost in the substance of the shell nacre. Such shell-pearls are in most cases affixed singly, without definite arrangement. Examples may be located anywhere, the largest, however, being usually either in the peripheral region of the nacre, or in the central region, corresponding with the lateral surfaces of the visceral mass.

Fig. 11. Diagram showing comparative frequency of cyst pearls in the various parts of the mantle.

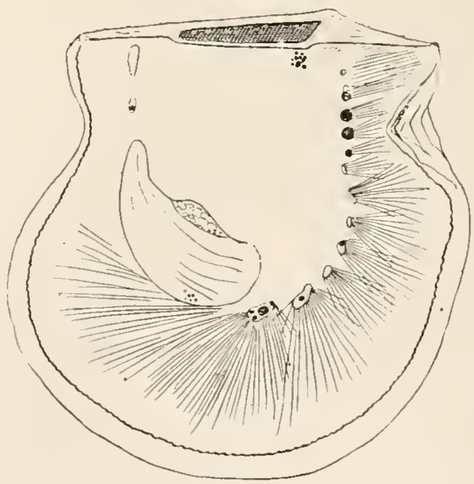


Fig. 12. Diagram showing the positions most frequently occupied by muscle pearls.

" Smaller attached pearls are not infrequently either singly or in a serial line of from two to five along the pallial line, each pearl coinciding in position with a muscle scar. Very rarely small ones may be seen along the edge of the adductor. Most frequent of all are pearl masses of irregular or even botryoidal form attached at or adjacent to the levator insertions. Decalcification of these pearls reveals no organic nuclei, whereas the pearls irregularly disposed have cestode embryos as nuclei, exactly as 'fine' pearls have.

"Examination of these 30,000 shells gives, therefore, strong confirmatory evidence in support of the theory set forth by Professor HERDMAN and myself* associating such pearls as have no organic nuclei (cestode or other platyhelminthian embryos) with the attachment surfaces of those muscles which are inserted on the shell, especially the small and comparatively weak levator and pallial muscles. Figs. 11 and 12 show the distribution in the body of cyst pearls and muscle pearls respectively, and fig. 12 is very instructive in showing the perfect way in which the positions of the shell pearls there depicted coincide with the series of pallial muscle scars.

"PHOSPHORESCENT AND OTHER PHENOMENA.

"On the evenings of April 9th, 10th, 11th, and 12th, when at anchor on the Western Cheval, we beheld a repetition of the strange phosphorescent phenomenon witnessed by Professor HERDMAN on March 13th, 1902 (see this Report, Part I., 1903, p. 81). The display began at about the same hour each evening, varying from 8.45 to 9.30 P.M., the sea being dotted with large isolated flashing lights that pulsated and vanished ghost-like at regular and frequent intervals.

"The rhythmic and progressive blotting out and rekindling of these phosphorescent fires was as if the sea were swept by regularly recurring search-light rays. The beginning of each successive light-wave appeared to lie to the south; the intervals were approximately of two seconds' duration. All the four nights were dark, but the weather was variable, one night tempestuous, another fairly calm, a moderately strong swell prevailing the whole time. The displays lasted approximately for an hour each evening. The cause remains undetermined.

"**Trichodesmian calm.**—During several days in March vast quantities of the red-brown scum of *Trichodesmium erythræum* lay profuse and filthy upon the surface of the sea. So abundant was this scum that twice did it extend the period of noontide calm, acting precisely as a film of oil does. At midday when the first puffs of the sea-breeze came out of the north-west, while the breeze was evident enough otherwise, yet it failed for sometime to disturb the surface where lay this scum. Where it was absent, or where the progress of the launch broke a lane through the film, the wind raised ripples and wavelets which little by little spread and encroached upon the Trichodesmian calm. This with the gradual freshening of the wind finally scattered the particles, driving them downwards.

* 'Brit. Assoc. Report,' Southport, 1903, p. 695.

" **Surface drift.**—Nothing can be done towards the solution of this question without the employment of bottle-drifters, except to note the direction of the current from day to day, when at anchor on the banks. This was attended to from 19th February to 19th April, the result being to show that during February the current set in the main to the south and to the south-west in dependence upon the general direction of the wind which at this period was mostly north-east. The following month, March, distinguished for its alternate land and sea breezes, showed a to-and-fro motion of the water upon the banks, the current altering with every change of wind and never attaining any strength. In April, consequent upon the continuous south-west wind and swell, the current ran strongly northwards, frequently at a rate of from 2 to 3 knots per hour."

Finally, Mr. Hornell has sent me a series of "Recommendations" in regard to the further exploitation and conservation of the pearl banks. Some of his paragraphs deal with matters treated of above, while others are better left over for discussion in the Final Part of the Report. I give here the following headings of the chief points in his recommendations :—

Synopsis of Recommendations.

(*a.*) Improved and extended inspection.

(*b.*) The provision of a beacon on Aripu reef and the improvement of Kudiramalai Tower.

(*c.*) Transplantation on an extensive scale by means of steamer dredging whenever blank spaces occur upon the Cheval, coincident with the presence of young oysters in the neighbourhood, within a radius of 20 miles.

(*d.*) Cultching to go on concurrently with transplantation. If these operations can be carried out within the next twelve months, 500 tons of oyster shells and 300 tons of Kalpitiya stone to be provided for this purpose.

(*e.*) The thinning out of overcrowded beds by means of the dredge.

(*f.*) The cleaning of the oyster banks by means of the dredge.

(*g.*) Further investigation of the life-history of the pearl-inducing Cestode.

(*h.*) A series of drift-bottle experiments in conjunction with the Madras Presidency officials.

(*i.*) The establishment of a chank fishery on Government account and under Government management in the neighbourhood of the Aripu pearl banks.

TABLE showing the Principal Facts relating to the Oyster-population on the Pearl Banks in November, 1904—to illustrate "The Present Condition of the Pearl Banks" (p. 37).

Name of Paar.	Estimated number of oysters on the bank.	Valuation per 1000 oysters.	Age (November, 1904).	Condition.	Prospects.
South Cheval . . . South-east Cheval .	40,000,000 23,600,000	Rs. 24.65 10.76½	years $2\frac{2}{3}$ to $3\frac{1}{6}$ $2\frac{2}{3}$,, $3\frac{1}{6}$	Healthy and vigorous	Should live through two more seasons without excessive diminution in numbers.
Mid-east and South-central Cheval	13,750,000	13.21	years $2\frac{2}{3}$ to $3\frac{1}{6}$	Healthy, but smothered in young oysters	The majority will die off within the next year owing to the smothering effects of the myriads of young oysters present.
South-west Cheval .	3,500,000	—	years $5\frac{1}{2}$	Healthy for their age	Too old to live beyond 1905.
The remainder of the Cheval	Thousands of millions	—	months $1\frac{1}{2}$ to $2\frac{1}{2}$	Healthy	Good. Should furnish fisheries in future years.
North Modragam . South Modragam .	4,700,000 21,000,000	— 17.86½	years $2\frac{2}{3}$ to $3\frac{1}{6}$ $2\frac{2}{3}$,, $3\frac{1}{6}$	Unhealthy, shells and bodies diseased; those on the south smothered in young oysters	Dying off rapidly.
Periya Paar . . .	Thousands of millions	—	months $1\frac{1}{2}$ to $2\frac{1}{2}$	Healthy	Will probably disappear during the next South-west Monsoon.
Muttuvaratu . . .	20,000,000	3.16½	years $2\frac{2}{3}$ to $5\frac{1}{2}$	Stunted and diseased	Dying off gradually.

THE PRESENT CONDITION OF THE PEARL BANKS.

[*Based on Mr.* Hornell's *Inspection in November, 1904.*]

Mr. Hornell left Colombo for the Pearl Banks on October 25th, 1904, with the inspection barque "Rangasami Puravi" and the dredging steamer "Violet"—a trawler recently acquired by the Government for pearl-fishery purposes. I have received a detailed MS. report from him which has furnished the quotations and facts that form the basis of the present section.

"The actual examination of the banks was begun on the morning of October 29th and lasted with but one day's partial interruption, caused by heavy rain squalls, until November 17th, when I brought the inspection to a close and went ashore [at Marichchukaddi] to superintend the washing of the samples obtained."

This last inspection of the Cheval, Modragam, Periya and Muttuvaratu paars was evidently unusually extensive and thorough for a November inspection, and examination of the valuation records since the year 1854 shows that the number of oysters (87,500) lifted by the divers was by far the largest ever collected.

The size of these samples affords a better opportunity than usual of ascertaining the true average value of the oysters upon the different banks.

The result of the inspection is briefly as follows (see also Table opposite, p. 36) :—

1. Mature oysters, aged from $2\frac{2}{3}$ to $5\frac{1}{2}$ years, were found in quantity upon the North and South Modragam and Muttuvaratu paars, and upon the South, South-east, South-central and Mid-east sections of the Cheval Paar, together with a small and thinly covered patch remaining from last year's fishery (1904) upon the South-west Cheval.

2. Very young oysters, aged from $1\frac{1}{2}$ to $2\frac{1}{2}$ months at the beginning of November, cover the whole area of the Cheval excepting the South-west, South and South-east sections, and are also found equally abundant on the Periya Paar and the South Modragam Paar. If we estimate their age from the average size it is evident that a fall of spat covering an immense extent of ground and quite unusual in numbers must have occurred between the middle of August and the middle of September. This is a most important occurrence which, though hoped for, was not expected and could not have been foreseen. It greatly improves the fishery prospects for some years to come and diminishes the need for any immediate transplantation from the Periya to the Cheval Paar.

Details of the Condition of Each Bank.

On the South and South-east sections of the Cheval Paar (see fig. 13) is a large and continuous bed of excellently grown oysters from $2\frac{2}{3}$ to $3\frac{1}{6}$ years old. The area covered with oysters Mr. Hornell computes at 6,705,000 square yards, but as the bed extends in one direction beyond the limit surveyed we may safely calculate upon a fishable area in this one locality alone of fully 7,000,000 square yards. But even taking the former figure and reckoning the population at an average of from 16 to 26 per dive, it is estimated that this bed has a total of 63,820,000 oysters. Mr. Hornell reports that "these oysters are extremely well grown for their age and while they contain but a small proportion of cyst-pearls and therefore yield, at present, but few pearls of high individual value, they give a remarkably heavy weight of muscle-pearls, so much so that the valuation of the sample pearls ranges from Rs. 10.76 per 1000 oysters in the case of the South-east to as much as Rs. 24.65 per 1000 in the case of those from the South section —a fact accounted for by the ready sale which comparatively low-class pearls meet with locally and in India."

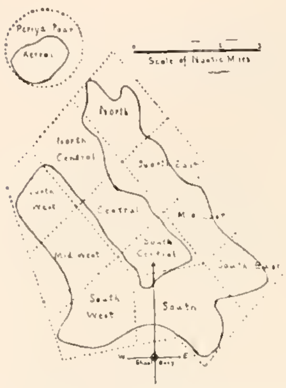

Fig. 13. Proposed culture areas recommended for the Cheval Paar and Periya Paar Kerrai.

Scarcely any young oysters are mixed with the mature individuals in this bed—a fact of some importance when considering the rotation of fishing operations. This point will be considered later on.

On the eastern part of the South-central and over the South-west quarter of the Mid-east Cheval another extensive bed of oysters occurs, continuous along the southern margin with the South Cheval bed. In area it contains about 2,300,000 square yards, bearing oysters averaging 15 to a dive, from which we estimate the number of oysters present to be fully 13,750,000. The bulk of this ground was fished, but imperfectly, in 1903, and, as a consequence, there are occasional patches of oysters nearly $5\frac{1}{2}$ years old, intermingled here and there with the younger generation, $2\frac{2}{3}$ to $3\frac{1}{6}$ years old, which forms the greater part of the bed (fig. 14). The presence of a proportion of older oysters might be thought to make the quality and value of the pearls from this locality higher than that of those from the South Cheval, but actually the valuation is only Rs. 13.21 per 1000 as against Rs. 24.65 per 1000 in the case of the latter bed. The difference seems due to a less vigorous growth upon the Mid-east Cheval, a character correlated with inferior power of nacre-secretion and consequent inferiority in the yield of pearls.

Over the whole of this bed of oysters, and extending west and north upon those portions of both sections (South-central and Mid-east) which are bare of mature oysters, myriads of the very young oysters before mentioned (now a few months old) occupy every available point of hard ground. Where older oysters are present the young ones crowd thickly upon the valves, ranging from 20 and 30 up to actually (and frequently) counted totals of 96 to 99 upon each individual. Where cultch and unoccupied outcropping rock occur every inch is crowded, the little oysters seeming to shoulder each other in their fight for vantage ground. Mr. HORNELL goes on to state: "Towards the west, upon the sandy cultch-barren stretches of the South-central Cheval, the struggle for existence among the young oysters is already intense; clusters of individuals are grouped round nuclei of absurdly small and inadequate dimensions, and often I have counted from 30 to 50 oysters in a bunch having for its centre a fragment of stone or shell no larger than a pea in size. In other cases even this may be wanting, the oysters adhering to one another."

The danger to these unstable clusters is obvious; a strong current or under-tow will sweep them hither and thither, and while this may have a certain value in possibly bringing about the stocking of bare stretches of the bank elsewhere, the dangers that these young oysters run of being swept into unsuitable localities far outweigh the advantage to be gained by wider dispersion.

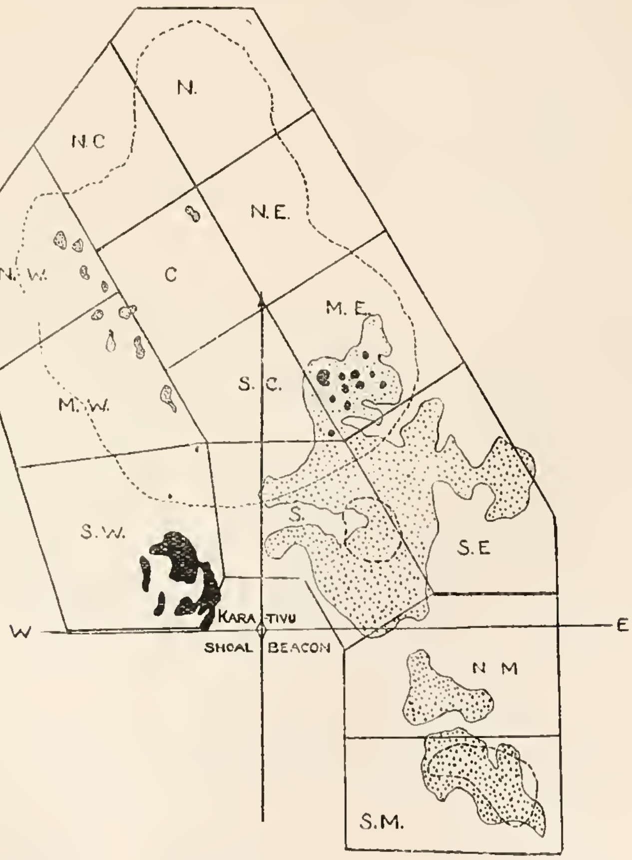

Fig. 14. Sketch-plan of the Cheval and Modragam paars, showing the distribution of pearl oysters in November, 1904. Scale: Half an inch to one nautical mile. The broken line surrounds the areas covered with spat a few months old, the dotted areas are those with oysters about 3 years old, the solid black indicates those beds of oysters over 5 years old.

No other fishable oysters in any quantity are to be found on the Cheval Paar, with the exception of an irregular and sparsely populated patch on the south-west corner of the South-west Cheval—a remnant left from the last fishery. The quantity is just under 3,500,000, reckoning the area at 1,150,000 square yards and the number of oysters per dive as 9. No spat is here present, and as there is no admixture of a younger generation, these oysters, which will be nearly 6 years old in March next, should give a high valuation in pearls. They are too unevenly distributed to permit of being dredged to any advantage. The native divers should, however, find the patch remunerative, and it will probably be found advisable to begin next year's fishery on this ground. The rest of this area (south-west) is blank, without even a trace of the very young oysters found elsewhere (see fig. 14).

The whole of the remaining sections without exception—the Mid-west, the North-west, the North-central, the Central, the North and the North-east—were everywhere packed densely in the beginning of November with very young oysters of from $1\frac{1}{2}$ to $2\frac{1}{2}$ months of age, healthy in condition, vigorous in growth, and too abundant to estimate in numbers. Indeed, so great is the profusion that Mr. HORNELL reports that "the remainder of the $2\frac{1}{4}$- to 3-year-old oysters that abundantly stocked much of this region in the early part of the present year are so masked by the covering of spat as to be unrecognisable by sight. The divers cannot distinguish between rock and old oysters; both are submerged in this young brood of oysters, and till the masses are brought to the surface the differences are not seen. Even if the quantity of old oysters were considerable, fishing under such circumstances would be well nigh impossible; but, as it is, we are saved having to face this difficulty by the fact that the North-west, Mid-west, and North-east sections have been ravaged by ray-fish (Trygonidæ) during the last few months, and the numbers of mature oysters so thinned that these regions, for all practical purposes, may be considered blank so far as concerns a fishery during the next 2 years. The prospects for an extensive fishery 4 years hence are on the other hand excellent; by that time the present spat will be old enough to be fished on those regions where growth progresses most rapidly."

On the North Modragam there is a small bed of 700,000 square yards in extent, covered with oysters of $2\frac{2}{3}$ to $3\frac{1}{6}$ years old, ranging in density from 16 to 24 per dive. This bed should yield at least 4,700,000 oysters if fished in March next. Spat is absent from the whole of this section.

The South Modragam bears a much larger bed, fully 2,200,000 square yards in area. At 24 oysters per dive the present population is estimated to be about 21,000,000. Unfortunately for fishing operations, very young oysters (spat) are extremely abundant, and may prove somewhat troublesome to the divers, as practically every old oyster will have to be, at the least partially, stripped of its load of young. Mr. HORNELL recommends that "fishing operations should be hastened as much as possible so far as this bank is concerned, as the health of the fishable generation is far from satisfactory. The oysters are thin and the shells of a large proportion are so diseased that if not fished within the next 4 months I shall expect to find the bank cleared of this generation in March, 1906. The age is the same as of those on the North Modragam."

The only other bank where, from our previous observations, there was the remotest possibility of finding fishable oysters is the Muttuvaratu Paar, lying off Dutch Bay (see Map. Mu., fig. 15). Three days were devoted to the inspection of this, with the

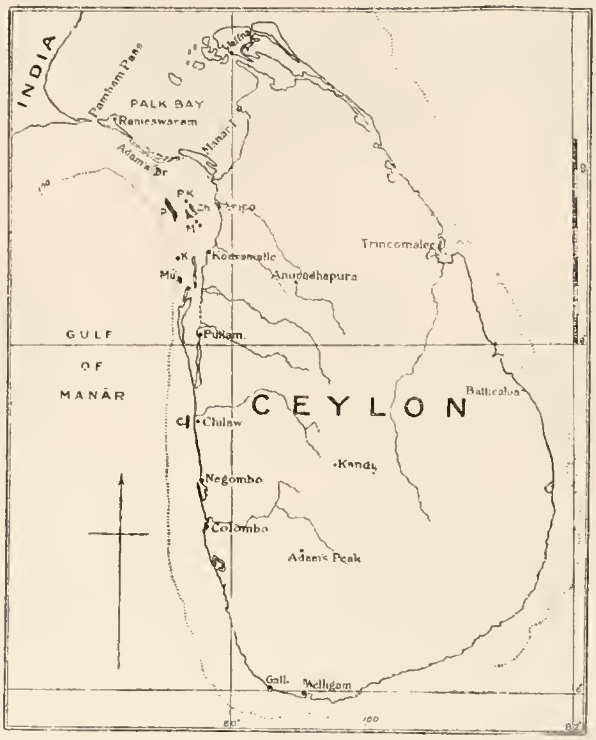

Fig. 15. Sketch-map showing the principal pearl-oyster banks in the Gulf of Manaar. C., Chilaw Paar; Ch., Cheval Paar; K., Dutch Modragam and Karativo paars; M., Modragam Paars; Mu., Muttuvaratu Paar; P., Periya Paar; P.K., Periya Paar Kerrai.

result that Mr. HORNELL estimates the number of oysters thereon, aged from $2\frac{2}{3}$ to $5\frac{1}{2}$ years, to be about 20,000,000. "All are stunted in outward appearance, the shells both small and unhealthy, covered and distorted in many cases with a parasitic growth of coral, while the substance is riddled and tunnelled by boring sponges, molluscs, and worms. The soft parts are in like condition, miserably thin and sickly, and many are obviously diseased." It is therefore not surprising to find that the sample of 10,000 average individuals which was collected by the divers on November 11th yielded only a very small quantity of pearls, valued at Rs. $3.16\frac{1}{2}$ per 1000 oysters.

The valuation of the same bank of oysters in the previous November (1903) gave Rs. 1.50 per 1000, so, as the value has more than doubled in the twelve months, there is the possibility that a remnant might provide a small fishery in 1906 if oysters be then scarce elsewhere. The only remaining bank inspected was the

Periya Paar. An examination of this remarkable region during the progress of the fishery of 1904* showed the entire extent to be densely packed with untold millions of young oysters from $1\frac{1}{2}$ to 3 months old. At the present time but a few handfuls of these survive; the others have, as usual, disappeared, having been no doubt swept from the bank into deep water or buried in sand during the turmoil of the south-west monsoon. Their place is, however, now taken by a new generation of young oysters of the same age as those so plentiful upon the Cheval Paar. They will be of excellent size for transplantation in March next, if there be then need of such an operation. If not utilised they must inevitably share the usual fate of oysters on this bank, and will without doubt disappear during the next south-west monsoon.

Enemies of the Pearl Oyster.

Mr. Hornell reports that "Oyster-eating fishes are at present abundant on the banks. Numbers of 'Kilati' (*Balistes mitis*, chiefly) and of 'Vellamīn' (*Lethrinus nebulosus* and other species) were caught by the crew whenever we anchored upon spat-covered ground, and unmistakable evidence of their diet was given by the stomach contents. In the stomach of one *Balistes* which I examined there was found a minute pearl."

The quantity of young oysters is, however, sufficient to afford ample margin of safety from such dangers, and with another 6 months' growth the shell will be sufficiently strong to give protection against these particular enemies. "Greater danger threatens from the huge ray called 'Walwadi tirikkai' by the Tamil fishermen (*Rhinoptera javanica*). This fish can destroy the strongest-shelled oyster, and so great is its appetite and the capacity of its mouth and stomach that a shoal is capable of destroying an entire bed of oysters within a few weeks or even days, as witness the destruction of the fine bed of oysters on the Periya Paar Kerrai, which was found to be in progress at the time of the fishery of 1903.† During the recent inspection traces of widespread havoc from this cause were much in evidence over the northern sections of the Cheval Paar, and this enemy is responsible for the greater part of the reduction in numbers of the younger generation of oysters so abundant on this area in March last."

The region of the bank in question is notably deficient in natural cultch, and till this defect is remedied this and other similar parts of the Cheval and Modragam paars must always be more or less subject to ravages and losses, even to the extent of occasional total destruction of a bed and the consequent failure of expected fisheries.

The boring sponge, *Cliona margaritiferæ*, Dendy, is doing great harm to the oysters of the Modragam paars. On these banks there is also an excessive abundance of

* See this volume, p. 28.

† See this Report, Part II., p. 25.

shell-tunnelling annelid worms (*Polydora*), of boring molluscs (*Lithodomus*), and of encrusting and enveloping sponges. This combination of parasites has induced in the oysters a weakly condition which doubtless predisposes to disease. "As a consequence the oysters here are sickly, the rate of mortality is increasing, and comparatively few are likely to survive to 1906. Star-fishes are also abundant on this bank and are aiding in the destruction of this bed of oysters."

On the Periya Paar, where very young oysters are plentiful, small carnivorous gastropod molluscs (*Sistrum* and other genera) are unusually abundant, and are causing, by boring through the shell, the death of considerable numbers of the young oysters. On the Cheval Paar they are less numerous, and, speaking generally, there is, saving for the great rays, no special or dangerous abundance of oyster enemies upon this the most important bank.

Valuation Results.

The exceptionally great number of oysters collected at this inspection was made up as follows :—

40,000	from the	South Cheval Paar.
15,000	,,	Mid-east Cheval Paar.
6,000	,,	South-east Cheval Paar.
1,500	,,	North-west Cheval Paar.
15,000	,,	South Modragam Paar.
10,000	,,	Muttuvaratu Paar.
87,500		

Mr. Hornell reports that "One-half (20,000) of the South Cheval sample was given to Mr. G. G. Dixon to be treated by his oyster-washing machine for comparison with the other half, which was to be hand-washed and hand-picked in the ordinary manner.* In addition, one bag containing 750 of the South-east Cheval oysters was handed by mistake of the landing boatmen to Mr. Dixon, who will account for it. All the rest of the samples which I collected were washed in the ordinary way by the divers and munducks."

The result shows that the two highest valuations were yielded respectively by the South Cheval and the South Modragam, the former being worth Rs. 24.65 per 1000 oysters, the latter Rs. 17.86½ per 1000. In the case of the former (higher) valuation the result is due to the great *weight* of pearls present, in the latter to the comparatively high value of the individual pearls. The one gives quantity, due to an unusual abundance of muscle-pearls, the other quality, owing to fine cyst-pearls being present in a higher ratio than in the former case.

* See this volume, p. 6.

Regarding the 40,000 oysters from the South Cheval Paar washed for comparison, half by hand and half by Mr. DIXON in his machine, Mr. HORNELL reports that "the half washed by hand gave a valuation of Rs. 24.65 per 1000 oysters as against Rs. 16.79 in the case of the machine-washed. The weight of pearls from the machine-washed oysters was also markedly inferior, being but 7 manchadi per 1000 as against a weight of a little over $11\frac{1}{20}$ manchadi in the case of the hand-washed."

Mr. HORNELL adds: "Lest it should be thought that the two lots might have been taken from different localities, I wish to state that the whole 40,000 oysters were lifted on the same days and from the same parts of the bank. They were originally all piled on the deck of the inspection vessel, bagged under my supervision, and sent ashore in one lot. The final division after being landed was carried out by Mr. SAUNDERS, Assistant Government Agent, Manaar, and by Mr. G. G. DIXON conjointly, I not being present."

FISHERY PROSPECTS AND RECOMMENDATIONS.

As the result of this inspection in November, 1904, Mr. HORNELL reports that at the present time there are available for fishing the following oysters, all yielding a pearl valuation above Rs. 10 per 1000, the minimum at which it is considered profitable to fish a bank, viz.:—

Paar.	Estimated number of oysters.	Value per 1000.	Age next March.
		Rs.	years.
South Cheval	40,220,000	24.65	3 to $3\frac{1}{2}$
South-east Cheval	23,600,000	$10.76\frac{1}{4}$	3 ,, $3\frac{1}{2}$
Mid-east and South-central Cheval	13,750,000	13.21	3 ,, 6
South-west Cheval	3,500,000	—	$5\frac{1}{2}$,, 6
North Modragam	4,700,000	—	3 ,, $3\frac{1}{2}$
South Modragam	21,000,000	$17.86\frac{1}{2}$	3 ,, $3\frac{1}{2}$
Total	106,770,000		

The highest recorded number of oysters landed at any one fishery has been 44,311,441 in 1891. At the utmost we could not hope to lift above 50,000,000 at the next fishery and this would therefore leave rather more than half the number to fish in 1906. Thus the number of fishable oysters appears amply sufficient to give two large fisheries in 1905 and 1906 respectively and possibly a small one in 1907. This can probably be brought about, if a careful watch be kept upon the banks and if we take note of the various biological contingencies likely to menace the different beds of oysters during the next 18 months. Mr. HORNELL recommends that the order in which the banks should be fished be as follows, provided the inspection of

February next shows the position of matters to be much the same as at present, viz. :—

In 1905—(*a.*)	3,500,000	oysters	on the	South-west Cheval,
(*b.*)	21,000,000	,,	,,	South Modragam,
(*c.*)	4,700,000	,,	,,	North Modragam,
(*d.*)	13,750,000	,,	,,	Mid-east and South-central Cheval.
Total . .	42,950,000	oysters,		

leaving for 1906 and 1907 the unmixed oysters now aged between $2\frac{2}{3}$ and $3\frac{1}{6}$ years upon the South and South-east Cheval.

The 40,000,000 oysters on the South Cheval are, with the exception of the small patch of $5\frac{1}{2}$-year-olds on the South-west Cheval, the richest in pearls at the present moment, and it might be thought that Mr. HORNELL was assuming a grave responsibility in advising the postponement for a whole year of a fishery upon this bank. It must be remembered, however, that the section of the Cheval in question is very reliable, and has scarcely ever disappointed the hopes of the authorities. There are also the following special reasons for the course recommended :—

(*a.*) The Modragam oysters are unhealthy and liable to die off in great numbers within the next 12 months.

(*b.*) The South-west Cheval oysters, being nearly 6 years old, have all but reached the span of oyster existence, and, though as yet fairly healthy, cannot be expected to survive to 1906, when they would be nearly 7 years of age.

(*c.*) The oysters on the Mid-east and South-central Cheval are so densely covered with very young oysters, a few months old, that, judging from the results of similar competition seen repeatedly elsewhere during the last 3 years, the inevitable consequence will be that in a year's time, or even less, the growth of such enormous numbers of young will smother and kill off so large a proportion of the old that the bed will cease to be one of mature or fishable oysters. Fishing on this bed will, therefore, only be possible if carried out within the next 3 or 4 months. If fished within this time the bulk of the young oysters could be returned to the sea, and the bank will then be one of young oysters holding out good prospects of a fishery in 1908 or 1909.

The above are arguments in favour of fishing certain banks first. Those against immediate fishing on the South Cheval and the South-east Cheval are :—

The oysters on these two beds are at present in a healthier condition than those on any of the others; their growth is vigorous and they are not overcrowded with young oysters. The oysters are clean and wholesome in appearance, food is plentiful, and, so far as we know, no harmful agencies are present in a marked degree. These oysters offer every prospect of being able to survive till 1906—which cannot be said of any other bed of mature individuals now known.

In the case of the South-east Cheval there is also the obvious additional argument against fishing in 1905, derived from the small pearl yield given by the present valuation sample; a year's growth would, no doubt, result in an enhanced pearl value.

On the other hand, there is, of course, always a certain risk in leaving a fishable bed of oysters unfished, and, once the biological facts given above have been stated, it lies with the Government to decide what risk can be run and what course should be taken. If the 40,000,000 oysters on the South Cheval Paar, or a considerable number of them, can be fished in addition to the 43,000,000 which certainly ought to be secured first, there will, no doubt, be a large additional profit now—a present certainty in place of the prospect of a possibly much greater result next year.

Summary of the Prospects of Fisheries from 1905–1909.

The following forecast assumes (*a*) the adoption of the suggestion made above as to the order in which the banks be fished; (*b*) that extensive cultching operations be undertaken next year to improve the purely sandy areas; and (*c*) that no exceptional catastrophe happens, such as an inroad of rays or abnormal weather conditions.

1905.—A fishery numerically as extensive as that of 1904, to be held on the North and South Modragam paars, South-west Cheval Paar, Mid-east Cheval Paar, South-central Cheval Paar. [Possibly also the South Cheval Paar.]

1906.—A fishery of large extent upon the South and South-east sections of the Cheval Paar. [Unless the South be fished in 1905.]

1907.—A small fishery on the same grounds and possibly upon some small patches elsewhere.

1908.—A portion of the Northern and Central thirds of the Cheval Paar now covered with young oysters, if the pearl yield be then found sufficiently high to give a remunerative return.

1909.—A fishery upon the remainder left from the preceding year's fishery.

That accounts for all the beds of oysters, old and young, now in sight. During these five years other deposits of spat may fall upon reliable paars such as the Cheval. If not, young oysters for future fisheries must be transplanted from the Periya Paar, where they will no doubt be present in abundance from time to time.

Culture of the Banks.

In various parts of this Report Mr. Hornell and I have urged the necessity of transplanting large quantities of young oysters by means of a dredging steamer, in the event of no fall of spat occurring in the immediate future upon the unoccupied sections of the Cheval Paar. Accordingly, on setting out upon the past inspection, Mr. Hornell was authorised to employ the dredging steamer "Violet" for this purpose if, upon examination of the banks, he still considered this procedure necessary, and provided the conditions on the Periya and Cheval paars respectively were found suitable. Nature, however, proved unexpectedly generous; the last spatting season (August to September, 1904) must have been unusually bountiful, and the currents favourable, as the result has been that all the great blanks on the Cheval Paar and elsewhere have been filled up with young oysters in profusion.

The need for transplantation in consequence of this quite exceptional spat-fall has ceased to be urgent for the present season. The Government has been saved the considerable outlay which transplantation on the scale contemplated would have entailed. The dredging steamer consequently became available at the inspection for fishing mature oysters, and means were thus provided to supply Mr. G. G. DIXON with large numbers of oysters for experimental washing in the machine devised by him for this purpose. It must not be thought, however, that the necessity for transplanting has disappeared altogether. It is only postponed for a season, and might become urgent again at the next inspection if, for example, it were found that any catastrophe had occurred to the young oysters over any large section of the Cheval Paar. The Inspector of the Pearl Banks should be authorised to transplant from the Periya Paar whenever he may find it necessary.

The spat-fall has taken place equally upon sandy and upon rocky ground. That upon the latter may for the present be safely left without special attention, but the deposit upon the sandy areas requires careful nursing if it is to be brought to maturity and yield a fishery. The prime necessity is extensive cultching operations, the enriching of the surface of the sandy wastes of the South-central and North-east Cheval especially with large quantities of fragmentary hard material in order to furnish foothold to a few, at least, of the many millions of young oysters now existing there in a very precarious condition. These young oysters have upon such sections of the bank but few opportunities to make attachment to any fragments of a size and weight sufficient to resist the strength of the bottom currents during even moderately severe monsoon weather. They are liable at such times to be swept from the banks, more especially during the first two years of existence, when the shells are still light in comparison with their bulk, and when the small bunches into which they are aggregated are of just the right form to permit of their being readily rolled along the level stretches of the sandy areas till they finally perish.

Time and opportunity did not permit of the adoption during this last inspection of active measures for the protection of these young oysters upon anything approaching an adequate scale. All that Mr. HORNELL could do was to take from the beach at Marichchukaddi a quantity of nullipore balls (*Lithothamnion*, see fig. 16), dead coral and broken calcrete ("paar-rock") and spread that hard material over a small portion of the South Cheval area. He also directed the Master of the dredging steamer to instruct his crew to break up all large masses of rock and coral that came up in the dredge and to return the fragments to the sea. This is being done at present, and if carried out consistently will go some little way towards effecting what is desired. Much more active measures must, however, be taken to ensure an immediate improvement of the ground, and to save the spat now on the sand a great deal of cultching work must be done during the next three months.

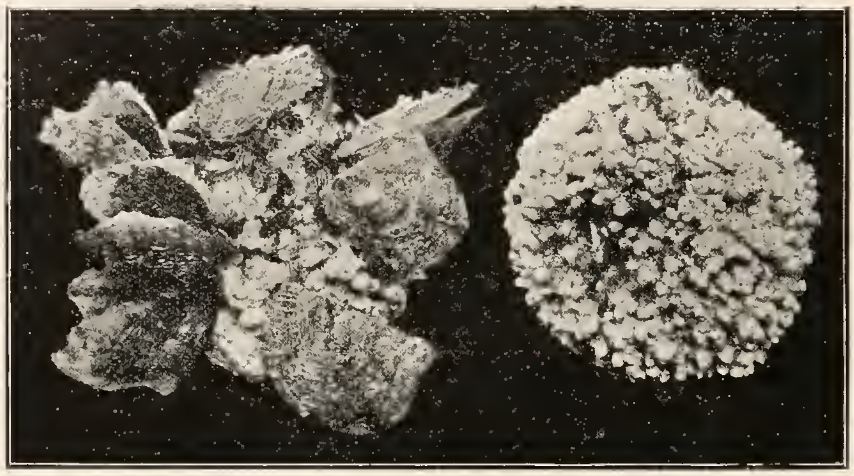

Fig. 16. Natural cultch (*Lithothamnion*) and, to the left, a similar Nullipore ball with a dozen young pearl oysters attached.

The cultching operation which Mr. Hornell has recommended to the Ceylon Government, and which I entirely approve of, is the disposal annually, for the next few years, of a quantity amounting to not less than 500 tons of rubble, carefully broken to a standard size of $3\frac{1}{2}$ inches $\times$ $3\frac{1}{2}$ inches $\times$ $2\frac{1}{2}$ inches, upon the South-central and North-east sections of the Cheval Paar. If it be possible to get any broken or waste tiles and bricks, such material is preferable to stone rubble and should be utilised so far as obtainable. The cost delivered on the banks of the above quantity should not exceed Rs. 1500, an insignificant sum compared with the enormous return in the form of oysters saved from destruction which we should reasonably expect to receive from this outlay. This quantity should, however, be regarded as the minimum annual amount; a much larger deposit of cultch would probably well repay the increased expenditure.* The ravages of ray-fish have been great during recent months upon some parts of the Cheval Paar, and it should be mentioned that the efficient strewing of rubble over the ground is probably one of the most feasible methods of stopping their depredations.

This section may appropriately end with a reference to the tabular statement on p. 36, drawn up by Mr. Hornell to show the present condition of the beds of oysters on the principal pearl banks.

* As this goes to the printer, I have received the information that the Ceylon Government has very wisely decided upon the larger measure of cultivation. Rs. 5000 in place of Rs. 1500 has, I understand, been placed upon the estimates to meet the expense of this year's cultching operations.

FURTHER REPORT ON PARASITES

FOUND IN CONNECTION WITH THE

PEARL OYSTER FISHERY AT CEYLON.

BY

ARTHUR E. SHIPLEY, M.A., F.R.S.,
FELLOW AND TUTOR OF CHRIST'S COLLEGE, CAMBRIDGE,

AND

JAMES HORNELL, F.L.S.,
MARINE BIOLOGIST TO THE CEYLON GOVERNMENT AND INSPECTOR OF PEARL BANKS.

[WITH ONE PLATE.]

THE following short Paper is based on material collected by Mr. HORNELL largely from Elasmobranchs which frequent the Pearl Beds of Ceylon. The specimens unfortunately arrived too late for our account of them to be incorporated in the article on the "Parasites of the Pearl Oyster," published in the second volume of this Report, but as some of the forms are new and the Cestodes may possibly, though perhaps not probably, be the parent form of the pearl-producing larvæ, it has seemed advisable to publish this further instalment. Unfortunately our further researches throw no direct light on the problem of the *provenance* of the pearl-producing parasite.

I. CESTODA.

Staurobothrium ætiobatidis, n. gen. et sp.—Plate, figs. 1 and 2.

A considerable number of tapeworms, with large cruciform heads, were taken from the intestine of the Bird or Cockle-eating Ray, *Ætiobatis narinari*, MARCG., at Marichchukaddi, the centre of the recent pearl fishery.

The head has the form of a cross with very short broad arms (Plate, fig. 1). Each arm ends in a sucker which, however, does not penetrate far into the arm, and whose lumen is rather shallow. From the centre of the cross posteriorly arises the trunk, whilst anteriorly the centre bears usually a slight papilla with rings round it; the distinctness and size of this latter varies, however, greatly with the state of contraction of the specimen (Plate, fig. 2). In some specimens the head was swollen, and then its longitudinal diameter equalled its greatest transverse diameter, but, as a rule, the transverse axis is three times the length of the antero-posterior. There is no armature. Also there is no neck, the strobilization commencing immediately behind the head. The proglottides are at first many times as broad as long, but these proportions alter as we pass backward, and at the posterior end of the body they are perhaps one and a half times as long as they are broad. Each proglottis has a very well marked salient posterior border, and their shape and relative size at different regions of the body are well shown in fig. 1. Altogether there are about 100 proglottides, and the whole tapeworm measures on an average 1·5 centims. in length, and about 0·5 millim. to 0·7 millim. in breadth where it is broadest. These tapeworms were, when preserved in formalin, stout and stiff, with well cut outlines.

In transverse sections the proglottides are circular, and the genital pore opens for, at any rate, some consecutive proglottides on the same side, if one may speak of the side of a cylindrical body. It was not possible to make out details of the sexual organs beyond this fact, and that the uterus in the posterior proglottides is follicular.

As it has been impossible to find any figures or descriptions which correspond at all closely with this animal, we have ventured to establish a new genus which we propose to call *Staurobothrium*, and since it is found in the Bird Ray, I suggest the specific name of *ætiobatidis*. The name *Staurocephalus* would better have fitted the facts, but unfortunately it has been used before.

The formal definition is as follows:—

Staurobothrium, n. gen.

Cestode with large cruciform head, without hooks, genital pore lateral, no neck.

Staurobothrium ætiobatidis, n. sp.—Head without hooks or any armature, it consists of four well marked arms projecting from a centre, like the arms of a Maltese cross; each arm ends in a shallow sucker; anteriorly where the arms meet is a low annulated papilla representing the rostrum, but, as said above, there are no hooks. There is no neck. Each proglottis overhangs the one which succeeds it by salient angles forming a funnel-shaped skirt. The genital opening is on one side. The uterus, when full of ova, is follicular. The average length of the worm, with about 100 proglottides, is 15 millims., the average width from 0·5 millim. to 0·7 millim.

The systematic position of this Cestode is obscure. In structure the head superficially resembles that of *Cylindrophorus*, Dies., but it bears no hooks. Very little change would be required in the architecture of the head to turn *Staurobothrium* into the *Calyptobothrium* of Monticelli, but the terminal sucker of the latter is absent in the new genus. In this respect it differs also from Linton's genus *Crossobothrium*. On the whole I think we are justified in placing *Staurobothrium* in the family Phyllobothriidæ, and not very far from the genus *Phyllobothrium*, van Ben.

Tetragonocephalum trygonis, n. gen. et sp.—Plate, figs. 3, 4, 5, 6, 7 and 8.

A number of very minute Cestodes were found in the alimentary canal of *Trygon walga*. It frequently happens that most delicate tapeworms are found in the most powerful and voracious Elasmobranchs, and nothing could be more delicate and fragile than the Cestodes in question. The worms are fragile, and very limp when preserved in formalin. They do not lie stiff and distinct as do those described above from *Ætiobatis narinari*, but they are entangled together and form a mass like a knot of chewed fine white cotton thread (Plate, fig. 3).

The head forms a distinct knob, hardly more than visible to the naked eye, borne on the slender neck. Its diameter is some 0·03 millim. and its antero-posterior axis is nsually rather less than its diameter from side to side. In some specimens, as in the one shown in fig. 3, the head is swollen, and its longitudinal axis is longer than its transverse. It is a cnrious cushiony-looking head, consisting of two distinct parts. Anteriorly there is a circular and rounded knob, about twice as broad as it is long and resembling in shape the stones which are used in the Scottish sport of cnrling. This probably corresponds with the rostellum of other forms. It is quite unarmed (Plate, fig. 4). This rounded rostellum rests on a second region like a crown upon a cushion. This second region is square in outline, and at each of its corners it carries a small bnt distinct sncker, the orifice of which is minute. From these suckers small papillæ protrude, passing through their orifice. The rostellum is separated from the sqnare sucker-bearing portion by a thick basement membrane, and it is traversed by many muscle bundles. Similar bundles are attached to the hinder surface of this basement membrane and run down into the neck, where they soon fade away.

The neck is short, and the narrow strictures separating the nascent proglottides commence close behind the head. The constrictions between the proglottides always remain slight; the older proglottides somewhat resemble those of *Dipylidium cucumerinum*, but are less distinct and, except for the slightest possible thinning between adjacent proglottides, the posterior part of the Cestode, after it has attained a certain dimension, remains the same width throughout. At the same time, every here and there there are constrictions which do not seem to correspond with the divisions between proglottides. These are well shown in Plate, fig. 3.

The reproductive apertures are lateral, and the penis lies concealed in a spacious recess (Plate, fig. 6). The pores irregnlarly alternate, some four being in the left followed by one or two on the right, then a few on the left and again perhaps four on the right. At its first appearance the nterus seems double, an anterior and a posterior part lying one in front and one behind the genital pore; the two are, however, in communication by a narrow channel (Plate, figs. 5, 6 and 7). The whole uterus in the ripe proglottides is thus somewhat dumb-bell-shaped, the narrow part being pinched in by the cirrus bulb. The ova are slightly oval.

At first it might be thought that we had to do with a tapeworm of the same genus as LINTON'S *Lecanicephalus*, but on referring to his description* and figures it is evident that this can hardly be the case. LINTON describes the head as "consisting of two disciform plates," but he figures a round anterior part lying in the foremost plate. The figure is very poor and we may be wrong in this interpretation, which, however, is strengthened by his comparison of *Lecanicephalum* with the *Discobothrium* of VAN BENEDEN, for in this genus the head is divided into three distinct parts. The disks of *Lecanicephalum* are nearly circular, and the posterior bears four suckers, but there is no mention of any papillæ projecting from them. VAN BENEDEN'S genus *Discobothrium* found in *Trygon pastinaca* is figured, but not described by him.† It has two distinct circular disks, corresponding with the rounded anterior part and the first disk of *Lecanicephalum*, and then a thicker somewhat cruciform disc with very salient angles which terminate in suckers. Our specimen has the anterior round part—the curling stone as we have described it—resting on a quadrangular cushion with suckers at the angles. On the whole it seems that we must describe it as a new genus, and this we do under the name *Tetragonocephalum*, from the square cushion which forms the larger part of the head.

Tetragonocephalum ætiobatidis, n. sp.—Plate, figs. 9 and 10.

A single specimen of another Cestode of apparently the same genus was found with those described above in *Ætiobatis narinari*. Its length was 1·3 centims., and its breath, which was remarkably uniform behind the head, was 0·5 millim. (Plate, fig. 9). The head was three times this breadth and consisted of a rostellum, long and conspicuous and unarmed, and of a swollen base, squarish in cross-section, with four small suckers at the anterior angles (Plate, fig. 10). Posteriorly the basal portion overlapped the anterior proglottides. There is no neck, but the proglottides appear immediately after the head, at first very narrow but with marked constrictions; as they increase in size the posterior angle becomes salient, less so, perhaps, than in *Staurobothrium ætiobatidis*, but more so than in *Tetragonocephalum trygonis*. The last three proglottides are twice the length of those which immediately precede them and this growth is somewhat sudden.

The head, though it differs greatly in its proportions, resembles in essentials the head of *T. trygonis*. The marked saliency of the posterior edge of the proglottides separates off the species in question from the species which inhabits *Trygon walga*. As there was but a single specimen, it did not seem advisable to cut it, and as it was preserved in osmic it was not possible to make out anything of the internal anatomy.

The definition of this genus is as follows:—

* 'U.S.A. Commission of Fish and Fisheries,' 1891, p. 802.

† 'Mem. Ac. Belgique,' xxxviii., 1871.

Tetragonocephalum, n. gen.

Head unarmed, consisting of an anterior knob-like portion arising from a cubical base; the four posterior corners of the cubical base have minute suckers, each with a papilla.

This genus would be a member of the family Lecanicephalidæ, and would probably come not very far from the genus *Lecanicephalum*, LINT., in BRAUN'S classification given in BRONN'S "Thierreich."

The species above described may be formally defined as follows:—

Tetragonocephalum trygonis, n. sp.—Fragile, minute, head hardly visible to the naked eye; length of body 2–4 centimetres: in section the head is circular and the proglottides almost so, their greater diameter being 0·03 millim.; head consisting of a curling-stone-shaped anterior portion resting on a square cushion with suckers at each corner from which a papilla protrudes; neck short; furrows between contiguous segments very slight and in some places invisible; reproductive pores lateral and irregularly alternate; genital recess large, and the remains of this constrict the ripe uterus into a dumb-bell-shaped structure.

Tetragonocephalum ætiobatidis, n. sp.—Minute head not much more than visible to the naked eye; length of body and head 1·5 centims.; head consists of an elongated rostellum, unarmed, which projects freely from an almost cubical base, this base is as long or longer than it is broad; at its anterior angles it bears four small suckers; there seems to be no, or at most a very short, neck; the proglottides overlap.

II. TREMATODA.

In the following account of two Trematodes, one from *Balistes* sp. and the other from either a species of *Carcharias* or *Rhinodon typicus*, the "basking shark"* of tropical waters, we are much indebted to Mr. NORMAN MACLAREN both for notes on the structure of the animals and for the drawing of fig. 11 on our Plate.

Distoma palleniscum, n. sp.—Plate, fig. 11.

This Trematode comes very near *D. pallens*,† but differs from it in having certain peculiarities which seem of specific rank. *D. pallens* was found in *Chrysophrys aurata*, CUV., by the authors mentioned in the footnote, and by LINTON in *Alutera*

* There is some doubt as to the host represented by the "basking-shark." The "basking-shark" of the Indian Ocean, according to the books, is the rather rare *Rhinodon typicus*, but Professor HERDMAN'S recollection is that the term was applied by the sea-going men to a *Carcharias*. A drawing of one of these sharks caught on the pearl banks has, however, been identified by Mr. BOULENGER as *Stegostoma tigrinum*.

† RUDOLPHI, 'Entozoorum Synopsis,' 1819, pp. 111 and 410; DUJARDIN, 'Hist. Nat. d. Helminthes,' pp. 457 and 458; DIESING, 'Syst. Helm.,' vol. 1, p. 348; STOSSICH, 'Saggio di una Fauna Elmint. di Trieste,' p. 47; 'LINTON, 'Proc. Nat. Museum,' vol. 20, pp. 526 and 527, plate xlvii., figs. 8 and 9.

schæpfii. The present species is from the intestine of *Balistes* sp., the File- or Trigger-fish found on the Ceylon pearl banks (Plate, fig. 11). The distoma is characterised as follows:—Length 5 millims.; perfectly smooth skin; anterior sucker almost globular, with a relatively small mouth; the pharynx does not directly abut on the anterior sucker; œsophagus wide; digestive cæca reach to posterior end; yolk-glands extraordinarily prominent, arranged in 2 rows, one on each side and behind the testes; the shell glands and receptaculum seminis not easy to distinguish, but they lie anterior to the ovary; the termination of the vas deferens is apparently eversible and is probably used as a penis; a definite penis is absent; numerous glands surround the terminal parts of both the male and the female ducts.

This species seems to differ from the *Distoma pallens* of RUDOLPHI in the facts (i.) that the ventral sucker is not twice the size of the oral, (ii.) the aperture of the ventral sucker is rounded and is not a transverse slit, (iii.) the ovary is not globular, (iv.) the yolk-glands are prominent and arranged in two rows.

Distomum richiardii, LOPEZ.

Many specimens of this elegant little Trematode were taken from the perivisceral cavity of *Rhinodon typicus.* The species has recently been described by MONTICELLI,* who has found it in the body-cavity of *Acanthias vulgaris* and more rarely in *Mustelus vulgaris* and *Myliobatis aquila*, in the Bay of Naples.

III. NEMATODA.

Cheiracanthus spinosissimus, n. sp.—Plate, figs. 12 and 13.

Length 13·7 millims., breadth 0·45 millim.; œsophagus $\frac{1}{15}$, and the conical tail, which is round quite at the end, is $\frac{1}{31}$ of the whole body-length; cuticle 0·022 millim. thick, tough, transversely wrinkled; head end rounded like the mouth of a Turkish pipe (Plate, fig. 12); four tongue-like projections pointing backwards in the intermediate areas; 30 to 33 transverse rings, each consisting of some hundreds of spines; six lips around the mouth; four neck glands of $\frac{2}{3}$ to $\frac{3}{4}$ the length of the œsophagus, in front these are thin, with two swellings, but they thicken behind and contain spiral muscles; intestine dark brown; the tail has on each side two præ-anal and four post-anal papillæ, arranged as shown in fig. 13; the papillæ in outline resemble a skittle; cirri equal and 0·7 millim. long.

This Nematode was obtained from *Myliobatis aquila*, in the Gulf of Manaar.

This above definition has been furnished by Dr. VON LINSTOW, who kindly undertook to investigate the *Cheiracanthus.* He adds that this new species differs from *C. unicinctus* both in its head and in its neck glands.

REPORT

ON THE

SPONGES

COLLECTED BY

PROFESSOR HERDMAN, AT CEYLON, IN 1902.

BY

ARTHUR DENDY, D.Sc., F.L.S.,

PROFESSOR OF ZOOLOGY IN THE SOUTH AFRICAN COLLEGE, CAPE TOWN.

[WITH PLATES I. TO XVI.]

INTRODUCTION.

CONSIDERING the frequent opportunities for collecting which have been afforded by the Pearl Fisheries of Ceylon, it is remarkable that our knowledge of the Sponge-Fauna of this locality, rich and varied as it is, should so long have remained in so backward a condition. In 1887, Mr. RIDLEY and I (1)* called attention to this fact in our Report on the Monaxonida collected by H.M.S. "Challenger," but as the "Challenger" unfortunately did not visit Ceylon, the results of that memorable voyage did nothing towards improving matters in this respect. In the same year, however, as that in which our "Challenger" Report was published, I was able to report (2) also upon a collection of sponges from Madras, made by Mr. EDGAR THURSTON, the Superintendent of the Government Central Museum, and again in 1889 I reported (3) on a second collection of sponges made by the same Zoologist in the Gulf of Manaar. In this way considerable additions were made to our knowledge of the Sponge-Fauna of Ceylon and Southern India, but Mr. CARTER's papers (4, 5) on the sponges collected in the Gulf of Manaar by Captain W. H. CAWNE WARREN still remained the principal works on the subject; a very remarkable fact, when we remember the extraordinarily

* The numbers in brackets refer to the List of Literature at the end of the Report.

small bulk of the material which he investigated and amongst which he found altogether something like 70 species—a notable addition indeed to the 13 or so previously described from the same neighbourhood by Esper (**6**), Haeckel (**7**), Bowerbank (**8**), and Holdsworth (**9**).

The collection of sponges (146 species) made by Professor Herdman is, however, far more extensive than any previously obtained in Ceylon waters, and includes not only a large proportion of the species already described by the authors mentioned, but also a considerable number (77 species) of new ones, some of which are of very great interest. With the exception of the Calcarea, which are singularly few in number, and of the Hexactinellida, which are, of course, a deep-water group and not likely to be met with in the neighbourhood of the pearl banks, the collection contains representatives of practically all the important sub-divisions of the Phylum. In dealing with so large a mass of material, the question of classification has assumed a very formidable aspect, and I have found it desirable to make certain modifications in this respect which I hope may be regarded as improvements. These modifications will be duly explained, and I hope justified, in the proper place.

Since, in spite of the enormous advances which have been made during the last twenty years in our knowledge of the sponges, our ideas as to taxonomy are not yet by any means in a settled condition, I have considered it desirable to give brief diagnoses of the various sub-divisions with which I have to deal, in order that there may be no mistake as to the sense in which I employ them. We are, undoubtedly, progressing rapidly towards a satisfactory and natural classification of the group, but the problem is an extremely difficult one, and every new collection of any considerable extent, such as the present, must for a long time to come necessitate more or less modification of existing views. The classification which I have adopted may at present be regarded as the latest of these modifications, based principally upon the writings of Sollas, Ridley, Lendenfeld, Topsent, and myself. Topsent, in particular, has done much in the last few years both in arranging and classifying the chaotic mass of information left by earlier writers, and in making notable additions to our systematic knowledge of this difficult but interesting group.

In order to facilitate reference to the type specimens by future workers and to make the systematic portion of this report as precise as possible, I have adopted the system, already employed in my Catalogue of Non-Calcareous Sponges collected by J. Bracebridge Wilson, &c. (**10**), of giving at the end of the description of each species the Register Number (R.N.), which I have attached to each specimen. This method also has the great advantage of enabling one to refer readily to individual specimens in the text.

At the conclusion of the Report I propose to give as complete a list as possible of the Sponge-Fauna of Ceylon and to discuss the problem of Geographical Distribution. In the meantime I append a list of the principal memoirs dealing with the subject arranged in chronological order.

Special Bibliography of the Ceylon Sponge-Fauna.*

1798–1806. Esper.—"Fortsetzung der Pflanzenthiere," Part 2.

1870. Ehlers.—"Die Esper'schen Spongien." (In this memoir the author re-describes two Ceylon species.)

1872. Haeckel.—"Die Kalkschwämme." (This work includes descriptions of half a dozen species of Calcareous Sponges collected by Wright in Ceylon waters.)

1873. Bowerbank.—"Report on a Collection of Sponges found at Ceylon by E. W. H. Holdsworth, Esq.," 'Proc. Zool. Soc. Lond.,' 1873, p. 25. (This paper contains descriptions of only four species. It was criticized by Gray in 'Ann. and Mag. Nat. Hist.,' Ser. 4, vol. XII., p. 266.)

1873. Holdsworth.—"Note on the Occurrence of *Xenospongia patelliformis*, Gray, on the Coast of Ceylon," 'Proc. Zool. Soc. Lond.,' 1873, p. 32.

1880. Carter.—"Report on Specimens dredged up from the Gulf of Manaar and presented to the Liverpool Free Museum by Captain W. H. Cawne Warren," 'Ann. and Mag. Nat. Hist.,' Ser. 5, vol. V., p. 437; vol. VI., p. 35 and p. 129. (In this paper the author describes fifty-four species, the great majority new, from material which he tells us would hardly fill a quart measure, the largest of the specimens being not more than three inches in its longest diameter.)

1881. Carter.—"Supplementary Report on Specimens dredged up from the Gulf of Manaar, &c.," 'Ann. and Mag. Nat. Hist.,' Ser. 5, vol. VII., p. 361. (A considerable number of species are added to the previous list.)

1884. Ridley.—"Zoological Collections of H.M.S. 'Alert,'" British Museum. (The author refers incidentally to the Sponge-Fauna of Ceylon.)

1887. Dendy.—"The Sponge-Fauna of Madras. A Report on a Collection of Sponges obtained in the neighbourhood of Madras by Edgar Thurston, Esq.," 'Ann. and Mag. Nat. Hist.,' Ser. 5, vol. XX., p. 153.

1888. Sollas.—"Report on the Tetractinellida collected by H.M.S. 'Challenger.'" (In this work the author deals critically with the Tetractinellida described by Carter from the Gulf of Manaar.)

1889. Dendy.—"Report on a Second Collection of Sponges from the Gulf of Manaar," 'Ann. and Mag. Nat. Hist.,' Ser. 6, vol. III., p. 73. (The list of the Ceylon Sponge-Fauna is herein considerably extended, and the report contains records made by Mr. Thurston of the colours of many of the species when alive.)

1889. Lendenfeld.—"Monograph of the Horny Sponges," 'Royal Society.'

* This list includes only works which deal directly with Ceylon species, and was inserted here on account of its historical interest. In the course of the Report I shall have occasion to refer to many other memoirs, and, in order to conform with the system adopted in the other Reports of this series and to save space, I have decided to give a full list of the literature cited at the end of the work and to refer to it by means of numbers.

SYSTEMATIC DESCRIPTION OF THE GENERA AND SPECIES OF SPONGES IN PROFESSOR HERDMAN'S COLLECTION.

Phylum PORIFERA.

Class: NON-CALCAREA.

Porifera without calcareous spicules.

The non-calcareous sponges are divisible into four natural groups, for which I propose to use the names Myxospongida, Triaxonida, Tetraxonida, and Euceratosa respectively, and which may be conveniently regarded as of ordinal rank.

Order: MYXOSPONGIDA.

Non-calcarea which are primitively destitute of spicules and horny fibre; with simple canal system and usually large flagellate chambers.

In this order I include the genera *Halisarca*, *Bajalus*, *Hexadella*, and *Oscarella*, all of which appear to me to be nearly related to one another, so that it is hardly necessary to divide them, as is usually done, into two families, Halisarcidæ and Oscarellidæ. All of them are, I believe, primitive forms, and should therefore stand at the bottom of the series of non-calcareous sponges.

It is quite possible that Lendenfeld's "Hexaceratina" may be closely related to the "Halisarcidæ," as supposed by that author; but, if so, it appears to me that the Halisarcidæ are the more primitive forms, from which both Hexactinellida and Hexaceratina have been derived. Lendenfeld, on the other hand, appears to regard the Halisarcidæ as being derived from the Hexaceratina by loss of horny fibres, and in this opinion he is followed by Topsent (**11**), who observes "Dépourvu à la fois de spicules et de fibres cornés, le genre *Hexadella* est vraiment le dernier chaînon de la chaîne des Hexaceratina et doit occuper la place qu'on a parfois assignée, sans raison valable, aux *Halisarca*."

The Myxospongida may therefore be regarded as representing a common starting point, from which have originated the Triaxonida, the Tetraxonida, and the Euceratosa, and I cannot agree with Professor Minchin (**12**) in placing this order at the end of the siliceous series instead of at the beginning. The primitive character of the canal system argues strongly against the belief that they are forms in which the skeleton has been lost by gradual reduction, and the case is obviously quite different from that of *Chondrosia*, whose highly specialized canal-system, strongly developed cortex, and evident relationship to *Chondrilla*, afford good grounds for regarding it as a reduced siliceous sponge in which the absence of skeleton is a secondary and not a primary character.

Hexadella, Topsent.

Myxospongida with large, sac-shaped flagellate chambers and a distinctly differentiated, tough ectosome.

The description given by Topsent (*loc. cit.*, p. 119) of this genus and of the two species which he includes in it is evidently of a preliminary character and is unfortunately without illustrations. His own diagnosis of the genus runs, "Hexaceratina revêtantes, molles, sans spicules ni fibres cornés; un peu plus épais que dans les genres voisins, l'ectosome jouit seul de quelque consistance et sert, dans une certaine mesure, de squelette externe à la masse."

As the genus is as yet so little known, I shall postpone the discussion of its relationship until I have described in some detail the anatomy of the Ceylon species.

Hexadella indica, n. sp.—Plate I., figs. 1–3.

Sponge thin, encrusting; spreading extensively over masses of calcareous Polyzoa and other organisms, but usually only about 1 millim. in thickness. Colour in spirit, grey (in life, red?). Surface smooth, glabrous, minutely reticulate. Vents few, minute, scattered. Consistence (in spirit) rather tough and membranous (owing chiefly to the ectosome), so that the sponge can be stripped off from the substratum like a skin.

The ectosome (Plate I., fig. 1, *Ect.*) forms a tough pellicle about 0·08 millim. thick, which can be stripped off from the underlying choanosome. The choanosome evidently consists of a thin lamella (fig. 1, *Ch.L.*, fig. 2), very much folded upon itself. The lamella itself is little, if any, thicker than the ectosome, and contains a single layer of large, sac-shaped flagellate chambers (figs. 1, 2, *F.C.*), whose arrangement, of course, follows the curvature of the lamella. The structure of the choanosome thus reminds one very strongly of what occurs in *Oscarella*, but there is no extensive internal portion free from flagellate chambers as in that genus.

Between the folds of the choanosomal lamella lie the primary inhalant (*P.I.C.*) and exhalant (*P.E.C.*) canals. The former expand at their outer ends into large, irregular crypts (fig. 1, *Cr.*), roofed over by the ectosome, which merges insensibly into the choanosome at the points of contact. These crypts, resembling subdermal cavities, may sometimes be seen from the surface, ramifying horizontally beneath the ectosome. The primary exhalant canals open at their inner ends into larger exhalant channels (fig. 1, *L.E.C.*).

Owing to the development of the ectosome, the water does not enter the primary inhalant canals directly, as in *Oscarella*, but by means of numerous well-developed "chones" (fig. 1, *Ch.*), which penetrate the ectosome at right angles to the surface. Each chone expands somewhat at its outer end in a trumpet-like manner, and is covered over by a membrane (fig. 3, *Mem.*) which doubtless contains the inhalant pores, but the pores are now all closed and cannot be recognised. I have, however, seen indications, in the form of fine, slit-like canals in the closing membrane, of the existence of several minute pores in the roof of each chone.

From the primary inhalant canals the water reaches the flagellate chambers by fine, sometimes branching canaliculi of considerable length (fig. 2, *I.Ca.*). The chambers themselves (figs. 1, 2, *F.C.*) are sac-shaped, unbranched (at any rate usually) and up to about 0·098 millim. long, though usually less (say about 0·065 millim.). They open into the primary exhalant canals either directly (eurypylous) or through short exhalant canaliculi.

The mesoglœa, both of the ectosome and choanosome, is abundantly developed and chiefly collenchymatous, with a profusion of small connective-tissue cells (fig. 2, *C.T.C.*) with much-branched processes. The mesoglœa of the ectosome passes insensibly into that of the choanosome at the points of contact; the former, however, stains rather more darkly than the latter, and is often distinctly, though very finely, fibrillated.

In the mesoglœa we also find embedded a large number of small, darkly staining, spherical cells (figs. 1, 2, 3, *Sy.A.*), about 0·006 millim. in diameter, sometimes apparently with small central nuclei. These cells are most abundant around the various parts of the inhalant canal-system, and are congregated in immense numbers in the inner portion of the ectosome. They sometimes appear to be broken up into groups of smaller cells. They are in all probability symbiotic algæ, such as are known to occur frequently in sponges, a conclusion which is rendered almost certain by the fact that, when treated with iodine and sulphuric acid, they give a distinct purple coloration (although it must be admitted that when tested for starch with SCHULTZE'S solution, only negative results were obtained). These bodies are probably closely comparable to the "cellules sphéruleuses" to which TOPSENT (*loc. cit.*, p. 120) attributes the red colour of his *Hexadella racovitzai*, and which are also (in my opinion) probably symbiotic algæ. Unfortunately, I have no information as to the colour of *Hexadella indica* in life, but if, as seems just possible, it is identical with CARTER'S *Halisarca rubitingens*, it is also red, and the colour may likewise be attributable to the symbiotic algæ.

This very interesting sponge appears to form a connecting link between the three genera *Oscarella*, *Halisarca*, and *Hexadella*, to which latter genus I have referred it only after long hesitation. It resembles the first in the distinctly folded character of the choanosomal lamella and the arrangement of the flagellate chambers, which are, however, much larger and usually (though not always) eurypylous, while a more important distinction is introduced by the strong development of the ectosome. The structure of the ectosome, the absence of the curious connective-tissue fibres, and the unbranched character of the flagellate chambers, together with the less extensive development of the mesoglœa, separate it from *Halisarca*. The mesoglœa appears, however (as far as one can judge from TOPSENT'S description), to be a good deal more extensively developed than in his species of *Hexadella*. TOPSENT says nothing about the existence of a distinctly folded choanosome lamella, or of inhalant chones, in his species, and it is quite possible that a new genus may be necessary for the reception of the Ceylon sponge, but this is a point which cannot be decided until we have more information as to the European species.

Hexadella indica may, as I have already suggested, possibly be identical with CARTER's *Halisarca rubitingens* (5), which was described from *dry* material from the Gulf of Manaar and referred to the genus *Halisarca* provisionally by its author. Having examined one of Mr. CARTER's original preparations of *Halisarca rubitingens*, now in my possession, I have come to the conclusion that we cannot say for certain what that organism was, and that it will be best to abandon the name altogether.

R.N. 26, 46 (Gulf of Manaar), 254 (south of Adams Bridge, 5 fathoms).

ORDER: TRIAXONIDA (HEXACTINELLIDA).

Non-calcarea in which the skeleton is composed of siliceous spicules whose fundamental form is triaxonid and hexactinellid.

Owing, doubtless, to the collecting operations having been confined to comparatively shallow water, there are no representatives of the Hexactinellida in the collection. There are, however, a few specimens of the so-called Hexaceratina which may be found ultimately to belong here. As, however, I do not consider that their systematic position is yet definitely settled, I have decided to deal with them later on, in connection with the other horny sponges (see below, p. 200).

ORDER: TETRAXONIDA.

Non-calcarea in which the fundamental form of the spicule is tetraxonid and tetractinellid. The spicules may, however, be more or less reduced, and also to a greater or less extent replaced by spongin or even sand.

It will be seen that I use the term Tetraxonida in a wider sense than that in which it is employed, for example, by MINCHIN, in his admirable article in LANKESTER's 'Zoology.' It appears to me necessary to do this in order to bring out the most fundamental character of the group, viz., the primitively tetraxonid and tetractinellid character of the spicule, in contrast with the triaxonid and hexactinellid character of the spicule in the Triaxonida.* The term Tetractinellida may be reserved for those non-Lithistid Tetraxonida which retain to a greater or less extent the primitive spicule-form, a form which doubtless characterised the ancestors of all the Tetraxonida, but has been lost by reduction in many of the existing members of the group.

The Lithistida have evidently developed along special lines of their own, and

* The occurrence of triods in the most primitive family of the Tetraxonida (viz., Plakinidæ) suggests a triaxonid (and triradiate) precursor of the tetraxonid and tetractinellid spicule. The triaxonid spicule of the Plakinidæ is, however, a fundamentally different form from that of the Triaxonida (Hexactinellida).

include both tetractinellid and monaxonellid forms, they may therefore be most conveniently regarded as constituting a separate "grade." By this exclusion of the Lithistida, the term Tetractinellida is confined to SOLLAS's group "Choristida," a sense in which it has already been employed by LENDENFELD in his work on the Tetractinellida of the Adriatic (13).

Recent researches, however, have shown that the Tetractinellida, Lithistida, Monaxonellida, and certain horny sponges which I propose to call Pseudoceratosa, are so closely related to one another that they must certainly be included in one and the same order. Indeed, it is difficult to draw a hard and fast line between these sub-divisions, which merge very gradually into one another. It is certain that the Monaxonellida have been derived (probably polyphyletically) from ancestral Tetractinellida, and the Pseudoceratosa (or, at any rate, the great majority of them) from ancestral Monaxonellida (probably polyphyletically), while the Lithistida may also be of polyphyletic origin and are closely related to the Tetractinellida on the one hand and to the Monaxonellida on the other.

The sharp separation of these four groups is, therefore, to a large extent artificial, but must be retained as a matter of convenience till we know a good deal more about their phylogeny. It must, however, be clearly recognised that the groups Tetractinellida, Lithistida, Monaxonellida, and Pseudoceratosa simply represent stages in a complex evolutionary series, commencing with the first-named group, and that each of the later stages may possibly have been reached along more than one line of descent.

GRADE: TETRACTINELLIDA.

Tetraxonida in which the primitive tetraxonid and tetractinellid condition (or a possibly still more primitive triaxonid and triradiate condition) is retained by some at least of the spicules, while no desmas are developed.

SUB-ORDER: HOMOSCLEROPHORA.

Tetractinellida in which microscleres and megascleres are not yet sharply differentiated from one another and no triænes are developed.

I venture to propose the name Homosclerophora to replace the old name Microsclerophora of SOLLAS. The latter is very misleading in that it does not indicate the primitive undifferentiated character of the spicules as regards size, and leaves it to be inferred that microscleres, as distinct from megascleres, are present.

TOPSENT (14), followed by MINCHIN (12), associates the Homosclerophora (Microsclerophora) with the "Microtriænosa" and the "Oligosilicina" in one group, to which he gives the old name "Carnosa." This appears to me a most undesirable proceeding, for while the Homosclerophora (especially the Plakinidæ) are evidently primitive forms, as SOLLAS (15) long since pointed out and as is clearly shown by their anatomical characters, the "Microtriænosa" are what MINCHIN terms "a heterogeneous collection of sponges of divers affinities," and the "Oligosilicina" ("Chondrosidæ," of SCHULZE) are simple only by the reduction of the skeleton and not primitively. I therefore consider that TOPSENT'S revived "Carnosa" should be again abandoned, the "Microtriænosa" placed amongst the other triæne-bearing Tetractinellida, and the "Oligosilicina" placed near the Tethyidæ, to which they are evidently allied by their corticate character, the general arrangement of their canal-system, and the astrose microscleres of Chondrilla.

The Homosclerophora are thus left as the natural starting point of the Tetraxonid series, a position already clearly indicated for them by LENDENFELD in his work on the Tetractinellida of the Adriatic. TOPSENT, it is true, fully recognises the artificial character of his "Carnosa" and places them after his "Tetractinellida." MINCHIN, on the other hand, places them first, a diversity of opinion which clearly indicates the impracticability of associating together such widely different forms as are included in the group.

Owing to their primitive character, the Homosclerophora form a very important and interesting sub-order, and it is here that we must seek for the origin, not only of the various types of canal-system, but also of the almost innumerable types of both micro- and megascleres met with amongst the Tetraxonida.

FAMILY: PLAKINIDÆ.

Homosclerophora in which no distinct cortex is developed.

This appears to be the most primitive family of the Tetraxonida. The genus *Plakinastrella*, formerly included herein, but possessing more or less well-developed triænes, finds a more natural position amongst the Pachastrellidæ.

Dercitopsis, n. gen.

Plakinidæ with calthrops, triods and smooth oxea, but no candelabra. The oxea vary greatly in size, and some of the smaller ones form a special dermal layer, in which they are commonly arranged at right angles to the surface.

It is, perhaps, doubtful whether this genus ought to be separated from *Plakortis*, but the species for which it is founded differs from the type species of *Plakortis* (*P. simplex*) in three respects:—(1) Calthrops are present as well as triods; (2) some of the oxea are so large as to deserve the name of megascleres, although they pass gradually into the smaller forms (microxea); (3) some of the microxea form a special dermal layer, in which they are commonly arranged at right angles to the surface.

In this genus we have a refutation of SOLLAS'S statement that "megascleres are absent" from the so-called "Microsclerophora" (including the Plakinidæ), and we see very clearly how oxeote megascleres may be derived directly from primitive triaxon or tetraxon spicules by suppression of one or two actines (see Plate II., fig. 1). From the same source are derived microxea, and these, being frequently curved, have probably given rise to the sigmata and toxa and, perhaps, other curvilinear microscleres of higher groups. Increase in the number of actines of the primitive spicule, on the other hand, accompanied by other modifications, has probably given rise to the astrose series of microscleres. Thus *Dercitopsis* and its allies may be regarded as representing at the present day the common ancestors of both Astrophora and Sigmatophora.

Dercitopsis ceylonica, n. sp.—Plate II., fig. 1.

This species is represented in the collection by two small, flat pieces which have probably been encrusting and may have formed parts of the same specimen. One is about 22 millims. in length, 13 millims. in greatest breadth, and 7 millims. in greatest thickness. The other is about 26 millims. in length, 16 millims. in greatest breadth, and 7 millims. in greatest thickness. The surface is smooth but rather uneven. Colour in spirit, dark slate grey on the outside, dull yellow internally. Vents minute, scattered singly, with a tendency towards marginal arrangement or grouping on prominent parts. Inhalant pores dispersed abundantly over the surface, not in sieves.

Skeleton very dense, for the most part quite confused and irregular, but with the smallest microxea forming a thin dermal crust, in which they are commonly arranged at right angles to the surface.

Spicules.—(1.) Calthrops and triods (Plate II., fig. 1, *a–h*); rays smooth, sharply and gradually pointed, commonly about 0·033 millim. long by 0·005 millim. in maximum diameter, but subject to considerable variation, and occasionally exhibiting monstrous forms such as twins.

(2.) Oxea (fig. 1, *i–o*); varying enormously in size, but in such a perfectly graduated series between the smallest and the largest that they cannot be divided into mega- and microscleres. The dermal microxea measure only about 0·025 millim. by 0·002 millim., while the oxea in the deeper parts of the sponge frequently measure as much as 0·42 millim. by 0·012 millim. Both large and small oxea are smooth, gradually and finely pointed at each end, and frequently centrotylote. They often exhibit a curvature, which may be sigmoid or toxoid, and thus strongly support the conclusion arrived at by Sollas (*loc. cit.*, p. 109) to the effect that the toxa of *Dercitus* are probably microxea which have acquired a curvilinear growth. The same author has also pointed out that the spinose microrhabds of *Dercitus* originate as smooth centrotylote microxea, which he regards as diactinal asters. From a similar origin we get, in the case of *Dercitopsis ceylonica*, comparatively large oxeote megascleres, which seems to indicate that this common type of spicule may also have been derived from an aster. It also seems probable that the well-known sigmata, so widely distributed in certain tetractinellid and monaxonid groups, may have originated from such microxea as we find here, in other words, from diactinal asters.

The distinction between ectosome and choanosome is not well-marked, and there is no properly defined cortex. The ectosome is, however, fairly thick (about 0·27 millim.), and much more densely spicular than the choanosome; it contains numerous small brown pigment cells (which are also met with in the outer part of the choanosome). There is no fibrous tissue in the ectosome, and what little mesoglœa there is between the densely packed spicules is probably collenchymatous. The mesoglœa of the choanosome is very finely and uniformly granular.

The dermal pores lead into short inhalant canals which penetrate the ectosome more or less vertically and, after uniting together to a greater or less extent, open beneath the ectosome into spacious "crypts," from which the inhalant canals of the choanosome take their origin. The flagellate chambers are rather large, pouch-shaped, about 0·04 millim. in longer diameter; eurypylous, or with short, wide exhalant canals.

R.N. 139, 235 (? Parts of the same specimen. From Station XLI., 12 miles off Galle, 100 fathoms).

Sub-order: ASTROPHORA.

Tetractinellida with triænes and with astrose microscleres; without sigmata.

Family: PACHASTRELLIDÆ.

Astrophora without long-shafted triænes and without sterrasters. Calthrops, in addition to short-shafted triænes resembling calthrops, may be present.

Plakinastrella, Schulze.

Pachastrellidæ with calthrops and (or) short-shafted triænes and oxea for megascleres; and oxyasters and microxea for microscleres; the microxea forming a special dermal skeleton.

This genus occupies an intermediate position between the Plakinidæ and the Stellettidæ, and probably indicates the first stage in the evolution of the long-shafted triæne from the calthrops. The relationship to the Plakinidæ is clearly shown by the form of the oxea, and the differentiation between megascleres and microscleres is not yet by any means complete.

Plakinastrella intermedia, n. sp.—Plate I., fig. 4; Plate II., fig. 2.

Specimen (Plate I., fig. 4) irregularly branched and shortly stalked; branches short, thick, irregularly nodose, spreading more or less horizontally, rounded at the extremities. Surface smooth but uneven, minutely porous in parts. Texture firm and incompressible, with many relatively large foreign bodies embedded in the substance of the sponge and sometimes projecting beyond the surface. Vents small and few, on rounded ends of branches. Pores scattered in irregular groups; many in each group, easily visible under a pocket lens. Colour in spirit, greyish brown. Total height, 20 millims.; greatest breadth, 26 millims.

The skeleton is for the most part very confused. The choanosome is densely strewn with large oxea lying in every direction and occasionally aggregated in loose bundles; with these are mingled oxea of smaller size and a few tetract spicules, while the interspaces are filled in with immense numbers of oxyasters, uniformly and thickly scattered through the soft tissues. On the surface of the sponge is a dense layer of small oxea, tangentially disposed, and for the most part lying so close together as to touch one another and form a continuous crust, perforated by the numerous circular inhalant pores where these occur. Beneath this dermal crust are extended horizontally a number of the large oxea and the heads of the dichotriænes.

Spicules.—(1.) Dichotriænes (Plate II., fig. 2, *a–d*), with cladi extended beneath the dermal crust and shaft projecting inwards at right angles to the surface. The shaft is short, stout, and fairly gradually sharp-pointed, only about as long as the radius of the cladome (or even shorter), measuring, say, about 0·37 millim. by 0·055 millim. The protocladi are short and stout, about 0·092 millim. by 0·055 millim. The deuterocladi are about two and a half times as long as the protocladi, but variable; fairly gradually and sharply pointed, commonly slightly curved and often unequal. Boiled-out preparations show various monstrous forms of this spicule, *e.g.*, one with one cladus unbranched, another with one deuterocladus itself branched, another with the shaft branched, and also a number of very much slenderer forms of the same spicule which are probably not fully developed. Although these dichotriænes are essentially characteristic of the sub-dermal skeleton, yet we find a good many branching spicules scattered through the deeper parts of the sponge, which evidently belong to the same type.

(2.) Oxea (Plate II., fig. 2, *e–p*). *a*, large; more or less curved or even angulated in the middle; fusiform; usually gradually and fairly sharply pointed; size about 1·2 millims. by 0·037 millim. Occasionally a slightly curved stylote spicule may be observed, with one end broadly rounded; apparently derived from an oxeote by suppression of one ray. *b*, small; found chiefly in the dermal crust; fusiform, gradually and sharply pointed, slightly curved; varying very much in size; averaging, say, about 0·18 millim. by 0·01 millim., but ranging from about a third of these dimensions through intermediate sizes to the large forms.

(3.) Rather large oxyasters (Plate II., fig. 2, *q–v*), abundantly strewn through the choanosome; with usually about five long, slender and gradually sharp-pointed rays, which are smooth and up to about 0·025 millim. in length; there is no centrum.

Stained sections show that the ectosome is rather thin, apparently consisting only of the dense spicular crust and with no fibrous tissue except a little around the oscular tubes. The choanosome is gelatinous (collenchymatous). Both ectosome and choanosome contain numerous pigment cells full of brown granules, especially in the walls of the canals. The material is not sufficiently well preserved to show the characters of the flagellate chambers. The inhalant pores, about 0·13 millim. in diameter, are the single openings of short cylindrical chones which penetrate the spicular dermal crust and are provided with well-developed sphincters near its inner limit; but there are no extensive subcortical crypts.

(A fragment of a large, massive anatriæne was found in a boiled-out preparation of the spicules of this sponge, but I could find no others, either in boiled-out preparations or in sections. Should this form of spicule prove to be proper to the species, it would necessitate its removal from the genus *Plakinastrella*).

R.N. 224 (from Station XLI., 12 miles off Galle, 100 fathoms).

Plakinastrella schulzei,* n. sp.—Plate II., fig. 3.

This well-characterised species is represented in the collection by an irregular massive specimen (or fragment) which has been cut off at the base from its attachment. The upper surface is strongly convex and is produced into irregular elevations. The specimen contains many foreign organisms, both internally and encrusting the surface (it is penetrated by the spiral shells of a species of *Tenagodes* (*Siliquaria*), a gastropod which habitually lives in sponges). The colour is purplish grey externally (owing to the presence of numerous granular pigment cells), yellowish within. The vents are irregularly scattered, well-defined circular openings, which may be crateriform; up to about 3 millims. in diameter, but usually a good deal smaller. Inhalant pores (?) are rather conspicuous on some parts of the surface, but irregularly scattered and varying much in size. The specimen measures about 50 millims. in length, 30 millims. in breadth, and 18 millims. in thickness.

The main skeleton is a very irregular interlacement of numerous large oxea and a few short-shafted triænes; the spicules occasionally forming loose wisps. The dermal skeleton is a dense feltwork of small oxea.

Spicules.—(1.) Short-shafted triænes (Plate II., fig. 3, *a–d*), resembling calthrops and subject to much variation in form; commonly with three rays long and bifid and the fourth short and simple, all fairly sharp-pointed; or all the rays may be simple; or one only may be bifid; or one may be trifid, and doubtless other variations could be found. Total diameter measured up to about 0·68 millim. from apex to apex of rays, with primary rays about 0·046 millim. thick.

(2.) Oxea (Plate II., fig. 3, *e–t*). The large oxea of the main skeleton (*e*) are stout, fusiform and gradually sharp-pointed at each end; more or less curved and occasionally slightly angulated at two points, but not centrotylote. They measure, when fully developed, about 1·3 millims. by 0·055 millim. The small dermal oxea (*r*, *s*, *t*) are commonly centrotylote, more or less sharply pointed at each end, and with the two terminal thirds bent upon the middle third at slight angles in the same direction;

* Named in honour of the most eminent of Spongologists, Professor F. E. Schulze.

they are quite smooth and measure about 0·35 millim. by 0·018 millim., but with considerable variation in size. Between the large and small oxea thus described we find so many intermediate in shape and size (*f–q*) that it is impossible to distinguish them as megascleres and microscleres respectively.

(3.) Oxyasters (Plate II., fig. 3, *r–x*) with smooth, slender, sharp-pointed rays and little or no centrum, are very abundant in the deeper parts of the sponge; they measure about 0·02 millim. in total diameter.

The irregular arrangement of the short-shafted triænes (which presumably originated phylogenetically at the surface of the sponge and acquired their characteristic form in direct relation to that position), and the absence or scarcity of typical calthrops, seem to indicate that this species is less primitive than the type of the genus (*P. copiosa*, SCHULZE), and, in fact, somewhat degenerate.

R.N. 149 (from Station XLI., 12 miles off Galle, 100 fathoms).

Stœba, SOLLAS.

Thin, encrusting Pachastrellidæ, with short-shafted triænes, resembling calthrops, for megascleres, and only spined microxea for microscleres.

In 1888 SOLLAS (*loc. cit.*, p. 102) proposed the genus *Stœba* for CARTER'S *Samus simplex* from the Gulf of Manaar, but LENDENFELD (**13**), followed by TOPSENT (**14**), has merged the genus in *Dercitus*. Inasmuch, however, as the type species of *Dercitus* (*D. bucklandi*, Bk. sp.) possesses toxa amongst its microscleres, while *Stœba* does not, it seems to me desirable to retain the distinction between the two, especially as we now know three more or less distinct species without toxa, viz., *Stœba simplex* (= *Samus simplex*, CARTER; *Dercitus simplex*, TOPSENT); *Stœba plicata* (= *Corticium plicatum*, SCHMIDT; *Calcabrina plicata*, SOLLAS; *Dercitus plicatus*, LENDENFELD and TOPSENT), and *Stœba extensa*, n. sp.

SOLLAS'S genus *Calcabrina*, founded for SCHMIDT'S *Corticium plicatum*, must be regarded merely as a synonym of *Stœba*.

Stœba extensa, n. sp.—Plate V., fig. 1.

Sponge thin, encrusting, spreading extensively over the surface of and into the cavities of a mass of calcareous *débris* (Melobesia, Polyzoa, Coral, Worm-tubes, &c., mixed together). Surface for the most part smooth and sub-glabrous, slightly rugose in parts; consistence tough and rather fleshy; colour in spirit, pale grey. Vents and pores not seen. The exposed part of the sponge forms an almost uninterrupted sheet about 45 millims. by 33 millims. in extent, but of irregular outline.

The main skeleton consists of short-shafted triænes scattered abundantly, but quite irregularly through the choanosome, but very sparsely in the ectosome, and there is a thin dermal crust of microxea.

Spicules.—(1.) Triænes (Plate V., fig. 1); with short, stout, sharp-pointed shaft, measuring about 0·136 millim. by 0·02 millim. when fully developed, with cladome about 0·2 millim. across; the cladi are usually extended nearly at right angles to the shaft; they are short and each usually divides into two short, sharp-pointed branches; occasionally, however, the cladi are unbranched and sometimes they are very irregular.

(2.) Spined microxea (Plate V., fig. 1); very slender, straight or very slightly curved, with spination minute but sharp and abundant and fairly uniform throughout the length, excepting that there is frequently a constriction in the middle of the spicule, in which the spination may be more or less wanting; size about 0·02 millim. by 0·00133 millim. (excluding spines). These spicules occur very abundantly in the dermal crust already mentioned and also scattered throughout the sponge.

The ectosome forms a cortex about 0·27 millim. thick, composed of large oval cystenchymatous cells with fibrous tissue between them, the fibres, for the most part at any rate, lying parallel with the surface. The cystenchyme cells measure about 0·06 millim. in longer diameter and are also abundant in the choanosome.

This species is obviously very closely related to the European *Stœba plicata*, on the one hand, and to *S. simplex*, from the Gulf of Manaar, on the other. From the former, which has been fully re-described by Topsent (**14**), it differs in its longer and slenderer and more sharply-pointed microxea, and in the fact that the triænes are nearly all dichotriænes. From the latter it differs in the smaller size of the triænes and the larger size of the microxea, and in the fact that the spines of the microxea are not "most prominent towards the ends," though, as I have pointed out above, they may be more or less absent from the middle of the spicule. It appears to be a good deal more robust in growth than either species. It is quite possible, however, that subsequent researches may make it possible to consider all three as mere varieties of one species, but for the present it seems desirable that they should be kept separate.

Topsent describes the ectosome of *Stœba plicata* as being collenchymatous, but he mentions and figures large "cellules sphéruleuses," which are evidently closely similar to the large cystenchyme cells of *S. extensa*. The partly fibrous cortex of the latter, almost devoid of megascleres, may possibly afford another means of specific distinction.

In external appearance (in spirit at any rate) *Stœba extensa* bears such a close resemblance to the thin encrusting form of *Chondrilla australiensis* that it is difficult, if not impossible, to distinguish the two without microscopical examination.

R.N. 167 (Station LXVI., off Mutwal Island, March 19, 1902, 10 to 35 fathoms).

Family: STELLETTIDÆ.

Astrophora with long-shafted triænes, without calthrops and without sterrasters.

Myriastra, Sollas.

Microsclere a euaster of one form only. Ectosome not a cortex.

Myriastra clavosa (Ridley).

1884, **Stelletta clavosa**, Ridley (16); 1888, **Myriastra clavosa**, Sollas (15).

I have no hesitation in referring to this species four small specimens from deep water off Galle. The specimens are approximately spherical in form and up to about 9 millims. in diameter. There is a single slightly depressed vent, which, in three of the specimens at any rate, has a membranous margin. The colour is grey-yellow. As this is an entirely new locality for the species, which has hitherto been obtained from waters north of Australia, I propose to give the details of spiculation of one specimen in justification of the identification.

Spicules.—(1.) Dichotriænes; shaft, 1·4 millim. by 0·025 millim., gradually and finely pointed; chord, 0·6 millim.; protocladi, 0·08 millim.; deuterocladi, 0·2 millim.

(2.) Anatriænes; shaft, 2·3 millims. by 0·02 millim., very finely and gradually pointed; chord, 0·1 millim.; cladi, 0·06 millim., rather stout; of the shape figured by Ridley.

(3.) Large oxea; fusiform, gradually and sharply pointed, 2·2 millims. by 0·025 millim.

(4.) Cloacal oxea; commonly 0·2 millim. by 0·004 millim., may be rather larger.

(5.) Chiasters; extremely minute, with no distinct centrum, and long, slender, tylote rays varying in number; total diameter, 0·01 millim.

It will be seen from the above that the shaft of the dichotriæne is a good deal shorter than in previously described specimens, but, considering the variation in this respect, we cannot regard this difference as being of specific importance.

R.N. 131, 132, 227, 228 (all from off Galle and onwards up the West Coast of Ceylon, depths up to 100 fathoms).

Myriastra tethyopsis (Carter).

1880, **Stelletta tethyopsis**, Carter (4); 1888, **Myriastra** (?) or **Anthastra** (?) **tethyopsis**, Sollas (15).

There are four specimens of this very remarkable sponge in the collection. Sollas regards the species as insufficiently characterised, but, as a matter of fact, Carter's description is very good, and leaves no doubt as to the identification. The fact that Sollas was unable to assign it definitely to any of his genera tends rather to show the unsatisfactory nature of his system of classification than the insufficiency of the original description.

The specimens (in spirit) are light grey in colour. The smallest is about 10 millims. and the largest about 42 millims. in diameter. The shape is very characteristically turbinate, more or less flattened below, and conical above. The surface is harsh to the touch and finely granular, very minutely and rather sparsely hispid. In the larger specimens a dense mass of long, hair-like spicules projects from more or less of the lower surface. The larger specimens were evidently attached below. The apparent total absence of vents is a remarkable feature. Only in the smallest specimen have I seen what looks like a small natural vent, and that is on the flattened (presumably lower) surface. Doubtless the exhalant apertures are completely concealed by contraction in preserved specimens. Owing to the enormously strong development of the dense radiating skeleton, and the manner in which the cladi of the triænes come close up to the surface (giving it its granular character), I have found it impossible to cut a tangential or surface section in the ordinary way in order to look for pores in the dermal membrane. On attempting to cut such a section the sponge splits up radially along the lines of the gigantic spicules.

The skeleton is remarkably strongly developed, the shafts of the huge oxea and triænes being arranged in dense bundles, which radiate from a central "nucleus" and leave only narrow interspaces between them; while the expanded cladi of the dichotriænes form a thin but dense dermal crust, in which innumerable very minute asters also occur.

Spicules.—(1.) Dichotriænes; shaft about 8·0 millims. long by 0·074 millim. thick a short way below the cladome, tapering very gradually to a narrow, long-drawn-out but rounded point; cladi short, stout, once-forked, expanded almost at right angles to the shaft; chord about 0·46 millim.

(2.) Protriænes; with long and very slender shafts and slender cladi about 0·05 millim. long, commonly projecting from the general surface. Much larger protriænes, with comparatively stout shafts and short stout cladi, occur in the anchoring tufts on the lower surface of the adult sponge.

(3.) Anatriænes; with long slender shafts, and rather stout cladi up to about 0·1 millim. long.

(4.) Oxea; associated in bundles with the shafts of the dichotriænes; fusiform, gradually and fairly sharply pointed at each end; size about 8·0 millims. by 0·073 millim.

(5.) Asters; very numerous at and near the surface of the sponge, with small centrum and numerous slender conical rays of equal length; total diameter about 0·01 millim. Such spicules are very rare in the deeper parts of the sponge, and those which I have seen do not differ in any important respect from the asters of the surface.

The smallest specimen possesses in one part, beneath the surface, in addition to the asters, numerous minute refractive globules, which look as if they might be siliceous.

Stained sections show that there is a very thick gelatinous (collenchymatous) ectosome, excavated by numerous large, irregular cavities, from which occasionally wide canals, provided with numerous transverse diaphragms, lead vertically inwards through the choanosome. Small dermal pores are scattered between the cladi of the dichotriænes. The choanosome is not sharply differentiated from the ectosome, but is finely granular. The flagellate chambers are oval and measure up to about

0·04 millim. in longer diameter; they are densely crowded together, and either eurypylous or with very short, wide exhalant canaliculi.

This species is so peculiar that it might almost form the type of a new genus, but I cannot fix upon characters which would separate it absolutely from Sollas's *Myriastra.* The sponge, however, is not exactly small, nor are the oscules distinct, nor are the pores in sieves, nor yet is the ectosome thin; all of which features are mentioned by Sollas as characters of *Myriastra*, though I should hardly consider them as being of generic value myself.

R.N. 128, 128a, 128b, 130 (Station XLI., 12 miles off Galle, 100 fathoms).

Pilochrota, Sollas.

Microsclere a euaster of one form only. Ectosome differentiated to form a cortex.

Pilochrota haeckeli, Sollas.—Plate II., fig. 4.

1888, **Pilochrota haeckeli,** Sollas (**15**).

There are eight specimens in the collection which agree so closely with Sollas's description as to leave no doubt of their specific identity with the "Challenger" species, represented in the "Challenger" collection by a single specimen from the Philippine Islands. The Ceylon specimens are irregularly spherical or oval in shape, and the largest is about 16 millims. in maximum diameter. The colour in spirit is grey. The vent (when visible) is single, small, and surrounded by a membranous lip, minutely hispid owing to projecting oxea. The inhalant pores are arranged in small sieves, which are irregularly scattered or situated in shallow meandering grooves. The sponge has a strong tendency to attach itself to foreign objects by means of short, root-like processes.

I subjoin the spicular measurements taken from one specimen (R.N. 127), in support of the identification :—

(1.) Orthotriænes (Plate II., fig. 4, *a*); shaft, 2·3 millims. by 0·074 millim., gradually and sharply pointed; cladi, 0·3 millim. long, stout, conical, sharp-pointed, expanded almost at right angles to the shaft, slightly recurved.

(2.) Anatriænes (Plate II., fig. 4, *c*); shaft, 2·8 millims. by 0·037 millim., long and slender, finely pointed; cladi, strongly recurved, fairly stout, sharp-pointed, 0·13 millim. long.

(3.) Somal oxea; fusiform, gradually and sharply pointed at each end, symmetrical, often slightly curved; measuring about 2·3 millims. by 0·04 millim.

(4.) Cloacal oxea; small and slender, about 0·2 millim. by 0·005 millim.

(5.) Chiasters, with very slender, tylote rays; total diameter about 0·012 millim., not very abundant.

(There are also a few curiously abnormal triænes with very short and stout shafts, as shown in fig. 4, *b*, *d*, *e*, but I think that these must be regarded as monstrous forms of the orthotriænes and anatriænes, and not as having any taxonomic value.)

R.N. 127, 127*a*, 127*b*, 127*c*, 127*d* (all from deep water off Galle and onwards up the West Coast); 197 (no special locality); 215 (deep water outside the pearl banks, Gulf of Manaar); 225 (Station XLI., 12 miles off Galle, 100 fathoms).

Pilochrota hornelli, n. sp.—Plate II., fig. 5.

The single specimen is shaped like a somewhat elongated potato, with a fairly smooth but rather uneven and finely granular surface, to which a number of foreign bodies, such as shell-fragments, Foraminifera, &c., are attached. In its present condition it measures about 45 millims. by 33 millims. by 33 millims., but a small piece has been cut off from one end. The texture is somewhat spongy internally, but with a firm, dense outer crust nearly 1 millim. thick in places. The colour is light brown throughout. The inhalant pores are arranged in small groups (pore-sieves) thickly and generally scattered over what was probably the lower half of the sponge; they are also scattered singly on the upper part. There is a single large vent near one end of the upper surface, elongated transversely to the long axis of the sponge and with a narrow, thickened, smooth, fleshy margin. The vent measures about 6 millims. by 2 millims., and is the opening of a short, wide oscular tube formed by the union of a number of large exhalant canals.

The skeleton in the interior of the sponge is loose and irregular, composed principally of large, scattered oxea, not arranged in definite fibres. Towards the surface the spicules tend to collect together into fibres which end in dense brushes composed almost entirely of ortho- and anatriænes. These brushes separate the wide subcortical crypts from one another, but their expanded outer ends form a continuous spicular crust at the surface. The cladi of the orthotriænes are for the most part extended at the surface of the sponge, but do not project beyond it, those of the anatriænes lie somewhat deeper down in the cortex. There are also a large number of orthotriænes whose cladi lie beneath the subcortical crypts while their shafts project inwards into the choanosome.

Spicules.—(1.) Orthotriænes (Plate II., fig. 5, *a–d*); with stout shaft tapering very gradually to a narrow, bluntly rounded or sharp apex, and with short, stout, conical cladi extended almost at right angles to the shaft; two typical examples from a boiled-out preparation gave the following measurements:—(*a.*) Shaft, 1·5 millims. by 0·032 millim.; cladi, 0·123 millim. by 0·03 millim. (*b.*) Shaft, 1·017 millim. by 0·04 millim.; cladi, 0·115 millim. by 0·033 millim. In the dermal crust one or two of the cladi not infrequently become bifurcate, but this takes place very irregularly, and a good many monstrous forms occur.

(2.) Anatriænes (Plate II., fig. 5, *e*); shaft long and fairly stout, not tapering to hair-like dimensions, though, of course, much narrower at the proximal than at the distal extremity; bluntly or sharply pointed; cladi stout, strongly recurved, sharply pointed; front of cladome flattened. A specimen from a boiled-out preparation, somewhat longer than usual, gave the following measurements:—Shaft, 1·96 millim. by 0·019 millim.; cladi, 0·0656 millim. by 0·0164 millim.

(3.) Oxea (Plate II., fig. 5, *f*); fairly stout, fusiform, gradually and usually fairly sharply pointed, gently curved, approximately iso-actinate, measuring about 1·3 millims. by 0·032 millim.

(4.) Chiasters (Plate II., fig. 5, *g*, *h*, *i*); with no centrum and very slender, slightly roughened and distinctly tylote rays; total diameter of spicule up to about 0·02 millim.; abundant, especially in the deeper parts of the sponge.

The histological structure of the strongly developed cortex agrees very closely in some respects with that described and figured by SOLLAS (*loc. cit.*, p. 122) for his *Pilochrota pachydermata.* The cortex itself, about 0·8 millim. in thickness, consists chiefly of very dense fibrous tissue, in which the fibres interlace in various directions. Imbedded in this tissue we find histological elements of two other kinds:—(1.) Large, rounded, deeply staining bodies up to about 0·2 millim. in diameter, each made up of an aggregation of much smaller bodies (cells?), and the whole very finely and uniformly granular. These remarkable bodies have a rather deep yellowish brown colour in unstained preparations, and they form a single layer beneath the surface in the outer part of the cortex. They are evidently homologous with what SOLLAS terms "oval or round clusters of granule-cells" in *P. pachydermata.* Sometimes the finely granular "cells" occur separately as well as aggregated in clusters, especially in the margin of the vent. (2.) Numerous irregularly scattered, small groups of faintly staining, homogeneous, spherical globules, varying in size in each group up to about 0·005 millim. in diameter; abundant in the deeper parts of the cortex and also in the choanosome. These bodies do not seem to have been observed in *P. pachydermata.*

Beneath the fibrous cortex lie extensive sub-cortical crypts, separated from one another by the radiating spicule bundles and a sparse development of ectosomal collenchyma.

The inhalant pore-sieves overlie well-developed chones which penetrate the fibrous cortex to reach the sub-cortical crypts, being provided with sphincters or diaphragms where they join the latter; the sphincters, however, do not lie quite so deeply as the lower limit of the fibrous cortex. From the sub-cortical crypts originate numerous fairly wide incurrent canals which penetrate the choanosome and sub-divide therein.

The choanosome is finely granular, and the flagellate chambers are approximately spherical, about 0·02 millim. in diameter, and apparently eurypylous.

It is not impossible that this species may be identical with SOLLAS's *Pilochrota cingalensis*, also from Galle, but the description of the latter (**15**), apparently based upon a mere fragment, for the author says "*Sponge* (?)," is too imperfect for safe recognition. SOLLAS, moreover, states that the cortex is thin, about 0·35 millim. in thickness, and all the megascleres seem to have their shafts characteristically bluntly pointed or even strongylote, a condition to which there is only a tendency in our specimen. Our species is also very closely related to *Pilochrota pachydermata*, SOLLAS, from Tahiti, but differs in certain respects, such as the form of the chiaster, which is not tylote in *P. pachydermata*.

R.N. 176 (collected in the lagoon inside the reef, Galle, shallow water, by Mr. HORNELL, after whom, on Professor HERDMAN'S suggestion, I have much pleasure in naming the species).

Stelletta, SCHMIDT.

Microscleres euasters of two forms.

It might be advisable to sub-divide this genus according to whether or not a fibrous cortex is present, as SOLLAS has done in similar cases. *Stelletta herdmani* would then come under the first sub-division and *S. vestigium* under the second. I do not, however, think it would be desirable to take such a step until we know more about the value of this character in classification.

Stelletta herdmani, n. sp.—Plate II., fig, 6.

Sponge quite irregular in shape; sometimes vallate; sometimes with occasional digitiform or mammiform projections; often very much mixed up with coarse calcareous débris. Surface uneven, very harsh to the touch and striate owing to the presence of the huge megascleres immediately beneath the thin dermal membrane; not hispid except where apparently worn. Vents few, scattered on prominent parts, up to about 3 millims. in maximum diameter; leading out of deep cloacal tubes, which are of about the same diameter and lined by a sieve-membrane. Inhalant pores scattered in the dermal membrane. Colour (external) ranging from pale yellowish to slate-grey in the same specimen The largest specimen is about 55 millims. in greatest diameter, but is a good deal damaged and much mixed up with foreign matter.

Skeleton very dense and more or less confused; consisting of irregular bundles of huge oxea and triænes, for the most part radiating towards the surface, but lying tangentially beneath the dermal membrane and thus forming an ill-defined but dense spicular cortex about 0·36 millim. thick.

Spicules.—(1.) Plagio- or protriænes (Plate II., fig. 6, *a*, *b*, *c*.); with short, stumpy, conical cladi projecting more or less forwards, and stout shaft, usually somewhat curved, more or less swollen at some distance below the cladi and tapering gradually to a sharp point at the other end. Size somewhat variable, shaft up to about 1·2 millims. by 0·074 millim., with cladi 0·18 millim. long.

(2.) Oxea (Plate II., fig. 6, *d*.); fusiform, straight or slightly curved, tapering gradually to a sharp point at each end; size about 2·8 millims. by 0·09 millim.

(3.) Chiasters (Plate II., fig. 6, *e*–*h*); very abundant in the dermal membrane, scarcer within; with numerous rather short, truncate conical rays, and often with a distinct but small centrum; total diameter about 0·012 millim. or less.

(4.) Oxyasters (Plate II., fig. 6, *i–k*); fairly numerous in the deeper parts, but may be difficult to find; with little or no centrum, and long, slender, conical, sharp-pointed, smooth rays, varying in number; total diameter about 0·029 millim.

Owing to the great size and abundance of the megascleres it is impossible to cut satisfactory sections by the ordinary paraffin method, but such as I have been able to obtain have yielded some interesting results. The ectosome is remarkably developed as a very thick gelatinous layer containing numerous stellate cells (collenchyma), and a thin layer of fibrous tissue (about 0·08 millim. thick), situated about 2·5 millims. beneath the surface and separating the gelatinous layer from the choanosome. The arrangement of the main skeleton appears to be in no way correlated with the differentiation between ectosome and choanosome, the large megascleres passing through the fibrous layer from one to the other without distinction. The mesoglœa of the choanosome ranges from collenchymatous to finely granular, and the flagellate chambers are more or less spherical and about 0·024 millim. in diameter.

There are six specimens of this sponge in the collection. The arrangement of the skeleton reminds one very strongly of Sollas's genus *Stryphnus*, but the absence of amphiasters or sanidasters prevents us from placing the species in that genus (according to Sollas's classification). The species also resembles to a considerable extent Kirkpatrick's *Stelletta* (*Astrella*) *horrens*, from South Africa (17), but is distinguished by its external form, by the arrangement of the pores and vents, and by the details of spiculation.

R.N. 66 (Gulf of Manaar); 89, 137, 137a, 157, 203 (all from off Galle and onwards up the West Coast, depths up to 100 fathoms).

Stelletta vestigium, n. sp.—Plate II., fig. 7.

Specimen irregular in shape, massive, encrusting, and containing many calcareous foreign bodies. (In the same mass as the two specimens of *Tethya lyncurium* var. *a*.) Maximum diameter about 23 millims. Colour in spirit, nearly black. Vents and pores not seen. No cortex.

The skeleton is a confused reticulation of megascleres, mingled with foreign bodies and sometimes collected into loose fibres; with a thin dermal crust of asters, also much mixed with foreign bodies.

Spicules.—(1.) Triænes (Plate II., fig. 7, *a–d*); with cladi reduced to three, two, or one mere spines or protuberances of varying size at the broad end of the spicule; the other end tapering gradually to a more or less sharp or irregular apex. These spicules are of about the same dimensions as the oxea.

(2.) Oxea (Plate II., fig. 7, *e*); rather slender, usually slightly curved; more or less gradually sharp-pointed or irregularly ended; measuring about 0·74 millim. by 0·016 millim.

(3.) Spherasters (Plate II., fig. 7, *f*, *g*); with well-developed centrum and sharp, conical rays; total diameter about 0·024 millim., with rays about 0·008 millim. long; most numerous in the dermal crust, but also abundant below. (A rather noteworthy feature of these spicules, in many cases, in the boiled-out preparations, is the conspicuous nature of the central canal in the rays, which gives the spicule a very peculiar appearance.)

(4.) Oxyasters (Plate II., fig. 7, *h*, *i*); with very small centrum and a rather small number of slender, finely-pointed, smooth rays; total diameter up to about 0·024 millim. Abundant in the choanosome.

This species is particularly interesting on account of the extreme reduction of the cladi of the triænes, affording an absolute transition from the tetractinellid to the monaxonellid condition. This vestigial condition of the cladi, an approach to which is already seen in *Stelletta herdmani*, appears to be associated in this genus with the irregularly scattered arrangement of the triænes (compare the vestigial condition of the cladi of the dermal anatriænes in *Geodia perunicinata*, described later on).

R.N. 200A (Station LXVII., off Talaivillu Paar, 10–14 fathoms).

Ecionema, Bowerbank.

The microscleres include microrhabds in addition to euasters; the former are commonly minutely spined or roughened, and usually form a dermal layer.

Ecionema carteri, n. sp.—Plate I., fig. 5; Plate III., fig. 1.

There are three specimens of this sponge in the collection. The largest and only well-developed example (R.N. 175, Plate I., fig. 5) may be taken as the type of the species. This specimen is massive and quite irregular in shape, with a number of foreign bodies attached to it. The maximum diameter is about 35 millims. The surface appears, in most places, distinctly porous, even to the naked eye, owing to the presence of very numerous, thickly scattered, small pore-sieves (Plate I., fig. 5, *p.s.*) containing the inhalant pores. It is also very minutely and sparsely hispid, at any rate in parts. The vents (Plate I., fig. 5, *o*) are rather numerous, without prominent margins; circular or oval openings varying up to about 2 millims. in diameter; mostly congregated in a depression on what was apparently the upper part of the sponge. They are the apertures of wide, diaphragm-bearing oscular tubes. The texture of the sponge is fairly firm, but compressible. The colour in spirit is pale grey.

Another specimen (R.N. 188) is almost spherical and only about 11 millims. in diameter, without visible vents; it is probably immature. The third (R.N. 259) is an irregular fragment.

The main skeleton in the interior of the sponge is an irregular interlacement of large oxea which, towards the surface, collect into loose radiating wisps, ending in dense brushes of triænes whose cladomes lie at varying depths beneath the dermal membrane, but never very deeply. The dermal membrane is strengthened by a thin crust of spinose microstrongyles, interrupted by the very numerous dermal pores. The minutely hispid character of the surface is due to the presence of very slender, hair-like anatriænes projecting beyond the dermal membrane.

Spicules.—(1.) Plagiotriænes (almost orthotriænes) (Plate III., fig. 1, *a*, *b*); with long shaft tapering very gradually to a sometimes almost filiform extremity, and rather short, stout, sharply pointed or rather blunt cladi; shaft about 1·5 millims. by 0·033 millim., with cladi about 0·148 millim. by 0·027 millim.

(2.) Plagiotriænes (almost protriænes) (Plate III., fig. 1, *c*, *c'*); with long, slender shaft tapering to almost hair-like dimensions. and short conical cladi projecting forwards at an angle of about 45°; shaft about 1·8 millims. by 0·0094 millim.; cladi about 0·028 millim. by 0·008 millim. Not very numerous.

(3.) Anatriænes (Plate III., fig. 1, *d*, *d'*); with long, slender shaft and short, sharp-pointed, strongly recurved cladi; cladome somewhat flattened in front; shaft and cladi of about the same dimensions as in the preceding.

(4.) Very slender, hair-like anatriænes with minute cladomes projecting beyond the surface of the sponge. These spicules seem to be fairly numerous and characteristic, but the cladomes are nearly always broken off in the preparations.

(5.) Oxea (Plate III., fig. 1, *e*); long and comparatively slender, usually slightly curved; fusiform; gradually and usually sharply pointed at each end; measuring, when fully developed, about 1·8 millims. by 0·037 millim.

(6.) Chiasters (Plate III., fig. 1, *g*); with little or no centrum and very slender, cylindrical, very minutely roughened, tylote rays; total diameter up to about 0·016 millim.

(7.) Microstrongyla (Plate III., fig. 1, *f*); straight, rather slender and minutely spined or roughened; measuring up to about 0·02 millim. by 0·002 millim., most abundant in the dermal membrane, but also plentiful in the choanosome.

There is a well-developed cortex about 0·25 millim. thick, composed of a mixture of chondrenchymatous, collenchymatous, and fibrous tissue, the first-named developed chiefly towards the outside and the last towards the inside. The mesoglœa of the choanosome is finely granular, but with an admixture of collenchymatous and chondrenchymatous tissue. The flagellate chambers are approximately spherical, about 0·02 millim. in diameter, and eurypylous. The dermal pore-sieves form the thin roofs of wide chones, which pass vertically through the cortex and are continued directly into the inhalant canals of the choanosome, without any specially differentiated subcortical crypts.

The presence of a fibrous cortex, though not very strongly developed, seems to indicate SOLLAS's genus *Psammastra* for this species, which is nearly related to three sponges described by Mr. CARTER under the names *Stelletta geodides* (18),* *Stelletta*

* *Vide* also SOLLAS, "Challenger" Tetractinellida, p. 200.

bacillifera (20) and *Stelletta bacillifera*, var. *robusta* (21),* the first and third from Australia and the second from the Mergui Archipelago. SOLLAS places the first in his genus *Psammastra*, while he places the last in *Ecionema*, which he distinguishes from *Psammastra* by the absence of cortex, but Mr. CARTER'S specimens of *Stelletta bacillifera*, var. *robusta*, were dry, and it is extremely probable that they possessed a fibrous cortex like that of *Ecionema carteri*; the type of *Stelletta bacillifera* from the Mergui Archipelago may also have been corticate for anything we know to the contrary, and it is almost certain that CARTER'S three sponges and the Ceylon species belong to the same genus. Moreover, we do not even know whether BOWERBANK'S original type of the genus *Ecionema* (*E. acervus*) was corticate or not, a question which it is impossible to decide without properly prepared sections of good material.

R.N. 175 (Lagoon inside reef, Galle, shallow water); 188 (Muttuvaratu Paar, Gulf of Manaar, 8 fathoms); 259 (Ceylon seas).

Ecionema laviniensis, n. sp.—Plate III., fig. 2.

The single specimen is somewhat finger-shaped, but flattened and slightly bifurcate at one (? the upper) end. It measures about 30 millims. in length and 13 millims. in breadth. The greater part of the surface is encrusted with coarse calcareous débris, chiefly Foraminifera and shell-fragments; where these bodies are absent there is a tendency to be minutely and sparsely hispid. In places there is a minutely porous appearance, easily visible under a pocket lens, due to the presence of small thickly scattered pore-sieves. The vents are probably very minute and scattered—I have only observed one. The colour in spirit is pale grey throughout, the texture firm and very compact.

The main skeleton is a confused interlacement of large oxea, towards the surface disposed more or less nearly at right angles to it and occasionally projecting beyond it. At the surface there is a spicular cortex, about 0·13 millim. thick, composed of microstrongyla with a thin layer of minute chiasters externally. Beneath the spicular cortex lie the cladomes of the comparatively few triænes, with their shafts penetrating the deeper parts of the sponge at right angles. (It is, perhaps, worth noting that in the deep groove at one end of the sponge, where it is beginning to bifurcate, the spicular cortex is not developed and there are apparently no triænes, but the large oxea project much further beyond the surface than they do elsewhere.) There are also a few slender anatriænes and protriænes (?) with cladomes projecting far beyond the surface.

Spicules.—(1.) Dichotriænes (Plate III., fig. 2, *a*, *b*); with stout shaft which typically tapers very gradually to a fine point, but may be blunted; protocladi short and stout; deuterocladi about the same length or a little longer or shorter, conical,

* *Vide* also SOLLAS, "Challenger" Tetractinellida, p. 197.

typically sharp-pointed, but may be blunted. A typical example gave the following measurements: shaft, 1·0 millim. by 0·0328 millim.; protocladus, 0·05 millim. by 0·027 millim.; deuterocladus, 0·065 millim. by 0·0164 millim.

(2.) Protriænes?

(3.) Anatriænes (Plate III., fig. 2, *c*, *c'*); with slender, often hair-like shaft and small, variable, often abnormal cladome, perhaps characteristically flattened in front. These spicules are evidently becoming vestigial and are so variable that it would be useless to give measurements; they are, however, still present in abundance.

(4.) Oxea (Plate III., fig. 2, *d*) large and usually stout; nearly always more or less curved, often strongly so, sometimes crooked; gradually and sharply pointed at each end, or more or less blunted; measuring up to about 1·4 millims. by 0·049 millim., but very variable in thickness.

(5.) Chiasters, with short, blunt, sub-cylindrical rays (Plate III., fig. 2, *e*), total diameter about 0·008 millim.; very abundant in the dermal membrane, and often met with in the choanosome, where they are commonly about half as large again and may vary into oxyasters (?) with very slender rays (Plate III., fig. 2, *f*).

(6.) Microstrongyla (Plate III., fig. 2, *g*) almost cylindrical, usually with rounded ends, but occasionally oxeote; minutely spined all over; usually slightly curved; sometimes centrotylote. A typical example measures about 0·1 millim. by 0·008 millim., but they are often much more slender. These spicules are found chiefly in the cortex, but may also be met with occasionally in the deeper parts of the sponge.

(A few slender, smooth microxea (Plate III., fig. 2, *h*) also occur, possibly young forms of other spicules.)

There is no distinct fibrous cortex, at any rate over the general surface, but a dense spicular cortex formed as described above. In the deep depression at the end of the sponge, however, where the spicular cortex is not developed, a certain amount of fibrous tissue is present in its place, and it is quite possible that such is also present concealed between the spicules of the spicular cortex elsewhere. (These facts serve to emphasise the unsatisfactoriness of the fibrous cortex as a generic distinction between *Ecionema* and *Psammastra*, to which attention has already been called under the head of *Ecionema carteri*.) The spicular cortex contains an immense number of rounded pigment cells filled with pigment granules of a rich brown colour.

Scattered abundantly throughout the choanosome are rounded groups of minute highly-refractive granules, staining with borax carmine, but in themselves practically colourless. These at first sight look like flagellate chambers, each group being about 0·02 millim. in diameter, but I do not think that they are really of that nature.

The species is evidently closely related to *Ecionema carteri* and its allies, but is well characterised by the dichotriænes and by the comparatively large size of the microstrongyles.

R.N. 265 (Station XLVI., off Mount Lavinia, 30 fathoms).

Family: GEODIIDÆ.

Astrophora, in which the characteristic microsclere is a sterraster, forming a dense cortical layer.

Geodia, Lamarck.

Geodiidæ, in which the somal microsclere is a polyactinose aster.

Geodia perarmata, Bowerbank.

1873, **Geodia perarmatus**, Bowerbank (22); 1880, **Geodia perarmata**, Carter (4); 1888, **Geodia perarmata**, Sollas (15).

There is an interesting series of specimens belonging to this species in the collection. The smallest is only 13 millims. in diameter, and is approximately spherical in shape; unfortunately, the surface of this specimen is considerably abraded, and I have not been able to make out the arrangement of either inhalant or exhalant apertures. The next in size, about 18 millims. in diameter, is also too much injured to show the arrangement of the apertures satisfactorily. The next is more irregular in shape, about 28 millims. in diameter, and flattened on one side so as to form an approximately circular oscular area about 14 millims. in diameter, but not definitely bounded. This area is covered by a pore-bearing, cribriform membrane, with pores about 0·08 millim. in diameter, and few, if any, larger apertures. The remainder of the surface of the sponge, outside the oscular area, is covered with a cribriform dermal membrane containing thickly scattered inhalant pores of somewhat smaller diameter than the exhalant pores. The specimen next in size is also irregular in shape, closely resembling a potato, and about 45 millims. in diameter. The oscular area now forms an ill-defined, but rather deep concavity on one side, whose floor is covered, as before, by a cribriform membrane, but with a few larger openings where the pores have apparently become confluent and thus formed small "vents"; the maximum diameter of this basin-shaped oscular area, which is not quite circular, is about 17 millims. The largest specimen is a very fine one, irregularly rounded in shape, and about 75 millims. in greatest diameter; it has been attached below at only a few points to calcareous débris. The depressed oscular area occupies the greater part of the flattened upper surface of the sponge, and is about 38 millims. in greatest diameter, and irregularly oval in shape. The floor of the depression is somewhat flattened, but rises up in the middle; the margin is much better defined than in the smaller specimens, but rounded off, except on one side, where it actually overhangs slightly. The pore-bearing membrane presents the same appearance as in the last-described specimen, but the small "vents," due to confluence of the pores, are more numerous; they are hardly 0·5 millim. in diameter. As before, the general surface of the sponge is covered by a richly porous cribriform membrane. There is also in the collection an irregularly-shaped sub-cylindrical specimen, about 36 millims. in length and 18 millims. in diameter, which does not show any distinct oscular area.

It appears, then, that the basin-like character of the oscular area, which was figured by BOWERBANK (22) in the type specimen, and which appears to form a characteristic feature of the adult sponge, is not developed until comparatively late in life, and it appears also that its development is due simply to more rapid growth of the surrounding parts. According to the classification adopted by SOLLAS in his work on the "Challenger" Tetractinellida, this mode of development would necessitate our placing the species in the genus *Cydonium*. SOLLAS himself, however, places the species in the genus *Geodia*, having been insufficiently acquainted with the characters in question. LENDENFELD, in his work on the Tetractinellida of the Adriatic, merges the genus *Cydonium* in *Geodia*, and in this I must agree with him, for the present instance demonstrates very clearly the impracticable character of a classification which involves a study of the development, at any rate until our knowledge is much more complete than at present.

The general surface of the sponge is smooth and, perhaps, even glabrous, where the dermal membrane is intact, but from a few points on the lower surface, in the immediate neighbourhood of the attachment, a few long, hair-like spicules (mostly anatriænes) project. The colour of the general surface (in spirit) is purplish brown, mottled with dull yellow, the pigment being lodged in an immense number of granular brown pigment cells which lie between the layer of sterrasters and the dermal membrane. Internally the sponge is nearly white.

The cortical layer of sterrasters is about 1·2 millim. thick in the largest specimen, and between this layer and the dermal membrane lies a zone about 0·27 millim. thick, in which the cladi of most of the triænes are found. The manner in which the shafts of these triænes pierce the layer of sterrasters, so that their cladi come to lie externally to it, is, as already pointed out by BOWERBANK, very characteristic of the species, and forms a conspicuous feature even in the smallest specimen which I have seen.

The spiculation, as observed in the largest specimen, is as follows:—

(1.) Dichotriænes; shaft stout, about 3·2 millims. by 0·07 millim.; chord, 0·48 millim. to 0·64 millim.

(2.) Protriænes; scarce (seen only in another specimen); cladi about 0·075 millim. long.

(3.) Anatriænes; shaft slender, about 4·2 millims. long; cladi about 0·07 millim. long.

(4.) Somal oxea; about 2·67 millims. by 0·042 millim.

(5.) Cortical oxea; about 0·3 millim. by 0·0083 millim.

(6.) Sterrasters; about 0·13 millim. in diameter.

(7.) Somal chiasters or spherasters; about 0·009 millim. in diameter.

(8.) Choanosomal spherasters with spined rays; about 0·04 millim. in diameter.

The spherasters with spined rays are found just beneath the layer of sterrasters and appear to be characteristic of the species. The fact that the spination of the rays is not figured by Bowerbank in his illustration, nor mentioned in the text, makes me a little doubtful of the identification of the Ceylon species with that originally described by Bowerbank (from an unknown locality). Carter, however, made the identification in the first instance and Sollas has accepted it; and the differences, if they really exist, must be extremely slight.

R.N. 119, 121, 124, 125, 126, 135. (All from deep water, up to 100 fathoms, off Galle and onwards up the West Coast of Ceylon.)

Geodia peruncinata, n. sp.—Plate III., figs. 3, 3a, 3b.

The single specimen in the collection is, unfortunately, only a fragment, amounting to probably somewhat more than half of a small spherical sponge, attached to a small calcareous nodule. The diameter of the specimen is about 11 millims. The colour in spirit is nearly white, both on the surface and in the interior. The cortex is rather thin and very brittle, and the interior of the sponge is soft and friable. It is impossible to make out the arrangement of the exhalant canal-system, but the thin dermal membrane contains numerous small pores, presumably inhalant.

The layer of sterrasters (Plate III., fig. 3, *e*, *e*) is about 0·33 millim. thick, and is separated from the dermal membrane by an interval of about 0·165 millim. occupied by extensive sub-dermal cavities. The dermal membrane is supported on the cladomes of dichotriænes (Plate III., fig. 3, *a′*), whose shafts pierce the layer of sterrasters and the zone of sub-dermal cavities; it is also strengthened and rendered hispid by the presence of immense numbers of short anatriænes which project from the surface at various angles (Plate III., fig. 3, *c*, *c*). Some of the dichotriænes (Plate III., fig. 3, *a*) have their cladi extended beneath the layer of sterrasters, and the remainder of the skeleton is arranged in the usual way, with radiate primary lines.

Spicules.—(1.) Dichotriænes (Plate III., fig. 3, *a*, *a′*); with stout shaft tapering gradually to a narrow, but blunt apex, and short cladi; the deuterocladi usually two or three times as long as the protocladi, but variable and often unequal, gradually and sharply pointed, slightly curved towards one another, or straight. Shaft measuring up to about 2·4 millims. by 0·044 millim., with cladome 0·62 millim. in total diameter and protocladi 0·038 millim. thick.

(2.) Protriænes; a few stout protriænes, more or less broken and sometimes with four cladi, occur amongst the mass of spicules projecting from the base of the sponge.

(3.) Anatriænes (Plate III., fig. 3, *b*); with well-developed cladome and very long, slender shaft. Shaft measured up to about 4·9 millims. in length (and then broken off), with a thickness of 0·016 millim. near the cladome, and cladi stout, conical, and about 0·057 millim. long. (Projecting from the base of the sponge one finds anatriænes with long, hair-like shafts and slender, very sharply recurved cladi.)

(4.) Anatriænes (Plate III., fig. 3, *c*; fig. 3a); with short, slender, fusiform shaft and very small, often vestigial cladome, which may be reduced to a mere knob. The attachment of the cladome to the shaft is so slender that the former is generally broken off and the spicules then may easily be mistaken for the well-known dermal oxea of other species of *Geodia*. The proximal end of the shaft may be oxeote or rounded off, or even tylote. In a typical example the shaft measures about 0·21 millim. by 0·006 millim. The cladome varies so much in its degree of reduction that it is useless to attempt exact measurements, but is generally not more than 0·008 millim. in total diameter. These spicules are found for the most part hispidating the surface of the sponge, but a few occur beneath the layer of sterrasters. I have seen one example which appears to be a reduced protriæne, with a single remaining cladus, but the great majority are anatriænes.

(5.) Oxea (Plate III., fig. 3, *d*); very long and comparatively slender, frequently curved, sometimes very crooked; fairly gradually and sharply pointed; size variable, *e.g.*, 2·5 millims. by 0·029 millim.

(6.) Sterrasters (Plate III., fig. 3, *e*, *e'*; fig. 3B, *c*); markedly oval in shape and measuring about 0·12 millim. by 0·082 millim.

(7.) Small spherasters (or chiasters?) (Plate III., fig. 3B, *a*); with small centrum and numerous almost cylindrical or slightly tylote rays about as long as the diameter of the centrum; total diameter of the spicule about 0·008 millim. Most abundant in the dermal membrane, but plentiful also in the interior.

(8.) Comparatively large spherasters (Plate III., fig. 3, *f*; fig. 3B, *b*); with large centrum and very numerous short, conical rays, whose length is only about one-third the diameter of the centrum or a little more. Total diameter when fully grown about 0·024 millim. Sparsely scattered beneath the layer of sterrasters.

In the structure of the ectosome and the presence of dichotriænes this species is evidently closely related to *Geodia perarmata*. It is, however, distinguished by three characters: (1) the absence of brown pigment cells in the outer part of the cortex; (2) the form of the larger spheraster, which, in *G. perarmata*, has (? always) distinctly spined rays; (3) the presence of the numerous short-shafted, cortical anatriænes,* which are replaced in *G. perarmata* by cortical oxea, though I am inclined to think that a few of these oxea may still show a vestige of a cladome even in *G. perarmata*, while it is quite possible that a few true cortical oxea may occur amongst the reduced anatriænes in *G. peruncinata*.

The presence of the vestigial anatriænes is extremely interesting as indicating the anatriænal origin of the cortical oxea of *Geodia*. Sollas (*loc. cit.*, p. cxlvii) has already observed, in his general remarks on the family Geodiidæ, that "A second finer hispidation is frequently produced by small oxeas, which are confined to the cortex (cortical oxeas). Associated with these, in some few instances, are minute anatriænes, which much remind one of the cladose tylostyles described by Dendy and Ridley in *Proteleia sollasi*." We have here an admirable example of the evolution

* Very similar small cortical anatriænes occur in Lindgren's *Geodia arripiens* from Cochin China (86).

of a monaxonellid spicule from a tetractinellid form by subordination and final suppression of three of the rays.

R.N. 223 (Station XLI., 12 miles off Galle, 100 fathoms).

Geodia areolata, Carter.

1880, **Geodia areolata**, Carter (4); 1888, **Geodia areolata**, Sollas (15).

There are several specimens of this sponge in the collection. They are approximately spherical in shape, and in form and colour closely resemble young specimens of *G. perarmata*, but the largest sent to me is only 21 millims. in diameter. The surface of the sponge is smooth and characteristically marked out into small stellate areas of a pale yellow colour, separated from one another by a reticulation of chestnut-brown pigment. This pattern, however, is not recognisable everywhere. Numerous small apertures appear irregularly scattered over some parts of the surface, but with a tendency towards grouping. These frequently occupy the centres of the pale stellate areas, and they are often guarded by a fringe of convergent dermal oxea. They are frequently covered over by a reticulate dermal membrane. They are the openings of chones, which pierce the layer of sterrasters, but whether they are inhalant or exhalant, or both, I have been unable to decide.

The layer of sterrasters is about 0·46 millim. thick in the largest specimen. The triænes almost invariably extend their cladi beneath this layer, and do not pierce it to reach the dermal membrane. The dermal oxea are abundant and arranged more or less perpendicularly to the surface; they extend from the outer surface of the layer of sterrasters and project for a short distance beyond the dermal membrane. The granular brown pigment cells, to which the sponge owes its characteristic colour, are scattered in the ectosome outside the layer of sterrasters.

The spiculation is as follows:—

(1.) Orthotriænes; with shaft about 2·37 millims. by 0·06 millim.

(2.) Anatriænes; with very long and slender shaft and cladi about 0·054 millim. long.

(3.) Somal oxea; about 2·0 millims. by 0·029 millim.

(4.) Cortical oxea; about 0·2 millim. by 0·008 millim.

(5.) Sterrasters; about 0·08 millim. in diameter, oval or nearly spherical.

(6.) Somal chiasters or spherasters; about 0·0083 millim. in diameter.

(7.) Choanosomal oxyasters or spherasters; mostly with few long and slender, smooth rays; about 0·0165 millim. in total diameter.

No typical protriænes were seen, but only small plagiotriænes, which may be young forms of the large orthotriænes.

In this case, as in that of *G. perarmata*, we can include the species in the genus *Geodia* only by abandoning the restricted definition thereof given by Sollas.

The species, as already indicated, is at first sight easily confounded with *G. perarmata*. The specimens of the two were mixed together in the collection, and only a part of the total number was forwarded to me for investigation, under the impression that they were all specifically identical. I am therefore unable to say how many of each were really collected by Professor HERDMAN and his assistants. Even small specimens are, however, very easily distinguished by microscopical examination, as will be evident from the above descriptions, and the species are not really even closely related.

Mr. CARTER received his material of this species from the Gulf of Manaar.

R.N. 120, 122, 123 (deep water off Galle, up to 100 fathoms).

Geodia ramodigitata, CARTER.

1880, **Geodia ramodigitata**, CARTER (4); 1888, **Geodia** (?) **ramodigitata**, SOLLAS (15).

There is one specimen in the collection which appears to be referable to this species. It is of remarkably irregular shape, with one strongly curved, finger-like projection or branch. Unfortunately the specimen is a good deal injured on one side, so that the exact shape cannot be determined. The maximum diameter of the specimen in its present condition is about 40 millims. The colour (in spirit) is pale grey, and a good many foreign bodies are attached to the surface here and there. The vents are minute, for the most part irregularly grouped over the ends of large exhalant canals, with which they communicate by means of narrow chones penetrating the cortex. The outer ends of these chones are usually covered over by a sieve-like dermal membrane which sub-divides the vent into a group of comparatively small pores. Inhalant pores irregularly scattered, perhaps sometimes in groups, but of the numerous pore-sieves present in the dermal membrane it is extremely difficult to say which are inhalant and which exhalant.

The layer of sterrasters is about 1 millim. thick and lies close up to the dermal membrane, with the cladi of the triænes spreading out beneath it. The dermal membrane is very minutely hispid with projecting oxea.

The spiculation is as follows:—(1.) Orthotriænes; shaft stout, gradually and finely pointed, about 2·5 millims. by 0·08 millim; cladi stout, sharp pointed, up to about 0·35 millim. long, extended nearly at right angles to the shaft. Sometimes one or more of the cladi undergoes reduction or may even become obsolete, leaving the spicule with two, one or no properly developed cladi, as the case may be.

(2.) Protriænes; shaft very long and slender, measured up to about 3·7 millims. by 0·023 millim., with sharp-pointed cladi about 0·18 millim. long.

(3.) Anatriænes; shaft very long and slender, measured up to 4·0 millims. by 0·018 millim.; with stout, recurved, sharp-pointed cladi about 0·09 millim. long; not very numerous.

(4.) Somal oxea; gradually and sharply-pointed at each end, about 2·57 millims. by 0·04 millim., often slightly curved.

(5.) Cortical oxea; about 0·2 millim. by 0·007 millim.

(6.) Sterrasters; about 0·09 millim. by 0·075 millim.

(7.) Chiasters; extremely minute, with short, truncate or slightly tylote rays; total diameter about 0·006 millim.; very abundant in the dermal membrane.

(8.) Oxyasters; of unusually large size, with no distinct centrum, with large, slender, smooth, sharp-pointed rays, rather few in number; total diameter about 0·066 millim.; very abundant in the deeper parts of the sponge.

There are two points in which the spiculation of Professor HERDMAN'S specimen, as given above, differs considerably from that given by CARTER (4) for the type of the species. In the first place, CARTER mentions no cortical oxea, but he remarks that the surface is much worn, so that we need lay but little stress upon this difference. In the second place, the internal oxyasters appear to be twice as large in our specimen as in the type; this also I do not consider a very important difference, as the internal asters of *Geodia* are subject to much variation in size. Their form, on the other hand, agrees very closely in the two cases and appears to be characteristic. The other spicules, also, with the exception of the sterraster, appear to be somewhat larger in the present specimen; but on the whole there can be very little doubt of the correctness of the identification, especially when we remember that Mr. CARTER'S type specimen came from the Gulf of Manaar.

R.N. 136 (Station XLI., 12 miles off Galle, 100 fathoms).

SUB-ORDER: SIGMATOPHORA.

Tetractinellida with triænes; with sigmata for microscleres (when present); without asters.

FAMILY: TETILLIDÆ.

Sigmatophora with well-developed protriænes and with skeleton usually strongly radiate in arrangement.

Tetilla, SCHMIDT.

Cortex absent or feebly developed; no special cortical skeleton.

Tetilla hirsuta, DENDY.

1889, **Tetilla hirsuta**, DENDY (3).

This remarkable species is represented in the collection by three specimens which differ somewhat amongst themselves, but all agree in the possession of the highly characteristic, cup-shaped, poriferous pits. In all the surface is more or less strongly hispid from projecting spicules, and encrusted with a layer of dirt between, to which the colour of the surface is due, this colour varying with the nature of the foreign matter. Two of the specimens are more or less spherical, one (R.N. 129) being attached to a mass of Nullipore; the third (R.N. 241) is constricted and slightly elongated below, where it has been torn off from its attachment. In one specimen (R.N. 129) there are, in addition to the characteristic spicules, a fair number of quite small oxea, varying much in size, and irregularly scattered in the choanosome. Such small oxea do not appear to be present in the type, but, in view of their variability in size and sporadic distribution, one can hardly regard their presence as constituting a specific or even varietal distinction. It should be noted, however, that very similar spicules appear to be characteristic of the next species (*T. poculifera*).

The arrangement of the pores and vents in this sponge is very peculiar and might be thought by some authorities to deserve generic recognition. The former are congregated in more or less deep, cup-shaped pits, guarded by very slender projecting protriænes and prodiænes; these pits occur, mostly, at any rate, on the lower parts of the sponge and may slope upwards. The vents (or better, cloacal cavities) are represented by pits containing the openings of excurrent canals. As SOLLAS has pointed out (**15**, p. cxxv), a somewhat similar arrangement is found in his genus *Cinachyra*, closely related to *Tetilla*, but that genus is also characterised by the presence of a thick cortex containing cortical oxea. In *Tetilla hirsuta* the cortex is only feebly developed, more or less fibrous, but without special cortical spicules.

For further specific details I must refer to the original description, to which I may add that the flagellate chambers are apparently eurypylous.

In the choanosome of R.N. 129 numerous minute and apparently siliceous spherules were observed, up to about 0·004 millim. in diameter. The nature of these bodies will be discussed under the head of *Tetilla anomala*, in which species they also occur.

R.N. 129 (deep water off Galle and onwards up West Coast); 177 (lagoon inside the reef, Galle, shallow water); 241 (Ceylon seas).

Tetilla poculifera, n. sp.—Plate I., fig. 6; Plate III., fig. 4.

The type specimen (R.N. 230, Plate I., fig. 6) is somewhat pear-shaped, with the broad end attached to a mass of calcareous organisms (Polyzoa, &c.). The apex of the sponge is occupied by a deep cup-shaped cloaca (Plate I., fig. 6, *Cl.*), whose margin is fringed with spicules, and whose floor is a sieve-membrane. The surface of the sponge is uneven, irregularly hispid, and thinly encrusted with sand-grains. Colour (in spirit) yellowish grey. Height of specimen 16 millims., transverse diameter 14 millims. Diameter of cloacal aperture 2·5 millims.

The skeleton consists chiefly of bands of large oxea radiating outwards from a central "nucleus"; the ends of these bands commonly project slightly beyond the surface.

Spicules.—(1.) Plagiotriænes (Plate III., fig. 4, *a*, *b*); few in number, but evidently proper to the sponge, though, perhaps, not specifically characteristic. A typical example from a boiled-out preparation has a fairly stout shaft, tapering gradually to a hair-like extremity, and about 1·3 millim. long by 0·0185 millim. thick below the cladome; cladi short and stout, about 0·13 millim. long, with apices fairly sharp and slightly incurved. (I have also seen fragments of two large dichotriænes, but it is doubtful whether these are proper to the sponge.)

(2.) Protriænes (Plate III., fig. 4, *d*, *d'*); with long, slender shaft, and long, slender, sharp-pointed cladi; conspicuous around the cloacal opening; size variable.

(3.) Anatriænes (Plate III., fig. 4, *c*, *c'*); of ordinary form, with short cladi and very long, slender, hair-like shaft. A specimen in a boiled-out preparation has cladi about 0·037 millim. long and shaft about 2·8 millims. long.

(4.) Oxea of the main skeleton (Plate III., fig. 4, *e*); stout, straight, fusiform, and tapering very gradually to the extremities, which may be sharply pointed, or rounded off or irregular; size about 3·1 millims. by 0·046 millim.

(5.) Sigmata (Plate III., fig. 4, *h*); slender, more or less contort, measuring about 0·017 millim. from bend to bend; abundant.

(6.) Small scattered oxea (microxea) (Plate III., fig. 4, *f*, *g*); straight or slightly curved; smooth, slender, fusiform, gradually and finely pointed at each end; size about 0·23 millim. by 0·005 millim. These spicules are scattered irregularly in enormous numbers throughout both choanosome and ectosome; in the latter position they may form quite a dense layer at the surface of the sponge, in which most of them lie tangentially. They may, perhaps, be regarded as microscleres.

Stained sections show that there is no cortex, and that the ectosome, though fairly thick, is not sharply differentiated from the choanosome. The material is not in a fit condition for minute histological investigation, but I have been able to make out that the flagellate chambers are oval and about 0·029 millim. in greater diameter. The inhalant pores are apparently scattered over the surface, and the inhalant canals appear to originate in irregular lacunar subdermal cavities. The larger exhalant canals are provided with numerous diaphragms, and terminate below the sieve-like floor of the cloaca.

The most characteristic features of this species are the structure of the cloaca and the presence of the very numerous smooth microxea. In *Tetilla* (?) *australiensis* (CARTER) minutely spined microxea, 0·21 millim. long, are present, and SOLLAS (**15**, p. 43) observes of this species that the oxeote microscleres are almost unique amongst the Tetillidæ.* The case of *T. hirsuta*, described above, however, seems to show that in the oxea of this genus (as in *Plakinastrella*, &c.) it is impossible to draw a hard and fast line between mega- and microscleres.

In addition to the type described above, there are in the collection two other specimens which may be referred to the same species, viz., R.N. 189 and 205. Both are somewhat imperfect. R.N. 205 has several cup-shaped (cloacal ?) cavities, with sieve-like floors, irregularly distributed; the other is too imperfect to show the character of the vents.

R.N. 189 (Muttuvaratu Paar, Gulf of Manaar); 205 (Gulf of Manaar); 230 (deep water off Galle and onwards up West Coast of Ceylon).

Tetilla anomala, n. sp.—Plate III., fig. 5.

There are two specimens of this sponge in the collection, the larger of which (R.N. 153) may be regarded as the type. It appears to be a fragment, amounting to

* Oxeote microscleres occur also in the genus *Paratetilla* (*vide infrà*).

nearly half, of an irregularly spherical sponge, about 35 millims. in greatest diameter. The surface is rather uneven, minutely hispid, and thinly encrusted with sand. Neither pores nor vents are visible externally. The colour, in spirit, is grey, the texture firm and compact and only slightly compressible.

The skeleton consists chiefly of stout bands of oxeote spicules radiating from a centrally (?) placed "nucleus" to the surface of the sponge. The outer portions of these bands are often abundantly echinated by the cladi of the anatriænes, lying chiefly in the ectosome.

Spicules.—(1.) Protriænes (Plate III., fig. 5, *a*); with rather short, stout cladi and fairly stout shaft, tapering to hair-like fineness. Shaft about 2·76 millims. by 0·015 millim. (at the thickest); cladi about 0·054 millim. by 0·00625 millim. The cladi may be slightly irregular, and I have seen one forked at the extremity. They are sometimes much longer than in the specimen measured. These spicules occur in positions similar to those of the anatriænes, but are very scarce.

(2.) Anatriænes (Plate III., fig. 5, *b*, *b′*); with fairly stout, sharp-pointed cladi and long hair-like shaft; length of shaft about 2·7 millims., of cladi about 0·058 millim. Abundant.

(3.) Oxea (Plate III., fig. 5, *c*); stout, fusiform, gradually and finely pointed at each end; size about 2·8 millims. by 0·046 millim.

(4.) Sigmata (Plate III., fig. 5, *d*); slender, usually contort; very numerous, especially in the walls of the inhalant canals; measuring up to about 0·01 millim. from bend to bend.

(5.) Spherules; smoothly rounded, but irregular in shape; up to about 0·004 millim. in diameter, but usually smaller. These bodies are enormously abundant in the choanosome, but are practically absent from the ectosome. In the type specimen they are thickly, but irregularly scattered; in R.N. 192 they are grouped in oval clusters about 0·11 millim. in longer diameter.

Stained sections show a fairly thick ectosome pretty sharply differentiated from the choanosome and, to some extent, fibrous, but composed chiefly of chondrenchyme with very numerous granular cells. The thickness of this ectosome, which almost amounts to a cortex, in the type specimen, is about 0·74 millim. It is penetrated here and there by narrow inhalant canals, leading almost vertically inwards from the surface. The flagellate chambers are oval or nearly spherical, up to about 0·033 millim. in diameter. Their mode of opening and the arrangement of the excurrent canal system have not been made out. The mesoderm of the choanosome ranges from collenchymatous to chondrenchymatous.

The extraordinary number of the siliceous spherules or globules in this sponge is very remarkable. In R.N. 192 they are, as already stated, grouped together in oval masses. They appear in this case to originate many together in special mother cells, in which they first appear as very minute, highly refringent points. The oval groups are probably still associated with the remains of the mother cells. The exact nature of these bodies and their taxonomic value are extremely doubtful. SOLLAS (15) mentions that such bodies occur in the Tetillidæ associated with sigmaspires, but in *Cinachyra barbata*, where they are said to be as much as 0·0535 millim. in diameter, he regards them as "accessory or accidental" forms, and the only species of *Tetilla* in which they are mentioned appears to be *Tetilla arabica* (CARTER), where they are of about the same size as in *T. anomala*. I myself have seen similar bodies in one specimen of *Tetilla hirsuta* (*vide supra*), but only very locally developed. That the spherules are really siliceous appears to be tolerably certain, for they appear abundantly in preparations of *T. anomala* which have been boiled out with nitric acid. Whether they can be regarded as definite and characteristic spicules is, however, another question, and it appears to me not impossible that they may be simply reserves of siliceous material destined to be re-absorbed later on and used for spicule formation. This view is strongly supported by their very sporadic distribution.

There is possibly a close relationship between *T. hirsuta*, *T. poculifera*, and *T. anomala*.

R.N. 153 (Station V., off Chilaw, 10 fathoms); 192 (Station LVII., outside Dutch Modragam Paar, $11\frac{1}{2}$ to 36 fathoms).

Tetilla limicola, n. sp.—Plate I., fig. 7; Plate III., fig. 6.

Sponge (Plate I., fig. 7) somewhat fig-shaped, constricted below, broadly rounded above; may be slightly lobose; may be laterally compressed; anchored in the mud by a great mass of fine silky spicules attached to the base. Surface glabrous, but at the same time minutely and sparsely hispid above, more strongly hispid on the sides; also very minutely reticulate on the upper parts. Texture soft and spongy, but very compact, *i.e.*, without wide canals or cavities in the interior. Colour in life, pink; in spirit, grey. Vents (Plate I., fig. 7, *o*) of fair size, several, slit-like, in deep or shallow depressions on the upper part of the sponge; each leading into a wide but shallow cloacal cavity with an almost flat floor perforated by numerous minute openings of very narrow exhalant canals. Inhalant pores scattered between the surface tufts of spicules. A spirit specimen (exclusive of the root tuft) measures about 43 millims. in height, 48 millims. in greatest breadth, and 31 millims. in greatest thickness. The root-tuft (Plate I., fig. 7, *r.t.*) is nearly as large as the specimen itself, and in its present condition consists of a mass of soft mud held together by the extremely long and slender silky anchoring spicules, which individually are scarcely visible to the naked eye.

The skeleton consists of the following parts:—

(1.) Loose longitudinal bands of very long, slender oxea run almost parallel to one another throughout the body of the sponge. In a longitudinal section taken across the greatest breadth of the sponge these fibres are seen to converge towards a point situated at a short distance below the depressed apex of the sponge. Owing to the constriction of the sponge below, the lower ends of these fibres approach the surface almost without diverging from one another.

(2.) More or less mingled with the foregoing in the lower parts of the sponge are long, silky bundles of the very long, sinuous, hair-like shafts of anatriænes, whose heads echinate the bundles at varying distances beneath the surface.

(3.) Dense surface brushes, composed partly of oxea which form the ends of the long fibres and partly of protriænes of hair-like thinness, whose cladomes project far beyond the surface.

(4.) Numerous oxea, much shorter than those of the fibres, scattered irregularly throughout the body of the sponge.

(5.) The root-tuft, composed of anatriænes with extremely long and slender shafts, irregularly matted together.

Spicules.—(1.) Protriænes (Plate III., fig. 6, *b.*), (and diænes); shaft and cladi often of hair-like thinness; cladi commonly of unequal length (one sometimes suppressed entirely), projecting forwards at only a very small angle with the shaft. In a perfect example in a boiled-out preparation the shaft is about 3·0 millims. long, about 0·004 millim. thick just below the cladi, and tapering to hair-like fineness at the other end. The longest of the cladi is about 0·05 millim. in length.

(2.) Anatriænes (Plate III., fig. 6, *a*); with extremely long, hair-like shafts, so long and slender that they appear to be invariably broken off even in boiled-out preparations, and I am therefore unable to give the measurements. The cladi are fairly stout, gradually sharp-pointed, recurved at a very acute angle to the shaft, and about 0·04 millim. long by 0·004 millim. thick at the base. In boiled-out preparations the shafts of these spicules stick together in silky wisps.

(3.) Oxea (Plate III., fig. 6, *c.*); long and slender, commonly slightly curved, very gradually and finely pointed, varying greatly in size according to position, measured up to about 2·1 millims. by 0·01 millim.

(4.) Sigmata (Plate III., fig. 6, *d*); slender and commonly contort, measuring about 0·008 millim. from bend to bend. Very numerous.

The material is hardly sufficiently well preserved for minute histological investigation, but the examination of sections prepared by the usual paraffin method shows us the following features. There is no cortex and no distinct dermal membrane, the ectosome not being sharply differentiated from the choanosome. The small inhalant pores, scattered between the dermal brushes of spicules, lead directly into narrow, elongated canals, which run inwards at right angles to the surface and unite below the spicular brushes in larger inhalant canals which penetrate the deeper parts of the sponge. The flagellate chambers are approximately spherical and about 0·025 millim. in diameter; they are probably eurypylous. The exhalant canals are all narrow, and converge towards the flask-shaped cloacal cavities already mentioned. Numerous large ova, many of them having very prominent pseudopodia, are scattered through the choanosome. These ova measure up to about 0·11 millim. in diameter. They have uniformly granular cytoplasm and large, well-defined nuclei, each typically with a single darkly-staining nucleolus.

Of this remarkable sponge eight specimens were found, anchored in the soft mud at the bottom of Tamblegam Lake (a large inlet from Trincomalee Bay); but only one was forwarded to Cape Town for more minute investigation.

The species is evidently nearly related to *Tetilla dactyloidea* (Carter), which that author records (20, 34, 43) from the south-east coast of Arabia, Bombay, and the Mergui Archipelago. The principal difference apparently concerns the excurrent canal-system. In *T. dactyloidea* there appears to be a single vent at the summit of the sponge, and Mr. Carter observes that the terminal aperture divides into a number of branches, which, sub-dividing, permeate the mass generally down to its base. In *T. limicola*, as we have seen, the sponge is very compact throughout, and there are no wide tubes in it, the excurrent canals being very narrow and opening by numerous minute apertures in the floors of somewhat flask-shaped cloacæ with slit-like vents on the surface of the sponge. It is highly probable that this arrangement is a special adaptation to the conditions of life, serving to hinder the entrance of the very fine soft mud, in which it lives, into the interior of the sponge; even as it is, a considerable amount of mud may be seen in the excurrent canals just beneath the floor of the cloaca.

R.N. 70 (one of eight specimens from Tamblegam Lake, Trincomalee).

Craniella, Schmidt.

The ectosome is differentiated into an inner fibrous layer, containing more or less radially arranged cortical oxea, and an outer collenchymatous layer excavated by large subdermal cavities.

Craniella elegans, n. sp.—Plate IV., fig. 1.

Sponge free, irregularly spherical. Surface covered with close-set conuli; hispid with brushes of spicules projecting from the conuli; minutely reticulate between the conuli. Vents not visible in the type specimen. Pores in the thin dermal membrane stretched between the conuli. Colour, in spirit, purplish grey externally, yellow internally. Greatest diameter of type (R.N. 193) about 20 millims. Consistence firm and compact.

The main skeleton consists of stout bundles of spicules radiating from a central "nucleus" and ending in the brushes which project from the surface conuli (Plate IV., fig. 1). These radiating bundles (*r.b.*) are separated from one another by fairly wide intervals, and are composed of large oxea, with anatriænes and protriænes. The cladi of the anatriænes are, for the most part, situated in the outermost part of the choanosome, just beneath the cortex, while those of the protriænes mostly project beyond the surface of the sponge in the hispidating brushes. The special cortical skeleton is, as usual in *Craniella*, confined to the inner, fibrous layer of the cortex, and is composed of stout oxea; these are not arranged strictly radially, but are inclined at various angles to the surface, with their outer extremities commonly abutting at more or less acute angles against the stout bundles of the main skeleton as the latter penetrate the cortex on their way to form the surface brushes.

Spicules.—(1.) Protriænes (Plate IV., fig. 1, *b*); with long shaft, rather stout distally but becoming setaceous proximally, and short, stout cladi of approximately equal length. Shaft in measured specimen 4·78 millims. by 0·0368 millim. (near cladome); cladi, 0·129 millim. long.

(2.) Anatriænes (Plate IV., fig. 1, *a*); with long and very slender, setaceous shafts, and short, stout, sharp-pointed cladi; shaft measured up to 4·87 millims. by 0·0138 millim. (near cladome), with cladi 0·0736 millim. long. Very numerous.

(3.) Oxea of the radiating bands (somal oxea); stout, aniso-actinate; more or less gradually sharp-pointed distally, but drawn out into long setaceous filaments proximally; size up to about 3·27 millims. by 0·046 millim.

(4.) Cortical oxea (Plate IV., fig. 1, *c.o.*); stout, fusiform, aniso-actinate, sharp-pointed at each end, the proximal end narrower than the distal, but not setaceous; commonly slightly curved; size about 1·0 millim. by 0·0368 millim.

(5.) Sigmata; slender, 0·0166 millim. from bend to bend.

The cortex of the type specimen measures, in places, as much as 1·8 millims. thick, and is very sharply differentiated into two layers, of which the outer appears to be usually somewhat thicker than the inner. The outer layer is excavated by very large subdermal (intra-cortical) cavities (Plate IV., fig. 1, *i.c.c.*), which occupy nearly all the space between the radiating spicule bundles of the main skeleton, with the thin dermal membrane stretched over them. The dermal membrane (*d.m.*), and also the deeper parts of the outer layer of the cortex, between the subdermal cavities, contain numerous small brown pigment granules grouped in more or less spherical cells. The inner layer of the cortex (*f.c.*) is densely fibrous and contains no pigment granules; it is strengthened by the special oxea above described, and the fibres lie, for the most part at any rate, parallel to the surface.

The flagellate chambers are about 0·02 millim. in diameter, spherical or oval, eurypylous or with short, wide excurrent canaliculi. The choanosome is crowded with large embryos (Plate IV., fig. 1, *emb.*).

In addition to the type above described, there is in the collection another very small specimen (R.N. 204) of pear-shaped form, with a single apical vent. The maximum diameter of this specimen is only about 8·5 millims. In the structure of the cortex and in the form and arrangement of the spicules, it agrees very well with the type, but the megascleres are all much smaller. This difference, however, is probably due to immaturity, the specimen being of very small size and containing no embryos, while the type, as we have seen, is crowded with them.

R.N. 193 (Station LVII., outside Dutch Modragam Paar, 11½ to 36 fathoms); 204 (Gulf of Manaar).

Paratetilla, n. gen.

Tetillidæ with a special layer of modified triænes, resembling calthrops, lying at the junction between the ectosome and choanosome (or in the ectosome).

The discovery by Professor HERDMAN of another species of Tetillid which shares the remarkable skeletal peculiarities of CARTER'S *Tethya merguiensis* (21), appears to justify the establishment of a new genus for the reception of the two. *Paratetilla merguiensis* is, like our species, an inhabitant of the Indian Ocean (Mergui Archipelago), but its area of distribution extends, according to SOLLAS (15), as far as Torres Straits. The synonymy of this species is, however, somewhat involved, according to LINDGREN (86) and THIELE (87) it should be known as *Tetilla bacca* (SELENKA), with which, according to THIELE, KIESCHNICK'S *Tetilla ternatensis*, *T. amboinensis*, *T. violacea*, and *T. rubra* are again synonymous. If these identifications be correct the range of the species must be yet further extended.

Paratetilla cineriformis,* n. sp.—Plate III., fig. 7.

This species is represented in the collection by four specimens, ranging in diameter from about 12 millims. to about 41 millims. The shape is irregularly hemispherical. All but the smallest have been injured below by tearing off from the attachment, the base of the sponge having evidently been left behind. The smallest, which appears to be fairly perfect, is cushion-shaped, flat beneath and convex above. The surface is more or less uneven, and to some extent hispid, though not very markedly so; it may be very irregular. The consistence is rather soft and spongy. The colour externally (in spirit) is almost black; internally much paler, purplish grey. The arrangement of the vents and pores is very difficult to determine. A few small, pocket-like depressions, irregularly scattered over the surface, probably represent cloacal cavities; their floors are perforated by the numerous minute apertures of slender, exhalant (?) canals; their external openings may be narrow and slit-like. The inhalant pores are probably scattered irregularly over the surface, but I have not been able to make them out distinctly. Some of the specimens are infested by parasitic cirripedes, living beneath the surface in cavities whose external apertures simulate vents.

The main skeleton consists of stout bands of spicules radiating from a large central "nucleus." In addition to these there is the layer of modified triænes lying at the junction of ectosome and choanosome.

Spicules.—(1.) Modified triænes (Plate III., fig. 7, *a–d*), lying at the junction of ectosome and choanosome. These spicules are so irregular in size and shape that it is almost impossible to describe them; the following have been measured: (*a.*) with four simple unbranched rays, one much shorter than the others, resembling a plagiotriæne with shaft shorter than cladi; length of longest ray 0·165 millim., with two

* The specific name is derived from the close resemblance which the sponge bears to a black cinder.

others a little shorter, and the fourth much shorter; (*b.*) with one very short unbranched ray (shaft) and three much longer rays (cladi), of which two are forked; cladi of somewhat unequal length; maximum diameter of cladome from tip to tip of rays 0·276 millim.; maximum diameter of cladi about 0·0166 millim.; (*c.*) similar to (*a.*), but with cladi much curved; the very short shaft, as is commonly the case, rounded off at the extremity; (*d.*) with only three rays, two almost in the same straight line and the third, much shorter (? = shaft) at right angles to them; length of each of longer rays about 0·147 millim.; of short ray about 0·055 millim. The rays of these spicules are often irregularly bent or curved. They are probably, as pointed out by CARTER and SOLLAS in the case of *P. merguiensis*, modified "zone-spicules" (plagiotriænes).

(2.) Protriænes (Plate III., fig. 7, *e*, *e′*); few in number and very variable in dimensions, with shaft and cladi all very slender or fairly stout, and cladome sometimes irregular. The cladome may or may not project beyond the surface.

(3.) Anatriænes (Plate III., fig. 7, *f*, *f′*); with short, stout cladi, and very long slender shaft, often inflated in a bulbous manner at a short distance below the cladome and tapering to hair-like dimensions at the other end. Length of shaft in measured specimen 3·3 millims.; diameter between bulb and cladome 0·007 millim.; length of cladi 0·027 millim. The cladomes of these spicules sometimes project beyond the surface of the sponge.

(4.) Oxea of the main skeleton (Plate III., fig. 7, *g*, *g′*, *g″*); stout, straight or nearly so; fusiform, with the ends gradually and finely pointed, or more or less irregular; size about 2·9 millims. by 0·0365 millim., but usually more slender. Numerous much smaller oxea, apparently young forms, also occur.

(5.) Sigmata (Plate III., fig. 7, *h*); extremely slender, frequently, if not always, contort, about 0·014 millim. from bend to bend; abundant.

In stained sections of the largest specimen the cortex measures up to about 0·28 millim. in thickness. It is composed of a compact tissue which appears to be cystenchymatous rather than collenchymatous, and the cells contain numerous minute brown pigment granules. The choanosome appears to be mostly collenchymatous and contains brown pigment granules similar to those of the cortex, but fewer in number. The flagellate chambers are oval or nearly spherical, up to about 0·0249 millim. in diameter.

This interesting sponge is evidently nearly related to CARTER'S *Tethya merguiensis* (21) (*Tetilla merguiensis* of SOLLAS) from the Mergui Archipelago, off the coast of Burmah, but differs to such an extent that there can hardly be any question of specific identity. The characteristic inhalant pore-sieves and dermal reticulation of CARTER'S species are not recognisable here; the dermal microxea are absent, and the modified "zone-spicules" appear to be much more irregular in shape.

R.N., 184, 187 (Stat. VI., Muttuvaratu Paar, Gulf of Manaar); 214 (deep water outside pearl banks, Gulf of Manaar); 245 (Ceylon seas).

Grade: LITHISTIDA.

Tetraxonida in which the megascleres form desmas, typically united with each other to form a continuous skeleton.

The relationships and classification of the Lithistida still require a great deal of investigation before we can consider our knowledge of the group as by any means satisfactory. They are, of course, usually considered as a sub-division of the Tetractinellida, but inasmuch as many of them have only monaxonid spicules this method of disposing of the group seems somewhat unjustifiable. There appear to be two logical alternatives. We may either regard the Lithistida as being of polyphyletic origin and partition them to the best of our ability amongst other groups, or we may regard them as representing another grade of evolution in a special direction and retain the group provisionally as a matter of convenience, without committing ourselves to an opinion as to whether it is a natural group or not. In the present state of our knowledge the latter appears to me the wisest course to adopt.

As regards the internal classification of the group, I have no doubt that important modifications of the existing arrangement of genera, which we owe to Sollas, must shortly be made. My own experience of the Lithistida is, however, so limited that I prefer not to experiment in this direction, but will content myself with a few critical remarks suggested by the investigation of certain species in Professor Herdman's collection.

Discodermia, Bocage.

Lithistida with tetracrepid desmas and ectosomal discotriænes, and with microscleres in the form of microxea or microstrongyla.

Discodermia emarginata, n. sp.—Plate IV., fig. 4.

The single specimen is of massive form with spreading base attached to a mass of calcareous worm-tubes. The upper surface is strongly convex, rising into two low, mammiform projections, from the broad apices of which (where the small vents are situated) radiate shallow grooves, the outward indications of convergent exhalant canals. Colour throughout (in spirit) pale yellow; texture compact and stony. Diameter of massive central portion about 12 millims., with the basal portion spreading a good deal further as a thin crust.

Skeleton composed of a close reticulation of firmly united tetracrepid desmas with a single layer of discotriænes on the surface. Below the surface are a few slender oxea, which become more numerous and are sometimes collected into loose fibres in the neighbourhood of the vent.

Spicules:—(1.) Stout tetracrepid desmas (Plate IV., fig. 4, *a–e*), more or less tuberculated, especially at the ends of the branches, which proliferate into numerous rounded tubercles, by the interlocking of which the union of adjacent desmas is effected. There are no transitional forms intermediate between these desmas and the discotriænes of the surface, such as Mr. CARTER describes (4), and the desmas are evidently not derived from discotriænes. Each originates from a tetract crepis (calthrops) by branching of the actines and secondary deposition of siliceous material. The initial stages in the development of the desmas are to be found in abundance just beneath the superficial layer of discotriænes, where the skeleton is evidently growing. The young crepis (Plate IV., fig. 4, *a*) is a regular tetract calthrops with minutely roughened surface. In one of the youngest I have seen, the actines measure about 0·04 millim. by 0·004 millim. One actine may be longer than the other three; they are sometimes conical and suddenly constricted at the base. Having attained a length of about 0·08 millim., or it may be less, the actines swell out at their ends and begin to branch irregularly (Plate VII., fig. 4, *c*). Presently the original minute roughening of the surface is covered over by smooth secondary deposits of silica, and the adult, much larger tuberculation appears, though the more central portions of the spicule may often be nearly smooth when fully developed. The diameter of the actines of the fully formed spicule ("epactines" of SOLLAS), between the centre and the point where they commence to branch, is about 0·036 millim. This account of the development of the desmas, while differing widely from that given by CARTER, agrees with the views expressed by SOLLAS in his "Challenger" report.

(2.) Discotriænes (Plate IV., fig. 4, *f*, *g*); disk flat, about 0·23 millim. in diameter; outer surface beset with numerous minute, conical papillæ; margin approximately circular, but minutely crenulated and usually strongly emarginate at one, two or three places, so as to form semi-circular bays or indentations; shaft well developed, stout, conical, fairly sharp-pointed, up to about 0·147 millim. long. These spicules form a single layer on the surface, with overlapping disks. The youngest stage I have recognised in their development is shown in Plate IV., fig. 4, *f*.

(3.) Monaxonid spicules (rhabdi); probably oxeote; long and slender, and commonly tapering very gradually to a fine point. These spicules are so long and slender and so interwoven with the desmas that I have never succeeded in seeing both ends of the same spicule *in situ*, and even in boiled-out preparations they are always broken. They are particularly numerous in the neighbourhood of the vent, but do not, at any rate usually, project beyond the surface. I have measured one up to a length of about 1·2 millims., with a maximum diameter of about 0·006 millim.

(4.) Microrhabds (Plate IV., fig. 4, *h*); usually fusiform and strongylote, with very minutely roughened surface; sometimes slightly curved; size about 0·016 millim. by 0·0027 millim. These spicules are very abundant beneath the layer of discotriænes; and especially in the membrane which immediately surrounds the vent, where they form a continuous layer, the discotriænes being absent.

It is with some reluctance that I have been constrained to add another species of *Discodermia* to the six already described by Mr. CARTER (4, 5) from the Gulf of Manaar (*D. papillata*, *D. aspera*, *D. spinispirulifera*, *D. lævidiscus*, *D. sinuosa*, and

D. sceptrellifera), but I cannot identify Professor HERDMAN'S specimen, from deep water off Galle, with any of these. The richness of the Ceylon seas in species of *Discodermia* is very remarkable. It is strange that I have not been able to find any of Mr. CARTER'S species in Professor HERDMAN'S collection, but they are apparently all small forms, which would not be likely to attract the attention of a collector.

R.N. 234 (Station XLI., 12 miles off Galle, 100 fathoms).

Aciculites, SCHMIDT.

Lithistida with monocrepid desmas and rhabdi, the latter forming a special dermal layer. Without microscleres.

SOLLAS, in his report on the "Challenger" Tetractinellida, places this genus in his family Scleritodermidæ in the "Sub-order" Hoplophora, but it seems to me that it would fall more naturally amongst the Azoricidæ (in the Sub-order Anoplia of SOLLAS). The fact that some of the rhabdi form a dermal layer can hardly be of sufficient importance to justify us in placing the genus not only in a different family, but even in a different "sub-order" from the Azoricidæ, to which it is naturally allied by the form of the desma, the presence of rhabdi, and the absence of microscleres.

Aciculites orientalis, n. sp.—Plate IV., fig. 3.

The single specimen is massive, compact, cushion-shaped, rather irregular, but with rounded outlines, somewhat flattened above and attached below by a broad base to a mass of calcareous débris. Height about 28 millims.; greatest breadth, 38 millims. Texture compact and stony, but with a comparatively soft dermal membrane, which, on the upper surface of the sponge, is easily separable from the underlying part. Vents numerous, minute (say about 0·2 millim. in diameter, but varying), scattered over the upper surface.* Pores scattered. Surface, in parts at any rate, slightly corrugated, with narrow, ramifying and meandering canals showing through the dermal membrane. Colour in spirit grey, both internally and externally.

The main skeleton is a very close and compact reticulation of monocrepid desmas, intermingled more or less abundantly with strongyla. In the dermal membrane the strongyla are very abundant and lie for the most part tangentially, forming a more or less continuous dermal skeleton. Beneath the dermal membrane, where the main skeleton is growing, the desmas are found in various stages of development, not as yet connected with one another.

Spicules.—(1.) Monocrepid desmas (Plate IV., fig. 3, *a–d*). The young spicule (*a*) is an irregular, elongated rod, with minutely roughened surface, which soon begins to branch. The fully grown spicule (*d*) usually consists of a strongly curved main axis with branches coming off chiefly on the convex side. These branches proliferate and

* One much larger opening looks as if it might be artificial.

end in rather sharp, conical papillæ. Similar papillæ may occur on the main axis, but when this is strongly curved they are usually absent from the concave side. The fully developed desma measures about 0·328 millim. in maximum length in a straight line from point to point.

(2.) Strongyla (Plate IV., fig. 3, *e*, *f*); slightly curved and a good deal broader at one end than at the other. The broad end, which may be slightly tylote, is covered with minute spines, while the narrow end is smooth, or nearly so, though often with a very few minute projections. Size, commonly about 0·328 millim. by 0·009 millim. (in the middle).

So far as I am aware, the only other species of *Aciculites* hitherto described is the type of the genus, *Aciculites higginsii*, SCHMIDT (**44**), from Havanna. Our species is evidently very closely related to the West Indian form, which has fortunately been re-examined and described by SOLLAS (**15**, p. 347). In fact, the only specific difference which the description of the latter has enabled me to detect lies in the fact that in the Ceylon species the vents are not protected by tent-like arrangements of radiating rhabdi as described by SOLLAS. Probably, however, other specific differences will be found to exist in the form of the desmas, &c.

We have here an interesting case of apparently discontinuous generic distribution, though the imperfect state of our knowledge of the sponge-fauna of intermediate localities makes it possible that the discontinuity is apparent rather than real.

It may be noted that TOPSENT's *Aciculites incrustans* has now been recognised by that author as belonging to a totally distinct genus, *Desmanthus* (**14**).

R.N. 150 (Ceylon seas).

Taprobane,* n. gen.

Lithistida of plate-like or cup-shaped form, with minute sphinctrate apertures abundantly scattered on each side of the plate; with monocrepid, tuberculate desmas and long, slender oxea; without special ectosomal spicules and with microscleres in the form of sigmata only.

We have here another proof of the artificial character of SOLLAS's classification of the Lithistida. It will be seen from the diagnosis that the sponge upon which the genus *Taprobane* is based might be regarded either as a Scleritodermid without ectosomal spicules or as an Azoricid with sigmata; it is thus very closely related on the one hand to *Scleritoderma*, and on the other to *Azorica*. We have already had occasion to notice, in speaking of the genus *Aciculites*, that SOLLAS places *Scleritoderma* and *Azorica* in different "sub-orders," his Hoplophora and Anoplia respectively, but the discovery of *Taprobane*, combining characters of these two groups, viz., the absence of special ectosomal spicules and the presence of microscleres, alone seems sufficient to necessitate a revision of SOLLAS's scheme.

* So called from the old Greek name for the Island of Ceylon.

Taprobane herdmani, n. sp. Plate I., fig. 8; Plate IV., fig. 2.

Specimen (Plate I., fig. 8) consisting of a stout, erect plate or lamella, strongly curved (almost into the shape of a cup). Surfaces more or less uneven, especially on the outside (which bears numerous galls due to parasitic barnacles). The upper edge is broadly rounded, and the base of attachment is slightly expanded, like the foot of a cup. Both surfaces are slightly and unevenly hispid, the hispidation being almost confined to the more depressed portions. Both surfaces are thickly studded with minute, pustule-like, circular areas, hardly visible to the naked eye. These areas are only about 0·3 millim. in diameter, and each bears the single aperture of an incurrent or excurrent canal surrounded by a well-developed sphincter membrane. The colour (in spirit) is dirty grey; the texture compact and stony. Greatest height about 70 millims.; thickness of lamella about 15 millims.

The main skeleton is a very dense and compact reticulation of desmas, together with loose wisps or brushes of long, slender oxea running at right angles to the surface, beyond which their ends project so as to give rise to the hispidation. The oxea seem to disappear more or less completely from the deeper parts of the sponge, while around the apertures of the canal system, at any rate on the outer surface, they may project as a scanty fringe.

Spicules.—(1.) Desmas (Plate IV., fig. 2); monocrepid and rather sparingly branched, the branches usually coming off almost exclusively from one side of the main axis, which is usually more or less strongly curved. Main axis and branches more or less abundantly ornamented with rounded tubercles; branches (? always) terminating in conical papillæ, which may be bifid at the apex. The union of these desmas is so close and compact that it seems almost impossible to isolate an adult spicule for measurement: but the total length, measured in a straight line from point to point, appears to be about 0·36 millim. The thickness of the main axis, exclusive of tubercles, is about 0·028 millim.

(2.) Oxea; very long and slender, gradually and sharply pointed at each end; commonly more or less curved or crooked; size variable: they are usually broken, but two complete spicules measured about 1·0 millim. by 0·008 millim. and 1·88 millim. by 0·008 millim. respectively.

(3.) Sigmata; slender, contort; total length in a straight line from bend to bend, about 0·01 millim.; abundant throughout the sponge.

One of the most characteristic features of this species is the arrangement of the apertures of the canal system. These appear to be identical in form and arrangement on the two sides of the sponge, but we may conclude from the analogy of other plate-like and cup-shaped sponges that the apertures on the outer side are inhalant pores, and those on the inner side vents. Each aperture, whether pore or vent, lies in the middle of a circular area, sharply defined by the sudden cessation of the reticulation of desmas at its margin. This area is occupied by a very well developed, iris-like diaphragm, with abundant circularly and perhaps also radially arranged myocytes, the contraction of the former of which has, in almost all cases, completely closed the aperture. The diaphragm contains sigmata, but no other spicules. A similar arrangement of the external apertures of the canal-system appears to be characteristic both of *Azorica* and *Scleritoderma;* indeed, our Ceylon species, except for the absence of microstrongyles, resembles very closely indeed SCHMIDT'S *Scleritoderma packardi* from the Gulf of Mexico, as described and figured by SOLLAS in his work on the "Challenger" Tetractinellida.

R.N. 40 (Stat. XV., Periya Paar, Gulf of Manaar, 9 fathoms).

Petromica, TOPSENT.

Lithistida of massive form; with scattered pores and vents; with thin dermal membrane destitute of special skeleton; with monocrepid desmas feebly united or quite separate; with monaxonid rhabdi often collected in fibres which may terminate in surface conuli; without microscleres.

This genus was founded by TOPSENT in 1898 (**45**) for a new Lithistid sponge from the Azores, very closely related to *Azorica.* TOPSENT gives the following diagnosis:—"Azoricidæ massives, en forme de cônes dressés, à surface conuleuse, à pores dispersés, à oscules membraneux, à ectosome dévellopé aspiculeux, à desmas peu ornés et faiblement reliés entre eux."

The discovery of a second species in Ceylon waters, closely related to the type of the genus, forms a further justification for separating *Petromica* from the other Azoricidæ.

Petromica massalis, n. sp.—Plate IV., fig. 5.

Sponge massive, may be attached by a broad base, may be compressed vertically or horizontally. Vents usually numerous, rather small, but variable in size; scattered on the upper part of the sponge, each forming the termination of a vertical oscular tube. Pores scattered. Surface uneven, variable, more or less corrugated; in places covered with a thin, reticulate, pore-bearing dermal membrane overlying large sub-dermal cavities and supported on bundles of large monaxonid spicules which sometimes terminate in conuli. Texture incompressible, but friable; colour (in spirit) yellowish grey throughout. The type specimen (R.N. 257) measures about 37 millims. in height, the same in breadth, and 24 millims. in thickness.

The main skeleton is a reticulation (sometimes close and sometimes so loose that the desmas do not touch one another) of much-branched monocrepid desmas, intermingled with numerous large monaxonid spicules which are partly collected together in coarse fibres (without being united together by any cementing substance). These fibres, as already noticed, sometimes terminate in surface conuli. There is no special dermal skeleton.

Spicules.—(1.) Monocrepid desmas (Plate IV., fig. 5, *a*); much and very irregularly branched; not tuberculate (or very slightly so); branches usually terminating in short, blunt, conical points, or in curved flattened expansions pressed against other desmas. Maximum length from apex to apex of branches about 0·74 millim., with main axis about 0·06 millim. thick.

(2.) Stout and slender monaxonid spicules (Plate IV., fig. 5, *b–e*); more or less curved and variously ended, ranging from oxeote to strongylote and stylote; size about 0·98 millim. by 0·0369 millim., 1·2 millims. by 0·0246 millim., 1·28 millims. by 0·0328 millim., &c.; very variable.

The most interesting feature of this sponge is the strong development of the monaxonid spicules (rhabdi), which, in three out of the four specimens (the fourth being dead and infested by another sponge), play an equal part with the desmas in the composition of the skeleton. This condition of the skeleton suggests that certain Monaxonellid sponges usually associated with the Axinellidæ may be derived from Lithistid ancestors by the suppression of the desmas, or that certain Lithistids with monocrepid desmas may possibly be derived from Monaxonellid ancestors.

Petromica massalis is evidently very closely related to Topsent's *P. grimaldii*, the type of the genus, from the Azores. The principal difference appears to concern the ornamentation of the desmas, which, in *P. grimaldii*, are ornamented at the extremities with little conical tubercles, not pointed. These are absent or very feebly developed in the Ceylon species, but subsequent researches may make it desirable to unite the two.

R.N. 198; 216 (dead, and infested by another sponge; deep water outside pearl banks, Gulf of Manaar); 257 (type); 269 (young; deep water off Galle and onwards up West Coast of Ceylon).

Grade: MONAXONELLIDA.

Tetraxonida in which the primitive tetraxonid and tetractinellid condition of the megascleres has been entirely lost and none but monaxonellid megascleres remain. No desmas are developed.

With the recognition of the true nature of the monaxonellid sponges as reduced Tetraxonida, it becomes once more desirable to modify the name of the group. The old name, "Monactinellidæ," which we owe to Zittel, was objectionable because implying that the spicules are necessarily monactinal (one-rayed), while, as a matter of fact, they may be also diactinal (two-rayed). Sollas therefore altered the name to "Monaxonidæ," which was afterwards altered to "Monaxonida," under which name the group appears in the '"Challenger" Reports' and other recent works.

The name "Monaxonida," however, becomes distinctly objectionable when used for a mere sub-division of the order Tetraxonida, contrasted with the Tetractinellida; and I therefore propose to again modify the name of the group, choosing this time the term "Monaxonellida," which is, I believe, both correct in meaning and in harmony with the scheme of classification adopted.

The Monaxonellida form, however, an unnatural group of polyphyletic origin, which we can only retain as a matter of convenience until we know more about their phylogeny. They are evidently descended from more than one group of tetractinellid ancestors by degeneration of the tetraxon megascleres, and have branched off into an immense number of genera and species, the classification of which, as in the case of all reduced forms, is extremely difficult.

We have seen that the two chief tetractinellid sub-orders are distinguished mainly by the form of the microscleres, the "Astrophora" possessing some form of aster and the "Sigmatophora" sigmata. This same distinction, broadly speaking, runs through the Monaxonellida also, and may be used as the basis of their sub-division into "Astromonaxonellida" and "Sigmatomonaxonellida," names which I now propose as the most appropriate for the two great groups into which the "Monaxonellida" are by general consent divided, and approximately equivalent to the "Clavulina" and "Halichondrina" of VOSMAER and of RIDLEY and DENDY, and to the "Hadromerina" and "Halichondrina" of TOPSENT, &c.

These two groups are sharply distinguished from one another. As far as I am aware, there are only three cases on record of the occurrence of astrose microscleres in association with sigmata or chelæ, and all three are probably to be explained as due to mixture of the spiculation of two distinct sponges—a very frequent occurrence.*

We may regard these two great monaxonellid sub-orders as being descended from the two corresponding tetractinellid sub orders, though this is no doubt but a crude way of looking at the problem, and it may well be that some of the forms which we find most difficult to classify are descended directly from the Homosclerophora, and others from the Lithistida.

The great difficulty in following out this system of classification to its logical conclusions lies in the fact that in many cases the microscleres, as well as the tetract megascleres, have entirely disappeared, apparently by degeneration, and we are then dependent upon the much less trustworthy guidance of other characters. Thus the genera *Halichondria*, *Reniera*, *Axinella*, *Suberites*, &c., with a very simple spiculation composed exclusively of monaxonid megascleres, are in reality more modified forms than *Gellius*, *Sigmaxinella*, *Hymedesmia*, *Spirastrella*, and so on, which have not lost their microscleres.

SUB-ORDER: ASTROMONAXONELLIDA.

Monaxonellida in which the microsclere, when present, is some form of aster.

This sub-order is practically equivalent to the Hadromerina of TOPSENT, which

* The cases in question are SCHMIDT'S *Sceptrella regalis* (23), p. 58 [*vide* also RIDLEY and DENDY (1), p. lxii., footnote]; FRISTEDT'S *Desmacella peachii* var. *stellifera* (24); and TOPSENT'S *Hymeraphia toureti* (25); all very doubtful cases. The so-called amphiasters (or "birotulates") of certain Desmaeidonidæ (*e.g.*, *Axoniderma*, *Iotrochota*, *Amphiastrella*) are not true asters at all, but merely modified isochelæ. [Further discussion on this subject, necessitated by the appearance of TOPSENT'S great work on the Sponges of the Azores (62), will be found in the general remarks on the sub-order Sigmatomonaxonellida.]

that author sub-divides into two sections, according to the prevailing form of megasclere, viz., "Clavulida" and "Aciculida." This sub-division, however, appears to me to be both unnecessary and unnatural, especially when its originator places the genus *Tethya*, with its stylote megascleres, in the division "Aciculida," which is characterized by oxeote megascleres.* I therefore propose to divide the sub-order immediately into families. Of these Topsent (26) makes nine, of which five are represented in the present collection.

In addition to these, I here include the family Chondrosidæ, which have completely lost their megascleres, and, in the genus *Chondrosia* itself, their microscleres also. Some of the old group Axinellidæ (*e.g.*, *Vibulinus*, with astrose microscleres) must likewise be included in this sub-order, and it may prove necessary to institute a new family—Astraxinellidæ—for their reception.

On the other hand, I am inclined to think that some of Topsent's families will prove to be superfluous. Thus I propose to abandon his "Coppatiidæ" and "Streptasteridæ" in favour of the older "Epipolasidæ" of Sollas.

Family: EPIPOLASIDÆ.

Astromonaxonellida with oxeote megascleres, and usually euasters for microscleres.

This family, founded by Sollas (15) for the reception of the genera *Amphius*, *Coppatias*, and *Asteropus*, is, at any rate as regards what we may consider to be its typical representatives, evidently very closely related to the Stellettidæ, a fact which has already been recognised by previous writers. In short, we may safely regard these forms as reduced Stellettids which have lost their tetraxon megascleres, and Sollas himself placed the family next to the Stellettidæ as an appendix to the Euastrosa, though apparently with some doubt.

Topsent divided the genera of Sollas's Epipolasidæ between his own families Coppatiidæ and Streptasteridæ. In the Coppatiidæ he also includes certain genera, such as *Spongosorites*, which have no microscleres at all. *Spongosorites* is well represented in the Sponge-Fauna of Ceylon, but, for reasons which will appear subsequently, I find it desirable to remove it to the Axinellidæ.

Coppatias, Sollas (15).

Epipolasidæ with the skeleton composed of an irregular interlacement of oxea, and microscleres in the form of euasters only.

This genus is almost synonymous with the genus *Stellettinopsis* as employed by Carter.

* It should be pointed out, however, that Sollas and Topsent regard the megascleres of *Tethya* as modified oxea, which they term strongyloxea, but it is impossible to distinguish these from styli.

Coppatias reptans, n. sp.—Plate V., fig. 2.

The single specimen is much elongated, irregularly sub-cylindrical, creeping over and to a slight extent encrusted by calcareous débris. It has apparently lain horizontally. The total length is about 11 centims., and the maximum thickness about 14 millims. One end is much narrower and forms a free digitiform process, strongly curved. The surface is slightly rugose, minutely conulose and minutely and slightly hispid. The colour (in spirit) is dark purplish-grey, paler below and internally. Vents small (mostly minute), numerous, scattered on the upper surface. Inhalant pores abundantly scattered.

The main skeleton is a very confused reticulation of oxeote megascleres, here and there collected into loose bundles. There is no special dermal layer of tangentially disposed oxea, but the surface is rendered more or less hispid by the projecting points of oxea which lie below it. There is, however, a thin dermal layer of densely crowded asters.

Spicules.—(1.) Oxea (Plate V., fig. 2, *a*, *b*, *c*) slightly curved and gradually and sharply pointed; varying a good deal in diameter; about 1·0 millim. by 0·022 millim. when fully grown.

(2.) Chiasters (Plate V., fig. 2, *d*); very minute, with rather numerous, slender, cylindrical rays and little or no distinct centrum; total diameter about 0·006 millim. (sometimes a little more); most abundant at the surface, but also plentiful in the choanosome.

The ectosome is fairly thick, but is excavated by numerous irregular, spacious sub-dermal cavities, into which the inhalant pores open and from which the inhalant canals of the choanosome take their origin. It is clearly differentiated into two layers: an inner, comparatively thin and densely fibrous layer, with the fibres mostly lying parallel to the surface, and an outer, much thicker layer composed of collenchyma with a considerable admixture of fibrous tissue, but with the fibres running irregularly in all directions.

It is a noteworthy fact that the fibrous cells of the ectosome contain a large proportion of the pigment to which the sponge owes its dark colour, arranged in them in the form of minute spherical granules. Similar pigment granules also occur in some of the ordinary stellate cells of the collenchyma, of which the fibre-cells are but a slight modification.

The outer part of the ectosome also contains immense numbers of large, spherical, darkly staining cells, crowded together in large groups or loosely scattered. Similar cells also occur very abundantly, scattered singly or grouped in dense masses, in the choanosome. They remind one strongly of the symbiotic Algæ of *Hexadella* and the corresponding cells of *Asteropus haeckeli*, and are probably of a similar nature. Their immense numbers and their occurrence in such dense masses in both ectosome and choanosome are alone enough to suggest that they are not true constituents of the sponge-tissues.

This species appears to be very closely related to CARTER's *Stellettinopsis* (*Coppatias*) *tuberculata* (18), an Australian species from which the Ceylon sponge differs chiefly in its external form and reptant habit.

R.N. 242 (Stat. XXVII., Cod Bay, Trincomalee, 5 fathoms).

Asteropus, SOLLAS (15).

Epipolasidæ with two sorts of asters, oxyasters and sanidasters.

Asteropus haeckeli, n. sp.—Plate V., fig. 3.

The single specimen is a small, irregular crust which has probably been attached by the base, to which fragments of calcareous débris are still adherent. The upper surface rises up into a broad, low, mammiform projection, with a single, rather large vent (about 2·5 millims. in diameter) at its apex. Surface smooth, but uneven and harsh to the touch, owing to the presence of huge oxea lying tangentially beneath the surface or projecting slightly beyond it. Colour (in spirit) pale grey. Texture internally coarse and cavernous, owing to the large exhalant canals.* Inhalant pores scattered. The specimen may be only a fragment of a much larger crust; its maximum breadth is about 25 millims., and its greatest height (where the vent is situated) about 11 millims.

The skeleton is a very dense and very confused interlacement of huge oxea, sometimes collected into very loose, ill-defined, coarse strands, which run towards the surface.

Spicules.—(1.) Oxea (Plate V., fig. 3, *a*); usually large and stout, fusiform, gradually and fairly sharply pointed at each end; curved; varying much in size, up to about 1·9 millims. by 0·065 millim. Numerous much shorter and more slender forms also occur, which may be immature.

(2.) Sanidasters (Plate V., fig. 3, *c*, *d*); with straight, slender axis dividing into two spines at each end, and with two irregular whorls of spines dividing the total length into three approximately equal parts; or with the axis irregularly spined, and perhaps angulated, so that the whole closely resembles a *Spirastrella* microsclere; total length up to about 0·016 millim. These spicules are very abundant at the surface and also common in the interior.

(3.) Oxyasters (Plate V., fig. 3, *b*); with few, slender, very slightly spined or roughened (? sometimes smooth), sharp-pointed rays and no distinct centrum; total diameter measured up to about 0·04 millim. These spicules are found in the interior of the sponge, but are scarce and easily overlooked.

The ectosome is very thick, and composed of a mixture of cystenchymatous and collenchymatous tissue, slightly fibrous in places, and with numerous darkly staining, oval cells scattered through it, which somewhat resemble the symbiotic Algæ of *Hexadella*, and are probably of a similar nature.

* The oscular tube is occupied by a Polychæte worm.

This species is closely related to CARTER'S "*Stellettinopsis simplex*," from Australia (Fremantle and Port Phillip Heads),* for which SOLLAS (15) established the genus *Asteropus*, and which, with the doubtful exception of SCHMIDT'S *Stellettinopsis annulata*, has, up to the present time, remained the only described species of the genus. (TOPSENT has shown (28) that LENDENFELD'S *Asteropus incrustans* is not referable to the genus *Asteropus* at all.)

The occurrence of another species in Ceylon waters is extremely interesting and affords a good illustration of the close relationship which exists between the Sponge-Fauna of this region and that of Australia. That the two species are not identical I have been able to convince myself by personal examination of a fragment of an Australian specimen kindly forwarded to me some years ago by the authorities of the British Museum (Natural History). The differences concern chiefly the arrangement of the vents, the colour (tawny-brown in the Australian species), and the size of the oxea (which are considerably more robust in the Ceylon species). Still, it is possible that the future discovery of intermediate forms may justify us in uniting the two.

I have taken the liberty of naming this species in honour of the most distinguished author of 'Die Kalkschwämme.'

R.N. 219 (deep water outside pearl banks, Gulf of Manaar).

Cryptotethya, n. gen.

Epipolasidæ in which the ectosome is differentiated into a thin, inner fibrous layer, very dense, and a thick, outer, more or less gelatinous layer. The outer layer is produced into more or less elongated, finger-like projections, between the bases of which the more or less spherical body of the sponge is largely concealed by agglutinated foreign bodies. The main skeleton is radially arranged, consisting of large oxea extending through choanosome and ectosome alike. The microscleres are euasters.

As regards its spiculation, this genus agrees very closely with *Coppatias*, and, like the latter, is evidently very nearly related to *Stelletta*. In the structure of the ectosome it makes a close approach to *Stelletta herdmani*, in which also the triænes have undergone considerable reduction. In fact, *Cryptotethya* may be regarded as derived from some such form as *Stelletta herdmani* by further reduction of the triænes and by the outgrowth of the ectosome into finger-like processes. In the spherical form of the body, and the radial arrangement of the skeleton, it is also related to *Tethya*, but perhaps its nearest ally is SOLLAS'S genus *Magog*, established (15) for the reception of CARTER'S *Chondrilla sacciformis*, from Mauritius, and included by SOLLAS amongst the Tethyidæ. In *Cryptotethya*, however, the oxea are not confined to the choanosome as in *Magog*. Both genera appear to me to come most naturally amongst the Epipolasidæ, though they certainly seem to indicate the manner in

* Mr. CARTER (27) also records the species from Hayti, but the Haytian form is very likely specifically distinct from the Australian.

which the Tethyidæ may have originated, through the Epipolasidæ, from stellettid ancestors.

Cryptotethya agglutinans, n. sp.—Plate V., figs. 4, 5.

The single specimen (Plate V., fig. 4) consists of a more or less spherical body from which radiate irregular finger-like processes of varying shape, long or short, cylindrical or flattened, and sometimes expanded at the free end. Between these projections the surface of the sponge is for the most part concealed by a great quantity of calcareous débris which firmly adheres to the sponge, including melobesian nodules of considerable size, worm-tubes, Foraminifera, &c., the whole forming an irregular mass in the midst of which the body of the sponge is scarcely recognisable. Calcareous débris may also be found in the interior of the sponge, even within the choanosome. I have not succeeded in making out the arrangement of the vents and pores. Some small openings on the ends of some of the projections resemble vents, but on close examination are found to be merely the apertures of cavities inhabited by parasitic barnacles. One at least of the shorter projections (fig. 4, *x*), however, contains longitudinal canals which are evidently either inhalant or exhalant canals proper to the sponge. The surface of the sponge, where exposed, is very uneven and very harsh to the touch, owing to the projection of the large oxea, which readily break off in one's skin and thus make the sponge very unpleasant to handle. The colour of the surface and of the thick outer layer of the ectosome (in spirit) is grey, of the thin fibrous layer of the ectosome white, and of the choanosome nearly white. The maximum diameter of the body of the sponge is about 40 millims., the length of the longest projection about 25 millims.

In the body of the sponge the huge oxea of which the skeleton is composed are for the most part arranged radially and without any distinction between choanosome and ectosome, passing indifferently from one to the other through the dense fibrous layer. Some of the oxea are associated in loose bands which spread out in brushes as they approach the surface. In the projections the oxea naturally lie for the most part longitudinally, but at the expanded end of a broad projection (containing longitudinal canals) I have found a good many placed tangentially at or near the surface. The asters are for the most part arranged (very abundantly) in a thin dermal layer, through which the points of the oxea may project for a short distance.

Spicules.—(1.) Oxea (Plate V., fig. 5, *a*, *b*); stout, fusiform, usually gradually and fairly sharply pointed, but subject to some irregularity at the ends and occasionally stylote. Size very variable, say about 2·5 millims. by 0·073 millim. when fully grown, but often less.

(2.) Chiasters (Plate V., fig. 5, *c*), with little or no centrum and smooth, slender, sub-cylindrical rays, ending bluntly, but not tylote; total diameter commonly about 0·012 millim. These spicules are most abundant at or near the surface of the sponge, but a few precisely similar forms occur in the choanosome.

Owing, on the one hand, to the enormous quantity of foreign matter adhering to the surface, and, on the other, to the great size of the megascleres, which interfere greatly with the cutting of thin sections, the investigation of the canal system of this sponge is attended with exceptional difficulties, and I have come to no satisfactory conclusions on the subject.

One of the most striking features of the sponge is the dense fibrous layer of the ectosome, which, when the sponge is cut in half, is conspicuous even to the naked eye as a white layer about 0·4 millim. thick, dividing the body into inner and outer portions, and forcibly calling to mind the similar layer of fibrous tissue in *Stelletta herdmani*. This dense fibrous layer consists of bundles of fine fibres closely matted together and running in all directions. It does not, perhaps, form quite the innermost portion of the ectosome, for beneath it lies a thin gelatinous layer containing subcortical crypts, from which the inhalant canals of the choanosome probably take their origin.

The outer layer of the ectosome varies much in thickness. It is partly collenchymatous, consisting of a clear gelatinous matrix with an immense number of large granular stellate cells embedded in it, and partly fibrous, the fibrous condition being apparently arrived at by elongation of similar cells in a direction parallel to the surface. Roughly speaking, this fibrous tissue may be said to occur between two layers of the collenchyma, but the two kinds of tissue are not sharply differentiated from one another, and the fibrous layer is not nearly so well defined or so dense as the inner fibrous layer already described. The outer layer of the ectosome alone takes part in the formation of the finger-like projections on the surface of the sponge, the inner fibrous layer not being continued into these.

The choanosome is rather compact and finely granular, but, owing perhaps to want of penetration by the preserving medium, my sections do not enable me to make out details of the histology or the arrangement of the flagellate chambers.

R.N. 62 (Gulf of Manaar).

Family: TETHYIDÆ.

Astromonaxonellida with stylote megascleres and euasters for microscleres; with strongly developed fibrous cortex and radially arranged skeleton.

I have discussed the probable origin of this family in speaking of the genus *Cryptotethya*.

Tethya, Lamarck.

More or less spherical Tethyidæ, without highly specialised pore-bearing grooves and without a sand-layer in the choanosome.

Tethya lyncurium, Lin.

There are in the collection a number of specimens of *Tethya* which have given me a great deal of trouble as regards their correct nomenclature. I have finally decided to regard them as belonging to three varieties of the well-known and extremely variable *Tethya lyncurium* of European waters. For convenience of reference we may distinguish the Ceylon varieties as *a*, *b*, and *c* respectively.

Tethya lyncurium, Lin., var. *a*.

This variety is represented by two approximately spherical specimens growing side by side on a mass of calcareous and other débris. The larger of the two is about 20 millims. in diameter, the other only a little less. The colour in spirit is dull yellowish-grey. The surface is irregularly conulose and gemmiparous, not distinctly tessellated, and to a considerable extent covered by adherent foreign matter. Each has a single prominent and widely open vent, about 2 millims. in diameter, at the summit of a thin-walled tubular projection. The pore-sieves between the conuli are for the most part inconspicuous.

The cortex is very dense and more or less fibrous throughout, but the fibrous tissue is most strongly developed in its deeper portion. The inhalant canals in the cortex are lacunar near the surface and constricted into definite canals deeper down.

The main skeleton consists of stout radiating bundles of megascleres, breaking up into divergent brushes in the cortex. In the choanosome (but not in the cortex) loose spicules of similar form are abundantly scattered (mostly lengthwise) between the bundles.

The megascleres are rather slender, faintly tylote styli, of the ordinary *Tethya* form. The feebly developed head is narrower than the middle of the shaft, and the apex is gradually and more or less sharply pointed. These spicules measure about 1·3 millims. by 0·02 millim. in the main fibres, but are much smaller in the surface brushes, while between the main fibres, in the choanosome, the sizes are mixed.

The microscleres are of two forms only, spherasters and chiasters. The spherasters are mostly found in the cortex, where they are rather sparingly scattered. The centrum is fairly large, and they have sharp-pointed conical rays which may be (rarely) spined or branched. The rays are about 12 in number, and nearly or quite touch one another at their bases. Total diameter about 0·076 millim., with rays 0·02 millim. long. In the cortex the chiasters are most abundant at the surface and in the walls of the inhalant canals; they are also numerous in the choanosome. They have no centrum and about from 6 to 9 distinctly tylote, rather slender rays. The total diameter of the chiaster is about 0·012 millim. Those of the choanosome are commonly six-rayed, and the rays are occasionally more elongated and proportionately more slender than in the ordinary form, but they are almost always distinctly tylote, and the whole spicule is never more than about 0·02 millim. in diameter.

I am convinced that the two specimens described above cannot be distinguished more than varietally from the common European species. The chiasters are, it is true, more distinctly tylote than is usually the case in *T. lyncurium*, but I cannot regard this character as of specific value, for in a specimen from Budleigh Salterton, in Mr. CARTER's collection (now in my possession), the rays of the chiasters are occasionally tylote, though not nearly so strongly as in the Ceylon specimens.*

R.N. 199, 200 (Stat. LXVII., off Talaivillu Paar, 10 to 14 fath., Gulf of Manaar).

Tethya lyncurium, LIN., var. *b.*

There are five specimens in the collection which may be referred to this variety, differing from the foregoing in the following respects :—

(1) There are no prominent vents.

(2) The surface is more or less distinctly tessellated.

(3) The spherasters are considerably larger and more numerous, and have more numerous rays and larger centra. Total diameter up to about 0·1 millim., with rays about 0·024 millim. long; sometimes they are a little smaller; usually they are densely crowded in the cortex ; the number of rays appears to be usually about 25.

(4) The chiasters are more distinctly differentiated into two kinds, the rays of those of the choanosome showing a strong tendency to lose their tylote character and become strongylote or even oxeote, while at the same time elongating somewhat (but not much) and being (? always) slightly roughened.

The largest of the five specimens is only about 21 millims. in diameter. The colour in spirit is dull grey.

R.N. 180, 180A, 180B (all from Lagoon, Galle); 196; 211 (Gulf of Manaar).

Tethya lyncurium, LIN., var. *c.*

This variety is represented by a single specimen, about 24 millims. in maximum diameter, with very strongly tessellated surface and one prominent vent. The cortex is very lacunar between the polygonal, flattened tesseræ.

As regards spiculation, this variety differs from the preceding only in the presence of numerous well-developed oxyasters, chiefly in the choanosome. These spicules have little or no centrum and usually six rays. The rays are rather slender and sharp-pointed, sometimes slightly roughened, but very rarely spined or branched; usually straight or nearly so. Total diameter of the oxyaster about 0·04 millim.

This variety might be justifiably identified either with SELENKA's *Tethya maza* or with PERCIVAL WRIGHT's *T. seychellensis*, but the two preceding varieties unite it so closely with *T. lyncurium* that it seems to me quite unnecessary to make a specific distinction.

R.N. 19 (Gulf of Manaar).

The occurrence of these three varieties of *Tethya lyncurium* within the same limited area is a very interesting fact, and their discovery is likely to be of great assistance in elucidating the relationship of the so-called species of this extremely difficult genus. In this connection it is interesting to note that WILSON (**29**) has lately recorded the occurrence of both *T. lyncurium* and *T. seychellensis* in Porto Rico.

* TOPSENT, however, entertains (**14**) a different view as to the taxonomic value of the tylote character.

Xenospongia, Gray.

Tethyidæ of discoidal form. Choanosome containing much sand in its deeper parts. Inhalant pores localized in well-defined grooves, partly concentric and partly radial in arrangement. Vents on slight prominences. Surface tuberculate. Skeleton composed of bundles of styli ending in brushes, which project from the surface tubercles and also form a slight marginal fringe. Microscleres euasters of various forms and sizes, forming a dense cortical layer, and also abundantly scattered in the choanosome.

The genus *Xenospongia* was established by Gray (**30**) as far back as 1858 for the reception of two remarkable sponges from Torres Straits, of which he gave a very poor description accompanied by excellent figures of the external characters only. He made no attempt to describe the spiculation, and, although this defect was partially remedied by Carter in 1882, our knowledge of the sponge has remained singularly incomplete up to the present day. The genus has only been recorded once since its original discovery, viz., by Holdsworth (**9**) from the Ceylon pearl banks in 1873. No description, however, has ever been published of Holdsworth's specimen, and the identification with Gray's species, though doubtless correct, was quite unsupported by evidence. Holdsworth's record and specimen (which appears to have been forwarded to Gray for further investigation) both seem to have been lost sight of by subsequent writers.

Under the circumstances, it is not remarkable that the systematic position of *Xenospongia* has hitherto remained doubtful. Gray himself, in 1868 (**31**), made it the type of a new family, for which he proposed the name "Xenospongiadæ." Carter, in 1875 (**32**), referred it to his group "Donatina," along with *Tethya lyncurium*, but expressed the opinion that it might ultimately have to come amongst the "Suberitida." In 1882, however, this author (**33**) reverted to Gray's opinion, and proposed "a group named Xenospongina = Xenospongiadæ, Gray." Sollas, in 1888 (**15**), referred the genus doubtfully to the Tethyidæ, pending further information. Topsent, in 1898 (**26**), made a new departure by referring it to the Spirastrellidæ, though, as it seems to me, with very slight justification.

The minute investigation which I have been able to make of Professor Herdman's well-preserved specimen proves beyond doubt that the opinion of Sollas is correct, and that *Xenospongia* is very closely related to *Tethya* itself, alike in spiculation, skeleton arrangement, histology, and canal system, although the external form and the arrangement of the inhalant pores are very peculiar. Even the surface tubercles or conuli, and the somewhat pinkish colour in spirit, remind one strongly of the genus *Tethya*. In *Tethya* also one sometimes sees the beginning of the development of pore-bearing grooves between the conuli, and the branching of the rays of the asters, which takes place so extensively in *Xenospongia*, may also be observed occasionally.

Xenospongia patelliformis, GRAY—Plate VI.

1858, **Xenospongia patelliformis**, GRAY (**30**); 1867, **Xenospongia patelliformis**, GRAY (**31**); 1873, **Xenospongia patelliformis**, HOLDSWORTH (**9**); 1875, **Xenospongia patelliformis**, CARTER (**32**): 1882, **Xenospongia patelliformis**, CARTER (**33**); 1888, **Xenospongia patelliformis**, SOLLAS (**15**); 1898, **Xenospongia patelliformis**, TOPSENT (**26**).

The single specimen in the collection (Plate VI., fig. 1) has the form of an almost circular disk, about 28 millims. in diameter, with convex upper and slightly concave lower surface and rather thin and slightly undulating margin. The lower surface is formed by the agglutinated sand which makes up the greater part of the thickness of the disk. The upper surface is covered with rather small, rounded tubercles or conuli, thickly scattered at fairly regular intervals. These tubercles are about 1 millim. in diameter, and are normally hispid from the projection of the ends of large spicules, now generally broken off short. The margin of the sponge is also very shortly hispid from the same cause (figs. 1, 2, *m.f.*). Just above the margin two narrow grooves (figs. 1, 2, *m.p.g.*) run round the disk, separated from one another by an interval of about 1·5 millim., across which they occasionally communicate with one another by oblique connecting grooves. The width of the grooves varies up to about 0·5 millim., and the floor is crossed at right angles by narrow parallel bands of fibrous tissue of a whitish appearance, arranged very regularly at short intervals. The inhalant pores are very minute and arranged in transverse rows between the fibrous bands in the floor of the grooves (fig. 2). (In the specimens described by GRAY similar grooves radiate more or less abundantly from near the centre of the disk towards the margin; in our specimen these radiating grooves are very feebly developed and recognizable in only a few places. fig. 1, *r.p.g.*) The vents, now more or less closed, are situated at the apices of three low, monticular elevations near the centre of the disk (figs. 1, 2, *o*); these elevations are not very conspicuous and are apparently formed each by the agglomeration of three or four of the surface conuli.* (Dr. GRAY appears to have mistaken the inhalant pores, or groups of pores, for vents; some of the prominent elevations figured by him on his larger specimen probably bear the true vents, though one, at least, of these elevations appears to contain a parasitic barnacle; there appear to be no barnacles in our specimen, but a parasitic worm occupied one of the larger exhalant canals.)

The colour of the sponge on the upper surface (in spirit) is pale yellowish grey, with a faint pinkish tinge in places, reminding one much of *Tethya*. The texture is firm and compact, leathery above, but the greater part of the thickness of the disk is composed almost entirely of coarse sand (fig. 2, *s.g.*), firmly cemented together by the tissues of the sponge. This sand is exposed only on the lower surface. The total thickness of the disk in the middle is about 6 millims.

The main skeleton consists in the lower two-thirds of the thickness of the disk, or

* In addition to the vent-bearing elevations, there is one larger, wart-like protuberance containing some hard foreign body (fig. 1, *a*).

thereabouts, of the above-mentioned sand-grains, between which there are also numerous styli, arranged, partly at any rate, in irregular bundles, and various forms of asters. The upper third of the thickness of the disk is free from sand, and includes a considerable thickness of the choanosome as well as the cortex. Here the main skeleton is formed by stout bundles of styli running vertically to the surface and entering the tubercles, from which they project as dermal brushes (fig. 2, *d*, *b*). These vertical bundles of styli are crossed at right angles by similar bundles which lie near the inner limit of the sand-free layer of the choanosome and terminate in the feebly-developed spicular fringe (*m.f.*) at the margin of the disk.

The cortex (figs. 2, 3, *cort.*) is strengthened by an immense number of asters of various shapes and sizes, forming a very dense skeleton, especially towards the surface. Asters of various kinds are also very abundantly scattered through all parts of the choanosome.

Spicules.—(1.) Styli (Plate VI., fig. 4); long, slender, nearly straight, evenly rounded off at the base and tapering very gradually to the apex. The size of these spicules is so variable that it seems almost useless to give measurements. The largest are so long that it is difficult to get them unbroken; 1·7 millims. by 0·012 millim. is perhaps a fair average size for the full-grown spicule, but considerably stouter (and presumably also longer) examples frequently occur (broken) in boiled-out preparations, while the styli which fringe the edges of the pore-bearing grooves, for example, are, on the other hand, very much smaller than the measurements given above.

(2.) Euasters (Plate VI., figs. 5, 6); enormously abundant and varying so greatly in form and size that it is impossible to separate the different kinds sharply from one another. The following may, however, be regarded as the principal types:—

(*a.*) Spherasters with very small centrum and long, conical, stout, sharply and gradually pointed, often slightly curved actines, about 11 in number; total diameter of spicule about 0·1 millim., with centrum 0·02 millim. in diametei and actines 0·044 millim. long. These asters pass gradually on the one hand into smaller oxyasters, and on the other into larger forms with very irregularly curved and more or less (often much) branched actines; the most copiously branched forms appear to be characteristic of the sandy layer of the choanosome, where they may attain a total diameter of as much as 0·18 millim.

(*b.*) Minute chiasters, with about 8 fairly stout, sub-cylindrical, tylote actines; total diameter about 0·008 millim.

(*c.*) Oxyasters or spherasters, with small centrum and about 11 slender, conical, oxeote, minutely spined actines; total diameter about 0·02 millim. The actines are occasionally branched.

(*d.*) Similar to (*c.*), but with tylote actines; this is perhaps the most uncommon form of the aster.

After carefully removing the sand-grains from below, it is possible to prepare microtome sections of the outer portion of the sponge, including the cortex and that portion of the choanosome which is free from sand. The cortex (Plate VI., figs. 2, 3, *cort.*) is about 0·13 millim. thick between the surface tubercles, but much thicker in the tubercles themselves, which are composed exclusively of cortical tissue and spicules. The greater part of the substance of the cortex is made up of asters of various forms and their accompanying scleroblasts, but it also contains bands of fibrous tissue running in various directions. Stout bands of dense fibrous tissue (figs. 2, 3, *f.b.*) also run vertically inwards from the cortex through the outer part of the choanosome to the sandy layer, where they appear to assist in binding the sand-grains together. The vertical spicule-bundles which run into the surface tubercles are also accompanied by similar bands of fibrous tissue (fig. 2), and the same kind of tissue is also developed in connection with the vents and the pore-bearing grooves.

A noteworthy feature of the cortex is the presence of the very numerous, approximately spherical, vesicular scleroblasts (fig. 3, *scl.*), about 0·016 millim. in diameter; each resembles a cystenchyme cell and encloses one of the smaller asters, the ends of whose actines abut against the thin limiting membrane of the cell, or perhaps sometimes project beyond it. Similar scleroblasts may be observed in the choanosome. The outermost part of the cortex is composed of small-celled chondrenchymatous tissue; the inner part is more or less fibrous, and between the two we find collenchyma with stellate connective-tissue cells.

The flagellate chambers (fig. 3, *fl.c.*) are oval or nearly spherical, closely crowded together in the choanosome and about 0·028 millim. in diameter where least contracted by shrinkage. The state of preservation is not sufficiently good to enable me to make out minute details very satisfactorily, but the chambers are apparently eurypylous.

The inhalant pores are, as I have already observed, minute openings in the floor of the pore-bearing grooves (fig. 2, *m.p.g.*). They are very numerous, and 10 or more may be indicated in a single transverse section of the groove. From each pore a very narrow inhalant canal runs vertically inwards and opens, with its fellows, into a system of irregular crypts which lie beneath the thick floor of the groove and from which wider inhalant canals take their origin and run inwards to the choanosome, in which they sub-divide into smaller branches. Stout bands of dense fibrous tissue run across in the floor of the groove from side to side, between the transverse rows of inhalant pores and pore-canals. Probably, by the contraction of these bands of fibrous tissue, the prominent lips of the groove can be brought together and the groove thus closed.*

The main exhalant canals are only moderately wide and converge towards the vents. Owing to the state of contraction I am unable to say whether there is a single large vent or a group of small ones on each of the vent-bearing prominences. Sections indicate that there may also be small vents between the conuli, and it appears as if one exhalant canal sometimes opens through several small apertures.

* A very similar arrangement is found in a very different sponge, *Esperella murrayi*, as described in the Report on the 'Challenger' Monaxonida.

The geographical distribution of *Xenospongia patelliformis* is, as pointed out by Holdsworth (**9**), very interesting; the only records up to the present time being Torres Straits and Ceylon. That the specimens met with in these two localities are specifically identical, I have little doubt. Gray, in describing the species from Torres Straits, gave no description of the spicules, and did not even mention the occurrence of asters. Carter, to some extent, remedied this defect in 1882 (**33**), but he only figured two forms of aster, and those not very characteristic. His microscopical preparations, however, which are now in my possession and which were presumably made from one of the Torres Straits specimens (for Holdsworth's specimen and record from Ceylon appear to have been entirely lost sight of ever since his note on the subject was published), show both large and small asters of various forms, and the actines of the large ones may occasionally branch. Mr. Carter's preparations are only teased; had they been boiled out from all parts of the sponge, they would probably have shown all the forms of aster described above from Professor Herdman's example.

The external form is, of course, extremely characteristic, and so little does it look like a sponge that the specimen described above was in the first instance placed amongst the Clypeastroids.

R.N. 375. (Stat. I. First haul of trawl, off Negombo, 12 to 20 fathoms, January 31, 1902.)

Family: SPIRASTRELLIDÆ.

Astromonaxonellida usually of massive or encrusting form. Skeleton usually irregular or reticulate, at any rate internally. Megascleres usually stylote or tylostylote. Microscleres asters of various forms.

Hymedesmia, Bowerbank.

Thin encrusting Spirastrellidæ whose spiculation consists of smooth tylostyli and euasters of various forms (occasionally passing into spirasters).

Topsent has given an excellent account of the literary history of this genus in his Monograph of the Sponges of France (**14**). A very large proportion of the known species come from the Gulf of Manaar, and were described by Mr. Carter (**4**) in 1880: viz., *H. stellivarians*, *H. moorei*, *H. spinatostellifera*, *H. capitatostellifera*, and *H. trigonostellata*. Of these five species I have only met with one in Professor Herdman's collection.

The genus is an extremely interesting one from the phylogenetic point of view, for we see here, in the first place, the first appearance of the characteristic suberitid "pin-head" spicule (tylostyle), and, in the second place, the evolution of the typical spirastrellid microsclere from the euaster.

Hymedesmia forms a connecting link between *Coppatias* and *Spirastrella*, *Coppatias*, as we have already seen, is simply a reduced Stellettid in which the cladi of the triænes have become completely aborted, and the megascleres now consist solely of oxea. From the oxeote to the tylostylote form appears at first sight a big jump, but I think it is evident that the pin-headed type in *Hymedesmia* is simply the result of the thinly encrusting habit. The megascleres in this genus are typically arranged at right angles to the base of support, with their apices projecting outwards, often beyond the surface of the sponge, an arrangement which is admirably adapted both to support the soft tissues and to protect the sponge from the attacks of parasitic Crustaceans or other enemies. In this position the proximal end of the megasclere, pressed against the hard base of attachment, is unable to elongate in the normal manner, and siliceous material, which would otherwise have been devoted to its elongation, is accumulated in a swelling or knob—the "pin-head."

Such is, I believe, the origin of the spirastrellid and suberitid tylostyle, and an exactly analogous process appears to have taken place in the echinating spicules of the Ectyoninæ, which are commonly swollen into a "head" at the end which abuts against the skeleton fibre. The at first sight tempting idea that the head of the tylostyle is the vestige of the cladome of a triæne is put completely out of court by the fact that it lies at the wrong end of the spicule, viz., the proximal instead of the distal end.

The evolution of the typical spirastrellid spiraster from the euaster has evidently taken place by elongation and bending of the centrum of the latter, and various stages of the process may be seen in different species of *Hymedesmia*; indeed, the two forms of aster pass so insensibly into one another that it is impossible to base a generic distinction upon their character alone. In the spirastrellid spiraster the rays (actines) are commonly reduced to mere spines or minute blunt projections.

Hymedesmia stellivarians, Carter.

1880, **Hymedesmia stellivarians**, Carter (4).

The single specimen forms a thin yellowish crust, attached to a small melobesian nodule, in company with *Paresperella serratohamata*, &c. In spite of the somewhat meagre character of Mr. Carter's description and figures, I think there can be little doubt of the correctness of the identification, especially as Mr. Carter's specimen also came from Ceylon waters.

All three forms of aster mentioned by Mr. Carter are present, but they are not all of the same size, as might, perhaps, be inferred from his description and figures. Moreover, in our specimen the megascleres are usually a good deal longer in proportion to their thickness than Mr. Carter's figure indicates, but they are also very variable in dimensions.

Under the circumstances it seems desirable to give the following particulars as to the spiculation:—

(1.) Tylostyli; only slightly curved, if at all; with oval head at one end and gradually and more or less sharply pointed at the other; size variable, up to about 0·47 millim. by 0·01 millim.

(2.) Spherasters; (*a*) comparatively large, with large centrum and stout, smooth, conical, sharply pointed rays; closely resembling the large spherasters of *Tethya;* total diameter about 0·02 millim.; (*b*) of medium size, with moderately developed centrum and stout, sub-cylindrical, very distinctly tylote rays (? heads sometimes roughened), about as long as the diameter of the centrum; total diameter of spicule about 0·012 millim.; (*c*) small, with very small centrum and comparatively long, slender, sharp-pointed rays; total diameter about 0·008 millim. (possibly young forms of one or both of the others).

R.N. 220B (deep water off Galle and onwards up West Coast of Ceylon).

Hymedesmia curvistellifera, n. sp.—Plate V., fig. 6.

Sponge thin, encrusting. (The single specimen has evidently been removed from the surface of some Alcyonarian, the large calcareous spicules of which still adhere in great numbers to the base of the sponge.) Surface uneven, corrugated, very slightly hispid. Colour (in spirit) light brown; texture rather friable. Vents and pores not seen. Average thickness of specimen about 0·5 millim.

The main skeleton consists of loose fascicles of tylostyles, springing from the base of attachment and running to the surface, where they spread out in loose brushes and give rise to the more or less hispid character.

Spicules.—(1.) Tylostyli (Plate V., fig. 6, *a*); straight, or nearly so, with large, oval or sub-globular heads and rather slender, sub-fusiform shafts, gradually and usually finely pointed at the apex. Size, when fully developed, about 0·38 millim. by 0·006 millim. Many much more slender forms, with proportionally larger heads, sometimes pear-shaped, also occur; these I take to be immature spicules.

(2.) Asters (Plate V., fig. 6, *b*, *c*, *d*); with strongly-curved centrum and stout, conical, sharp-pointed, smooth spines (rays). The spines show a tendency in some cases to arrange themselves in three groups, one group at each end of the centrum and one in the middle, on the convex side of the curve. The middle of the concave side of the centrum is free from spines, but the curvature is so great that this part of the centrum is often concealed from view, and the spicule then resembles a spheraster. The total diameter of the aster, when fully developed, is about 0·032 millim., but numerous smaller (young) forms also occur. The asters are most abundant in the dermal layer, where they form an almost continuous crust.

This species finds a near relative in TOPSENT's *Hymedesmia tristellata* (14), from Banyuls and the Azores. Closely similar asters occur in that species, but their rays are often covered with minute spines, which I have never seen in the Ceylonese form. I cannot agree with TOPSENT's view that the "triple spherasters" (as he terms them) have resulted from the concrescence of three centra covered with actines; it appears to me, on the other hand, that they have arisen by elongation of the centrum and grouping of the actines, and that we have here the first stage in the evolution of the typical *Spirastrella* microsclere. From this point of view it is of great interest to compare RIDLEY'S *Spirastrella transitoria* (**16**), from the Amirante Group. This is a thinly encrusting species, with "spinispirular, extremely concentrated, composed of only one entire bend," in fact, very closely resembling the aster of *Hymedesmia curvistellifera.* As RIDLEY further observes, "in *S. transitoria* we have the spinispirular almost in the form of the stellate, with which SCHMIDT . . . . . and CARTER . . . . . consider it to be homologous."

S. transitoria is evidently closely related to *S. curvistellifera*, but differs in the proportions of the spicules. Both species, together with *H. tristellata*, and possibly some others, undoubtedly occupy a position intermediate between the typical species of *Hymedesmia* on the one hand and of *Spirastrella* on the other, so that they might, with almost equal propriety, be referred to either genus.

R.N. 320 (Ceylon seas).

Spirastrella, SCHMIDT.

Massive Spirastrellidæ with styli or tylostyli for megascleres and spirasters for microscleres; the spirasters usually forming a dermal crust.

Spirastrella vagabunda, RIDLEY.

1884, **Spirastrella vagabunda**, RIDLEY (**16**).

There are in the collection a number of specimens which, while differing greatly in external form, agree so closely in spiculation that I am obliged to regard them merely as varieties of one and the same species, which appears to be identical with RIDLEY'S *Spirastrella vagabunda.* This species was originally described by RIDLEY from Torres Straits, but at the same time he assigned to it certain specimens in the British Museum Collection which came from Trincomalee and the Galle Coast, Ceylon, a fact which, of course, strongly supports my identification of Professor HERDMAN'S specimens. The Trincomalee specimen referred to was very briefly described by CARTER (**33**) under the name "*Suberites* ? sp." RIDLEY, having examined the same specimen, suggested (*loc. cit.*) that it should be distinguished as "*S. vagabunda* var. *trincomaliensis*," on account of certain slight differences in spiculation. In Mr. CARTER'S cabinet, now in my possession, there is a preparation, labelled in his handwriting "*Suberites trincomaliensis*," which is evidently from the specimen examined and described by him. Subsequently, in 1886, Mr. CARTER (**20**) described a sponge from the Mergui Archipelago under the name *Suberites trincomaliensis*, identifying it with the Ceylonese form.

Spirastrella vagabunda thus appears to be a widely-distributed and variable species. RIDLEY'S *Spirastrella congenera*, from Torres Straits, is probably a mere variety of the same, and perhaps, also, his *S. punctulata*, from Mozambique and Mauritius. The principal characters of the species appear to be the dense, confused arrangement of the main skeleton, the usually stout and distinctly headed tylostyles, and the slender, more or less elongated spirasters.

I propose to regard Professor HERDMAN'S specimens as belonging to four varieties of the species, which may be distinguished as *trincomaliensis*, *tubulodigitata*, *fungoides*, and *gallensis* respectively.

Spirastrella vagabunda, var. **trincomaliensis**, RIDLEY.

1882, "**Suberites**, ? sp., undescribed, Trincomalee," CARTER (**33**); 1884, **Spirastrella vagabunda**, var. **trincomaliensis**, RIDLEY (**16**); 1886, **Suberites trincomaliensis**, CARTER (**20**).

The single specimen in the collection evidently agrees very closely with the specimen examined by CARTER and RIDLEY. It consists of a massive base rising up into a few short, stout, finger-shaped processes. The surface is sub-glabrous, but slightly corrugated vertically; not warty as described by CARTER (this character having probably been due to drying). The colour (in spirit) externally is nearly black, with a greenish tinge, internally dark greenish-brown. Texture compact throughout, but fleshy and fairly compressible, with little or no imbedded foreign matter. The exhalant canals are (in spirit) extremely narrow and surrounded by gelatinous tissue almost free from spicules; they run vertically upwards through the finger-shaped processes in considerable numbers and probably open by minute vents (now nearly all closed) at the apices of these projections. Greatest height of specimen 56 millims.; greatest breadth of massive base 52 millims.; length of finger-shaped projections about 23 millims.

The skeleton is a very dense and confused reticulation of megascleres, interlaced in all directions. On the surface some of them form, in places at any rate, very poorly developed surface brushes.

Spicules.—(1.) Styli and tylostyli; moderately stout, usually more or less curved or crooked; apices, and heads when developed, very variable and apt to be irregular; size of fully grown spicule about 0·62 millim. by 0·009 millim., but variable.

(2.) Spirasters; not very abundant and varying in form from the ordinary zig-zag to one with a simply but strongly curved axis with blunt projections on the convex side; length about 0·012 millim. These spicules agree closely in form and size with those in Mr. CARTER'S preparation, although a good deal shorter than in the type of the species (according to RIDLEY'S measurements).

R.N. 52 (Gulf of Manaar).

Spirastrella vagabunda, var. **tubulodigitata**, nov.

In this variety the sponge consists of hollow, finger-shaped processes or "fistulæ" rising from a sandy base to a total height of about 50 millims. Each process contains several wide, longitudinal exhalant canals, separated from one another by narrow partitions, and usually ends in a single conspicuous vent. The colour varies from light to dark grey.

The skeleton arrangement and spiculation agree closely with those of the last-named variety. The surface brushes of megascleres may or may not be well-developed in different parts of the same specimen.

In one specimen (R.N. 246) a single finger-shaped process swells up at its free end into an irregular nodular mass, and thus makes an approach to the variety *fungoides*.

In R.N. 218 the spirasters are rather longer and the megascleres have better developed heads, and are perhaps usually somewhat stouter than in the type of the variety.

R.N. 154 (type of variety); 218 (deep water outside pearl banks, Gulf of Manaar); 246; 352 (Ceylon seas).

Spirastrella vagabunda, var. **fungoides**, nov.

The type of this variety is an extremely irregular, massive specimen, growing amongst a quantity of nullipore and other calcareous débris. It is characterised especially by the presence of definite porous areas, either forming irregular depressions on the surface, like large pock-marks, or on the flattened tops of fungoid outgrowths. These are probably inhalant pore-areas, for there are at least two fairly large vents forming the outlets of wide oscular tubes; one of these vents is situated on a level with the general surface of the sponge, and the other on a low mammiform projection. The structure internally is somewhat cavernous, and the specimen contains a great deal of imbedded foreign matter. The size of the entire mass is about 88 millims. by 47 millims. by 47 millims., but a large proportion of it consists of nullipore, &c. The colour in spirit is pale yellowish-grey.

The main skeleton is dense and confused; surface brushes are developed in the pore-areas and, as usual, many at any rate of the spicules in these brushes are much smaller than those of the main skeleton.

Spicules.—(1.) Tylostyli; usually slightly curved; with stout fusiform shafts, well-developed, oval heads and finely and evenly pointed apices; size in main skeleton about 0·5 millim. by 0·0167 millim.

(2.) Spirasters; mostly long, slender and zig-zag; occasionally up to as much as 0·048 millim. long, but usually much shorter. Rarely more than 0·002 millim. thick, exclusive of spines; occasionally nearly straight.

In the possession of the occasionally much elongated spirasters this variety resembles Ridley and Dendy's *Spirastrella solida* (1) from the Philippine Islands, which should perhaps be regarded merely as another variety of *S. vagabunda*.

R.N. 54 (type of variety, Gulf of Manaar); 253 (Ceylon seas).

Spirastrella vagabunda, var. **gallensis**, nov.

The larger of the two fragments by which this variety is represented in the collection is an irregularly cylindrical piece, about 52 millims. in length, and varying in diameter from about 10 millims. to about 19 millims. The texture is compact and firm and the specimen contains a good deal of coarse sand imbedded in it. The colour (in spirit) is pale yellowish-grey. The surface is smooth, but rather uneven. No vents visible. Pores scattered in small groups ?

The main skeleton is a very dense and confused reticulation of stout megascleres. The preparation only shows very feebly developed surface brushes.

Spicules.—(1.) Tylostyli; usually curved, with stout, fusiform or sub-fusiform shafts and well-developed ovoid heads; apex gradually and evenly and fairly sharply pointed. Size when full grown about 0·5 millim. by 0·019 millim.

(2.) Spirasters; short and slender, closely resembling those of var. *trincomaliensis;* about 0·012 millim. long; not very abundant.

R.N. 178 (type of variety), 179 (both from Lagoon, Galle, June, 1902).

Spirastrella tentorioides, n. sp.—Plate V., fig. 7.

The single specimen bears a striking resemblance in external form to *Tentorium semisuberites*, consisting of a short columnar body ending above in a strongly convex and sharply-defined pore- and vent-bearing area of darker colour* than the remainder of the surface. The surface of the column is subglabrous and irregularly furrowed longitudinally. On one side a much smaller column is given off as a vertical offshoot, terminating above like the large one. The specimen is attached below to a mass of calcareous débris by a broad base and narrows somewhat towards the apex of the column. Total height about 24 millims. Diameter of the column in the middle about 15 millims. Colour (in spirit) light grey. There are several wide exhalant canals running vertically through the column, and probably several smallish vents at the apex. Only one vent, however, is now visible, forming the outlet of the largest canal, and measuring only about 1·5 millim. in diameter. The inhalant pores are scattered between the surface brushes of spicules on the rounded apex of the column, around the vents.

The main skeleton is a very dense, confused reticulation of megascleres, permeating the whole of the soft tissues, close up to the walls of the canals, on the one hand, and to the dermal surface on the other. In this reticulation the spicules lie in all directions, but around the inhalant canals they are mostly placed lengthwise, with their apices pointing upwards. Surface brushes are confined to the rounded summit of the column, where they are well-developed.

Spicules.—(1.) Tylostyli (Plate V., fig. 7, *a*, *b*); straight or slightly curved, with stout, sub-fusiform shafts gradually and sharply pointed at the apex, and well-developed oval heads; size when full grown about 0·66 millim. by 0·0164 millim., but much smaller in the surface brushes.

(2.) Spirasters (Plate V., fig. 7, *c–g*); varying much in shape and size, usually slender, but sometimes stout; *e.g.*, (*a*) short, slender, simply curved, with projections (hardly spines) on the convex side; length about 0·008 millim.; (*b*) short, slender,

* The darker colour is due to the entanglement of dirt amongst the spicule-brushes.

zig-zag, with projections on all sides; length about 0·016 millim., thickness about 0·002 millim. (excluding projections); (*c*) long, slender, zig-zag or crooked, with small, sharp spines on all sides; size about 0·048 millim. by 0·0027 millim. (excluding spines); (*d*) short, stout, zig-zag, with stout conical spines on all sides; size about 0·022 millim. by 0·004 millim. (excluding spines), with spines about 0·006 millim. long. The spirasters are abundant and form a thin dermal crust.

The canal system of this sponge is somewhat remarkable and, like the external form, reminds one of *Tentorium*. The wide exhalant canals, running vertically upwards to the apex of the sponge, have already been noticed. The inhalant pores, situated also at the summit of the sponge, lead into subdermal cavities from which very narrow inhalant canals run vertically downwards, more or less parallel with the oscular tubes. These canals unite together as they descend and, even in hand-cut and unstained sections, can be easily traced by the brown colour of their walls.

Considering the extraordinary variation which the species of *Spirastrella* exhibit, alike in external form and in the arrangement of pores and vents, I should hardly have considered characters of this nature alone sufficient to justify the establishment of a new one, but should have regarded this form as yet another variety of *Spirastrella vagabunda*. We have here, however, a stout form of the spiraster which is, perhaps, not represented in any of the varieties of that species, and this fact, taken in conjunction with the other characters, seems to me to justify a specific separation.

R.N. 239 (Ceylon seas).

Placospongia, Gray.

Spirastrellidæ with a stony spicular axis and a similar cortex, both composed of closely packed sterrospiræ; with bundles of tylostyles radiating from the axis towards the periphery. Cortex divided into polygonal areas by grooves containing the inhalant and exhalant apertures.

Placospongia carinata (Bowerbank).

[For Literature and Synonymy, see Vosmaer and Vernhout (35).]

In view of the very recent publication of the elaborate monograph on the genus *Placospongia*, by Vosmaer and Vernhout, it is unnecessary to say much about this interesting species. The presence of numerous parenchymatous spirasters ("spinispiræ"), and the fact that the dermal spicule is a microspire, justify the specific identification according to the views of the authors quoted. I also agree with Keller in placing the genus amongst the Spirastrellidæ, it having been shown that the "sterraster" of this sponge is a modified spiraster.

Carter (4) has described a species of *Placospongia* from the Gulf of Manaar which he identified as *P. melobesioides*, and this identification will no doubt hold good, for he expressly mentions the absence of spirasters ("spinispirulæ"). He has also (5) recorded the same species from the vicinity of the Basse Rocks, off the south-east coast of Ceylon. It appears, therefore, that the two species, *melobesioides* and *carinata*, both occur in Ceylon waters.

R.N. 118 (Stat. V., off Chilaw, 10 fathoms).

Negombo, n. gen.

Spirastrellidæ consisting (? always) of tubular processes (? arising from a common base). Megascleres smooth styli; microscleres sanidasters.

This genus may, perhaps, have arisen independently from some sanidastrose form of Tetractinellid, but as regards its existing characters it is so closely related to *Spirastrella* that it may be included in the same family. It is also quite possible that its sanidaster may be merely a modified spiraster.

Negombo tennistellata, n. sp.—Plate V., fig. 8.

Sponge consisting of a group of short, rather thin-walled tubes of very variable diameter, growing up close together, side by side, and more or less fused with one another laterally. Each tube ends above in a single widely-open vent, ranging in diameter from about 3 millims. to about 8 millims. All the tubes are broken off and widely open below, so that it is impossible to say whether or not there was a basal mass from which they sprung, but probably there was. The walls of the tubes contain a great number of large sand-grains embedded rather sparsely in them. The colour (in spirit) is pale yellowish-grey, translucent; the texture rather soft and flexible, but fairly tough. The tubes do not vary greatly in height, the height of the longest being about 31 millims., while its width in the middle is about 6 millims.; the tube next to it is of about the same height, but as much as 12 millims. wide in the middle. The walls of the tubes are scarcely 2 millims. thick in the middle, thinning out somewhat towards the margin of the vent and thickening slightly towards the base. The outer surface of the tube-wall is rough, with more or less embedded sand-grains, and also, between the grains, irregularly reticulate with slightly-projecting ridges; I have not been able to find dermal pores in it. The inner surface of the tube-wall, on the other hand, is covered by a kind of dermal membrane, strengthened by a reticulation of megascleres, and bearing numerous small pores, resembling dermal pores but presumably exhalant, in the interstices of this reticulation.

The main skeleton consists of long styli, not forming definite fibres but sometimes collected into loose wisps. They mostly lie lengthwise in the thickness of the tube-wall and are more abundant in the middle of its thickness than elsewhere. On the inside of the tube-wall there is, as already indicated, a well-developed "dermal" reticulation of styli, crossing one another singly, or in twos or threes, in all directions parallel with the surface. On the outer surface of the tube-wall the dermal membrane contains very numerous microscleres and the megascleres lie at a slightly lower level. On both surfaces the dermal membrane is supported to some extent on the outer ends of very loose, irregular wisps of styli which come off from the dense central portion of the main skeleton.

Spicules.—(1.) Styli (Plate V., fig. 8, *a*, *b*, *c*); rather long and rather slender, subfusiform, with the base rather narrower than the middle and the apex fairly gradually sharp-pointed; usually slightly curved; size about 0·54 millim. by 0·012 millim., but variable. The apices have a tendency to be irregular and occasionally the spicule becomes oxeote.

(2.) Sanidasters (Plate V., fig. 8, *d*); each in the form of a very slender rod, straight or slightly crooked, terminating at each end in a slight swelling or, perhaps, a couple of small spines, and bearing very slender spines along its length, usually most strongly developed in, or perhaps even confined to, a whorl on each side of the middle of the spicule. Total length about 0·012 millim.; maximum diameter, including spines, about 0·004 millim. These spicules appear to be almost, if not quite, confined to the dermal membrane on the outer surface of the sponge.

R.N. 362 (Stat. I., hauls 1–4, January 31, 1902, off Negombo, 12 to 20 fathoms).

Family: CLIONIDÆ.

Astromonaxonellida of boring habit; forming excavations in the shells of Mollusca and other calcareous bodies.

Cliona, Grant.

Clionidæ of which the complete spiculation is composed of tylostyli, oxea, and spirasters. One or two of these forms of spicule may be absent by atrophy.

It will be seen that I have adopted Topsent's views (**36, 37**) as to this genus and its systematic position, in preference to those expressed in the Report on the "Challenger" Monaxonida.

Cliona margaritiferæ, n. sp.—Plate V., fig. 9.

The specimens in the collection consist of pieces of the shell of *Margaritifera vulgaris* (the Ceylon Pearl Oyster), abundantly excavated by the sponge. The chambers which it makes are rounded or oval in form, more or less crowded together, according to age, and connected with one another by narrow tunnels. From the inner sides of the chambers slender, elongated, conical canals radiate at various angles towards the inner surface of the shell. These outgrowths are shaped like spines, and, as in certain other species which I shall refer to later on, give the chambers a very characteristic appearance when viewed by transmitted light. From the outer side of each chamber are given off usually about two cylindrical canals, which perforate the outer layer of the shell at right angles to the surface and terminate in circular vents or pore-areas (fig. 2, on p. 144, shows a shell excavated by this sponge).

The walls of the excavations have a finely granulated or, under the microscope, frothy appearance, due to the presence of innumerable shallow, conchoidal depressions, which are in contact with one another all over the surfaces of the walls.

There is only room in the thickness of the shell for a single layer of chambers. When these have attained their full size, their transverse diameter is about 1·5 millims., but they may be considerably elongated. The diameter of the cylindrical canals which terminate on the outer surface of the shell varies up to about 0·65 millim. The outer end of each is closed, completely or partially, by a thin membrane containing numerous micro- and megascleres. Where the membrane in question stretches completely across the end of the canal, I assume it to be an inhalant pore-sieve, though the pores cannot now be seen; such a membrane may be supported by bundles of tylostyles converging towards the centre. The vents, on the other hand, are more or less widely open and surrounded by a thin, membranous diaphragm, also supported by tylostyles.

The body of the sponge itself (in spirit) forms for the most part a very thin lining (of a pale yellowish-brown colour) to the chambers.

Spicules.—(1.) Tylostyli (Plate V., fig. 9, *a*); straight, or nearly so, slender, very gradually and sharply pointed, and with well-developed globular heads; size about 0·25 millim. by 0·004 millim., with head about 0·006 millim. in diameter. These spicules occur scattered generally, as well as in the neighbourhood of the vents and pores.

(2.) Spirasters (Plate V., fig. 9, *b*, *c*, *d*); usually with about four angulations, fairly stout, and abundantly but rather minutely spinous, size about 0·024 millim. by 0·004 millim., but variable. These spicules pass by transitional forms (Plate V., fig. 9, *e*, *f*, *g*) into

(3.) Spined microxea (Plate V., fig. 9, *h*, *k*); usually bent or angulated in the middle, and measuring about 0·06 millim. by 0·0027 millim., but variable. These forms are extremely numerous in the deeper parts of the sponge. The gradual transition between spirasters and microxea in this species is extremely interesting.

The excavations made by *Cliona margaritiferæ*, even down to the spine-shaped outgrowths of the chambers, are closely similar to those of Hancock's *Cliona spinosa* (38) and *Thoosa cactoides* (38), but the spiculation is very different. *Cliona spinosa* occurs in shells of *Perna* and *Placuna*, and *Thoosa cactoides* in shells of *Meleagrina margaritifera*. Another distinct species, of closely similar form, occurs in shells of *Meleagrina albina?* and has been described by the same author (38) under the name *Cliona cervina*; the spiculation of this species makes a much closer approach to that of *C. margaritiferæ*, but the two appear to be quite distinct.

Topsent (37) has already described, under the name *Cliona indica*, a boring sponge infesting a pearl oyster from Ceylon. This species is evidently nearly related to ours, but the describer gives no information as to the character of the excavations or apertures, and the spiculation differs so much from that of our species that it is impossible to suppose that the two are identical. Both belong, however, to TOPSENT'S third division of the genus *Cliona*.

THIELE'S *Cliona concharum* (**39**), from Japan, perhaps comes nearer to our species than any other, at any rate so far as the spiculation is concerned, the differences in this respect being so slight that subsequent researches may make it desirable to consider the two as being only varietally distinct. In the Japanese form, however, the chambers excavated by the sponge seem to be much smaller, while the spined microxea are a good deal longer (0·09 millim.), than in that from Ceylon.

CARTER'S *Cliona warreni* (**5**), also from the Gulf of Manaar, on the other hand, is a very different species, and, according to TOPSENT (**37**), is identical with the European *Cliona celata*.

R.N. 261 (Gulf of Manaar—very abundant, and destructive, on the pearl banks).

FAMILY: SUBERITIDÆ.

Astromonaxonellida in which the megascleres are styli or tylostyli, and the microscleres have completely disappeared.

Suberites, NARDO.

Suberitidæ of varying form, but without mammiform projections on the surface. Spicules tylostylote (nearly always). Skeleton usually arranged radially, with surface brushes of spicules smaller than those of the main skeleton.

The genus *Suberites*, at any rate so far as its typical species are concerned, for it may possibly be of polyphyletic origin, is, as I have already indicated, probably derived from *Spirastrella* by loss of the spirasters. CARTER even admitted into the genus certain species with spirasters.

It is remarkable that there is only one species of the genus, and of that only a single specimen, in the present collection. In making my preliminary examination in Liverpool (which had to be done very hastily), I identified one of the specimens as *Suberites inconstans*, var. *digitata*, a form previously described by me from near Ceylon, but more careful examination subsequently revealed the presence of spirasters and thus proved that the specimen was really a *Spirastrella*.

Curiously enough, THIELE (**39**) has come to the conclusion that *Suberites inconstans* is in reality a *Spirastrella* in which I have overlooked the spirasters, these being, according to him, small and scarce. This is, of course, possible, but it is by no means proved. THIELE has apparently never seen specimens from Ceylon or India, but identifies certain specimens from Celebes with the species, under the name *Spirastrella inconstans*. Unfortunately I am unable to re-examine the types of the species here in South Africa, as the original specimens and preparations remained in the British Museum.

TOPSENT has sub-divided the old genus *Suberites* into a number of separate genera, and there is a great deal to be said in favour of such a proceeding, though it is doubtful whether all of his distinctions can be maintained. *Suberites cruciatus*, for example, combines certain characters of TOPSENT'S *Laxosuberites* and *Axosuberites* with peculiarities of its own, and I prefer to make use of the old generic name in this instance.

Suberites cruciatus, n. sp.—Plate V., fig. 10.

Specimen consisting of a number of long, slender, flattened branches, springing from a short pedicel of similar structure to themselves and branching in an almost dichotomous manner, but with some of the branches fusing together again higher up. Total height of specimen about 91 millims.; length of pedicel to first fork about 14 millims., breadth 3·5 millims., thickness 2 millims.; breadth of separate branches about 2·5 millims.: thickness about 1·5 millims. Surface rather uneven, very minutely hispid, and beset with very numerous small rounded translucent areas, apparently pore-areas. Vents probably minute and scattered. Colour (in spirit) pale brown; consistence soft and very flexible.

The main skeleton consists of numerous loose bands of tylostyles running lengthwise through the sponge; with numerous similar spicules scattered between in a loose, irregular reticulation. I have not detected any spongin cement. Towards the surface this arrangement gives place to radiating brushes of tylostyles, whose apices project slightly beyond the dermal membrane. Between these brushes lie the fairly extensive sub-dermal cavities.

Spicules.—Tylostyli (Plate V., fig. 10), of rather peculiar form. Usually straight, slender, gradually and finely pointed at the apex: with heads usually elongated transversely at a little distance from the base of the spicule, so as to form a cross. This cruciate character is most pronounced in the youngest and slenderest spicules; in the mature forms the arms of the cross form rounded knobs projecting from the shaft usually at a very slight distance from the base; occasionally there are three of these knobs instead of two. The full-sized spicules measure about 0·31 millim. by 0·005 millim., with head about 0·0093 millim. across.

The shape of the tylostyle in this curious little sponge reminds one of the corresponding spicule in CARTER'S *Hymedesmia spinatostellifera* (4).

R.N. 315 (Stat. LV., outside Periya Paar, 24 fathoms).

FAMILY: CHONDROSIIDÆ.

Corticate Astromonaxonellida with complex canal system and small flagellate chambers. Without megascleres.

These sponges appear to be Astromonaxonellida in which the megascleres (and in the case of *Chondrosia* the microscleres also) have been lost by degeneration. Their strongly developed cortex and complex canal system show that they are not primitively simple forms like the Myxospongida, and, as the megascleres probably passed through a monaxonellid condition before finally disappearing, we may include the family in the monaxonellid rather than in the tetractinellid grade, though, perhaps, logically speaking, it ought to occupy a distinct grade of its own. The form of the microscleres (when present) and the corticate character suggest a close relationship with the Tethyidæ.

The family will always be historically interesting as having formed the subject of one of F. E. SCHULZE's classical memoirs (40).

Chondrilla, SCHMIDT.

Chondrosiidæ with microscleres in the form of euasters of various kinds.

Chondrilla australiensis, CARTER.

1873, **Chondrilla australiensis**, CARTER (41); 1885, **Chondrilla australiensis**, LENDENFELD (42).

The specimens of this sponge form thin crusts of a greyish colour (in spirit) and irregular outline, spreading over masses of calcareous débris. One large specimen is about 80 millims. in greatest breadth. The surface is smooth and sometimes glabrous; it may be minutely reticulate when seen under a lens, and in one specimen (R.N. 185) it is very minutely papillate, with the spherasters so thickly aggregated in the papillæ that they touch one another. The vents are minute and scattered.

Having in my possession several of Mr. CARTER's own microscopical preparations of this species, evidently from the original types, I have been able to make a direct comparison and to assure myself of the correctness of the identification. In both Mr. CARTER's and Professor HERDMAN's specimens the spheraster, with smooth conical rays, measures about 0·028 millim. in diameter, and the oxyaster, with minutely spined rays, sometimes branched at the ends, measures nearly as much. In a Ceylonese specimen I find that neither spicule is strictly confined to either the cortex or the interior of the sponge, but while the spherasters are much more abundant in the cortex, the oxyasters are much more abundant in the interior.

It is noteworthy that Mr. CARTER has recorded (5) the occurrence of *Chondrilla nucula*, the common European species, from the Gulf of Manaar. This species appears to be of very wide distribution.

R.N. 17 (Gulf of Manaar); 185 (Donnan's Paar); 251; 376 (encrusting a shell of *Margaritifera vulgaris*, Cheval Paar).

Chondrilla australiensis, var. **lobata**, nov.

This variety is represented by two specimens (apparently obtained together) which differ conspicuously from the thin, encrusting form above described, being massively lobose, with comparatively large vents placed singly on the top of the lobes. The base of attachment is constricted to a few narrow projections on the lower surface, and the entire body of the sponge exhibits a swollen, tumid appearance. The vents measure up to 2 millims. in diameter, and each is surrounded by a thick, membranous margin, which, in its turn, is usually surrounded by a shallow groove. The surface is sub-glabrous, but uneven and very minutely reticulate. The colour below (in spirit) is very pale grey, but on the upper parts of the lobes the grey is mottled with brown. The texture is compact and fleshy; compressible.

The two specimens are of about equal size; the one selected for measurement is about 42 millims. in length, 17 millims. in breadth, and 18 millims. in height. The cortex is about 0·164 millim. thick.

The spicules agree closely in form with those of the thin, encrusting variety. The spherasters are, however, rather smaller. They have, in both varieties, a strongly marked tendency for their rays to be reduced to low warts or even, perhaps, to disappear, so that in some cases the large centrum is left almost smooth, as in KELLER'S *C. globulifera*, which is, however, specifically distinct.

A lobate variety of *C. australiensis* occurs also in Australia.

R.N. 286, 286A (deep water off Galle and onwards to Colombo. Hauls off Kaltura and off Mount Lavinia, 20 to 30 fathoms, February 19, 1902).

Chondrosia, NARDO.

Chondrosiidæ in which all the spicules have completely disappeared.

Chondrosia reniformis, NARDO.

This well-known Mediterranean species is represented in the collection by two specimens, both attached to the same fragment of a horny sponge. Each is roughly hemispherical in form, with wide base spreading out into a broad, thin "stolon" on one side. The surface is covered with low, irregular tubercles, which may be due in part to contraction. The vents are small and difficult to make out, sometimes, at any rate, on low mammiform projections. The structure of the dense fibrous cortex, with its pigment cells, and that of the choanosome, agree very closely, so far as can be made out in the material at my disposal, with SCHULZE'S classical description (**40**). The pigment cells, however, appear to be mostly in the inner part of the cortex, instead of in the outer part as figured by SCHULZE; but this is not an important difference. Each specimen is about 13 millims. in diameter, and the colour (in spirit) is mottled grey and brown on the surface, and pale greyish-yellow internally.

R.N. 226 (two specimens; deep water off Galle and onwards up West Coast of Ceylon).

SUB-ORDER: SIGMATOMONAXONELLIDA.

Monaxonellida in which the typical microscleres are sigmata, or forms derived therefrom, normal astrose microscleres being absent.

The sponges which comprise this large sub-order may be regarded as descended from the tetractinellid sub-order Sigmatophora (family Tetillidæ) by reduction of the megascleres, in the same way that the Astromonaxonellida may be regarded as being derived from the tetractinellid Astrophora.

In dealing with the Astromonaxonellida I have already had occasion to point out that no reliable instance of the occurrence of true astrose microscleres in conjunction with sigmatose forms has ever been recorded, a fact which argues very strongly in favour of the primary cleavage of the Monaxonellida into two great groups corresponding to the tetractinellid sub-orders Astrophora and Sigmatophora. Since that part of my report was completed, however, and sent to England, TOPSENT's latest work on the 'Sponges of the Azores' (**62**), has been received here. In this work the author describes two apparent Sigmatomonaxonellida in which asters were met with, viz., *Yvesia alecto* and *Leptosastra constellata*, but in neither of these are other microscleres present.

In *Yvesia alecto* the asters are, as TOPSENT himself shows, simply transformed megascleres (spined oxea) with the spines greatly developed, so that they are clearly of secondary origin. It may be pointed out, further, that an analogous transformation takes place in the echinating megascleres of the genus *Cyamon*,* and, probably, also in the genus *Trikentrion*, giving rise to spicules which simulate true asters. It appears, therefore, that in certain Sigmatomonaxonellida astrose spicules have arisen secondarily by transformation of spined megascleres. It is obvious, however, that these cases do not affect the primary division of the Monaxonellida here adopted.

The case of *Leptosastra constellata* offers a more serious difficulty, for here there is no indication that the asters, which form a superficial crust, are other than true astrose microscleres. It is, however, a suggestive fact that the sponge in which they occur is an Ectyonine with spined styli. Two explanations appear to me possible:—(1.) The asters may not belong to the same sponge as the megascleres. Considering the well-known and frequent accidental admixture of the spicules of different species, caused either by the sponges growing over one another or by the taking in of foreign spicules in the same way that grains of sand are taken in, and especially in view of the fact that only a single specimen of the sponge has been obtained; although TOPSENT has assured himself to the contrary, I venture to think that we may be here dealing with a composite spiculation. (2.) It is not impossible that the asters, if proper to the sponge, may be derived secondarily from the spined styli, in much the same way as in the genus *Cyamon*. Their position at the surface of the sponge, however, and their apparently normal form, are opposed to this view. However, until we have further evidence before us, it is quite unnecessary to allow this isolated case of a single specimen to make us alter our views on the classification of the Monaxonellida.

Assuming then that the Sigmatomonaxonellida are derived from the tetractinellid Sigmatophora, the question arises where are we to seek for the point of contact between the two groups? The answer to this question is easily given, for in the genus *Gellius* we have a near approach to the massive species of *Tetilla*, such as *T. limicola*. The replacement of the tetractinellid megascleres by oxea in a massive

* See later under *Cyamon*.

Tetilla, accompanied by the complete loss of the radiate skeleton arrangement, both of which changes are already partially accomplished in such forms as *T. limicola*, would give us a typical *Gellius*, and in *Gellius* I believe we have the starting point of the entire sigmatomonaxonellid series.

From this starting point the Sigmatomonaxonellida have branched off in various directions in the course of their evolution. Total loss of microscleres has given rise to forms with the spiculation composed entirely of oxeote megascleres, constituting the family Homorrhaphidæ of Ridley and Dendy, and the strong development of spongin cement has led to the evolution of the very large sub-family Chalininæ, from which in turn some of the so-called Ceratosa have been derived by total suppression of the spicules and their replacement by horny fibre. The arrangement of the megascleres in a characteristic plumose fashion, accompanied in most cases by the replacement of many of the oxea by styli and the loss of microscleres, has given rise to the family Axinellidæ. The development of a new type of microsclere—the chela—by modification of the sigma, has given rise to the great family group Desmacidonidæ, within which the Ectyoninæ have arisen by development of spined echinating spicules.

In the Report on the "Challenger" Monaxonida, published 17 years ago, Mr. Ridley and I proposed to divide the Sigmatomonaxonellida (= Halichondrina) into four families, viz., Homorrhaphidæ, Heterorrhaphidæ, Desmacidonidæ and Axinellidæ, an arrangement which has been variously modified by subsequent writers, chief amongst whom is Topsent. This author (59) has united our Homorrhaphidæ and Heterorrhaphidæ in one family which he terms "Haploscleridæ," a proceeding which appears to me justifiable in view of the obviously close relationship between the two, and especially in view of the fact that the Renierinæ and Chalininæ have very probably arisen independently from different though closely related genera, the Renierinæ from *Gellius* (and perhaps other genera), and the Chalininæ from *Gelliodes* and *Toxochalina*, as well as, perhaps, in some cases from Renierinæ.

Topsent has also proposed the name "Pœciloscleridæ" in replacement of "Desmacidonidæ"—a proceeding which appears quite unnecessary, although the extent of his family is not quite the same as that of ours.

I therefore propose in this Report to sub-divide the Sigmatomonaxonellida amongst three families, viz., Haploscleridæ (including the Homorrhaphidæ and Heterorrhaphidæ of Ridley and Dendy), Desmacidonidæ and Axinellidæ. The Haploscleridæ, there can be little doubt, should stand first, and indeed occupy the position of a parent group from which the other two families have descended.

Family: HAPLOSCLERIDÆ.

Sigmatomonaxonellida in which microscleres when present are usually in the form of sigmata, or derivatives thereof, but never chelæ. The skeleton is reticulate and the fibre is typically not plumose. The megascleres are usually diactinal.

The most primitive sub-family of this group is undoubtedly the Gelliinæ, from which the Renierinæ and Chalininæ are clearly derived. The other sub-families may be in part Desmacidonidæ which have lost their chelæ; this I am able in the present Report to demonstrate pretty clearly in the case of the Phlœodictyinæ, which I have accordingly removed. TOPSENT has already removed the Tedaniinæ, Desmacellinæ, and Hamacanthinæ as being Desmacidonidæ without chelæ; this may be quite right, but until clear evidence that they are descended from chela-bearing forms is forthcoming, it seems to me equally justifiable to leave them in the parent group. A *Desmacella*, for example, may very well be an *Esperella* which has lost its chelæ, but it seems at least equally probable that it has never reached the stage of having any.

SUB-FAMILY: GELLIINÆ.

Haplosceridæ with diactinal megascleres, and sigmata or toxa or microxea for microscleres.

Gellius, GRAY.

Gelliinæ with little or no spongin, the main skeleton being formed by a reticulation of oxea.

Gellius fibulatus (SCHMIDT).

1862, **Reniera fibulata**, SCHMIDT (47); 1880, **Reniera fibulifera**, CARTER (4); 1892, **Gellius fibulatus**, TOPSENT (48).

There is in the collection a considerable quantity of this sponge growing amongst the branches of a Floridean Alga. I identify it with the European species by direct comparison with a preparation from a specimen from Budleigh Salterton in Mr. CARTER'S cabinet. The differences in spiculation are very slight. In our specimen the slightly curved and gradually sharp-pointed oxea measure about 0·184 millim. by 0·007 millim., and the sigmata about 0·02 millim. from bend to bend.

R.N. 51 (Gulf of Manaar); 299; 348; 350 (all growing in association with apparently the same kind of alga; the last three probably fragments of one and the same specimen).

Gellius angulatus (BOWERBANK), var. **canaliculata**, nov.—Plate IX., fig. 7.

[For synonymy and references *vide* RIDLEY and DENDY (1)].

The single specimen is massive, rounded and slightly elongated, about 18 millims. long by 12 millims. in transverse diameter. It was probably attached by one end, and bears a group of vents at the other. The surface is even and smooth, conspicuously veined by ramifying exhalant canals, which run towards the (upper ?) end of the specimen and open there by means of the moderate-sized vents. Many of these exhalant canals lie just beneath the surface and are covered over only by a thin, translucent membrane, which easily gets rubbed off, leaving the canals as open grooves. Between the exhalant canals there is no separable dermal membrane, and there are no conspicuous sub-dermal cavities. Texture between the canals very compact, but not very hard and rather friable. Colour (in spirit) very pale grey.

The skeleton is a very close and pretty uniform reticulation of single oxea, crossing one another in every direction. The dermal skeleton consists only of scattered oxea placed tangentially.

Spicules.—(1.) Oxea (Plate IX., fig. 7, *a*); rather slender, slightly curved, usually somewhat abruptly or even hastately pointed; about 0·25 millim. by 0·008 millim. to 0·01 millim.

(2.) Sigmata (Plate IX., fig. 7, *b*); slender, C-shaped, with shortly and sharply incurved and sharply pointed ends; often with a slight indication of enlargement or angulation near the middle; measuring about 0·028 millim. from bend to bend when full grown.

(3.) Toxa (Plate IX., fig. 7, *c*); rather short and moderately stout; sharply angulated in the middle and only slightly recurved at the extremities; length up to about 0·044 millim.

This is a pretty little sponge, evidently very nearly related to the European *Gellius angulatus*, from which it differs in the somewhat shorter oxea, the considerably larger sigmata, and the much shorter toxa. It is possible also that the arrangement of the exhalant canals may be characteristic. It is interesting as indicating that sigmata and toxa are simply slightly different modifications of the same form of microsclere.

R.N. 140 (deep water off Galle and onwards up West Coast of Ceylon).

Gelliodes, Ridley.

Gelliinæ with much spongin, more or less completely enveloping or even replacing the megascleres and forming distinct fibres. The microscleres are sigmata.

Gelliodes carnosa, Dendy—Plate VII., fig. 5.

1889, **Gelliodes carnosa,** Dendy (3).

There is one fine specimen of this sponge in the collection, easily recognized by its characteristic external form (Plate VII., fig. 5). The megascleres are much slenderer than in the types and appear to be becoming vestigial, as in so many chalinine sponges, being functionally replaced by the strongly developed horny fibre. The sigmata are still numerous, about 0·02 millim. long, but very slender.

This species forms a conspicuous feature of the Ceylon Sponge-Fauna.

R.N. 69 (Stat. XXVII., Cod Bay, Trincomalee, 5 fathoms; also Gulf of Manaar).

Gelliodes incrustans, n. sp.—Plate IX., fig. 6.

Sponge thin, encrusting; the single specimen growing over both valves of a *Pecten* (which was evidently alive when collected). Maximum thickness about 7 millims.

Surface smooth, but rather uneven. Vents numerous and conspicuous, circular, from about 1 millim. to 2·5 millims. in diameter; mostly flush with the surface, but occasionally on low prominences. Colour (dry) dull greyish-brown, with a purplish tinge in places, which seems to indicate that it was purple in life. Texture (dry) compressible and resilient, but rather stiff.

The main skeleton is a rectangular-meshed network of horny fibre cored by spicules, in which the meshes vary greatly in size. The principal fibres are about 0·033 millim. in diameter, and contain a multispicular core of small oxea which occupy only about one-third (or less) of the total thickness of the fibre. The secondary fibres are more slender and contain fewer spicules. The dermal skeleton (Plate IX., fig. 6) is, for the most part, a unispicular reticulation of oxea with comparatively little spongin; sometimes one sees brushes of projecting oxea, but I am not sure how far these are proper to the dermal skeleton.

Spicules.—(1.) Oxea (Plate IX., fig. 6, *o*); short, slender, slightly curved, subfusiform, gradually and sharply pointed at each end; size about 0·1 millim. by 0·004 millim. A number of very slender, hair-like oxea, probably young or vestigial forms, also occur.

(2.) Sigmata (Plate IX., fig. 6, *s*); very slender and hair-like, C-shaped, up to about 0·02 millim. from bend to bend. Abundant.

This species is nearly related to *Gelliodes licheniformis* (LAMARCK),* but differs, at any rate from the "Challenger" specimen of that species, both in external form and in the much smaller size of the spicules and more regular arrangement of the skeleton.

R.N. 112 (Gulf of Manaar, dry).

Gelliodes petrosioides, n. sp.—Plate IX., fig. 3.

Sponge massive, depressed, cushion-shaped; flattened below, where it has apparently been attached by a broad base; evenly rounded off and strongly convex above. Surface coarsely granular, not hispid. Vents not visible. Pores numerous, scattered in the thin dermal membrane which roofs over the numerous small, rounded subdermal cavities. Colour (in spirit) pale yellowish-grey. Texture compact; hard and almost stony. Greatest diameter of specimen, which is irregularly rounded in outline, about 24 millims.

The main skeleton is a very dense but quite irregular reticulation of very coarse, stout, densely spicular fibre, with a great many loose megascleres scattered between. The stout fibres have a thickness of about 0·164 millim., and probably contain a certain amount of spongin, which, however, is not visible in ordinary sections. The dermal skeleton cannot be sharply distinguished from the main skeleton, and consists of an irregular reticulation of coarse spicular fibre, the interspaces in which are occupied by the thin, pore-bearing dermal membrane.

* *Vide* RIDLEY and DENDY, '"Challenger" Monaxonida,' p. 48.

Spicules.—(1.) Short, stout, fusiform, slightly curved oxea (Plate IX., fig. 3, *a*, *b*, *c*), usually sharply and fairly gradually pointed at each end (often becoming strongylote or stylote); measuring about 0·25 millim. by 0·017 millim., but varying a good deal in thickness.

(2.) Sigmata (Plate IX., fig. 3, *d*); slender, C-shaped or contort, about 0·022 millim. from bend to bend; very numerous.

Were it not for the presence of the sigmata, this species would be a typical *Petrosia*. It appears to be very nearly related to TOPSENT's *Gelliodes fayalensis*,* from the Straits of Pico-Fayal, but is distinguished by the absence of the large oscula, and, perhaps, by other characters.

R.N. 146 (deep water off Galle and onwards up West Coast of Ceylon).

Gelliodes petrosioides, var. **fibrosa**, nov.

I propose this name, at any rate provisionally, for a single small, much-damaged specimen of irregular shape and cavernous structure, with large exhalant canals and vents (?) and very soft, fibrous texture; agreeing very closely with the type of the species in spiculation and in the structure of the main skeleton fibres, but with the fibres better defined and the meshes of the reticulation mostly very wide and not filled up by scattered spicules. The soft texture of the specimen, which is in striking contrast with the hardness and density of the type, is due simply to this greater laxity in the skeleton arrangement.

Except for the presence of the sigmata, this variety closely resembles a *Pachychalina*. It may ultimately, when better specimens are forthcoming, have to be considered as a distinct species.

R.N. 272 (deep water off Galle and onwards up West Coast of Ceylon).

Toxochalina, RIDLEY.

Gelliinæ with much spongin, more or less completely enveloping or even replacing the megascleres, and forming distinct fibres. The microscleres are toxa.

This genus differs from *Gelliodes* only in the replacement of the sigmata by toxa, and in view of the occurrence of both these forms in the same species of *Gellius* (*vide* under *Gellius angulatus*, var. *canaliculata*), it may be questioned whether the two should be kept distinct. They are interesting as forming an obvious starting point in the evolution of the great sub-family Chalininæ.

Toxochalina robusta, RIDLEY.

1884, **Toxochalina robusta**, RIDLEY (16).

There are a number of specimens of this sponge in the collection, agreeing closely, both as regards external form and skeletal characters, with RIDLEY's description of the type from Port Jackson. It is perhaps noteworthy, however, that the megascleres

* TOPSENT (48), p. 78.

are abundant *between* the stout horny fibres, as well as (sometimes) in their axes. The species has also been recorded from off Bahia ("Challenger").

R.N. 8, 9, 38 (all three from Gulf of Manaar); 351 (Ceylon seas).

Toxochalina robusta, var. **ridleyi**, nov.—Plate IX., fig. 2.

The type specimen is very irregular in shape; massive and angular, with a slight tendency towards branching. It has evidently been attached by a broad base to one valve of a Lamellibranch shell (? *Margaritifera vulgaris*), the impress of which is still clearly visible. The surface is smooth and sub-glabrous, but uneven and very distinctly granular when viewed under a lens. The vents are rather numerous (five), about 4 millims. in diameter, with very prominent margins; each is the opening of a wide, deep oscular tube of the same diameter as itself. The texture (in spirit) is compressible and resilient, but stiff and tough. Colour, pale brown. The specimen is about 66 millims. long, 38 millims. broad, and 31 millims. high.

The main skeleton is a reticulation of horny fibre, with very few and slender spicules (Plate IX., fig. 2). The primary fibres are very stout, sometimes as much as 0·164 millim. in diameter, but very variable; typically they run at right angles to the surface and are united by short secondaries to form rectangular meshes, but the network often becomes very irregular and the size of the meshes is very variable. The secondary fibres are usually, but not always, more slender than the primaries. The primaries are cored by a multispicular axis of slender oxea arranged in a plumose manner (as in typical Axinellidæ), but all entirely enveloped in spongin to such an extent that the entire column of spicules only occupies one-third (or less) of the thickness of the fibre. The secondary fibres contain only a few isolated spicules arranged uniserially.

The dermal skeleton consists of a rather close-meshed reticulation of rather slender, unispicular horny fibre. From the nodes of this reticulation brushes of oxeote spicules project vertically. In certain places this dermal skeleton appears to become many layers deep, and the vertical brushes of oxea are continued inwards as more or less plumose columns enveloped in spongin and connected by numerous unispicular cross-fibres, so as to form a close skeleton network beneath the surface, very conspicuous in vertical section, and strongly contrasted with the much coarser, more widely meshed and less abundantly spicular main skeleton below it.

Spicules.—(1.) Oxea (Plate IX., fig. 2, *o*); short and rather slender, slightly curved, fairly gradually sharp-pointed at each end; measuring about 0·08 millim. by 0·004 millim. near the surface, but usually smaller, and especially more slender, in the fibres of the main skeleton. These spicules—at any rate, in the main skeleton—are evidently becoming vestigial.

(2.) Toxa (Plate IX., fig. 2, *t*); slender, more or less strongly curved in the middle, very slightly re-curved at the apices; sometimes slightly roughened in the middle, gradually sharp pointed at the ends; size varying up to about 0·08 millim. (in a straight line from end to end) by 0·002 millim. (in the middle); very abundantly distributed through the soft tissues in association with scattered oxea.

R.N. 109 (Gulf of Manaar. Type); 306 (Stat. XXIV., off Trincomalee).

Strongylophora, n. gen.

Gelliinæ with the skeleton composed of a reticulation of strongyla of various sizes, partly collected in fibres, but with little (if any) spongin. With microscleres in the form of smooth microxea, chiefly found in the dermal membrane.

This is a remarkable genus of somewhat doubtful systematic position. The presence of the fusiform (and often angulated) dermal microxea suggests an affinity with the Homosclerophora and Pachastrellidæ amongst the Tetractinellida, rather than with the Sigmatophora. We cannot, however, lay very much stress upon this character when we remember the generalized character of microxea and the fact that such spicules also occur in the Ectyonine genus *Fusifer* (*vide* DENDY, **10**).

Strongylophora durissima, n. sp.—Plate IX., fig. 1.

Sponge massive, irregular; may be depressed and cake-like or subcylindrical and slightly ramose. Surface very uneven, sometimes with angular grooves and ridges, giving it a curious crumpled appearance; minutely and uniformly granular. Vents few, scattered; circular and often rather large, up to about 4 millims. in diameter; each the opening of a wide cylindrical oscular tube which runs vertically inwards for a considerable distance. Inhalant pores minute, abundantly scattered in the meshes of the dermal reticulation. Colour (in spirit) greyish-brown throughout. Texture hard and stony, but brittle, and rather cavernous internally owing to the presence of the numerous canals of varying diameter. The larger of the two specimens measures about 45 millims. in maximum diameter.

The main skeleton is an irregular but fairly close-meshed and, towards the surface, sub-rectangular reticulation of more or less stout spicular fibre composed of closely packed strongyla, with numerous loose strongyla scattered between the fibres. The dermal skeleton (Plate IX., fig. 1) is a reticulation of mostly large and single strongyla; their ends come in contact with one another, many together, at the principal nodes of the reticulation, from which they radiate, and at each of these nodes there is also a little heap of very short strongyla. The presence of these nodal heaps gives the characteristic granular appearance to the surface of the sponge.

Spicules.—(1.) Strongyla (Plate IX., fig. 1, *s.*); usually stout, more or less curved or angulated in the middle; evenly rounded off at each end; ranging in size from about 0·026 millim. by 0·006 millim. (or perhaps even less) to about 0·26 millim. by 0·02 millim. (A few long and very slender spicules, oxeote and strongylote, occur in the interior of the sponge; they are probably abnormal forms of the strongyla, with which they are connected by intermediates.)

(2.) Microxea (Plate IX., fig. 1, *m.*); fusiform and usually angulated in the middle, from which they taper gradually to a very sharp point at each end; size fairly uniform, about 0·028 millim. by 0·002 millim. Very abundant in the thin transparent dermal membrane in the meshes of the dermal skeleton; also found less frequently in the interior of the sponge.

R.N. 156; 244 (Ceylon seas).

Sub-Family: RENIERINÆ.

Haplosclerida in which the microscleres have entirely disappeared and the skeleton consists of a reticulation of oxeote megascleres with little or no spongin.

This sub-family is apparently derived from the Gelliinæ by loss of microscleres. Inasmuch, however, as the microscleres constitute the most important guides to the classification of monaxonellid sponges, their total loss may in certain cases leave one in considerable doubt as to the true systematic position of the species concerned. The close relationship of *Reniera* to *Gellius* I take to be fully established by the form of the megascleres and by their arrangement. In the genus *Halichondria*, on the other hand, there appears to me to be less certainty, and the long, slender, slightly curved form and confused arrangement of the oxea suggest a possible origin from some astromonaxonellid genus, such as *Coppatias*, by loss of the astrose microscleres. It is impossible in the present state of our knowledge to decide this question definitely, but it is quite likely that, as regards the genera *Reniera* and *Halichondria*, we are dealing with a case of convergent evolution rather than of close genetic relationship.

Reniera, Nardo.

Renierinæ in which the skeleton is composed of a close reticulation of usually single megascleres, each forming one side of a rectangular, triangular or polygonal mesh. Spicules short, oxeote or strongylote, usually united together at the ends only by spongin cement.

Reniera implexa, Schmidt.

1868, **Reniera implexa**, Schmidt (**50**); 1887, **Reniera implexa**, Ridley and Dendy (**1**).

I identify with this species a single small specimen consisting of a few irregularly branched tubes, mostly about 5 millims. in diameter and widely open at the end. The surface has a minutely reticulate or porous appearance. The colour (in spirit) is brownish-yellow, and the consistence very soft, compressible and tender.

The skeleton is a rather irregular, triangular-meshed reticulation, for the most part of single spicules, with occasional loose plurispicular bands feebly developed.

The spicules are slender, slightly curved oxea, gradually sharp-pointed at each end and measuring up to about 0·136 millim. by 0·004 millim., usually perhaps a little less.

This species has been recorded from the Adriatic by Schmidt, and from the Azores by Ridley and Dendy (**1**) and Topsent (**62**).

R.N. 201 (Stat. LXIV., south of Modragam Paar, 5 fathoms, March 17, 1902).

Reniera pigmentifera, n. sp.—Plate IX., fig. 10.

This species is represented in the collection by a large number of small fragments which may perhaps represent only a single specimen. The external form appears to have been more or less flabellate, with rounded margin. The vents are about 2 millims. in diameter and appear to have been scattered singly along the margin (and elsewhere ?). The surface has a porous appearance to the naked eye, and is very minutely hispid. The colour (in spirit) is dark brown throughout, sometimes with a purplish tint, and the texture is very soft and crumbling.

The skeleton is an irregular "Isodictyal" network of short spicules, sometimes connected together at their ends by spongin cement; primary fibres, from one to about three spicules in thickness, are recognisable in places. There is no distinct dermal skeleton.

Spicules.—(1.) Oxea (Plate IX., fig. 10, *a*); slightly curved and gradually sharp pointed at each end; measuring about 0·144 millim. by 0·007 millim., but often much more slender.

(2.) Strongyla (Plate IX., fig. 10, *b*); stout, very slightly curved, broadly rounded off at each end; variable in length, up to about 0·12 millim. by 0·009 millim.; may be shorter and at the same time somewhat stouter.

(3.) Styli (Plate IX., fig. 10, *c*, *d*); short and stout, very similar in size and shape to the strongyla, but pointed at one end. Of course, intermediate forms of spicules also occur.

A remarkable feature of this sponge is the immense number of granular, brown or purple-coloured pigment cells which it contains. These cells are rounded in outline and about 0·002 millim. in diameter, and are thickly scattered all through the sponge.

R.N. 290 (numerous fragments. Jokkenpiddi Paar, 10 fathoms).

Reniera zoologica, n. sp.—Plate IX., fig. 8.

The single specimen appears to be half of a pear-shaped sponge which has been torn in two longitudinally. It has probably been fixed by the narrower end, and bears a single rather large vent (?) opening out of a wide oscular tube near the broad upper end. The surface is encrusted with large Foraminifera and sand-grains. The colour (in spirit) is pale grey, and the texture (internally) crumb-of-bread-like. Total height of specimen 34 millims., greatest breadth about 20 millims.

The main skeleton is an irregular network of spicules, partly arranged singly in an "Isodictyal" manner and partly collected in irregular multispicular bands. No spongin cement is recognisable in my preparation.

The dermal skeleton is a dense but thin layer of oxea, lying very close together and crossing one another in all directions parallel with the surface.

Spicules.—Oxea (Plate IX., fig. 8); moderately stout, slightly curved, gradually sharp pointed at each end; size when fully developed about 0·18 millim. by 0·007 millim. Numerous very slender forms, probably young, also occur.

R.N. 262 (Gulf of Manaar).

Reniera, sp. ?

A small massive specimen with a couple of short, mammiform, vent-bearing projections. Surface smooth. Colour (in spirit) pale yellow; texture compact and firm, but brittle.

Main skeleton a compact, irregular, "Isodictyal" reticulation of spicules without any fibres. Dermal skeleton a dense but thin layer of tangentially placed oxea crossing one another in all directions parallel with the surface.

Spicules.—Oxea; slightly curved, usually gradually sharp-pointed at each end; occasionally strongylote; size about 0·164 millim. by 0·008 millim.

This species may possibly be identical with one of the numerous imperfectly known European species of *Reniera* (*Isodictya*).

R.N. 232 (deep water off Galle and onwards up West Coast of Ceylon).

Petrosia, Vosmaer.

Renierinæ usually of hard or even stony texture, owing to the density of the skeleton, which is composed of an irregular reticulation of oxeote or strongylote megascleres (usually short and thick), packed close together, sometimes in stout fibres.

Those species of this genus which have a more or less fibrous skeleton make a close approach to the genus *Pachychalina*.

Petrosia testudinaria (Lamarck).

[For literature and synonymy *vide* Dendy (**3**).]

This handsome sponge (see text-figure 1) has been recorded from Queensland (Ridley)

Fig. 1. *Petrosia testudinaria* (Lamk.), Gulf of Manaar; reduced one-half.

Fig. 2. Pearl-oyster shell honeycombed by *Cliona margaritiferæ* Dendy (see p. 128).

and from the Mergui Archipelago (CARTER, DENDY), as well as from the Gulf of Manaar (DENDY).

R.N. 42 (Stat. LXI., Gulf of Manaar); 238 ? (deep water off Galle; fragments).

Petrosia similis, RIDLEY and DENDY.

1887, **Petrosia similis**, RIDLEY and DENDY (1).

There are in the collection a number of irregular, massive or more or less lobate specimens, with numerous rather large, scattered vents, which I refer to this species. The spicules measure about 0·22 millim. by 0·014 millim. The character of their ends varies greatly, from strongylote to apiculate and sharp-pointed.

The species was originally obtained by the "Challenger" from south of the Cape of Good Hope and between Kerguelen and Heard Islands.

R.N. 12, 61 (both from Gulf of Manaar); 289; 327 (Ceylon seas).

Petrosia similis, var. **delicatula**, nov.

This variety is distinguished from the typical form of the species by its more delicate texture and smaller vents, which are usually more or less blocked up by a strong development of gelatinous tissue. The spiculation differs little, if at all, from that of the types.

R.N. 84, 133, 276 (all from deep water off Galle and onwards up West Coast).

Petrosia similis, var. **halichondrioides**, nov.

In external appearance this variety closely resembles *P. similis*, var. *delicatula*. The single specimen is strongly compressed, with the rather small but conspicuous and widely open vents placed on prominent ridges. The texture (in spirit) is firm and compact, but brittle. The skeleton is very confused and dense, without distinct fibres, and the spicules are much more slender and *Halichondria*-like than in the typical form, being gently curved oxea, for the most part gradually sharp-pointed at each end, and measuring, say, about 0·2 millim. by 0·006 millim.

R.N. 79 (Gulf of Manaar).

Petrosia densissima, n. sp.—Plate IX., fig. 9.

Sponge massive, sub-conical, attached by the broad base; with rather irregular surface bearing feebly developed, meandering grooves. Surface minutely granular, without distinct dermal membrane, slightly sandy. Vents very small and scattered Colour (in spirit) rather dark greyish-brown on the surface; pale yellowish-grey internally. Texture extremely compact and hard; stony; incompressible. The larger of the two specimens (R.N. 138A) measures about 40 millims. in height by 42 millims. in greatest breadth.

The skeleton is extraordinarily dense and compact, consisting of a sub-rectangular-meshed reticulation of very stout spicular fibres, in which both primary and secondary fibres are about as thick as the width of the meshes between them, say about

0·13 millim. The fibres are compact, but the arrangement of the spicules in them is very confused and there is no visible spongin. Many spicules occur scattered irregularly between the fibres, so that the whole skeleton forms an almost solid mass of spicules. There is no special dermal skeleton.

Spicules.—Stout, fusiform oxea (Plate IX., fig. 9); slightly curved and usually sharply and fairly gradually pointed; size when fully developed about 0·24 millim. by 0·02 millim., but with numerous smaller forms which are presumably young.

This species is evidently very closely related to THIELE'S *Petrosia imperforata* from Celebes (**39**).

R.N. 138, 138A (both from deep water off Galle and onwards up West Coast of Ceylon).

Halichondria, FLEMING.

Renierinæ in which the skeleton consists of a confused reticulation of long and slender oxea (or strongyla) with little or no spongin; the spicules sometimes associated in ill-defined bands or fibres.

I have already indicated the doubt which exists as to the true relationship of this genus. Possibly it is, as at present understood, of polyphyletic origin, including species derived from several ancestral forms by loss of microscleres.

Halichondria panicea, JOHNSTON.

[For literature and synonymy *vide* RIDLEY and DENDY (**1**) and DENDY (**2**).]

This widely distributed species is represented in the collection by two well differentiated form-varieties, so that it seems desirable to distinguish them by varietal names. In both varieties many of the more superficial oxea are arranged more or less at right angles to the surface, with their apices projecting to a greater or less extent, thus making an approach to the genus *Trachyopsis*. In both the full-grown spicules measure up to about 1·0 millim. in length and are of the usual *Halichondria* type. Their arrangement in the interior of the sponge is quite irregular and confused.

Halichondria panicea, JOHNSTON, var. **megalorhaphis**, CARTER.

1881, **Amorphina megalorhaphis**, CARTER (**5**).

This variety is irregularly encrusting, growing out into lobose or digitiform processes, and with small scattered vents.

R.N. 87, 231, 248 (all from deep water off Galle and onwards up West Coast).

Halichondria panicea, JOHNSTON, var. **hemispherica**, nov.

This variety is massive and compact, more or less hemispherical or cushion-shaped, with vents usually arranged in conspicuous groups on the convex upper surface. It attains a considerable size, the largest specimen measuring about 100 millims. in greatest diameter and about 40 millims. in thickness in the middle.

R.N. 67 (Gulf of Manaar); 96 (Gulf of Manaar, dry); 141?, 142 (both from deep water off Galle and onwards up West Coast); 249 (Stat. XV., Periya Paar).

Trachyopsis, n. gen.

Renierinæ in which the main skeleton is composed of a dense, irregular network of oxea, while the surface is protected by similar (or perhaps more slender) spicules arranged in dense vertical brushes, which support the pore-bearing dermal membrane.

This genus is of somewhat doubtful systematic position; in certain features it recalls the genera *Trachya* and *Spongosorites*, and it differs from typical Renierinæ in the replacement of the reticulate dermal skeleton characteristic of that group by radially arranged brushes of oxea.

Trachyopsis halichondrioides, n. sp.—Plate X., fig. 10.

Sponge massive (or thickly encrusting?); upper surface slightly convex, rising up at irregular intervals into a few short, thick-walled, cylindrical, tubular processes, each terminated by a single circular vent. General surface smooth and almost glabrous, but uneven; very minutely reticulate as seen under a lens. Inhalant pores minute and scattered. Colour in spirit, pale yellowish-grey. Texture of body hard and compact, penetrated by numerous narrow vertical canals. Greatest diameter of specimen, which is irregular in outline, 44 millims.; thickness about the middle 15 millims. (but the specimen has evidently been cut off from its base). Height of largest projection about 8 millims.; diameter in the middle about 5·5 millims.; diameter of the vent at its apex 2·5 millims.

The main skeleton is an extremely dense and very irregular reticulation of stout oxea, with a tendency to arrange themselves in ill-defined tracts running towards the surface. Immediately beneath the surface the oxea, here perhaps somewhat more slender than usual, are arranged in dense brushes perpendicularly to the dermal membrane, beyond which their apices may project very slightly.

Spicules.—Oxea (Plate X., fig. 10); short, usually stout, sub-fusiform, gently curved or (often) biangulate, fairly gradually and sharply pointed at each end; size, when fully developed, about 0·64 millim. by 0·0328 millim.; frequently more slender.

R.N. 147 (deep water off Galle and onwards up West Coast of Ceylon).

Sub-family: CHALININÆ.

Haplosclerida without microscleres and with diactinal megascleres. Skeleton a network of more or less strongly developed horny fibre cored by megascleres.

It is highly probable that this sub-family is of polyphyletic origin, being derived from several genera of Gelliinæ and Renierinæ by loss of microscleres and strong development of spongin. Some species have probably been derived from *Toxochalina* and *Gelliodes* simply by loss of microscleres, the horny fibre being already strongly developed in those genera, while others have probably arisen from *Reniera* and *Petrosia* simply by strong development of the horny fibre, the microscleres having been already lost.

The excessive development of spongin appears to have taken place independently in many genera, and this fact, coupled with the loss of the characteristic microscleres and the uniform character of the megascleres, renders it extremely difficult to arrive at a natural classification of the Chalininæ.* The subject is, however, much too complex to be discussed here at length, especially as there are not a very large number of species in the collection. For our present purposes it will suffice to make use of the established genera, *Pachychalina*, *Chalina*, *Ceraochalina*, and *Siphonochalina*, without committing ourselves to an expression of opinion as to their genetic relationships. Owing to their degenerate character, it is impossible to define even these in such a way as to distinguish them quite sharply from one another.

Pachychalina, SCHMIDT.

Chalininæ of various external form, lobose or digitate, not tubular; with stout skeleton fibres, containing very numerous well developed spicules arranged multiserially.

Pachychalina subcylindrica, n. sp.—Plate X., figs. 1, 2.

Sponge elongated, rather slender, irregularly cylindrical or angular, probably branched and repent. Surface fairly smooth but uneven, with a very few coarse aculeations; minutely reticulate to the naked eye. Vents fairly large (about 2·25 millims. in diameter), irregularly scattered, with slightly prominent margins. Colour (in spirit) light brown. Texture compressible, resilient, rather coarsely fibrous, but somewhat fragile. The largest piece measures about 95 millims. in length, with a very variable thickness up to about 9 millims.

The main skeleton is a sub-rectangularly meshed network of very stout multispicular fibre, about 0·066 millim. in diameter; with meshes varying greatly in size, and with numerous spicules scattered irregularly between the fibres. The fibres themselves contain a very large number of spicules, but no visible spongin. The dermal skeleton (Plate X., fig. 1) is an irregular, polygonal-meshed network of similar coarse multispicular fibre.

Spicules.—Oxea (Plate X., fig. 2); more or less curved or angulated; when fully developed stout and very sharply pointed at each end; measuring about 0·14 millim. by 0·008 millim. Numerous slender forms also occur, probably immature.

In the feeble development of the spongin this species occupies an intermediate position between the genus *Petrosia* and the more typical Chalininæ.

R.N. 292; 360 (Stat. II., north of Negombo, 9 fathoms).

* Compare LENDENFELD (**51**) and DENDY (**63**). In the paper referred to I have explained the reasons why I cannot accept LENDENFELD's classification of the Chalininæ.

Pachychalina delicatula, Dendy.

1889, **Pachychalina delicatula,** Dendy (3).

With this species I identify three specimens, all characterized by their great softness and delicacy of texture, but all containing a good deal of sand.

R.N. 55, 264 (both from Gulf of Manaar); 364 (Stat. I., hauls 1–4, January 31, 1902, Colombo to Negombo, 12 to 20 fathoms).

Pachychalina brevispiculifera, n. sp.—Plate X., fig. 7.

The single specimen is compressed, digitate to flabellate (presumably erect), branching and anastomosing. The branches or fronds are sometimes narrow and sometimes broad, but always greatly flattened, and only about 6 millims. in thickness. The surface is beset with small conical aculeations, which form the principal nodes in a very strongly developed dermal skeletal reticulation. Vents rather large (about 4 millims. in diameter) but very shallow; numerous, but confined almost or quite entirely to one of the flattened sides of the frond or branch. Colour (in the dry state) light brown; texture coarsely fibrous, compressible, resilient, fragile. The single specimen measures about 120 millims. in height by 110 millims. in greatest width.

The main skeleton is a very coarse, sub-rectangularly or irregularly meshed network of very stout horny fibre almost filled with well developed and very abundant spicules arranged multiserially in all the fibres. The primary fibres, running lengthwise through the branches, measure up to about 0·164 millim. in thickness, and the secondaries are sometimes nearly as stout, though usually a good deal slenderer. Sometimes two or more primary fibres run close together side by side, connected with one another at frequent intervals by numerous very short secondaries. The dermal skeleton is a coarse, irregular reticulation of similar fibre, varying greatly in thickness and with meshes of varying diameter. The fibres, especially those of the dermal skeleton, are occasionally echinated by projecting oxea.

Spicules.—Oxea (Plate X., fig. 7); slightly curved; sub-fusiform; short, stout and sharp-pointed at each end; measuring about 0·1 millim. by 0·0055 millim.

R.N. 110 (Gulf of Manaar, dry).

Pachychalina spinilamella, Dendy.—Plate VII., fig. 4.

1889, **Pachychalina spinilamella,** Dendy (3).

I identify with this species a number of specimens of somewhat variable external form, but all characterised by their strongly conulose surface and with closely similar skeleton arrangement. A fairly typical example is represented in Plate VII., fig. 4. R.N. 14, 296 and 326 are characterised by their more slender, irregularly branching form and smaller vents.

R.N. 14, 25, 94 (Periya Paar, &c., Gulf of Manaar); 172, 296, 326 (Ceylon seas).

Chalina, Grant.

Chalininæ of various external form; not tubular. Skeleton reticulation typically rectangular; fibres usually slender, with much spongin and few but usually well developed spicules.

Chalina subarmigera (Ridley)—Plate X., fig. 5.

1884, **Cladochalina subarmigera**, Ridley (**16**); 1887, **Chalinopora subarmigera**, Lendenfeld (**51**); 1898, **Chalina subarmigera**, Lindgren (**86**).

This species is represented in the collection by two specimens, which agree very well with Ridley's original description, except that the margins of the vents are slightly prominent and there are fewer spicules in the fibres of the main skeleton. The characteristic external form is shown in Plate X., fig. 5.

The species was obtained by the "Alert" in Torres Straits and at Albany Island (north coast of Australia), and has also been recorded by Lendenfeld from Port Jackson, and by Lindgren from the Coast of Cochin China.

R.N. 116 (Gulf of Manaar, dry): 288 (Ceylon seas).

Chalina obtusispiculifera, n. sp.—Plate X., fig. 9.

Sponge elongated, slender, cylindrical; may be irregularly branched (? erect or repent). Surface even, very minutely hispid in its present condition. Texture (in spirit) soft and resilient, but fairly tough. Colour pale yellowish-brown. Vents and pores not seen. The largest specimen (R.N. 370) is about 130 millims. long by 3·5 millims. in diameter.

The skeleton is a well-developed reticulation of pale-coloured horny fibre cored by strongyla. The principal fibres run lengthwise through the sponge, branching as they go, and the branches curve outwards towards the surface; they are connected by short secondary fibres to form an irregular network. The principal fibres are about 0·04 millim. in diameter and contain many spicules arranged multiserially as well as much spongin extending well beyond the spicular core. The secondary fibres are only about half as thick and contain fewer spicules. There is no specially differentiated dermal skeleton, unless we consider the outermost secondary fibres of the main skeleton as such (Plate X., fig. 9).

Spicules.—Cylindrical strongyla (Plate X., fig. 9); broadly rounded off at each end, never pointed; nearly straight; measuring up to about 0·12 millim. by 0·007 millim., but frequently much more slender.

This species is easily recognised by its external form and blunt cylindrical spicules. Both specimens are more or less washed out and contain numerous foreign spicules and other débris. In R.N. 285 none of the spicules appear to attain as great a thickness as that given above for the type.

R.N. 285 (deep water off Galle and onwards up West Coast); 370 (deep water outside pearl banks, Gulf of Manaar).

Chalina clathrata, n. sp.—Plate X., fig. 3.

Sponge massively encrusting, the single specimen being attached to the valve of a *Pinna;* clathrous; with very uneven surface proliferating into numerous small, blunt outgrowths. Vents numerous and large (up to about 8 millims. in diameter), scattered singly, each at the end of a short tubular projection and forming the termination of a wide cylindrical oscular tube. Surface minutely reticulate. Texture very delicate, soft, compressible, resilient; colour (after drying) light yellowish-brown, with a tinge of purple. The single specimen measures about 220 millims. in maximum diameter.

The main skeleton is a sub-rectangularly or irregularly meshed network of very pale-coloured horny fibre. The fibre varies greatly in diameter (averaging, say, about 0·025 millim.) and contains very few spicules, arranged for the most part uniserially and absent altogether in places. The dermal skeleton is a close, polygonally or rectangularly meshed network of horny fibre cored by uniserially arranged spicules; the fibres being about 0·0165 millim. in diameter and the meshes about 0·1 millim. in diameter.

Spicules.—Very slender, usually slightly curved oxea or strongyla, measuring about 0·112 millim. by 0·002 millim., occurring in and between the fibres and often reduced to vestiges (Plate X., fig. 3).

With its large prominent vents and deep oscular tubes this species makes an approach to the genus *Siphonochalina*, while its massive (though clathrous) form recalls RIDLEY'S *Acervochalina*.

R.N. 102 (Gulf of Manaar, dry).

Chalina cymæformis (ESPER ?).

? 1798–1806, **Spongia cymæformis**, ESPER (**6**); ? 1870, **Spongia cymæformis**, EHLERS (**58**).

Sponge shortly stipitate, bushily lamellar or frondose or sub-digitate. Lamellæ about 9 millims. thick, with broadly rounded margins. Surface rather uneven, minutely conulose, especially where the dermal membrane has been rubbed off. Vents small (about 2 millims. in diameter), more or less abundantly scattered, chiefly on the inner surfaces of the lamellæ. Inhalant pores scattered in the dermal membrane. Texture (in spirit) soft and compressible, but very tough and resilient; rather woolly. Colour brown. The most typical specimen (R.N. 16) is about 67 millims. high by 90 millims. in greatest breadth, with a stalk about 22 millims. high and 18 millims. thick. It bears a very close resemblance to the figure of *Chalina palmata*, given by RIDLEY and DENDY (**1**), as well as to ESPER'S figure of his *Spongia cymæformis* (Plate 69).

The main skeleton consists of what, at first sight, look like rather slender, ill-defined, plurispicular fibres running towards the surface at irregular intervals and branching as they go, connected by still less well-defined secondary fibres from one to about four spicules broad. No spongin is at first sight visible, but closer examination shows that a very large quantity is really present in the fibres, more or less completely imbedding the spicules; owing to its very pale colour and great transparency, however, it readily escapes observation. Numerous spicules occur scattered irregularly between the fibres. There is no special dermal skeleton, the dermal membrane being practically destitute of spicules.

Spicules.—Slender, slightly or rather strongly curved oxea; more or less gradually sharp-pointed at the ends; size variable, say about 0·12 millim. by 0·003 millim.

It is probable that this species is identical with Esper's *Spongia cymæformis* (from Ceylon). It also appears to be nearly related to *Chalina palmata* from European, Indian and Australian waters; differing, however, in the absence of the dermal skeleton reticulation. In habit the species reminds one very much of some species of *Axinella*, a resemblance which appears from Ehlers' description to have been increased in the case of Esper's specimen by the presence of styli mingled with the oxea.

R.N. 16 (Gulf of Manaar); 349 (Stat. LV., west of Periya Paar, 20 fathoms).

Ceraochalina, Lendenfeld.

Chalininæ of various external form; not tubular. Texture hard, owing to the great thickness of the skeleton fibres, in which the spongin is very strongly developed and the spicules much reduced in size and sometimes also in number.

Ceraochalina retiarmata, n. sp.—Plate X., fig. 4.

The single specimen forms an erect, thin lamella, attached below by a constricted base; sub-dividing into flattened branches and giving off irregular digitiform processes almost exclusively in one plane; the branches to a slight extent anastomosing with one another. Surface glabrous, minutely granular under a lens; rather uneven. Vents minute, about 0·5 millim. in diameter, mostly arranged uniserially on the narrow margins. Inhalant pores scattered in the meshes of the dermal reticulation. Colour (in spirit) rather dark brown; texture compressible, resilient, tough and fibrous. Total height of specimen about 33 millims.; greatest breadth about 66 millims.; thickness of lamella about 3·5 millims.

The main skeleton is a network of stout horny fibre, sparingly cored by very slender vestigial oxea. The primary fibres are about 0·1 millim. in diameter and curve upwards and outwards towards the surface, branching as they go. They are connected together by short secondaries about 0·05 millim. in diameter and containing fewer spicules. There is also a system of tertiary fibres, much more slender (from about 0·008 millim. to about 0·024 millim. in diameter) and containing from one to about four rows of well-developed oxea imbedded in spongin. These tertiary fibres form an irregular network which seems to bear no relation to the rest of the main skeleton, except that its fibres are attached frequently to those of the latter.

The dermal skeleton is very strongly developed, forming a close polygonal-meshed reticulation of horny fibres cored by usually two or three rows of well developed oxea and echinated abundantly by similar oxea projecting from the fibre singly or in small groups. The diameter of the dermal fibre is about 0·024 millim.; of the meshes between the fibres about 0·16 millim., but variable.

Spicules.—Rather short, slightly curved, gradually sharp-pointed oxea (Plate X., fig. 4), measuring about 0·084 millim. by 0·004 millim. in the dermal skeleton and in the tertiary fibres of the main skeleton, but becoming more or less vestigial in the other fibres.

R.N. 342 (Stat. V., off Chilaw, 10 fathoms).

Ceraochalina reticutis, n. sp.—Plate X., fig. 8.

The type specimen (R.N. 58) forms an agglomeration of short, irregular, sub-cylindrical or angular branches, slightly anastomosing with one another and branching with great irregularity. The branches vary greatly in diameter, from about 4 millims. to about 11 millims., and have a slightly nodose appearance. The entire mass measures about 80 millims. in greatest breadth. Vents small (about 1 millim. in diameter), but conspicuous and with slightly projecting margins; scattered abundantly and sometimes in ill-defined longitudinal series. The dermal membrane is parchment-like, and under a pocket lens appears very finely and regularly reticulate in triangular meshes, which are the coarser meshes of the dermal skeleton composed of dark brown spongin fibre. Texture (in spirit) compressible, very resilient, tough; colour dark brown.

The main skeleton is a fairly regular, sub-rectangularly meshed network of strong horny fibre. The principal fibres run longitudinally through the branches, sub-dividing as they go and curving outwards to the surface. They measure up to about 0·08 millim. in diameter, and contain a considerable number of slender vestigial spicules, irregularly and multiserially arranged. The secondary fibres are about as thick as the primaries, but contain fewer spicules (which are also vestigial). The meshes of the main skeleton reticulation vary a good deal in size; averaging, say, about 0·33 millim. in diameter.

The dermal skeleton (Plate X., fig. 8) is a very well developed, close, polygonal-meshed reticulation of horny fibre containing only a very few slender spicules scattered here and there. The fibres of which this reticulation is made up are of two principal sizes: (*a*) stout, about 0·03 millim. to 0·05 millim. in diameter, radiating from the ends of the primary fibres of the main skeleton and forming the coarser triangular-meshed reticulation visible under a pocket lens; (*b*) more slender, but very variable in diameter, forming a very close-meshed but irregular reticulation in the meshes of the coarser reticulation. A large number of well developed spicules may be irregularly scattered in the dermal membrane outside the horny fibres of the dermal skeleton.

Spicules.—Oxea; varying greatly in degree of development; in the horny fibres very slender and vestigial (Plate X., fig. 8, *v.s.*), but often well developed in the soft tissues between the fibres, especially in the dermal membrane (Plate X., fig. 8, *o*). When fully developed they are slightly curved and somewhat hastately sharp-pointed, measuring about 0·072 millim. by 0·00265 millim.

R.N. 58 (Gulf of Manaar); 321; ? 346 (distinguished from the type chiefly by the numerous well developed oxea arranged uniserially in the slenderer fibres of the dermal skeleton and multiserially in the stouter fibres; while the spicules themselves are occasionally strongylote).

Ceraochalina multiformis, Lendenfeld, var. **manaarensis**, Dendy—Plate VII., fig. 2.

1889, **Pachychalina multiformis**, var. **manaarensis**, Dendy (**3**).

I identify with this variety a single specimen attached to a pearl oyster, which is represented in Plate VII., fig. 2. A feature which I omitted to mention in my original description of the variety is the echination of the fibres of the dermal skeleton by projecting oxea, singly or in groups.

The species was recorded by Lendenfeld (**51**) from Australia and New Zealand.

R.N. 98 (Gulf of Manaar, dry).

Ceraochalina ceylonica, n. sp.—Plate VII., fig. 3: Plate X., fig. 6.

Sponge (Plate VII., fig. 3) massive, irregular, sometimes clathrous, with a slight tendency to become lobose or digitate. Surface strongly and copiously aculeated by sharp-pointed conuli about 4 millims. in height; minutely fibro-reticulate between the conuli. Vents numerous, scattered, about 4 millims. or 5 millims. in diameter; the openings of deep, cylindrical oscular tubes. Colour (in spirit) pale brown; texture firm and tough, but compressible and resilient. The largest specimen (R.N. 5, figured) measures 200 millims. by 160 millims. in horizontal dimensions, by 90 millims. in height.

The main skeleton is a very strongly developed, irregular or rectangularly meshed network of stout, horny fibre, containing usually a large number of small oxea scattered irregularly throughout the spongin substance, but almost always more or less parallel with the long axis of the fibre. Occasionally (R.N. 5) the spicules are much less strongly developed and may be completely absent from some of the fibres. Numerous spicules also occur scattered between the fibres. The thickness of the fibres is variable, say about 0·08 millim. for the primaries and not much less for the secondaries

The dermal skeleton is a polygonally meshed network of fibre containing a very large proportion of spongin and a good many spicules. The latter are, for the most part, imbedded in the spongin substance more or less longitudinally; at frequent intervals, however, little groups of oxea, or single spicules, project more or less at right angles from the fibre in an echinating manner, and thus give a rather characteristic appearance to the dermal skeleton. The meshes of the dermal reticulation are about 0·2 millim. in diameter, and the fibres from about 0·008 millim. upwards.

Spicules.—Slender oxea (Plate X., fig. 6), slightly curved and more or less gradually and sharply pointed; size about 0·088 millim. by 0·003 millim., but subject to a good deal of variation, and frequently, if not usually, more slender.

R.N. 4, 5, 50, 108, 113 (all from Gulf of Manaar).

Siphonochalina, SCHMIDT.

Chalininæ of tubular form. Tubes smooth, both inside and out, usually narrow; each with a large circular vent at the summit.

Siphonochalina communis (CARTER), var. **tenuispiculata**, nov.—Plate VII., fig. 1.

This variety (Plate VII., fig. 1) agrees very closely in external form with the specimens of *Siphonochalina communis* described by CARTER (5) and myself (3) from the Gulf of Manaar. Mr. CARTER gave no measurements of the spicules in the case of the type of the species, but the specimens in Professor HERDMAN's collection differ rather strikingly from that collected by Mr. THURSTON and described by myself, in that the spicules are very much more slender and very much more numerous in both primary and secondary fibres and in the fibres of the dermal skeleton. In fact, the spicules, though very abundant in all the fibres and occurring throughout the entire, or almost the entire, thickness of each fibre, are so slender as to be almost vestigial, measuring about 0·072 millim. by 0·001 millim.

In skeletal characters, although the spicules are more slender, this variety agrees much more closely with my *Siphonochalina crassifibra* from the same locality (3) than with CARTER's *S. communis;* differing from *S. crassifibra* chiefly in the smaller size of the tubes. Thus it has the external form of *S. communis* combined with the skeletal characters of *S. crassifibra*, and I therefore propose to regard all three forms as mere varieties of one and the same species.

Professor HERDMAN informs me that the sponge in life had a violet-pink colour.

RIDLEY (16) records the species (under CARTER's name *Tabulodigitus communis*) from Port Jackson, Australia, and also from Kurrachee.

R.N. 6, 7, 117 (dry, figured; all from Gulf of Manaar, Stat. II., 8 fathoms).

SUB-FAMILY: DESMACELLINÆ.

Haploscleridæ with monactinal megascleres. Microscleres various.

Desmacella, SCHMIDT.

Desmacellinæ with reticulate skeleton composed of styli or tylostyli. Microscleres sigmata, toxa and trichodragmata variously combined.

Desmacella tubulata, n. sp.—Plate IX., fig. 4.

Sponge consisting of cylindrical, tubular processes, more or less widely open above

(? always) and (sometimes, at any rate) united together below. (Possibly they may have been attached to a common body, but only fragmentary tubes are present in the collection.) Diameter of individual tubes about 6 millims.; thickness of tube-wall about 1·25 millims. Outer surface slightly granular and very minutely hispid. Inner surface with numerous very minute openings of exhalant canals. Colour (in spirit) pale greyish-yellow. Texture very soft, compressible, fragile.

The main skeleton is a very irregular but close reticulation of slender styli, either isolated or in loose bundles; with no visible spongin cement. There is no special dermal skeleton.

Spicules.—(1.) Long slender styli (Plate IX., fig. 4, *a*, *b*); slightly curved or bent, broadly and evenly rounded off at the base, sharply and more or less gradually pointed at the apex; size about 0·28 millim. by 0·005 millim.

(2.) Trichodragmata (Plate IX., fig. 4, *d*); extraordinarily abundant, especially beneath the outer surface, and very variable in size, sometimes forming wisp-like fibres, sometimes breaking up into separate microxea (Plate IX., fig. 4, *e*); varying in length from about 0·02 millim. upwards, and always very slender.

(3.) Sigmata (Plate IX., fig. 4, *c*); also extraordinarily abundant; slender, commonly much contort, also C-shaped; occasionally in small bundles (sigmodragmata); length from bend to bend variable, say about 0·02 millim.

This appears to be a very well characterized species, and I know of no other which comes very near it. The immense number of microscleres is very remarkable.

R.N. 209 (Gulf of Manaar); 324.

SUB-FAMILY: HETEROXYINÆ.

Haploscleridæ with a dense cortex composed of radially arranged megascleres. Megascleres smooth and spined oxea. Microscleres present or absent.

I propose this sub-family for the reception of the genera *Heteroxya*, TOPSENT, and *Acanthoxifer*, n. gen., the former of which is, apparently with very slight justification, placed by its founder amongst the Tethyidæ.

Acanthoxifer, n. gen.

Heteroxyinæ with a dense spicular cortex broken up into polygonal plates by pore-bearing grooves. Main skeleton a confused reticulation of oxea. Cortical skeleton composed chiefly of dense brushes of oxea arranged at right angles to the surface. Megascleres smooth and spined oxea. Microscleres trichodragmata.

This remarkable genus is evidently nearly related to TOPSENT'S *Heteroxya* (45), but differs in several respects, notably in the presence of trichodragmata, which indicates that the true position both of *Acanthoxifer* and *Heteroxya* is amongst the Haploscleridæ and not amongst the Tethyidæ, where TOPSENT has placed *Heteroxya*. The presence of the spined oxeote megascleres suggests a possible relationship to the Spongillinæ.

The breaking up of the cortex into polygonal plates or nodules by pore-bearing (and ? vent-bearing) grooves remind one forcibly of the genus *Placospongia* amongst Spirastrellidæ, but the resemblance is entirely superficial.

Acanthoxifer ceylonensis, n. sp.—Plate IX., fig. 5.

Sponge massively encrusting, irregular, with flattened or convex upper surface and broad base of attachment. Surface very minutely hispid or granular, uneven, nodular or tubercular, the nodules or tubercles being very low and roundedly polygonal in shape, separated by grooves of varying distinctness. Generally the grooves are broad and shallow: sometimes they are narrow, with prominent margins. Diameter of nodules, say, about 4 millims., but variable and irregular. Colour (in spirit) light brown. Texture compact, fleshy, but with much calcareous débris embedded. Pores and vents not recognisable externally. The largest specimen is cake-shaped, about 42 millims. in horizontal diameter, and up to 17 millims. in thickness.

The main skeleton is a quite confused, lax reticulation of very abundant, long, oxeote megascleres, occasionally collected together into loose, ill-defined bands, but without any distinct fibre, and with a little spongin becoming visible in stained sections. The cortical skeleton is very strongly developed and consists of dense brushes of oxea placed side by side and lying at right angles to the surface, beyond which their apices project (but are now nearly all broken off). These brushes are backed up internally by a very dense, irregular reticulation of oxea. The cortical skeleton is absent beneath the grooves which separate the surface nodules. Thus there is a separate section of the cortical skeleton for each nodule or tubercle, thinning out as it approaches the grooves in such a manner as to become strongly convex on the inner aspect.

Spicules.—(1.) Smooth oxea (Plate IX., fig. 5, *a*); long and rather slender, slightly curved or bent, variously and often irregularly ended, sometimes stylote (Plate IX., fig. 5, *b*). Size variable, say about 0·74 millim. by 0·012 millim. Abundant in the main skeleton and occasionally met with in the surface brushes.

(2.) Spined oxea (Plate IX., fig. 5, *c*); usually slightly and symmetrically curved (or angulated) in the middle; tapering fairly gradually to a sharp point at each end; provided with numerous very minute, sharp spines, most abundantly developed towards the two ends; size about 0·38 millim. by 0·008 millim. Characteristic of the cortical skeleton, but also common in the interior of the sponge.

(3.) Trichodragmata (Plate IX., fig. 5, *d*); oblong bundles of extremely slender rhaphides, which do not usually become dissociated even on boiling with nitric acid. Size usually about 0·016 millim. by 0·004 millim.; occasionally much longer.

Stained sections show that the ectosome (between the spicules) is chiefly collenchymatous, sometimes with a tendency to become fibrous near the surface. In both ectosome and choanosome are an immense number of minute granules of a pale yellowish colour, aggregated in rounded masses of very varying size. These may be symbiotic algæ.

R.N. 213, 217 (both from deep water outside pearl banks, Gulf of Manaar); 247.

Family: DESMACIDONIDÆ.

Sigmatomonaxonellida in which some of the microscleres are chelæ (except when these have been lost by degeneration).

The presence of microscleres in the form of chelæ constitutes a natural character by which the Desmacidonidæ are, as a rule, easily distinguished from all other sponges. Unfortunately, however, the chelæ are very apt to disappear by degeneration, especially in the sub-families Ectyoninæ and Phlœodictyinæ, and we have then to depend upon other characters—such as the presence of spined echinating styli—for guidance in classification. That the chela, one of the most remarkable forms of microsclere known to us, has originated by modification of the sigma, there can, I think, be little doubt. In the Report on the "Challenger" Monaxonida* we showed that in ontogeny the chela arises from a sigmoid form (*Esperella mammiformis*) and that sigmata and chelæ must therefore be grouped in the same category. Nor are intermediate forms of adult spicules unknown to us, such as the curious "bipocilli" of the genus *Iophon*, especially those of *Iophon chelifer*, Ridley and Dendy (**1**), and, most notable of all, the bidentate sigmata of Topsent's *Gellius bidens* (**64**).

We are, therefore, justified in regarding the Desmacidonidæ as derived from the Haplosceridæ by modification of the sigmoid microscleres into chelæ, though why this modification should have taken place is very hard to understand. It is extremely difficult to see how the very peculiar and highly specialized chelate form of microsclere can be of any special advantage to its possessor, and we have here one of those numerous cases in which, so far as we can see at present, the theory of natural selection signally fails to account for the facts.

I have already pointed out that the sub-family Phlœodictyinæ must be transferred to the Desmacidonidæ on account of the presence of chelate microscleres in the genus *Histoderma*, certain species of which are obviously very closely related to *Phlœodictyon* and *Oceanapia*. For the purposes of this Report the three sub-families Esperellinæ, Phlœodictyinæ and Ectyoninæ will be sufficient. Topsent's sub-family Dendoricinæ appears to me to be an unnatural group which cannot be maintained, the differentiation of the ectosomal megascleres being far too general and widespread a character to be utilised as distinguishing the sub-family, whose members fall very naturally in one or other of the remaining sub-families. The sub-family Bubarinæ, proposed by the same author, has, I am glad to see, been again abandoned by him in his latest work (**62**).

* Page xx.

Sub-family: ESPERELLINÆ.

Desmacidonidæ without echinating spicules, and without fistular outgrowths of the sponge body.

Esperella, Vosmaer.

Esperellinæ of various external form, usually massive, lobose or ramose. Skeleton usually fibrous, often with much spongin. Megascleres monactinal, stylote or tylostylote. Characteristic microscleres palmate anisochelæ, to which may be added smooth sigmata, toxa, trichodragmata and small isochelæ* in various combinations.

Esperella parishii (Bowerbank ?), Ridley.

[For synonymy and literature *vide* Ridley and Dendy (**1**), p. 65.]

There is one small, thinly encrusting specimen of this sponge in the collection, growing on a calcareous nodule in association with *Paresperella serratohamata* and *Hymedesmia stellivarians*. The specimen agrees very closely in spiculation with the description given by Ridley (**16**), except that the megascleres are a little larger and the trichodragmata contain many more spicules.

The species has been hitherto recorded from the Straits of Malacca (Bowerbank); Port Darwin, Australia (Ridley), and the Philippine Islands ("Challenger"). Re-examination of the "Challenger" specimen, however, has convinced me that it does not belong to the same species as those described by Ridley from Australia and found by Professor Herdman in Ceylon waters, as it possesses toxa. It must be remembered that Bowerbank (**49**) originally described toxa as forming part of the spiculation, but Ridley regarded these as foreign elements. It is probable that we have here a confusion between two species.

It appears not improbable that the "thin fragment" recorded by Carter (**4**) from the Gulf of Manaar, under the name *Esperia tunicata*, Sdt., may be specifically identical with our specimen.

R.N. 220A (deep water off Galle and onwards up West Coast of Ceylon).

Esperella plumosa (Carter).

1882, **Esperia plumosa**, Carter (**33**); 1886, **Esperia plumosa**, Carter (**20**).

Sponge irregularly frondose or digitate; clathrous. Surface irregularly cactiform or conulose, covered by a very well-developed, stellately reticulate dermal membrane. Vents not seen; pores scattered in the meshes of the dermal reticulation. Texture (in spirit) coarsely fibrous, compressible, resilient, fragile. Colour grey. The largest fragment measures about 62 millims. in height by 41 millims. in greatest breadth.

The main skeleton is an irregular reticulation of coarse, stout, multispicular fibre without visible spongin; the main fibres running lengthwise and branching and

* Possibly young forms of the anisochelæ.

anastomosing with one another. The fibres are not very sharply defined and numerous megascleres occur scattered between them. The dermal skeleton is a very well-developed, triangular-meshed, stellate reticulation of stout, multispicular fibre (about 0·05 millim. in diameter).

Spicules.—(1.) Styli; fairly stout, often slightly crooked, with fairly well-developed oval heads and slightly constricted necks; sharply and rather abruptly pointed at the apex; size about 0·3 millim. by 0·009 millim.

(2.) Broad palmate anisochelæ, very similar to those of *Esperella simonis*;* about 0·048 millim. long; frequently in rosettes.

(3.) Minute palmate isochelæ; numerous, about 0·012 millim. long.

(4.) Large, stout sigmata, C-shaped and contort, with abruptly recurved and very sharply pointed ends; size about 0·08 millim. from bend to bend by 0·006 millim. thick in the middle.

(5.) Slender toxa with gently rounded curves; up to about 0·08 millim. long by 0·002 millim. thick in the middle; often in sheaves (toxodragmata) when young.

I have been able to satisfy myself by personal examination of Mr. CARTER's type preparation of his *Esperia plumosa* (now in my possession) of the specific identity of the Ceylon form with the sponge recorded by CARTER from Mauritius, and subsequently from the Mergui Archipelago also. As Mr. CARTER's descriptions are very scanty, I have thought it desirable to give the above details concerning what is evidently a widely distributed and characteristic species in the Indian Ocean, distinguished by an exceptionally varied and beautiful spiculation.

R.N. 298, 328, 361 (three fragments amongst a large number; all from Ceylon seas).

Esperella crassissima, n. sp.—Plate XI., fig. 6.

The single specimen is rounded, cushion-shaped, attached by the base to a mass of calcareous débris. The upper surface is strongly convex and bears a single large prominent vent about 3 millims. in diameter. Surface with a more or less strongly marked reticulate appearance, due to the coarse sub-dermal network of very stout spicular fibre, the oval meshes of which are normally covered over by a thin pore-bearing membrane, now mostly rubbed off. Pores scattered in the meshes of the dermal skeleton. Texture (in spirit) rather hard but slightly compressible and resilient; coarsely fibrous. Colour pale grey. Maximum diameter of specimen about 24 millims.

The main skeleton is a very well-developed reticulation of very stout, compact spicular fibre up to about 0·33 millim. in diameter, composed of very numerous closely packed spicules and without visible spongin. The meshes of this reticulation vary greatly in size and shape; perhaps 1·3 millims. would be a fair average diameter. Immediately beneath the surface the main skeleton passes into the more compact

* *Vide* (1), Plate XV., fig. 16.

sub-dermal reticulation, with rounded meshes averaging about 0·5 millim. in diameter, separated by fibres of about the same diameter (more or less). Over this lies a true dermal reticulation composed mostly of loosely scattered spicules (sometimes aggregated in slender fibres) lying tangentially in the pore-bearing dermal membrane.

Spicules.—(1.) Tylostyli (Plate XI., fig. 6, *a*); slightly curved, rather stout; with well developed oval heads narrower than the middle of the shaft, from which they are separated by a well marked constriction; gradually or rather abruptly sharp pointed at the apex. Size about 0·49 millim. by 0·016 millim.

(2.) Large palmate anisochelæ of the ordinary form (Plate XI., fig. 6, *b*, *c*), measuring about 0·06 millim. by 0·024 millim. Very numerous, mostly in groups which look like disorganised rosettes; found chiefly just beneath the surface. In the dermal membrane numerous small palmate isochelæ occur scattered singly; these are about 0·012 millim. long and are probably young forms.

(3.) Sigmata (Plate XI., fig. 6, *d*); slender, C-shaped and contort, up to about 0·036 millim. long; numerous.

(4.) Trichodragmata (Plate XI., fig. 6, *e*); short, compact; about 0·02 millim. by 0·006 millim. Very abundant.

This species is very closely related to *Esperella fusca*, Ridley and Dendy (1), obtained by the "Challenger" off Bahia; it differs, however, in the more strongly developed main skeleton and consequently greater hardness of texture, and in the sharply pointed character of the tylostyles; possibly also in colour.

R.N. 240 (Ceylon seas).

Esperella tenuispiculata, n. sp.

Sponge irregularly massive, with a tendency to grow out into rounded lobes or short, thick branches. Surface very uneven, covered over by a soft dermal membrane. Vents few, small, scattered. Pores scattered (perhaps in irregular groups) in the dermal membrane. Texture (in spirit) soft and spongy, but intensely gritty from the presence of an immense quantity of coarse sand, chiefly in the interior of the sponge. Colour varying from grey to brown. The largest specimen is about 63 millims. long by 36 millims. in greatest breadth.

The skeleton is to a large extent replaced by the abundant sand-grains, which may be held together in very irregular bands by spongin cement. Between and in association with these we have loose, wispy bands of styli running towards the surface, or simply scattered styli. There is no dermal skeleton.

Spicules.—(1.) Tylostyli, very much reduced; straight, slender; with distinct oval heads, constricted necks and fairly gradually sharp-pointed apices; size about 0·21 millim. by 0·004 millim., but often more slender.

(2.) Small palmate anisochelæ, about 0·02 millim. long; rather scarce but constant.

(3.) Slender sigmata, C-shaped and contort, about 0·036 millim. from bend to bend; sometimes very abundant.

In its intensely arenaceous habit and the consequent reduction of the proper skeleton, this species resembles *Esperella arenicola*, Ridley and Dendy (1), and *E. crassa*, Dendy (10), both from Bass Straits. It differs from the former, however, in the absence of trichodragmata, and from the latter in the presence of sigmata.

R.N. 293; 305; 334; 344 (Ceylon seas).

Paresperella, n. gen.

Encrusting or massive Esperellinæ, with megascleres in the form of tylostyli or styli; with microscleres in the form of palmate anisochelæ and serrated sigmata, to which others (such as toxa) may be added.

The existence of several esperelline species with serrated sigmata justifies the erection of a new genus, of which the type will be Carter's *Esperia serratohamata*, I am not aware that this very extraordinary form of spicule has hitherto been met with in any other genus.

There are probably at least three species of the genus *Paresperella* in the neighbourhood of Ceylon, for in an indeterminable sponge encrusting a calcareous nodule from "Deep water off Galle and onwards" I have found (as a foreign body) a huge serrated sigma (Plate XI., fig. 3) like those of *Paresperella serratohamata*, but far too large to be referred to that species. It measures 0·3936 millim. from bend to bend and 0·0146 millim. thick in the middle of the shaft, while, according to Mr. Carter's measurements, the corresponding spicule in *P. serratohamata*, though large, measures only 0·1 millim. by 0·0052 millim. Curiously enough, *P. serratohamata* was also first known from a single spicule.

Lindgren (86) has described, under the name *Esperella macrosigma*, a species of *Paresperella* in which the serrated sigmata attain still more enormous dimensions, measuring 0·48 millim. in length by 0·024 millim. in diameter. This species comes from the straits of Korea, and it is quite likely that it occurs also in Ceylon waters and may be represented by the single spicule above described.

The genus is, of course, very closely related to *Esperella*, from which it has evidently been derived.

Paresperella serratohamata (Carter)—Plate XI., fig. 2.

1880, **Esperia serratohamata**, Carter (4).

A minute specimen of this remarkable sponge occurs on a calcareous nodule in association with *Hymedesmia stellivarians* and *Esperella parishii*. The spiculation agrees very well with Mr. Carter's description, but the apices of the tylostyles are uniformly mucronate (Plate XI., fig. 2, *a*). This character is not mentioned in Mr. Carter's description, and the figure which he gives of the tylostyle is on too small a scale to afford satisfactory evidence.

Lambe (85) records this species from Vancouver, but I am doubtful, from the measurements which he gives of the spicules, whether his identification is correct; we have probably here yet another species of the genus.

R.N. 220c (deep water off Galle and onwards up the West Coast of Ceylon).

Paresperella bidentata, n. sp.—Plate XI., fig. 1.

Sponge intensely arenaceous, the single specimen consisting of a friable mass of coarse yellow sand, held together and permeated by the soft sponge-tissues. Somewhat cavernous internally. Surface uneven, with a soft dermal membrane visible in places. The single specimen is an irregular massive fragment about 25 millims. in maximum diameter.

The main skeleton of the sponge, between the closely aggregated sand-grains, consists of slender megascleres, mostly loosely scattered, but occasionally collected in fairly stout multispicular fibres. In the dermal membrane there is a distinct but very loose and wide-meshed reticulation of slender spicular fibre, three or four spicules wide, supported here and there on very loose sub-dermal brushes belonging to the main skeleton.

Spicules.—(1.) Tylostyli (Plate XI., fig. 1, *a*); long, slender, straight or nearly so, with oval heads, about equal in diameter to the middle of the shaft, and slightly constricted necks; typically with the apex slightly enlarged, truncated, and provided with two (sometimes three ?) minute conical teeth placed side by side on the truncated end (with their long axes parallel with the long axis of the spicule). The enlargement from which these teeth project contains a diverticulum of the central canal of the spicule. These spicules are best developed in the dermal membrane (and in the lining membrane of the large canals ?). In the dermal membrane they form the reticulation of spicular fibre mentioned above, and measure about 0·27 millim. by 0·0053 millim. In the deeper parts of the sponge, between the sand-grains, they are more slender and their apices sometimes appear to end in simple, long-drawn-out points.

(2.) Palmate anisochelæ (Plate XI., fig. 1, *c*, *d*), about 0·028 millim. long; mostly in rosettes near the surface, very abundant and similar to those of *P. serratohamata*.

(3.) Sigmata (Plate XI., fig. 1, *b*, *b*); long and slender, usually contort, with sharply incurved apices and (? always) with more or less distinct teeth on the outer side of each bend, similar to those on the sigmata of *P. serratohamata*, but much less strongly developed. Size about 0·052 millim. from bend to bend by 0·002 millim. thick in the middle.

This species differs from *P. serratohamata* in the presence of two teeth, instead of one, at the apex of the tylostyle; in the much more slender and less distinctly toothed or serrate character of the sigmata, and in the absence of toxa; as well as in the arenaceous habit, which has doubtless caused considerable reduction in the proper skeleton. I know of no other case where one can trace such a close and evident relationship between an arenaceous sponge with reduced skeleton and a non-arenaceous congener. The bidentate character of the apex of the tylostyle is very remarkable, especially in comparison with the mucronate character of the corresponding spicule in *P. serratohamata*.

R.N. 263A (Gulf of Manaar).

Iotrochota, Ridley.

Esperellinæ of massive, ramose, or flabellate form, and usually of dark purple or brown colour. Skeleton reticulate. Megascleres styli, to which diactinal forms may be added, especially in the more superficial parts of the sponge. Typical microscleres birotulate (apparently modified isochelæ).

In previous papers I have used the term "Amphiaster" for the birotulate spicules of this and certain other genera of Esperellinæ. There can, however, be little doubt that these microscleres are modified isochelæ, and do not belong to the astrose series at all. They are connected with the more typical isochelæ by the peculiar isochelæ of the genera *Chondrocladia* and *Axoniderma*, and may conveniently be termed "birotulate isochelæ."

Iotrochota purpurea (Bowerbank), Ridley.

1875, **Halichondria purpurea**, Bowerbank **(49)**; 1884, **Iotrochota purpurea**, Ridley **(16)**.

The Ceylon variety of this species is characterized by its dark brown instead of purple colour in spirit.* It is also easily distinguished from *Iotrochota baculifera* by this character as well as by the replacement of the tylote megascleres by slender styli, commonly arranged in radiating tufts at the surface.

The specimens are for the most part irregularly cylindrical in shape, may be much branched; and the surface is covered irregularly with small, sharp conuli. The styli of the main skeleton are usually sharp-pointed and very variable in size. The birotulate isochelæ are numerous and about 0·02 millim. long. Not infrequently, the straight, slender styli in the radiating tufts at the surface of the sponge exhibit an inflation not far from the middle of the shaft, causing them to resemble a pipette. The fibres of the main skeleton reticulation are stout and contain much spongin as well as very many spicules.

The original type of the species was described by Bowerbank from the Straits of Malacca. Ridley recorded it from Torres Straits, Albany Island, Port Molle, and the Amirante Group. The West Indian *Iotrochota birotulata* (Higgin) **(53)** and the Southern Australian *Iotrochota coccinea* (Carter)† are very possibly identical with this species, or only varietally distinct.

R.N. 258; 297; 309; 343; 354; 366 (Stat. V., off Chilaw, 10 fathoms, and elsewhere in Ceylon seas. Some are mere fragments).

* It should, however, be noted, that a portion of the collection was preserved in formalin and transferred to spirit afterwards. I do not know which specimens were treated in this way, nor do I know what effect such treatment may have had upon the colour.

† *Vide* Dendy **(10)**.

Iotrochota baculifera, Ridley.

1884, **Iotrochota baculifera**, Ridley (**16**); 1887, **Iotrochota baculifera**, Ridley, var. **flabellata**, Dendy (**2**).

There are in the collection a number of dark purple-coloured specimens, mostly small or mere fragments, which I identify with this species. The flabellate habit, characterizing my variety *flabellata*, is not recognisable in most of them, and it seems hardly worth while to retain a special varietal name for the Ceylon form. In a boiled-out preparation of R.N. 164 I find the styli frequently much stouter than the measurements which I gave from Mr. Thurston's specimens, often measuring about 0·2 millim. by 0·012 millim., but very variable in diameter, while the tylota measure about 0·246 millim. by 0·007 millim., and the birotulate isochelæ about 0·02 millim. long. It will be seen that these measurements agree very closely with those given by Ridley for the type specimen from Port Darwin.

Thiele (**39**) has recorded the species also from Celebes.

R.N. 47 (Gulf of Manaar); 164; 317; 322; 331 (all from Ceylon seas).

Sub-family: PHLŒODICTYINÆ.

Desmacidonidæ in which the sponge body is provided with fistular outgrowths, and, usually at any rate, with a spicular rind or cortex.

In this sub-family I include the genera *Phlœodictyon*, *Oceanapia*, *Histoderma*, *Sideroderma* and *Amphiastrella*, which appear to me to form a very natural group.

The microscleres are usually more or less completely suppressed.

Phlœodictyon, Carter.

Phlœodictyinæ with oxeote or strongylote megascleres and no microscleres at all.

Lundbeck (**88**) has shown pretty conclusively that Carter's name "*Phlœodictyon*" must be revived for this genus, the type species of "*Rhizochalina*," described by Schmidt, being true Chalininæ.

Phlœodictyon fistulosum (Bowerbank).

1873, **Desmacidon fistulosa**, Bowerbank (**22**); 1880, **Desmacidon Jeffreysii**, Carter (**4**); 1884, **Rhizochalina fistulosa**, Ridley (**16**); 1888, **Rhizochalina fistulosa**, Ridley and Dendy (**1**); 1897, **Oceanapia fistulosa**, Topsent (**83**); 1904, **Phlœodictyon fistulosum**, Topsent (**62**).

Mr. Carter recorded this species from the Gulf of Manaar under the name *Desmacidon Jeffreysii*. It differs, however, from the British *Oceanapia jeffreysi*, as Mr. Carter himself pointed out, in the absence of sigmata. In this respect it agrees with the Australian *Phlœodictyon fistulosum*, with which I have no hesitation in identifying it.

In a footnote to the account of this species in the Report on the "Challenger"
